Abstract

Different approaches to high-quality grammatical error correction have been proposed recently, many of which have their own strengths and weaknesses. Most of these approaches are based on classification or statistical machine translation (SMT). In this paper, we propose to combine the output from a classification-based system and an SMT-based system to improve the correction quality. We adopt the system combination technique of Heafield and Lavie (2010). We achieve an $F_{0.5}$ score of 39.39% on the test set of the CoNLL-2014 shared task, outperforming the best system in the shared task.

1 Introduction

Grammatical error correction (GEC) refers to the task of detecting and correcting grammatical errors present in a text written by a second language learner. For example, a GEC system to correct English promises to benefit millions of learners around the world, since it functions as a learning aid by providing instantaneous feedback on ESL writing.

Research in this area has attracted much interest recently, with four shared tasks organized in the past several years: Helping Our Own (HOO) 2011 and 2012 (Dale and Kilgarriff, 2010; Dale et al., 2012), and the CoNLL 2013 and 2014 shared tasks (Ng et al., 2013; Ng et al., 2014). Each shared task comes with an annotated corpus of learner texts and a benchmark test set, facilitating further research in GEC.

Many approaches have been proposed to detect and correct grammatical errors. The most dominant approaches are based on *classification* (a set of classifier modules where each module addresses a specific error type) and *statistical machine translation (SMT)* (formulated as a translation task from "bad" to "good" English). Other approaches combine the classification and SMT approaches, and often have some rule-based components.

Each approach has its own strengths and weaknesses. Since the classification approach is able to focus on each individual error type using a separate classifier, it may perform better on an error type where it can build a custom-made classifier tailored to the error type, such as subject-verb agreement errors. The drawback of the classification approach is that one classifier must be built for each error type, so a comprehensive GEC system will need to build many classifiers which complicates its design. Furthermore, the classification approach does not address multiple error types that may interact.

The SMT approach, on the other hand, naturally takes care of interaction among words in a sentence as it attempts to find the best overall corrected sentence. It usually has a better coverage of different error types. The drawback of this approach is its reliance on error-annotated learner data, which is expensive to produce. It is not possible to build a competitive SMT system without a sufficiently large parallel training corpus, consisting of texts written by ESL learners and the corresponding corrected texts.

In this work, we aim to take advantage of both the classification and the SMT approaches. By combining the outputs of both systems, we hope that the strengths of one approach will offset the weaknesses of the other approach. We adopt the system combination technique of (Heafield and Lavie, 2010), which starts by creating word-level alignments among multiple outputs. By performing beam search over these alignments, it tries to find the best corrected sentence that combines parts of multiple system outputs.

The main contributions of this paper are as fol-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 951–962,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

lows:

- It is the first work that makes use of a system combination strategy to improve grammatical error correction;
- It gives a detailed description of methods and experimental setup for building component systems using two state-of-the-art approaches; and
- It provides a detailed analysis of how one approach can benefit from the other approach through system combination.

We evaluate our system combination approach on the CoNLL-2014 shared task. The approach achieves an $F_{0.5}$ score of 39.39%, outperforming the best participating team in the shared task.

The remainder of this paper is organized as follows. Section 2 gives the related work. Section 3 describes the individual systems. Section 4 explains the system combination method. Section 5 presents experimental setup and results. Section 6 provides a discussion and analysis of the results. Section 7 describes further experiments on system combination. Finally, Section 8 concludes the paper.

2 Related Work

2.1 Grammatical Error Correction

Early research in grammatical error correction focused on a single error type in isolation. For example, Knight and Chander (1994) built an article correction system for post-editing machine translation output.

The classification approach has been used to deal with the most common grammatical mistakes made by ESL learners, such as article and preposition errors (Han et al., 2006; Chodorow et al., 2007; Tetreault and Chodorow, 2008; Gamon, 2010; Dahlmeier and Ng, 2011; Rozovskaya and Roth, 2011; Wu and Ng, 2013), and more recently, verb errors (Rozovskaya et al., 2014b). Statistical classifiers are trained either from learner or non-learner texts. Features are extracted from the sentence context. Typically, these are shallow features, such as surrounding n-grams, part-of-speech (POS) tags, chunks, etc. Different sets of features are employed depending on the error type addressed.

The statistical machine translation (SMT) approach has gained more interest recently. Earlier work was done by Brockett et al. (2006), where they used SMT to correct mass noun errors. The major impediment in using the SMT approach for GEC is the lack of error-annotated learner ("parallel") corpora. Mizumoto et al. (2011) mined a learner corpus from the social learning platform Lang-8 and built an SMT system for correcting grammatical errors in Japanese. They further tried their method for English (Mizumoto et al., 2012).

Other approaches combine the advantages of classification and SMT (Dahlmeier and Ng, 2012a) and sometimes also include rule-based components. Note that in the hybrid approaches proposed previously, the output of each component system might be only *partially* corrected for some subset of error types. This is different from our system combination approach, where the output of each component system is a *complete* correction of the input sentence where all error types are dealt with.

State-of-the-art performance is achieved by both the classification (Dahlmeier et al., 2012; Rozovskaya et al., 2013; Rozovskaya et al., 2014a) and the SMT approach (Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014), which motivates us to attempt system output combination from both approaches.

2.2 System Combination

System combination is the task of combining the outputs of multiple systems to produce an output better than each of its individual component systems. In machine translation (MT), combining multiple MT outputs has been attempted in the Workshop on Statistical Machine Translation (Callison-Burch et al., 2009; Bojar et al., 2011).

One of the common approaches in system combination is the confusion network approach (Rosti et al., 2007b). In this approach, a confusion network is created by aligning the outputs of multiple systems. The combined output is generated by choosing the output of one single system as the "backbone", and aligning the outputs of all other systems to this backbone. The word order of the combined output will then follow the word order of the backbone. The alignment step is critical in system combination. If there is an alignment error, the resulting combined output sentence may be ungrammatical.

Rosti et al. (2007a) evaluated three system combination methods in their work:

- **Sentence level** This method looks at the combined N-best list of the systems and selects the best output.
- **Phrase level** This method creates new hypotheses using a new phrase translation table, built according to the phrase alignments of the systems.
- **Word level** This method creates a graph by aligning the hypotheses of the systems. The confidence score of each aligned word is then calculated according to the votes from the hypotheses.

Combining different component sub-systems was attempted by CUUI (Rozovskaya et al., 2014a) and CAMB (Felice et al., 2014) in the CoNLL-2014 shared task. The CUUI system employs different classifiers to correct various error types and then merges the results. The CAMB system uses a pipeline of systems to combine the outputs of their rule based system and their SMT system. The combination methods used in those systems are different from our approach, because they combine individual *sub*-system components, by piping the output from one sub-system to another, whereas we combine the outputs of *whole* systems. Moreover, our approach is able to combine the advantages of both the classification and SMT approaches. In the field of grammatical error correction, our work is novel as it is the first that uses system combination to improve grammatical error correction.

3 The Component Systems

We build four individual error correction systems. Two systems are pipeline systems based on the classification approach, whereas the other two are phrase-based SMT systems. In this section, we describe how we build each system.

3.1 Pipeline

We build two different pipeline systems. Each system consists of a sequence of classifier-based correction steps. We use two different sequences of correction steps as shown in Table 1. As shown by the table, the only difference between the two pipeline systems is that we swap the noun number and the article correction step. We do this because there is an interaction between noun number and article correction. Swapping them generates system outputs that are quite different.

Step	Pipeline 1 (*P1*)	Pipeline 2 (*P2*)
1	Spelling	Spelling
2	Noun number	Article
3	Preposition	Preposition
4	Punctuation	Punctuation
5	Article	Noun number
6	Verb form, SVA	Verb form, SVA

Table 1: The two pipeline systems.

We model each of the article, preposition, and noun number correction task as a multi-class classification problem. A separate multi-class confidence weighted classifier (Crammer et al., 2009) is used for correcting each of these error types. A correction is only made if the difference between the scores of the original class and the proposed class is larger than a threshold tuned on the development set. The features of the article and preposition classifiers follow the features used by the NUS system from HOO 2012 (Dahlmeier et al., 2012). For the noun number error type, we use lexical n-grams, ngram counts, dependency relations, noun lemma, and countability features.

For article correction, the classes are the articles *a*, *the*, and the *null article*. The article *an* is considered to be the same class as *a*. A subsequent post-processing step chooses between *a* and *an* based on the following word. For preposition correction, we choose 36 common English prepositions as used in (Dahlmeier et al., 2012). We only deal with preposition replacement but not preposition insertion or deletion. For noun number correction, the classes are *singular* and *plural*.

Punctuation, subject-verb agreement (SVA), and verb form errors are corrected using rule-based classifiers. For SVA errors, we assume that noun number errors have already been corrected by classifiers earlier in the pipeline. Hence, only the verb is corrected when an SVA error is detected. For verb form errors, we change a verb into its base form if it is preceded by a modal verb, and we change it into the past participle form if it is preceded by *has*, *have*, or *had*.

The spelling corrector uses Jazzy, an open source Java spell-checker[1]. We filter the suggestions given by Jazzy using a language model. We accept a suggestion from Jazzy only if the suggestion increases the language model score of the sentence.

[1] http://jazzy.sourceforge.net/

3.2 Statistical Machine Translation

The other two component systems are based on phrase-based statistical machine translation (Koehn et al., 2003). It follows the well-known log-linear model formulation (Och and Ney, 2002):

$$\begin{aligned}\hat{e} &= \arg\max_{e} P(e|f) \\ &= \arg\max_{e} \exp\left(\sum_{m=1}^{M} \lambda_m h_m(e,f)\right) \quad (1)\end{aligned}$$

where f is the input sentence, e is the corrected output sentence, h_m is a feature function, and λ_m is its weight. The feature functions include a translation model learned from a sentence-aligned parallel corpus and a language model learned from a large English corpus. More feature functions can be integrated into the log-linear model. A decoder finds the best correction $\hat{e}$ that maximizes Equation 1 above.

The parallel corpora that we use to train the translation model come from two different sources. The first corpus is NUCLE (Dahlmeier et al., 2013), containing essays written by students at the National University of Singapore (NUS) which have been manually corrected by English instructors at NUS. The other corpus is collected from the language exchange social networking website Lang-8. We develop two versions of SMT systems: one with two phrase tables trained on NUCLE and Lang-8 separately (*S1*), and the other with a single phrase table trained on the concatenation of NUCLE and Lang-8 data (*S2*). Multiple phrase tables are used with alternative decoding paths (Birch et al., 2007). We add a word-level Levenshtein distance feature in the phrase table used by *S2*, similar to (Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014). This feature is not included in *S1*.

4 System Combination

We use MEMT (Heafield and Lavie, 2010) to combine the outputs of our systems. MEMT uses METEOR (Banerjee and Lavie, 2005) to perform alignment of each pair of outputs from the component systems. The METEOR matcher can identify exact matches, words with identical stems, synonyms, and unigram paraphrases.

MEMT uses an approach similar to the confusion network approach in SMT system combination. The difference is that it performs alignment on the outputs of every pair of component systems, so it does not need to choose a single backbone. As MEMT does not choose any single system output as its backbone, it can consider the output of each component system in a symmetrical manner. This increases word order flexibility, as choosing a single hypothesis as the backbone will limit the number of possible word order permutations.

After creating pairwise alignments using METEOR, the alignments form a confusion network. MEMT will then perform a beam search over this graph to find the one-best hypothesis. The search is carried out from left to right, one word at a time, creating a partial hypothesis. During beam search, it can freely switch among the component systems, combining the outputs together into a sentence. When it adds a word to its hypothesis, all the words aligned to it in the other systems are also marked as "used". If it switches to another input sentence, it has to use the first "unused" word in that sentence. This is done to make sure that every aligned word in the sentences is used. In some cases, a heuristic could be used to allow skipping over some words (Heafield et al., 2009).

During beam search, MEMT uses a few features to score the hypotheses (both partial hypotheses and full hypotheses):

- **Length** The number of tokens in a hypothesis. It is useful to normalize the impact of sentence length.
- **Language model** Log probability from a language model. It is especially useful in maintaining sentence fluency.
- **Backoff** The average n-gram length found in the language model.
- **Match** The number of n-gram matches between the outputs of the component systems and the hypothesis, counted for small order n-grams.

The weights of these features are tuned using Z-MERT (Zaidan, 2009) on a development set.

This system combination approach has a few advantages in grammatical error correction. METEOR not only can match words with exact matches, but also words with identical stems, synonyms, and unigram paraphrases. This means that it can deal with word form, noun number, and verb form corrections that share identical stems, as well

Data set	# sentences	# source tokens
NUCLE	57,151	1,161,567
Lang-8	1,114,139	12,945,666
CoNLL-2013	1,381	29,207
CoNLL-2014	1,312	30,144
English Wikipedia	86,992,889	1,778,849,655

Table 2: Statistics of the data sets.

as word choice corrections (with synonyms and unigram paraphrases). Also, MEMT uses a language model feature to maintain sentence fluency, favoring grammatical output sentences.

In this paper, we combine the pipeline system $P1$ (Table 1) with the SMT system $S1$, and also combine $P2$ with $S2$. The two component systems in each pair have comparable performance. For our final system, we also combine all four systems together.

5 Experiments

Our approach is evaluated in the context of the CoNLL-2014 shared task on grammatical error correction. Specific details of the shared task can be found in the overview paper (Ng et al., 2014), but we summarize the most important details relevant to our study here.

5.1 Data

We use NUCLE version 3.2 (Dahlmeier et al., 2013), the official training data of the CoNLL-2014 shared task, to train our component systems. The grammatical errors in this corpus are categorized into 28 different error types. We also use the "Lang-8 Corpus of Learner English v1.0"[2] (Tajiri et al., 2012) to obtain additional learner data. English Wikipedia[3] is used for language modeling and collecting n-gram counts. All systems are tuned on the CoNLL-2013 test data (which serves as the development data set) and tested on the CoNLL-2014 test data. The statistics of the data sets can be found in Table 2.

5.2 Evaluation

System performance is evaluated based on precision, recall, and $F_{0.5}$ (which weights precision twice as much as recall). Given a set of n sentences, where $\mathbf{g}_i$ is the set of gold-standard edits for sentence i, and $\mathbf{e}_i$ is the set of system edits for sentence i, precision, recall, and $F_{0.5}$ are defined as follows:

$$P = \frac{\sum_{i=1}^{n} |\mathbf{g}_i \cap \mathbf{e}_i|}{\sum_{i=1}^{n} |\mathbf{e}_i|} \quad (2)$$

$$R = \frac{\sum_{i=1}^{n} |\mathbf{g}_i \cap \mathbf{e}_i|}{\sum_{i=1}^{n} |\mathbf{g}_i|} \quad (3)$$

$$F_{0.5} = \frac{(1 + 0.5^2) \times R \times P}{R + 0.5^2 \times P} \quad (4)$$

where the intersection between $\mathbf{g}_i$ and $\mathbf{e}_i$ for sentence i is defined as

$$\mathbf{g}_i \cap \mathbf{e}_i = \{e \in \mathbf{e}_i | \exists g \in \mathbf{g}_i, match(g, e)\} \quad (5)$$

The official scorer for the shared task was the *MaxMatch* (M^2) scorer[4] (Dahlmeier and Ng, 2012b). The scorer computes the sequence of system edits between a source sentence and a system hypothesis that achieves the maximal overlap with the gold-standard edits. Like CoNLL-2014, $F_{0.5}$ is used instead of F_1 to emphasize precision. For statistical significance testing, we use the sign test with bootstrap re-sampling on 100 samples.

5.3 Pipeline System

We use ClearNLP[5] for POS tagging and dependency parsing, and OpenNLP for chunking[6]. We use the WordNet (Fellbaum, 1998) morphology software to generate singular and plural word surface forms.

The article, preposition, and noun number correctors use the classifier approach to correct errors. Each classifier is trained using multi-class confidence weighted learning on the NUCLE and Lang-8 corpora. The classifier threshold is tuned using a simple grid search on the development data set for each class of a classifier.

5.4 SMT System

The system is trained using Moses (Koehn et al., 2007), with Giza++ (Och and Ney, 2003) for word alignment. The translation table is trained using the "parallel" corpora of NUCLE and Lang-8. The table contains phrase pairs of maximum length seven. We include five standard parameters in the translation table: forward and reverse phrase translations, forward and reverse lexical translations,

[2] http://cl.naist.jp/nldata/lang-8/

[3] http://dumps.wikimedia.org/enwiki/20140102/enwiki-20140102-pages-articles.xml.bz2

[4] http://www.comp.nus.edu.sg/∼nlp/sw/m2scorer.tar.gz

[5] https://code.google.com/p/clearnlp/

[6] http://opennlp.apache.org/

and phrase penalty. We further add a word-level Levenshtein distance feature for *S2*.

We do not use any reordering model in our system. The intuition is that most error types do not involve long-range reordering and local reordering can be easily captured in the phrase translation table. The distortion limit is set to 0 to prohibit reordering during hypothesis generation.

We build two 5-gram language models using the corrected side of NUCLE and English Wikipedia. The language models are estimated using the KenLM toolkit (Heafield et al., 2013) with modified Kneser-Ney smoothing. These two language models are used as separate feature functions in the log-linear model. Finally, they are binarized into a probing data structure (Heafield, 2011). Tuning is done on the development data set with MERT (Och, 2003). We use BLEU (Papineni et al., 2002) as the tuning metric, which turns out to work well in our experiment.

5.5 Combined System

We use an open source MEMT implementation by Heafield and Lavie (2010) to combine the outputs of our systems. Parameters are set to the values recommended by (Heafield and Lavie, 2010): a beam size of 500, word skipping using length heuristic with radius 5, and with the length normalization option turned off. We use five matching features for each system: the number of exact unigram and bigram matches between hypotheses and the number of matches in terms of stems, synonyms, or paraphrases for unigrams, bigrams, and trigrams. We use the Wikipedia 5-gram language model in this experiment.

We tune the combined system on the development data set. The test data is input into both the pipeline and SMT system respectively and the output from each system is then matched using METEOR (Banerjee and Lavie, 2005). Feature weights, based on BLEU, are then tuned using Z-MERT (Zaidan, 2009). We repeat this process five times and use the weights that achieve the best score on the development data set in our final combined system.

5.6 Results

Our experimental results using the CoNLL-2014 test data as the test set are shown in Table 3. Each system is evaluated against the same gold standard human annotations. As recommended in Ng et al. (2014), we do not use the revised gold standard to ensure a fairer evaluation (i.e., without using alternative answers).

System	P	R	$F_{0.5}$
Pipeline			
P1	40.24	23.99	35.44
P2	39.93	22.77	34.70
SMT			
S1	57.90	14.16	35.80
S2	62.11	12.54	34.69
Combined			
P1+S1	53.85	17.65	38.19
P2+S2	56.92	16.22	37.90
P1+P2+S1+S2	53.55	19.14	39.39
Top 4 Systems in CoNLL-2014			
CAMB	39.71	30.10	37.33

Table 3: Performance of the pipeline, SMT, and combined systems on the CoNLL-2014 test set. All improvements of combined systems over their component systems are statistically significant ($p < 0.01$). The differences between P1 and S1 and between P2 and S2 are not statistically significant.

First, we can see that both the pipeline and SMT systems individually achieve relatively good results that are comparable with the third highest ranking participant in the CoNLL-2014 shared task. It is worth noting that the pipeline systems only target the seven most common error types, yet still perform well in an all-error-type setting. In general, the pipeline systems have higher recall but lower precision than the SMT systems.

The pipeline system is also sensitive to the order in which corrections are applied; for example applying noun number corrections before article corrections results in a better score. This means that there is definitely some interaction between grammatical errors and, for instance, the phrase *a houses* can be corrected to *a house* or *houses* depending on the order of correction.

We noticed that the performance of the SMT system could be improved by using multiple translation models. This is most likely due to domain differences between the NUCLE and Lang-8 corpus, e.g., text genres, writing style, topics, etc. Note also that the Lang-8 corpus is more than 10 times larger than the NUCLE corpus, so there

is some benefit from training and weighting two translation tables separately.

The performance of the pipeline system *P1* is comparable to that of the SMT system *S1*, and likewise the performance of *P2* is comparable to that of *S2*. The differences between them are not statistically significant, making it appropriate to combine their respective outputs.

Every combined system achieves a better result than its component systems. In every combination, there is some improvement in precision over the pipeline systems, and some improvement in recall over the SMT systems. The combination of the better component systems (*P1*+*S1*) is also statistically significantly better than the combination of the other component systems (*P2*+*S2*). Combining all four component systems yields an even better result of 39.39% $F_{0.5}$, which is even better than the CoNLL-2014 shared task winner. This is significant because the individual component systems barely reached the score of the third highest ranking participant before they were combined.

6 Discussion

In this section, we discuss the strengths and weaknesses of the pipeline and SMT systems, and show how system output combination improves performance. Specifically, we compare *P1*, *S1*, and *P1*+*S1*, although the discussion also applies to *P2*, *S2*, and *P2*+*S2*.

Type performance. We start by computing the recall for each of the 28 error types achieved by each system. This computation is straightforward as each gold standard edit is also annotated with error type. On the other hand, precision, as mentioned in the overview paper (Ng et al., 2014), is much harder to compute because systems typically do not categorize their corrections by error type. Although it may be possible to compute the precision for each error type in the pipeline system (since we know which correction was proposed by which classifier), this is more difficult to do in the SMT and combined system, where we would need to rely on heuristics which are more prone to errors. As a result, we decided to analyze a sample of 200 sentences by hand for a comparatively more robust comparison. The results can be seen in Table 4.

We observe that the pipeline system has a higher recall than the SMT system for the following error types: *ArtOrDet*, *Mec*, *Nn*, *Prep*, *SVA*, *Vform*, and *Vt*. Conversely, the SMT system generally has a higher precision than the pipeline system. The combined system usually has slightly lower precision than the SMT system, but higher than the pipeline system, and slightly higher recall than the SMT system but lower than the pipeline system. In some cases however, like for *Vform* correction, both precision and recall increase.

The combined system can also make use of corrections which are only corrected in one of the systems. For example, it corrects both Wform and Pform errors, which are only corrected by the SMT system, and SVA errors, which are only corrected by the pipeline system.

Error analysis. For illustration on how system combination helps, we provide example output from the pipeline system *P1*, SMT system *S1*, and the combined system *P1*+*S1* in Table 5. We illustrate three common scenarios where system combination helps: the first is when *P1* performs better than *S1*, and the combined system chooses the corrections made by *P1*, the second is the opposite where *S1* performs better than *P1* and the combined system chooses *S1*, and the last is when the combined system combines the corrections made by *P1* and *S1* to produce output better than both *P1* and *S1*.

7 Additional System Combination Experiments

We further evaluate our system combination approach by making use of the corrected system outputs of 12 participating teams in the CoNLL-2014 shared task, which are publicly available on the shared task website.[7] Specifically, we combined the system outputs of the top $2, 3, \ldots, 12$ CoNLL-2014 shared task teams and computed the results.

In our earlier experiments, the CoNLL-2013 test data was used as the development set. However, the participants' outputs for this 2013 data are not available. Therefore, we split the CoNLL-2014 test data into two parts: the first 500 sentences for the development set and the remaining 812 sentences for the test set. We then tried combining the n best performing systems, for $n = 2, 3, \ldots, 12$. Other than the data, the experimental setup is the same as that described in Section 5.5. Table 6 shows the ranking of the participants on the 812 test sentences (without alter-

Table 7: Performance with different numbers of combined top systems.

native answers). Note that since we use a subset of the original CoNLL-2014 test data for testing, the ranking is different from the official CoNLL-2014 ranking.

Table 7 shows the results of system combination in terms of increasing numbers of top systems. We observe consistent improvements in $F_{0.5}$ when we combine more system outputs, up to 5 best performing systems. When combining 6 or more systems, the performance starts to fluctuate and degrade. An important observation is that when we perform system combination, it is more effective, in terms of $F_{0.5}$, to combine a handful of high-quality system outputs than many outputs of variable quality. Precision tends to increase as more systems are combined although recall tends to decrease. This indicates that combining multiple systems can produce a grammatical error correction system with high precision, which is useful in a practical application setting where high precision is desirable. Figure 1 shows how the performance varies as the number of combined systems increases.

8 Conclusion

We have presented a system combination approach for grammatical error correction using MEMT. Our approach combines the outputs from two of the most common paradigms in GEC: the pipeline and statistical machine translation ap-

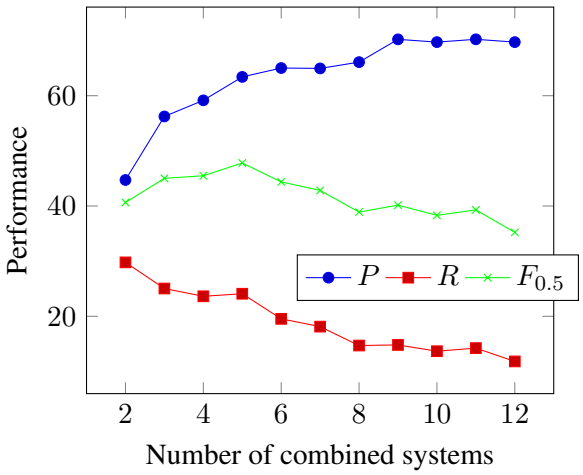

Figure 1: Performance in terms of precision (P), recall (R), and $F_{0.5}$ versus the number of combined top systems.

proach. We created two variants of the pipeline and statistical machine translation approaches and showed that system combination can be used to combine their outputs together to yield a superior system.

Our best combined system achieves an $F_{0.5}$ score of 39.39% on the official CoNLL 2014 test set without alternative answers, higher than the top participating team in CoNLL 2014 on this data set. We achieved this by using component systems which were individually weaker than the top three systems that participated in the shared task.

Abstract

In this paper we propose a method to increase dependency parser performance without using additional labeled or unlabeled data by refining the layer of predicted part-of-speech (POS) tags. We perform experiments on English and German and show significant improvements for both languages. The refinement is based on generative split-merge training for Hidden Markov models (HMMs).

1 Introduction

Probabilistic Context-free Grammars with latent annotations (PCFG-LA) have been shown (Petrov et al., 2006) to yield phrase structure parsers with state-of-the-art accuracy. While Hidden Markov Models with latent annotations (HMM-LA) (Huang et al., 2009), stay somewhat behind the performance of state-of-the-art discriminative taggers (Eidelman et al., 2010). In this paper we address the question of whether the resulting latent POS tags are linguistically meaningful and useful for upstream tasks such as syntactic parsing. We find that this is indeed the case, leading to a procedure that significantly increases the performance of dependency parsers. The procedure is attractive because the refinement of predicted part-of-speech sequences using a coarse-to-fine strategy (Petrov and Klein, 2007) is fast and efficient. More precisely, we show that incorporating the induced POS into a state-of-the-art dependency parser (Bohnet, 2010) gives increases in Labeled Attachment Score (LAS): from 90.34 to 90.57 for English and from 87.92 to 88.24 (resp. 88.35 to 88.51) for German without using (resp. with using) morphological features.

2 Related Work

Petrov et al. (2006) introduce generative split-merge training for PCFGs and provide a fully automatic method for training state-of-the-art phrase structure parsers. They argue that the resulting latent annotations are linguistically meaningful. Sun et al. (2008) induce latent sub-states into CRFs and show that noun phrase (NP) recognition can be improved, especially if no part-of-speech features are available. Huang et al. (2009) apply split-merge training to create HMMs with latent annotations (HMM-LA) for Chinese POS tagging. They report that the method outperforms standard generative bigram and trigram tagging, but do not compare to discriminative methods. Eidelman et al. (2010) show that a bidirectional variant of latent HMMs with incorporation of prosodic information can yield state-of-the-art results in POS tagging of conversational speech.

3 Split-Merge Training for HMMs

Split-merge training for HMMs (Huang et al., 2009) iteratively splits every tag into two subtags. Word emission and tag transition probabilities of subtags are then initialized close to the values of the parent tags but with some randomness to break symmetry. Using expectation–maximization (EM) training the parameters can then be set to a local maximum of the training data likelihood. After this split phase, the merge phase reverts splits that only lead to small improvements in the likelihood function in order to increase the robustness of the model. This approach requires an approximation of the gain in likelihood of every split analogous to Petrov et al. (2006) as an exact computation is not feasible.

We have observed that this procedure is not

only a way to increase HMM tagger performance but also yields annotations that are to a considerable extent linguistically interpretable. As an example we discuss some splits that occurred after a particular split-merge step for English and German. For the sake of comparability we applied the split to the Universal Tagset (Petrov et al., 2011). Table 1 shows the statistics used for this analysis. The Universal POS tag set puts the three Penn-Treebank tags RP (particle), POS (possessive marker) and TO into one particle tag (see "PRT" in English part of the table). The training essentially reverses this by splitting particles first into possessive and non-possessive markers and in a subsequent split the non-possessives into TO and particles. For German we have a similar split into verb particles, negation particles like *nicht* 'not' and the infinitive marker *zu* 'to' ("PRT") in the German part of the table). English prepositions get split by proximity to verbs or nouns ("ADP"). Subordinate conjunctions like *that*, which in the Penn-Treebank annotation are part of the preposition tag IN, get assigned to the sub-class next to verbs. For German we also see a separation of "CONJ" into predominantly subordinate conjunctions (Tag 0) and predominantly coordinating conjunctions (Tag 1). For both languages adjectives get split by predicative and attributive use. For English the predicative sub-class also seems to hold rather atypical adjectives like "such" and "last." For English, verbs ("VERB") get split into a predominantly infinite tag (Tag 0) and a predominantly finite tag (Tag 1) while for German we get a separation by verb position. In German we get a separation of pronouns ("PRON") into possessive and non-possessive; in English, pronouns get split by predominant usage in subject position (Tag 0) and as possessives (Tag 1).

Our implementation of HMM-LA has been released under an open-source licence.[1]

In the next section we evaluate the utility of these annotations for dependency parsing.

4 Dependency Parsing

In this section we investigate the utility of induced POS as features for dependency parsing. We run our experiments on the CoNLL-2009 data sets (Hajič et al., 2009) for English and German. As a baseline system we use the latest version of the mate-tools parser (Bohnet, 2010).[3] It was the highest scoring syntactic parser for German and English in the CoNLL 2009 shared task evaluation. The parser gets automatically annotated lemmas, POS and morphological features as input which are part of the CoNLL-2009 data sets.

In this experiment we want to examine the benefits of tag refinements isolated from the improvements caused by using two taggers in parallel, thus we train the HMM-LA on the automatically tagged POS sequences of the training set and use it to add an additional layer of refined POS to the input data of the parser. We do this by calculating the forward-backward charts that are also used in the E-steps during training — in these charts base

	107	87.43	(87.73)	0.16	89.81	(90.14)	0.17
	134	87.38	(87.53)	0.08	89.75	(89.89)	0.08

Table 2: LAS and UAS[1] mean (μ), best value ($\max$) and std. deviation (σ) for the development set for English and German dependency parsing with (feat.) and without morphological features (no feat.).

tags of the refined tags are constrained to be identical to the automatically predicted tags.

We use 100 EM iterations after each split and merge phase. The percentage of splits reverted in each merge phase is set to .75.

We integrate the tags by adding one additional feature for every edge: the conjunction of latent tags of the two words connected by the edge.

Table 2 shows results of our experiments. All numbers are averages of five independent runs. For English the smaller models with 58 and 73 tags achieve improvements of ≈.1. The improvements for the larger tag sets are ≈.2. The best individual model improves LAS by .3. For the German experiments without morphological features we get only marginal average improvements for the smallest tag set and improvements of ≈.15 for the bigger tag sets. The average ULA scores for 107 and 134 tags are at the same level as the ULA scores of the baseline with morph. features. The best model improves LAS by .3. For German with morphological features the absolute differences are smaller: The smallest tag set does not improve the parser on average. For the tag set of 107 tags the average improvement is .08. The best model improves LAS by .38. In all experiments we see the highest improvements for tag set sizes of roughly the same size (115 for English, 107 for German). While average improvements are low (esp. for German with morphological features), peak improvements are substantial.

Running the best English system on the test set gives an improvement in LAS from 90.34 to 90.57; this improvement is significant[4] ($p < .02$). For German we get an improvement from 87.92 to 88.24 without and from 88.35 to 88.51 with morphological features. The difference between the values without morphological features is significant ($p < .05$), but the difference between models with morphological features is not ($p = .26$). However, the difference between the baseline system with morphological features and the best system without morphological features is also not significant ($p = .49$).

We can conclude that HMM-LA tags can significantly improve parsing results. For German we see that HMM-LA tags can substitute morphological features up to an insignificant difference. We also see that morphological features and HMM-LA seem to be correlated as combining the two gives only insignificant improvements.

5 Contribution Analysis

In this section we try to find statistical evidence for why a parser using a fine-grained tag set might outperform a parser based on treebank tags only.

The results indicate that an induced latent tag set as a whole increases parsing performance. However, not every split made by the HMM-LA seems to be useful for the parser. The scatter plots in Figure 1 show that there is no strict correlation between tagging accuracy of a model and the resulting LAS. This is expected as the latent induction optimizes a tagging objective function, which does not directly translate into better parsing performance. An example is lexicalization. Most latent models for English create a subtag for the preposition "of". This is useful for a HMM as "of" is frequent and has a very specific context. A lexicalized syntactic parser, however, does not benefit from such a tag.

[4] Approx. randomization test (Yeh, 2000) on LAS scores

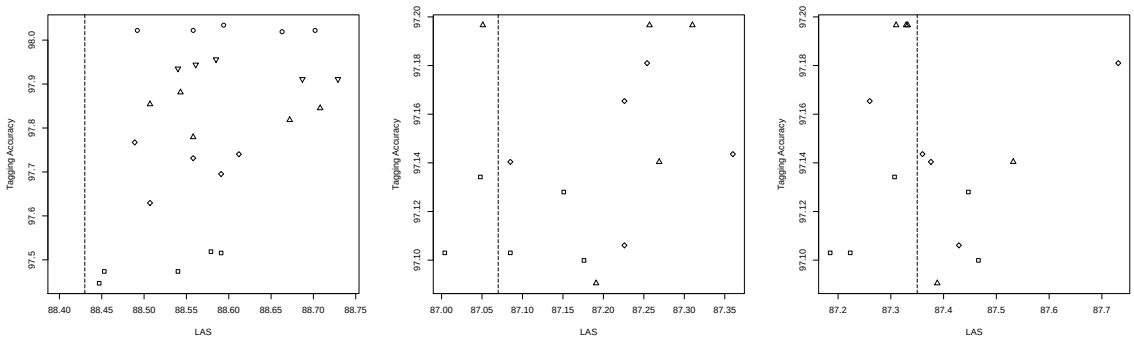

Figure 1: Scatter plots of LAS vs tagging accuracy for English (left) and German without (middle) and with (right) morphological features. English tag set sizes are 58 (squares), 73 (diamonds), 92 (triangles), 115 (triangles pointing downwards) and 144 (circles). German tag set sizes are 85 (squares), 107 (diamonds) and 134 (triangles). The dashed lines indicate the baselines.

We base the remainder of our analysis on the results of the baseline parser on the English development set and the results of the best performing latent model. The best performing model has a LAS score of 88.73 vs 88.43 for the baseline, a difference of .3. If we just look at the LAS of words with incorrectly predicted POS we see a difference of 1.49. A look at the data shows that the latent model helps the parser to identify words that might have been annotated incorrectly. As an example consider plural nouns (NNS) and two of their latent subtags NNS_1 and NNS_2 and how often they get classified correctly and misclassified as proper nouns (NNPS):

	NNS	NNPS
NNS	**2019**	**104**
NNS_1	90	72
NNS_2	**1100**	13
...	...	...

We see that NNS_1 is roughly equally likely to be a NNPS or NNS while NNS_2 gives much more confidence of the actual POS being NNS. So one benefit of HMM-LA POS tag sets are tags of different levels of confidence.

Another positive effect is that latent POS tags have a higher correlation with certain dependency relations. Consider proper nouns (NNP):

	NAME	NMOD	SBJ
NNP	**962**	**662**	**468**
NNP_1	10	27	**206**
NNP_2	24	50	**137**
...	...	...	...

We see that NNP_1 and NNP_2 are more likely to appear in subject relations. NNP_1 contains surnames; the most frequent word forms are *Keating*, *Papandreou* and *Kaye*. In contrast, NNP_2 contains company names such as *Sony*, *NBC* and *Keystone*. This explains why the difference in LAS is twice as high for NNPs as on average.

For German we see similar effects and the anticipated correlation with morphology. The 5 determiner subtags, for example, strongly correlate with grammatical case:

	Nom	Gen	Dat	Acc
ART	**1185**	**636**	**756**	**961**
ART_1	**367**		7	38
ART_2	11	28	**682**	21
ART_3	6	**602**	7	3
ART_4	39		43	**429**
ART_5	**762**	6	17	**470**

6 Conclusion and Future Work

We have shown that HMMs with latent annotations (HMMLA) can generate latent part-of-speech tagsets are linguistically interpretable and can be used to improve dependency parsing. Our best systems improve an English parser from a LAS of 90.34 to 90.57 and a German parser from 87.92 to 88.24 when not using morphological features and from 88.35 to 88.51 when using morphological features . Our analysis of the parsing results shows that the major reasons for the improvements are: the separation of POS tags into more and less trustworthy subtags, the creation of POS subtags with higher correlation to certain dependency labels and for German a correlation of tags and morphological features such as case.

7 Future Work

The procedure works well in general. However, not every split is useful for the parser; e.g., as

discussed above lexicalization increases HMM accuracy, but does not help an already lexicalized parser. We would like to use additional information (e.g., from the dependency trees) to identify useless splits. The different granularities of the hierarchy induced by split-merge training are potentially useful. However, the levels of the hierarchy are incomparable: a child tag is in general not a subtag of a parent tag. We think that coupling parents and children in the tag hierarchy might be one way to force a consistent hierarchy.

Importance weighting and unsupervised domain adaptation of POS taggers: a negative result

Barbara Plank, Anders Johannsen and Anders Søgaard

bplank@cst.dk,ajohannsen@hum.ku.dk,soegaard@hum.ku.dk

Abstract

Importance weighting is a generalization of various statistical bias correction techniques. While our labeled data in NLP is heavily biased, importance weighting has seen only few applications in NLP, most of them relying on a small amount of labeled target data. The publication bias toward reporting positive results makes it hard to say whether researchers have tried. This paper presents a negative result on unsupervised domain adaptation for POS tagging. In this setup, we only have *unlabeled* data and thus only indirect access to the bias in emission and transition probabilities. Moreover, most errors in POS tagging are due to unseen words, and there, importance weighting cannot help. We present experiments with a wide variety of weight functions, quantilizations, as well as with randomly generated weights, to support these claims.

1 Introduction

Many NLP tasks rely on the availability of annotated data. The majority of annotated data, however, is sampled from newswire corpora. The performance of NLP systems, e.g., part-of-speech (POS) tagger, parsers, relation extraction systems, etc., drops significantly when they are applied to data that departs from newswire conventions. So while we can extract information, translate and summarize newswire in major languages with some success, we are much less successful processing microblogs, chat, weblogs, answers, emails or literature in a robust way. The main reasons for the drops in accuracy have been attributed to factors such as previously unseen words and bigrams, missing punctuation and capitalization, as well as differences in the marginal distribution of data (Blitzer et al., 2006; McClosky et al., 2008; Søgaard and Haulrich, 2011).

The move from one domain to another (from a *source* to a new *target* domain), say from newspaper articles to weblogs, results in a sample selection bias. Our training data is now biased, since it is sampled from a related, but nevertheless different distribution. The problem of automatically adjusting the model induced from source to a different target is referred to as *domain adaptation*.

Some researchers have studied domain adaptation scenarios, where small samples of labeled data have been assumed to be available for the target domains. This is usually an unrealistic assumption, since even for major languages, small samples are only available from a limited number of domains, and in this work we focus on unsupervised domain adaptation, assuming only unlabeled target data is available.

Jiang and Zhai (2007), Foster et al. (2010; Plank and Moschitti (2013) and Søgaard and Haulrich (2011) have previously tried to use importance weighting to correct sample bias in NLP. Importance weighting means assigning a weight to each training instance, reflecting its importance for modeling the target distribution. Importance weighting is a generalization over post-stratification (Smith, 1991) and importance sampling (Smith et al., 1997) and can be used to correct bias in the labeled data.

Out of the four papers mentioned, only Søgaard and Haulrich (2011) and Plank and Moschitti (2013) considered an unsupervised domain adaptation scenario, obtaining mixed results. These two papers assume *covariate shift* (Shimodaira, 2000), i.e., that there is only a bias in the marginal distribution of the training data. Under this assumption, we can correct the bias by applying a weight function $\frac{P_t(\mathbf{x})}{P_s(\mathbf{x})}$ to our training data points (labeled sentences) and learn from the weighted data. Of course this weight function cannot be

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 968–973,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

computed in general, but we can approximate it in different ways.

In POS tagging, we typically factorize sequences into emission and transition probabilities. Importance weighting can change emission probabilities and transition probabilities by assigning weights to sentences. For instance, if our corpus consisted of three sequences: 1) *a/A b/A*, 2) *a/A b/B*, and 3) *a/A b/B*, then $P(B|A) = 2/3$. If sequences two and three were down-weighted to 0.5, then $P(B|A) = 1/2$.

However, this paper argues that importance weighting cannot help adapting POS taggers to new domains using only unlabeled target data. We present three sources of evidence: (a) negative results with the most obvious weight functions across various English datasets, (b) negative results with randomly sampled weights, as well as (c) an analysis of annotated data indicating that there is little variation in emission and transition probabilities across the various domains.

2 Related work

Most prior work on importance weighting use a *domain classifier*, i.e., train a classifier to discriminate between source and target instances (Søgaard and Haulrich, 2011; Plank and Moschitti, 2013) ($y \in \{s, t\}$). For instance, Søgaard and Haulrich (2011) train a n-gram text classifier and Plank and Moschitti (2013) a tree-kernel based classifier on relation extraction instances. In these studies, $\hat{P}(t|\mathbf{x})$ is used as an approximation of $\frac{P_t(\mathbf{x})}{P_s(\mathbf{x})}$, following Zadrozny (2004). In §3, we follow the approach of Søgaard and Haulrich (2011), but consider a wider range of weight functions. Others have proposed to use kernel mean matching (Huang et al., 2007) or minimizing KL-divergence (Sugiyama et al., 2007).

Jiang and Zhai (2007) use importance weighting to select a subsample of the source data by subsequently setting the weight of all selected data points to 1, and 0 otherwise. However, they do so by relying on a sequential model trained on labeled target data. Our results indicate that the covariate shift assumption fails to hold for cross-domain POS tagging. While the marginal distributions obviously *do* differ (since we can tell domains apart without POS analysis), this is most likely not the only difference. This might explain the positive results obtained by Jiang and Zhai (2007). We will come back to this in §4.

Cortes et al. (2010) show that importance weighting potentially leads to over-fitting, but propose to use quantiles to obtain more robust weight functions. The idea is to rank all weights and obtain q quantiles. If a data point $\mathbf{x}$ is weighted by w, and w lies in the ith quantile of the ranking ($i \leq q$), $\mathbf{x}$ is weighted by the average weight of data points in the ith quantile.

The weighted structured perceptron (§3) used in the experiments below was recently used for a different problem, namely for correcting for bias in annotations (Plank et al., 2014).

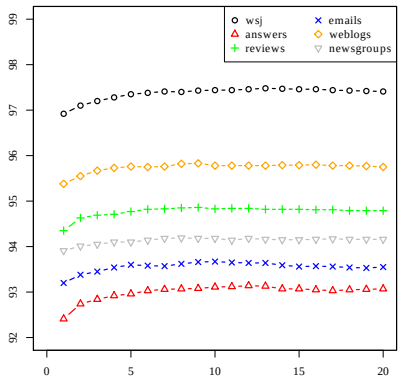

Figure 1: Training epochs vs tagging accuracy for the baseline model on the dev data.

3 Experiments

3.1 Data

We use the data made available in the SANCL 2012 Shared Task (Petrov and McDonald, 2012). The training data is the OntoNotes 4.0 release of the Wall Street Journal section of the Penn Treebank, while the target domain evaluation data comes from various sources, incl. Yahoo Answers, user reviews, emails, weblogs and newsgroups. For each target domain, we have both development and test data.

3.2 Model

In the weighted perceptron (Cavallanti et al., 2006), we make the learning rate dependent on the current instance $\mathbf{x}_n$, using the following update:

$$\mathbf{w}^{i+1} \leftarrow \mathbf{w}^i + \beta_n \alpha(y_n - \text{sign}(\mathbf{w}^i \cdot \mathbf{x}_n))\mathbf{x}_n \quad (1)$$

where β_n is the weight associated with $\mathbf{x}_n$. See Huang et al. (2007) for similar notation.

We extend this idea straightforwardly to the structured perceptron (Collins, 2002), for which

we use an in-house implementation. We use commonly used features, i.e., w,w_{-1}, w_{-2}, w_{+1}, w_{+2}, digit, hyphen, capitalization, pre-/suffix features, and Brown word clusters. The model seems robust with respect to number of training epochs, cf. Figure 1. Therefore we fix the number of epochs to five and use this setting in all our experiments. Our code is available at: `https://bitbucket.org/bplank/importance-weighting-exp`.

3.3 Importance weighting

In our first set of experiments, we follow Søgaard and Haulrich (2011) in using document classifiers to obtain weights for the source instances. We train a text classifier that discriminates the two domains (source and target). For each sentence in the source and target domain (the unlabeled text that comes with the SANCL data), we mark whether it comes from the source or target domain and train a binary classifier (logistic regression) to discriminate between the two. For every sentence in the source we obtain its probability for the target domain by doing 5-fold cross-validation. While Søgaard and Haulrich (2011) use only token-based features (word n-grams $\leq$ 3), we here exploit a variety of features: word token n-grams, and two generalizations: using Brown clusters (estimated from the union of the 5 target domains), and Wiktionary tags (if a word has multiple tags, we assign it the union of tags as single tag; OOV words are marked as such).

The distributions of weights can be seen in the upper half of Figure 2.

3.3.1 Results

Table 1 shows that our baseline model achieves state-of-the-art performance compared to SANCL (Petrov and McDonald, 2012)[1] and FLORS (Schnabel and Schütze, 2014). Our results align well with the second best POS tagger in the SANCL 2012 Shared Task. Note

[1] `https://sites.google.com/site/sancl2012/home/shared-task/results`

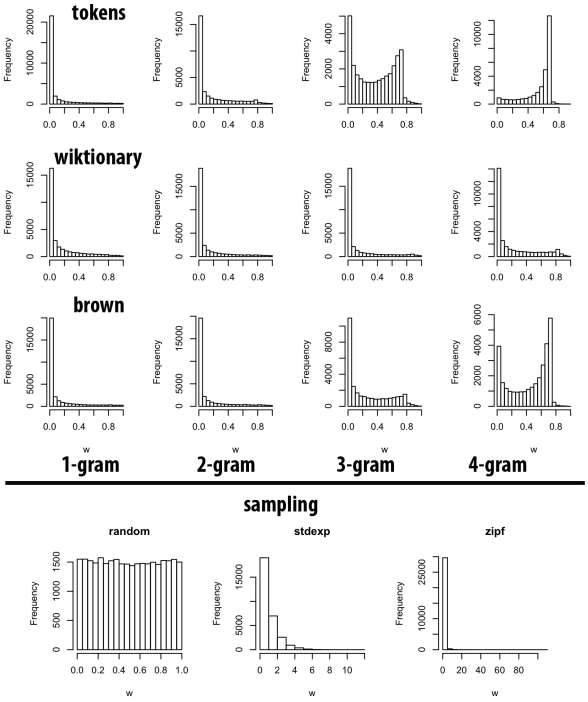

Figure 2: Histogram of different weight functions.

that the best tagger in the shared task explicitly used normalization and various other heuristics to achieve better performance. In the rest of the paper, we use the universal tag set part of the SANCL data (Petrov et al., 2012).

Figure 3 presents our results on development data for different importance weighting setups. None of the above weight functions lead to significant improvements on *any* of the datasets. We also tried scaling and binning the weights, as suggested by Cortes et al. (2010), but results kept fluctuating around baseline performance, with no significant improvements.

3.4 Random weighting

Obviously, weight functions based on document classifiers may simply not characterize the relevant properties of the instances and hence lead to bad re-weighting of the data. We consider three random sampling strategies, namely sampling random uniforms, random exponentials, and random

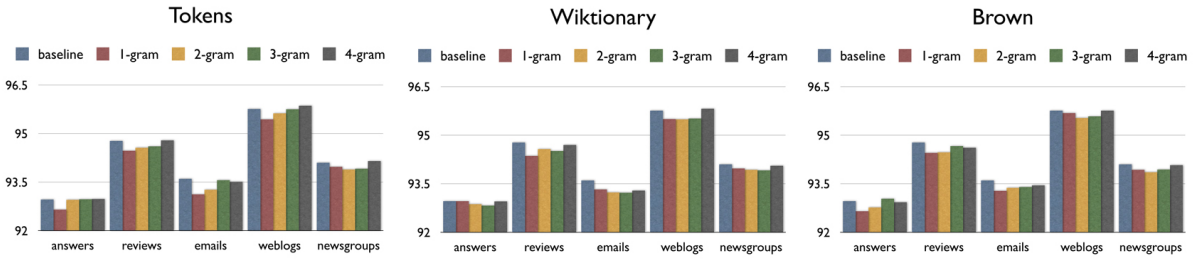

Figure 3: Results on development data for different weight functions, i.e., document classifiers trained on a) raw tokens; b) tokens replaced by Wiktionary tags; c) tokens replaced by Brown cluster ids. The weight was the raw $p_t(y|x)$ value, no scaling, no quantiles. Replacing only open-class tokens for b) and c) gave similar or lower performance.

Zipfians and ran 500 samples for each. For these experiments, we estimate significance cut-off levels of tagging accuracies using the approximate randomization test. To find the cut-off levels, we randomly replace labels with gold labels until the achieved accuracy significantly improves over the baseline for more than 50% of the samples. For each accuracy level, 50 random samples were taken.

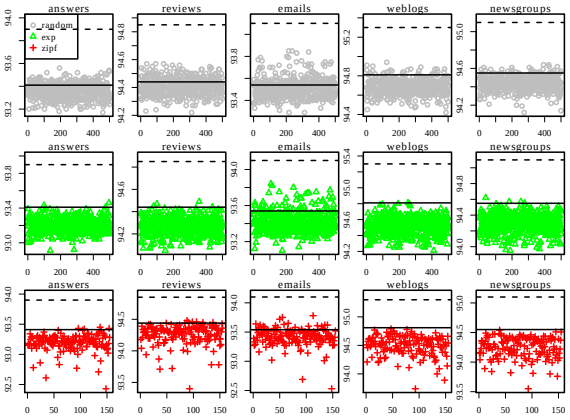

Figure 4: Random weight functions (500 runs each) on test sets. Solid line is the baseline performance, while the dashed line is the p-value cut-off. From top: random, exponential and Zipfian weighting. All runs fall below the cut-off.

3.4.1 Results

The dashed lines in Figure 4 show the p-value cut-offs for positive results. We see that most random weightings of data lead to slight drops in performance or are around baseline performance, and no weightings lead to significant improvements. Random uniforms seem slightly better than exponentials and Zipfians.

domain (tokens)	**avg tag ambiguity**		**OOV**	**KL**	ρ

Table 2: Relevant statistics for our analysis (§4) on the test sets: average tag ambiguity, out-of-vocabulary rate, and KL-divergence and Pearson correlation coefficient (ρ) on POS bigrams.

4 Analysis

Some differences between the gold-annotated source domain data and the gold-annotated target data used for evaluation are presented in Table 2. One important observation is the low ambiguity of word forms in the data. This makes the room for improvement with importance weighting smaller. Moreover, the KL divergencies over POS bigrams are also very low. This tells us that transition probabilities are also relatively constant across domains, again suggesting limited room for improvement for importance weighting.

Compared to this, we see much bigger differences in OOV rates. OOV rates do seem to explain most of the performance drop across domains. In order to verify this, we implemented a version of our structured perceptron tagger with type-constrained inference (Täckström et al., 2013). This technique only improves performance on unseen words, but nevertheless we saw significant improvements across all five domains (cf. Table 3). This suggests that unseen words are a more important problem than the marginal distribution of data for unsupervised domain adaptation of POS taggers.

	ans	rev	email	webl	newsg
base	93.41	94.44	93.54	94.81	94.55

Table 3: Results on the test sets by adding Wiktionary type constraints. †=p-value < 0.001.

We also tried Jiang and Zhai's subset selection technique (§3.1 in Jiang and Zhai (2007)), which assumes labeled training material for the target domain. However, we did not see any improvements. A possible explanation for these different findings might be the following. Jiang and Zhai (2007) use labeled target data to learn their weighting model, i.e., in a supervised domain adaptation scenario. This potentially leads to very different weight functions. For example, let the source domain be 100 instances of $a/A\ b/B$ and 100 instances of $b/B\ b/B$, and the target domain be 100 instances of $a/B\ a/B$. Note that a domain classifier would favor the first 100 sentences, but in an HMM model induced from the labeled target data, things look very different. If we apply Laplace smoothing, the probability of $a/A\ b/B$ according to the target domain HMM model would be $\sim 8.9e^{-7}$, and the probability of $b/B\ b/B$ would be $\sim 9e^{-5}$. Note also that this set-up does not assume covariate shift.

5 Conclusions and Future Work

Importance weighting, a generalization of various statistical bias correction techniques, can potentially correct bias in our labeled training data, but this paper presented a negative result about importance weighting for unsupervised domain adaptation of POS taggers. We first presented experiments with a wide variety of weight functions, quantilizations, as well as with randomly generated weights, none of which lead to significant improvements. Our analysis indicates that most errors in POS tagging are due to unseen words, and what remains seem to not be captured adequately by unsupervised weight functions.

For future work we plan to extend this work to further weight functions, data sets and NLP tasks.

Abstract

Code-mixing is frequently observed in user generated content on social media, especially from multilingual users. The linguistic complexity of such content is compounded by presence of spelling variations, transliteration and non-adherance to formal grammar. We describe our initial efforts to create a multi-level annotated corpus of Hindi-English code-mixed text collated from Facebook forums, and explore language identification, back-transliteration, normalization and POS tagging of this data. Our results show that language identification and transliteration for Hindi are two major challenges that impact POS tagging accuracy.

1 Introduction

Code-Switching and *Code-Mixing* are typical and well-studied phenomena of multilingual societies (Gumperz, 1964; Auer, 1984; Myers-Scotton, 1993; Danet and Herring, 2007; Cardenas-Claros and Isharyanti, 2009). Linguists differentiate between the two, where Code-Switching is juxtaposition within the same speech exchange of passages of speech belonging to two different grammatical systems or sub-systems (Gumperz, 1982), and Code-Mixing (CM) refers to the embedding of linguistic units such as phrases, words and morphemes of one language into an utterance of another language (Myers-Scotton, 1993). The first example in Fig. 1 features CM where English words are embedded in a Hindi sentence, whereas the second example shows codeswitching. Here, we will use CM to imply both. Work on computational models of CM have been few and far between (Solorio and Liu, 2008a; Solorio and Liu, 2008b; Nguyen and Dogruoz, 2013), primarily due to the paucity of CM data in conventional text-corpora which makes data-intensive methods hard to apply. Solorio and Liu (2008a) in their work on English-Spanish CM use models built on smaller datasets to predict valid switching points to synthetically generate data from monolingual corpora, and in another work (2008b) describe parts-of-speech (POS) tagging of CM text.

CM though typically observed in spoken language is now increasingly more common in text, thanks to the proliferation of the Computer Mediated Communication channels, especially social media like Twitter and Facebook (Crystal, 2001; Herring, 2003; Danet and Herring, 2007; Cardenas-Claros and Isharyanti, 2009). Social media content is tremendously important for studying trends, reviews, events, human-behaviour as well as linguistic analysis, and therefore in recent times has spurred a lot of interest in automatic processing of such data. Nevertheless, CM on social media has not been studied from a computational aspect. Moreover, social media content presents additional challenges due to contractions, non-standard spellings and non-grammatical constructions. Furthermore, for languages written in scripts other than Roman, like Hindi, Bangla, Japanese, Chinese and Arabic, Roman transliterations are typically used for representing the words (Sowmya et al., 2010). This can prove a challenge for language identification and segregation of the two languages.

In this paper, we describe our initial efforts to POS tag social media content from English-Hindi (henceforth **En-Hi**) bilinguals while trying to address the challenges of CM, transliteration and non-standard spelling, as well as lack of annotated data. POS tagging is one of the fundamental pre-processing steps for NLP, and while there

have been works on POS tagging of social media data (Gimpel et al., 2011; Owoputi et al., 2013) and of CM (Solorio and Liu, 2008b), but we do not know of any work on POS tagging of CM text from social media that involves transliteration. The salient contributions of this work are in formalizing the problem and related challenges for processing of **En-Hi** social media data, creation of an annotated dataset and some initial experiments for language identification, transliteration, normalization and POS tagging of this data.

2 Corpus Creation

For this study, we collected data from Facebook public pages of three celebrities: Amitabh Bachchan, Shahrukh Khan, Narendra Modi, and the BBC Hindi news page. All these pages are very popular with 1.8 to 15.5 million "likes". A total of 40 posts were manually selected from these pages, which were published between 22nd – 28th October 2013. The posts having a long thread of comments (50+) were preferred, because CM and non-standard usage of language is more common in the comments. We shall use the term *post* to refer to either a post or a comment. The corpus thus created has 6,983 posts and 113,578 words. The data was semi-automatically cleaned and formatted. The user names were removed for anonymity, but the names appearing in comments, which are mostly of celebrities, were retained.

2.1 Annotation

There are various interesting linguistic as well as socio-pragmatic features (e.g., user demographics, presence of sarcasm or humor, polarity) for which this corpus could be annotated because CM is influenced by both linguistic as well as extra-linguistic features. However, initial attempts at such detailed and layered annotation soon revealed the resource-intensiveness of the task. We, thus, scaled down the annotation to the following four layers:

Matrix: The posts are split into contiguous fragments of words such that each fragment has a unique *matrix language* (either **En** or **Hi**). The matrix language is defined as the language which governs the grammatical relation between the constituents of the utterance. Any other language words that are nested into the matrix constitute the *embedded* language(s). Usually, matrix language can be assigned to clauses or sentences.

Word origin: Every word is marked for its origin or source language, **En** or **Hi**, depending on whether it is an English or Hindi word. Words that are of neither Hindi nor English origin are marked as **Ot** or Other. Here, we assume that code-mixing does not happen at sublexical levels, as it is uncommon in this data; **Hi** and **En** have a simpler inflectional morphology and thus, sub-lexical mixing though present (e.g., `computeron` has a **En** root - `computer` and a **Hi** plural marker `on`) is relatively less common. In languages with richer morphology and agglutination, like Bangla and most Dravidian languages, more frequent sublexical mixing may be observed. Also note that words are borrowed extensively between **Hi** and **En** such that certain English words (e.g., bus, party, vote etc) are no longer perceived as English words by the Hindi speakers. However, here we will not distinguish between CM and borrowing, and such borrowed English words have also been labeled as **En** words.

Normalization/Transliteration: Whenever the word is in a transliterated form, which is often the case for the **Hi** words, it is labeled with the intended word in the native script (e.g., Devanagari for **Hi**). If the word is in native script, but uses a non-standard spelling, it is labeled with the correct standard spelling. We call this the spelling normalization layer.

Parts-of-Speech (POS): Finally, each word is also labeled with its POS. We use the Universal POS tagset proposed by Petrov et al. (2011) which has 12 POS tags that are applicable to both **En** and **Hi**. The POS labels are decided based on the function of a word in the context, rather than a decontextualized lexical category. This is an important notion, especially for CM text, because often the original lexical category of an embedded word is lost in the context of the matrix language, and it plays the role of a different lexical category. Though the Universal POS tagset does not prescribe a separate tag for Named Entities, we felt the necessity of marking three different kinds of NEs - people, location and organization, because almost every comment has one or more NEs and strictly speaking word origin does not make sense for these words.

Annotation Scheme: Fig. 1 illustrates the annotation scheme through two examples. Each post is enclosed within <s></s> tags. The matrices within a post are separated by the <matrix></matrix> tags which take the matrix language as an argument. Each word is anno-

```
<s>
      <matrix name="Hindi">
      love_NOUN/E affection_NOUN/E lekar_VERB=”ले कर” salose_NOUN=सालों
se_ADP=से sunday_NOUN/e ke_ADP=के din_NOUN=दिन chali_VERB=चली aarahi_VERB=”आ

       <matrix name="English">
       may_ADP his_PRON sol_NOUN=soul rest_VERB in_ADP peace_NOUN
       </matrix>
 </s>
```

Figure 1: Two example annotations.

tated for POS, and the language (/E or /H for **En** or **Hi** respectively) only if it is different from the language of the matrix. In case of non-standard spelling in English, the correct spelling is appended as “sol_NOUN=soul”, while for the Hindi words, the correct Devanagari transliteration is appended. The NEs are marked with the tags P (person), L (location) or O (organization) and multiword NEs are enclosed within square brackets “[]”.

A random subsample of 1062 posts consisting of 10171 words were annotated by a linguist who is a native speaker of **Hi** and proficient in **En**. The annotations were reviewed and corrected by two experts linguists. During this phase, it was also observed that a large number of comments were very short, typically an eulogism of their favorite celebrity and hence were not interesting from a linguistic point of view. For our experiments, we removed all posts that had fewer than 5 words. The resulting corpus had 381 comments/posts and 4135 words.

2.2 CM Distribution

Most of the posts (93.17%) are in Roman script, and only 2.93% were in Devanagari. Around 3.5% of the posts contain words in both the scripts (typically a post in Devanagari with hashtags or urls in Roman script), and a very small fraction of the text (0.4% of comments/posts and 0.6% words) was in some other script. The fraction of words present in Roman and Devanagri scripts are 80.76% and 15.32% respectively, which shows that the Devanagari posts are relatively longer than the Roman posts. Due to their relative rarity, the posts containing words in Devanagari or any other script were not considered for annotation.

In the annotated data, 1102 sentences are in a single matrix (398 **Hi**, 698 **En** and 6 **Ot**) and in 45 posts there is at least one switch of matrix (mostly between **Hi** and **En**. Thus, 4.2% of the data shows *code-switching*. This is a strict definition of code-switching; if we consider a change in matrix within a conversation thread as a code-switch, then in this data all the threads exhibit code-switching. However, out of the 398 comments in **Hi**-matrix, 23.37% feature CM (i.e., they have at least one or more non-**Hi** (or rather, almost always **En**) words embedded. On the other hand, only 7.34% **En**-matrix comments feature CM (again almost always with **Hi**). Thus, a total of 17.2% comments/posts, which contains a quarter of all the words in the annotated corpus, feature either CM or code-switching or both. We also note that more than 40% words in the corpus are in **Hi** or other Indian languages, but written in Roman script; hence, they are in transliterated form. See (Bali et al., 2014) for an in-depth discussion on the characteristics of the CM data.

This analysis demonstrates the necessity of CM and transliterated text processing in the context of Indian user-generated social media content. Perhaps, the numbers are not too different for such content generated by the users of any other bilingual and multilingual societies.

3 Models and Experiments

POS tagging of **En-Hi** code-mixed data requires language identification at both word and matrix level as well back-transliteration of the text into

Actual Label	Predicted Label Hi	En	Recall
Hi	1057	515	0.672
En	45	2023	0.978
Precision	0.959	0.797	

Table 1: Confusion matrix, precision and recall of the language identification module.

the native script. Additionaly, since we are working with content from social media, the usage of non-standard spelling is rampant and thus, normalization of text into some standard form is required. Ideally, these tasks should be performed jointly since they are interdependent. However, due to lack of resources, we implement a pipelined approach in which the tasks - language identification, text normalization and POS tagging - are performed sequentially, in that order. This pipelined approach also allows us to use various off-the-shelf tools for solving these subtasks and quickly create a baseline system. The baseline results can also provide useful insight into the inherent hardness of POS tagging of code-mixed social media text. In this section, we first describe our approach to solve these three tasks, and then discuss the experiments and results.

3.1 Language identification

Langauge identification is a well studied problem (King and Abney, 2013; Carter et al., 2013; Goldszmidt et al., 2013; Nguyen and Dogruoz, 2013), though for CM text, especially those involving transliterations and orthographic variation, this is far from a solved problem (Nguyen and Dogruoz, 2013). There was a shared task in FIRE 2013 (Saha Roy et al., 2013) on language identification and back transliteration for **En** mixed with **Hi**, Bangla and Gujarati. Along the lines of Gella et al (Gella et al., 2013), which was the best performing system in this shared task, we used the word-level logistic regression classifier built by King and Abney (2013). This system provides a source language with a confidence probability for each word in the test set. We trained the classifier on 3201 English words extracted from the SMS corpus developed by Choudhury et al (2007), while the Hindi data was obtained by sampling 3218 Hindi transliterations out of the **En-Hi** transliteration pairs developed by Sowmya et al. (Sowmya et al., 2010). Ideally, the context of a token is important for identifying the language. Again, following (Gella et al., 2013) we incorporate context information through a code-switching probability, P_s. A higher value of P_s implies a lower probability of code-switching, i.e., adjacent words are more likely to be in the same language.

Table 1 shows the token (word) level confusion matrix for the language identification task on our dataset. The language labels of 84.6% of the tokens were correctly predicted by the system. As can be seen from the Table, the precision for predicting **Hi** is high, whereas that for **En** is low. This is mainly due to the presence of a large number of contracted and distorted **Hi** words in the dataset, e.g. `h` for `hai` (Fig. 1), which were tagged as **En** by our system because the training examples had no contracted **Hi** words, but short and non-conventional spellings were in plenty in the **En** training examples as those were extracted from the SMS corpus.

3.2 Normalization

In our dataset, if a word is identified as **Hi**, then it must be back-transliterated to Devanagari script so that any off-the-shelf Hindi POS tagger can be used. We used the system by Gella et al. (Gella et al., 2013) for this task, which is part rule-based and part statistical. The system was trained on the 35000 unique transliteration pairs extracted from Hindi song lyrics (Gupta et al., 2012). This corpus has a reasonably wide coverage of Hindi words, and past researchers have also shown that transliteration does not require a very large amount of training data. Normalization of the **En** text was not needed because the POS tagger (Owoputi et al., 2013) could handle unnormalized text.

3.3 POS tagging

Solorio and Liu (2008b) describes a few approaches to POS-tagging of code-switched Spanglish text, all of which primarily relies on two monolingual taggers and certain heuristics to combine the output from the two. One of the simpler heuristics is based on language identification, where the POS tag of a word is the output of the monolingual tagger of the language in which the word is. In this initial study, we apply this basic idea for POS tagging of CM data. We divide the text (which is already sentence-separated) into contiguous maximal chunks of words which are in the same language. Then we apply a **Hi** POS tagger to the **Hi** chunks, and an **En** POS tagger to the **En** chunks.

Model	LI	HN	Tagger	Hi Acc.	En Acc.	Total Acc.	Hi CA	En CA	Total CA
1a	K	K	Standard	75.14	81.91	79.02	27.34	39.67	34.05
1b	K	K	Twitter	75.14	82.66	79.02	27.34	35.74	31.91
2	K	NK	Twitter	65.61	81.73	74.87	17.58	33.77	26.38
3	NK	NK	Twitter	44.74	80.68	65.39	40.00	13.17	25.00

Table 2: POS Tagging accuracies for the different models. K=Known, NK = Not Known. LI = Language labels, HN = Hindi normalized forms, Acc. = Token level accuracy, CA = Chunk level accuracy.

We use a CRF++ based POS tagger for **Hi**, which is freely available from `http://nltr.org/snltr-software/`. For **En**, we use the Twitter POS tagger (Owoputi et al., 2013). It also has an inbuilt tokenizer and can work directly on unnormalized text. This tagger has been chosen because Facebook posts and comments are more Twitter-like. We also use the Stanford POS Tagger (Toutanova et al., 2003) which, unlike the Twitter POS Tagger, has not been tuned for Twitter-like text. These taggers use different tagsets - the ILPOST for **Hi** (Sankaran et al., 2008) and Penn-TreeBank for **En** (Marcus et al., 1993). The output tags are appropriately mapped to the smaller Universal tagset (Petrov et al., 2011).

3.4 Experiments and Results

We conducted three different experiments as follows. In the first experiment, we assume that we know the language identities and normalized/transliterated forms of the words, and only do the POS tagging. This experiment gives us an idea of the accuracy of POS tagging task, if normalization, transliteration and language identification could be done perfectly. We conduct this experiments with two different **En** POS taggers: the Stanford POS tagger which is trained on formal English text (Model 1a) and the Twitter POS tagger (Model 1b). In the next experiment (Model 2), we assume that only the language identity of the words are known, but for Hindi we apply our model to generate the back transliterations. For English, we apply the Twitter POS tagger directly because it can handle unnormalized social media text. The third experiment (Model 3) assumes that nothing is known. So language identifier is first applied, and based on the language detected, we apply the **Hi** translitertaion module, and **Hi** POS tagger, or the **En** tagger. This is the most challenging and realistic setting. Note that the matrix information is not used in any of our experiments, though it could be potentially useful for POS tagging and could be explored in future.

Table 2 gives a summary of the four models along with the POS tagging accuracies (in %). It shows token level as well as chunk leve accuracies (**CA**), i.e., what percentage of chunks have been correctly POS tagged. As can be seen, **Hi** POS tagging has relatively low accuracies than **En** POS tagging at word level for all cases. This is primarily due to the errors of the transliteration module, which in turn, is because the transliteration does not address spelling contractions. This is also reflected in the drop in the accuracies for the case where LI is unknown. The very low **CA** for **En** for model 3 is primarily because some of the **Hi** chunks are incorrectly identified as **En** by the language identification module (see Table 1). However, the gradual drop of token and chunk level accuracies from model 1 to model 3 clearly shows the effect of gradual error accumulation from each of the modules. We observe that Nouns were usually confused most with Verbs and vice versa, while the Adj were mostly confused with Nouns, Pronouns with Determiners, and Adpositions with Conjunctions.

4 Conclusion

This is a work in progress. We have identified normalization and transliteration as two very challenging problems for **En-Hi** CM text. Joint modelling of language identification, normalization, transliteration as well as POS tagging is expected to yield better results. We plan to continue our work in that direction, specifically for conversational text in social media in a multilingual context. CM is a common phenomenon found in all bilingual and multilingual societies. The issue of transliteration exist for most of the South Asian languages as well as many other languages such as Arabic and Greek, which use a non-Roman based script (Gupta et al., 2014). The challenges and issues identified in this study are likely to hold for many other languages as well, which makes this a very important and globally prevalent problem.

Abstract

We investigate grammatical error detection in spoken language, and present a data-driven method to train a dependency parser to automatically identify and label grammatical errors. This method is agnostic to the label set used, and the only manual annotations needed for training are grammatical error labels. We find that the proposed system is robust to disfluencies, so that a separate stage to elide disfluencies is not required. The proposed system outperforms two baseline systems on two different corpora that use different sets of error tags. It is able to identify utterances with grammatical errors with an F1-score as high as 0.623, as compared to a baseline F1 of 0.350 on the same data.

1 Introduction

Research into automatic grammatical error detection has primarily been motivated by the task of providing feedback to writers, whether they be native speakers of a language or second language learners. Grammatical error detection, however, is also useful in the clinical domain, for example, to assess a child's ability to produce grammatical language. At present, clinicians and researchers into child language must manually identify and classify particular kinds of grammatical errors in transcripts of children's speech if they wish to assess particular aspects of the child's linguistic ability from a sample of spoken language. Such manual annotation, which is called *language sample analysis* in the clinical field, is expensive, hindering its widespread adoption. Manual annotations may also be inconsistent, particularly between different research groups, which may be investigating different phenomena. Automated grammatical error detection has the potential to address both of these issues, being both cheap and consistent.

Aside from performance, there are at least two key requirements for a grammatical error detector to be useful in a clinical setting: 1) it must be able to handle spoken language, and 2) it must be trainable. Clinical data typically consists of transcripts of spoken language, rather than formal written language. As a result, a system must be prepared to handle disfluencies, utterance fragments, and other phenomena that are entirely grammatical in speech, but not in writing. On the other hand, a system designed for transcripts of speech does not need to identify errors specific to written language such as punctuation or spelling mistakes. Furthermore, a system designed for clinical data must be able to handle language produced by children who may have atypical language due to a developmental disorder, and therefore may produce grammatical errors that would be unexpected in written language. A grammatical error detector appropriate for a clinical setting must also be trainable because different groups of clinicians may wish to investigate different phenomena, and will therefore prefer different annotation standards. This is quite different from grammatical error detectors for written language, which may have models for different domains, but which are not typically designed to enable the detection of novel error sets.

We examine two baseline techniques for grammatical error detection, then present a simple data-driven technique to turn a dependency parser into a grammatical error detector. Interestingly, we find that the dependency parser-based approach massively outperforms the baseline systems in terms of identifying ungrammatical utterances. Furthermore, the proposed system is able to identify specific error codes, which the baseline systems cannot do. We find that disfluencies do not degrade performance of the proposed detector, obviating the need (for this task) for explicit disfluency detection. We also analyze the output of our system to see which errors it finds, and which it misses.

Code	Description	Example
[EO]	Overgeneralization errors	He falled [EO] .
[EW]	Other word level errors	He were [EW] looking .
[EU]	Utterance level errors	And they came to stopped .
[OM]	Omitted bound morpheme	He go [OM] .
[OW]	Omitted word	She [OW] running .

Table 1: Error codes proposed in the SALT manual. Note that in SALT annotated transcripts, [OM] and [OW] are actually indicated by '*' followed by the morpheme or word hypothesized to be omitted. When treating codes (other than [EU]) as tags, they are attached to the previous word in the string.

Finally, we evaluate our detector on a second set of data with a different label set and annotation standards. Although our proposed system does not perform as well on the second data set, it still outperforms both baseline systems. One interesting difference between the two data sets, which does appear to impact performance, is that the latter set more strictly follows SALT guidelines (see Section 2.1) to collapse multiple errors into a single label. This yields transcripts with a granularity of labeling somewhat less amenable to automation, to the extent that labels are fewer and can be reliant on non-local context for aggregation.

2 Background

2.1 Systematic Analysis of Language Transcripts (SALT)

The Systematic Analysis of Language Transcripts (SALT) is the de facto standard for clinicians looking to analyze samples of natural language. The SALT manual includes guidelines for transcription, as well as three types of annotations, of which two are relevant here: *maze* annotations, and *error codes*.[1]

Mazes are similar to what is referred to as 'disfluencies' in the speech literature. The SALT manual defines mazes as "filled pauses, false starts, repetitions, reformulations, and interjections" (Miller et al., 2011, p. 6), without defining any of these terms. Partial words, which are included and marked in SALT-annotated transcripts, are also included in mazes. Mazes are delimited by parentheses, and have no internal structure, unlike disfluencies annotated following the Switchboard guidelines (Meteer et al., 1995), which are commonly followed by the speech and language processing communities. An example maze annotation would be: "He (can not) can not get up."

The SALT manual proposes the set of error codes shown (with examples) in Table 1, but research groups may use a subset of these codes, or augment them with additional codes. For example, the SALT-annotated Edmonton Narrative Norms Instrument (ENNI) corpus (Schneider et al., 2006) rarely annotates omitted morphemes ([OM]), instead using the [EW] code. Other SALT-annotated corpora include errors that are not described in the SALT manual. For example the CSLU ADOS corpus (Van Santen et al., 2010) includes the [EX] tag for extraneous words, and the Narrative Story Retell corpus (SALT Software, 2014b) uses the code [EP] to indicate pronominal errors (albeit inconsistently, as many such errors are coded as [EW] in this corpus). We note that the definitions of certain SALT errors, notably [EW] and [EU], are open to interpretation, and that these codes capture a wide variety of errors. For example, some of the errors captured by the [EW] code are: pronominal case and gender errors; verb tense errors; confusing 'a' and 'an'; and using the wrong preposition.

The SALT guidelines specify as a general rule that annotators should not mark utterances with more than two omissions ([OM] or [OW]) and/or word-level errors (ex [EW], [EP]) (SALT Software, 2014a). Instead, annotators are instructed to code such utterances with an utterance-level error ([EU]). How strictly annotators adhere to this rule affects the distribution of errors, reducing the number of word-level errors and increasing the number of utterance-level errors. Following this rule also increases the variety of errors captured by the [EU] code. The annotations in different corpora, including ENNI and NSR, vary in how strictly they follow this rule, even though this is not mentioned in the the published descriptions of

[1] SALT also prescribes annotation of bound morphemes and clitics, for example -ed in past tense verbs. We preprocess all of the transcripts to remove bound morpheme and clitic annotations.

these corpora.

2.2 Grammatical Error Detection

The most visible fruits of research into grammatical error detection are the spellchecking and grammar checking tools commonly included with word processors, for example Microsoft Word's grammar checker. Although developed for handling written language, many of the techniques used to address these tasks could still be applicable to transcripts of speech because many of the same errors can still occur. The earliest grammaticality tools simply performed pattern matching (Macdonald et al., 1982), but this approach is not robust enough to identify many types of errors, and pattern matching systems are not trainable, and therefore cannot be adapted quickly to new label sets. Subsequent efforts to create grammaticality classifiers and detectors leveraged information extracted from parsers (Heidorn et al., 1982) and language models (Atwell, 1987). These systems, however, were developed for formal written English produced by well-educated adults, as opposed to spoken English produced by young children, particularly children with suspected developmental delays.

There have been a few investigations into techniques to automatically identify particular constructions in transcripts of spoken English. Bowden and Fox (2002) proposed a rule-based system to classify many types of errors made by learners of English. Although their system could be used on either transcripts of speech, or on written English, they did not evaluate their system in any way. Caines and Buttery (2010) use a logistic regression model to identify the zero-auxiliary construction (e.g., 'you going home?') with over 96% accuracy. Even though the zero-auxilliary construction is not necessarily ungrammatical, identifying such constructions may be useful as a preprocessing step to a grammaticality classifier. Caines and Buttery also demonstrate that their detector can be integrated into a statistical parser yielding improved performance, although they are vague about the nature of the parse improvement (see Caines and Buttery, 2010, p. 6).

Hassanali and Liu (2011) conducted the first investigation into grammaticality detection and classification in both speech of children, and speech of children with language impairments. They identified 11 types of errors, and compared three types of systems designed to identify the presence of each type of error: 1) rule based systems; 2) decision trees that use rules as features; and 3) naive Bayes classifiers that use a variety of features. They were able to identify all error types well ($F1 > 0.9$ in all cases), and found that in general the statistical systems outperformed the rule based systems. Hassanali and Liu's system was designed for transcripts of spoken language collected from children with impaired language, and is able to detect the set of errors they defined very well. However, it cannot be straightforwardly adapted to novel error sets.

Morley et al. (2013) evaluated how well the detectors proposed by Hassanali and Liu could identify utterances with SALT error codes. They found that a simplified version of one of Hassanali and Liu's detectors was the most effective at identifying utterances with any SALT error codes, although performance was very low (F1=0.18). Their system uses features extracted solely from part of speech tags with the Bernoulli Naive Bayes classifier in Scikit (Pedregosa et al., 2012). Their detector may be adaptable to other annotation standards, but it does not identify which errors are in each utterance; it only identifies which utterances have errors, and which do not.

2.3 Redshift Parser

We perform our experiments with the redshift parser[2], which is an arc-eager transition-based dependency parser. We selected redshift because of its ability to perform disfluency detection and dependency parsing jointly. Honnibal and Johnson (2014) demonstrate that this system achieves state-of-the-art performance on disfluency detection, even compared to single purpose systems such as the one proposed by Qian and Liu (2013). Rasooli and Tetreault (2014) have developed a system that performs disfluency detection and dependency parsing jointly, and with comparable performance to redshift, but it is not publicly available as of yet.

Redshift uses an averaged perceptron learner, and implements several feature sets. The first feature set, which we will refer to as ZHANG is the one proposed by Zhang and Nivre (2011). It includes 73 templates that capture various aspects of: the word at the top of the stack, along with its

[2]Redshift is available at `https://github.com/syllog1sm/redshift`. We use the version in the `experiment` branch from May 15, 2014.

leftmost and rightmost children, parent and grandparent; and the word on the buffer, along with its leftmost children; and the second and third words on the buffer. Redshift also includes features extracted from the Brown clustering algorithm (Brown et al., 1992). Finally, redshift includes features that are designed to help identify disfluencies; these capture rough copies, exact copies, and whether neighboring words were marked as disfluent. We will refer to the feature set containing all of the features implemented in redshift as FULL. We refer the reader to Honnibal and Johnson (2014) for more details.

3 Data, Preprocessing, and Evaluation

Our investigation into using a dependency parser to identify and label grammatical errors requires training data with two types of annotations: dependency labels, and grammatical error labels. We are not aware of any corpora of speech with both of these annotations. Therefore, we use two different sets of training data: the Switchboard corpus, which contains syntactic parses; and SALT annotated corpora, which have grammatical error annotations.

3.1 Switchboard

The Switchboard treebank (Godfrey et al., 1992) is a corpus of transcribed conversations that have been manually parsed. These parses include EDITED nodes, which span disfluencies. We preprocess the Switchboard treebank by removing all partial words as well as all words dominated by EDITED nodes, and converting all words to lowercase. We then convert the phrase-structure trees to dependencies using the Stanford dependency converter (De Marneffe et al., 2006) with the basic dependency scheme, which produces dependencies that are strictly projective.

3.2 SALT Annotated Corpora

We perform two sets of experiments on the two SALT-annotated corpora described in Table 2. We carry out the first set of experiments on on the Edmonton Narrative Norms Instrument (ENNI) corpus, which contains 377 transcripts collected from children between the ages of 3 years 11 months and 10 years old. The children all lived in Edmonton, Alberta, Canada, were typically developing, and were native speakers of English.

After exploring various system configurations, we evaluate how well our method works when it is applied to another corpus with different annotation standards. Specifically, we train and test our technique on the Narrative Story Retell (NSR) corpus (SALT Software, 2014b), which contains 496 transcripts collected from typically developing children living in Wisconsin and California who were between the ages of 4 years 4 months and 12 years 8 months old. The ENNI and NSR corpora were annotated by two different research groups, and as Table 2 illustrates, they contain a different distribution of errors. First, ENNI uses the [EW] (other word-level error) tag to code both overgeneralization errors instead of [EO], and omitted morphemes instead of [OM]. The [EU] code is also far more frequent in ENNI than NSR. Finally, the NSR corpus includes an error code that does not appear in the ENNI corpus: [EP], which indicates a pronominal error, for example using the wrong person or case. [EP], however, is rarely used.

	ENNI		NSR	
	Words	Utts	Words	Utts
Train	360,912	44,915	103,810	11,869
Dev.	45,504	5,614	12,860	1,483
Test	44,996	5,615	12,982	1,485
% with error		13.2		14.3

(a) Word and utterance counts

	ENNI	NSR
[EP]	0	20
[EO]	0	495
[EW]	4,916	1,506
[EU]	3,332	568
[OM]	10	297
[OW]	766	569
Total	9,024	3,455

(b) Error code counts

Table 2: Summary of ENNI and NSR Corpora. There can be multiple errors per utterance. Word counts include mazes.

We preprocess the ENNI and NSR corpora to reconstruct surface forms from bound morpheme annotations (ex. 'go/3S' becomes 'goes'), partial words, and non-speech sounds. We also either excise manually identified mazes or remove maze annotations, depending upon the experiment.

3.3 Evaluation

Evaluating system performance in tagging tasks on manually annotated data is typically straight-

Evaluation Level:	ERROR			UTTERANCE
	Individual error codes			Has error?
Gold error codes:	[EW]	[EW]		Yes
Predicted error codes:	[EW]		[OW]	Yes
Evaluation:	TP	FN	FP	TP

Figure 1: Illustration of UTTERANCE and ERROR level evaluation
TP = true positive; FP = false positive; FN = false negative

forward: we simply compare system output to the gold standard. Such evaluation assumes that the best system is the one that most faithfully reproduces the gold standard. This is not necessarily the case with applying SALT error codes for three reasons, and each of these reasons suggests a different form of evaluation.

First, automatically detecting SALT error codes is an important task because it can aid clinical investigations. As Morley et al. (2013) illustrated, even extremely coarse features derived from SALT annotations, for example a binary feature for each utterance indicating the presence of any error codes, can be of immense utility for identifying language impairments. Therefore, we will evaluate our system as a binary tagger: each utterance, both in the manually annotated data and system output either contains an error code, or it does not. We will label this form of evaluation as UTTERANCE level.

Second, clinicians are not only interested in how many utterances have an error, but also which particular errors appear in which utterances. To address this issue, we will compute precision, recall, and F1 score from the counts of each error code in each utterance. We will label this form of evaluation as ERROR level. Figure 1 illustrates both UTTERANCE and ERROR level evaluation. Note that the utterance level error code [EU] is only allowed to appear once per utterance. As a result, we will ignore any predicted [EU] codes beyond the first.

Third, the quality of the SALT annotations themselves is unknown, and therefore evaluation in which we treat the manually annotated data as a gold standard may not yield informative metrics. Morley et al. (2014) found that there are likely inconsistencies in maze annotations both within and across corpora. In light of that finding, it is possible that error code annotations are somewhat inconsistent as well. Furthermore, our approach has a critical difference from manual annotation: we perform classification one utterance at a time, while manual annotators have access to the context of an utterance. Therefore certain types of errors, for example using a pronoun of the wrong gender, or responding ungrammatically to a question (ex. 'What are you doing?' 'Eat.') will appear grammatical to our system, but not to a human annotator. We address both of these issues with an in-depth analysis of the output of one of our systems, which includes manually re-coding utterances out of context.

4 Detecting Errors in ENNI

4.1 Baselines

We evaluate two existing systems to see how effectively they can identify utterances with SALT error codes: 1) Microsoft Word 2010's grammar check, and 2) the simplified version of Hassanali and Liu's grammaticality detector (2011) proposed by Morley et al. (2013) (mentioned in Section 2.2). We configured Microsoft Word 2010's grammar check to look for the following classes of errors: negation, noun phrases, subject-verb agreement, and verb phrases (see `http://bit.ly/1kphUHa`). Most error classes in grammar check are not relevant for transcribed speech, for example capitalization errors or confusing *it's* and *its*; we selected classes of errors that would typically be indicated by SALT error codes.

Note that these baseline systems can only give us an indication of whether there is an error in the utterance or not; they do not provide the specific error tags that mimic the SALT guidelines. Hence we evaluate just the UTTERANCE level performance of the baseline systems on the ENNI development and test sets. These results are given in the top two rows of each section of Table 3. We apply these systems to utterances in two conditions: with mazes (i.e., disfluencies) excised; and with unannotated mazes left in the utterances. As can be seen in Table 3, the performance Microsoft Word's grammar checker degrades severely when

(a)

Him [EW] (can not) can not get up .

(b)

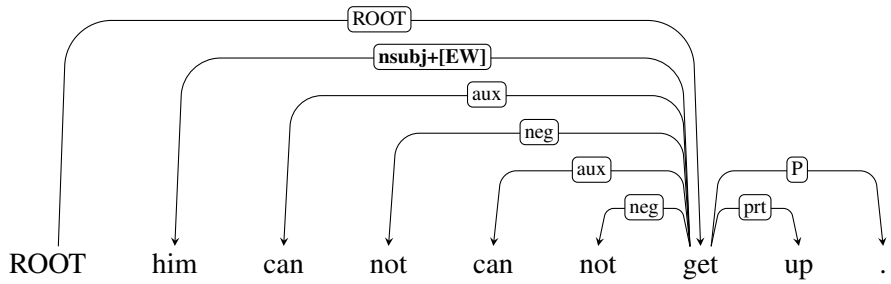

Figure 2: (a) SALT annotated utterance; mazes indicated by parentheses; (b) Dependency parse of same utterance parsed with a grammar trained on the Switchboard corpus and augmented dependency labels. We use a corpus of parses with augmented labels to train our grammaticality detector.

mazes are not excised, but this is not the case for the Morley et al. (2013) detector.

4.2 Proposed System

Using the ENNI corpus, we now explore various configurations of a system for grammatical error code detection. All of our systems use redshift to learn grammars and to parse. First, we train an initial grammar G_0 on the Switchboard treebank (Godfrey et al., 1992) (preprocessed as described in Section 3.1). Redshift learns a model for part of speech tagging concurrently with G_0. We use G_0 to parse the training portion of the ENNI corpus. Then, using the SALT annotations, we append error codes to the dependency arc labels in the parsed ENNI corpus, assigning each error code to the word it follows in the SALT annotated data. Figure 2 shows a SALT annotated utterance, as well as its dependency parse augmented with error codes. Finally, we train a grammar G_{Err} on the parse of the ENNI training fold that includes the augmented arc labels. We can now use G_{Err} to automatically apply SALT error codes: they are simply encoded in the dependency labels. We also apply the [EW] label to any word that is in a list of overgeneralization errors[3].

We modify three variables in our initial trials on the ENNI development set. First, we change the proportion of utterances in the training data that contain an error by removing utterances.[4] Doing so allows us to alter the operating point of our system in terms of precision and recall. Second, we again train and test on two versions of the ENNI corpus: one which has had mazes excised, and the other which has them present (but not annotated). Third, we evaluate two feature sets: ZHANG and FULL.

The plots in Figure 3 show how the performances of our systems at different operating points vary, while Table 3 shows the performance of our best system configurations on the ENNI development and test sets. Surprisingly, we see that neither the choice of feature set, nor the presence of mazes has much of an effect on system performance. This is in strong contrast to Microsoft Word's grammar check, which is minimally effective when mazes are included in the data. The Morley et al. (2013) system is robust to mazes, but still performs substantially worse than our proposed system.

4.3 Error Analysis

We now examine the errors produced by our best performing system for data in which mazes are present. As shown in Table 3, when we apply our system to ENNI-development, the UTTERANCE P/R/F1 is 0.831 / 0.502 / 0.626 and the ERROR P/R/F1is 0.759 / 0.434 / 0.552. This system's performance detecting specific error codes is shown in Table 4. We see that the recall of [EU] errors is quite low compared with the recall for [EW] and [OW] errors. This is not surprising, as human annotators may need to leverage the context of an utterance to identify [EU] errors, while our system makes predictions for each utterance in isolation.

[3]The list of overgeneralization errors was generously provided by Kyle Gorman

[4]Of course, we never modify the development or test data.

Table 4: ERROR level detection performance for each code (system trained on ENNI; 30% error utterances; ZHANG feature set; with mazes)

We randomly sampled 200 utterances from the development set that have a manually annotated error, are predicted by our system to have an error, or both. A speech-language pathologist who has extensive experience with using SALT for research purposes in both clinical and typically developing populations annotated the errors in each utterance. She annotated each utterance in isolation so as to ignore contextual errors. We compare our annotations to the original annotations, and system performance using our annotations and the original annotations as different gold standards. The results of this comparison are shown in Table 5.

Comparing our manual annotations to the original annotations, we notice some disagreements. We suspect there are two reasons for this. First, unlike the original annotators, we annotate these utterances out of context. This may explain why we identify far fewer utterance level error [EU] codes than the original annotators (20 compared with 67). Second, we may be using different criteria for each error code than the original annotators. This is an inevitable issue, as the SALT guidelines do not provide detailed definitions of the error codes, nor do individual groups of annotators. To illustrate, the "coding notes" section of

Table 6: Error detection performance on NSR-development, mazes included

the description of the ENNI corpus[5] only lists the error codes that were used consistently, but does not describe how to apply them. These findings illustrate the importance of having a rapidly trainable error code detector: research groups will be interested in different phenomena, and therefore will likely have different annotation standards.

5 Detecting Errors in NSR

We apply our system directly to the NSR corpus with mazes included. We use the same parameters set on the ENNI corpus in Section 4.2. We apply the model trained on ENNI to NSR, but find that it does not perform very well as illustrated in Table 6. These results further underscore the need for a trainable error code detector in this domain, as opposed to the static error detectors that are more common in the grammatical error detection literature.

We see in Table 6 that retraining our model on NSR data improves performance substantially (UTTERANCE F1 improves from 0.178 to 0.277), but not to the level we observed on the ENNI corpus. The Morley et al. (2013) system also performs worse when trained and tested on NSR, as compared with ENNI. When mazes are included, the performance of Microsoft Word's grammar check is higher on NSR than on ENNI (F1=0.261 vs 0.084), but it it still yields the lowest performance of the three systems. We find that combining our proposed system with either or both of the baseline systems further improves performance.

The NSR corpus differs from ENNI in several ways: it is smaller, contains fewer errors, and uses a different set of tags with a different distribution from the ENNI corpus, as shown in Table 2. We found that the smaller amount of training data is not the only reason for the degradation in performance; we trained a model for ENNI with a set of training data that is the same size as the one for NSR, but did not observe a major drop in performance. We found that UTTERANCE F1 drops from 0.626 to 0.581, and ERROR F1 goes from 0.552 to 0.380, not nearly the magnitude drop in accuracy observed for NSR.

We believe that a major reason for why our system performs worse on NSR than ENNI may be that the ENNI annotations adhere less strictly to certain SALT recommendations than do the ones in NSR. The SALT guidelines suggest that utterances with two or more word-level [EW] and/or omitted word [OW] errors should only be tagged with an utterance-level [EU] error (SALT Software, 2014a). ENNI, however, has many utter-

[5] http://www.saltsoftware.com/salt/databases/ENNIRDBDoc.pdf

ances with multiple [EW] and [OW] error codes, along with utterances containing all three error codes. NSR has very few utterances with [EU] and other codes, or multiple [EW] and [OW] codes. The finer grained annotations in ENNI may simply be easier to learn.

6 Conclusion and Future Directions

We have proposed a very simple method to rapidly train a grammatical error detector and classifier. Our proposed system only requires training data with error code annotations, and is agnostic as to the nature of the specific error codes. Furthermore, our system's performance does not appear to be affected by disfluencies, which reduces the burden required to produce training data.

There are several key areas we plan to investigate in the future. First, we would like to explore different update functions for the parser; the predicted error codes are a byproduct of parsing, but we do not care what the parse itself looks like. At present, the parser is updated whenever it produces a parse that diverges from the gold standard. It may be better to update only when the error codes predicted for an utterance differ from the gold standard. Second, we hope to explore features that could be useful for identifying grammatical errors in multiple data sets. Finally, we plan to investigate why our system performed so much better on ENNI than on NSR.

Abstract

We introduce a new CCG parsing model which is factored on lexical category assignments. Parsing is then simply a deterministic search for the most probable category sequence that supports a CCG derivation. The parser is extremely simple, with a tiny feature set, no POS tagger, and no statistical model of the derivation or dependencies. Formulating the model in this way allows a highly effective heuristic for A* parsing, which makes parsing extremely fast. Compared to the standard C&C CCG parser, our model is more accurate out-of-domain, is four times faster, has higher coverage, and is greatly simplified. We also show that using our parser improves the performance of a state-of-the-art question answering system.

1 Introduction

CCG is a strongly lexicalized grammatical formalism, in which the vast majority of the decisions made during interpretation involve choosing the correct definitions of words. We explore the effect of modelling this explicitly in a parser, by only using a probabilistic model of lexical categories (based on a local context window), rather than modelling the derivation or dependencies.

Existing state-of-the-art CCG parsers use complex pipelines of POS-tagging, supertagging and parsing—each with its own feature sets and parameters (and sources of error)—together with further parameters governing their integration (Clark and Curran, 2007). We show that much simpler models can achieve high performance. Our model predicts lexical categories based on a tiny feature set of word embeddings, capitalization, and 2-character suffixes—with no parsing model beyond a small set of CCG combinators, and no POS-tagger. Simpler models are easier to implement, replicate and extend.

Another goal of our model is to parse CCG optimally and efficiently, without using excessive pruning. CCG's large set of lexical categories, and generalized notion of constituency, mean that sentences can have a huge number of potential parses. Fast existing CCG parsers rely on aggressive pruning—for example, the C&C parser uses a supertagger to dramatically cut the search space considered by the parser. Even the loosest beam setting for their supertagger discards the correct parse for 20% of sentences. The structure of our model allows us to introduce a simple but powerful heuristic for A* parsing, meaning it can parse almost 50 sentences per second exactly, with no beam-search or pruning. Adding very mild pruning increases the speed to 186 sentences per second with minimal loss of accuracy.

Our approach faces two obvious challenges. Firstly, categories are assigned based on a local window, which may not contain the necessary context for resolving some attachment decisions. For example, in *I saw a squirrel 2 weeks ago with a nut*, the model cannot make an informed decision on whether to assign *with* an adverbial or adnominal preposition category, as the crucial words *saw* and *squirrel* fall outside the local context window. Secondly, even if the supertagger makes all lexical category decisions correctly, then the parser can still make erroneous decisions. One example is in coordination-scope ambiguities, such as *clever boys and girls*, where the two interpretations use the same assignment of categories.

We hypothesise that such decisions are relatively rare, and are challenging for any parsing model, so a weak model is unlikely to result in substantially lower accuracy. Our implementation of this model[1], which we call EASYCCG, has high

accuracy—suggesting that most parsing decisions can be made accurately based on a local context window.

Of course, there are many parsing decisions that can only be made accurately with more complex models. However, exploring the power and limitations of simpler models may help focus future research on the more challenging cases.

2 Background

2.1 Combinatory Categorial Grammar

CCG (Steedman, 2000) is a strongly lexicalized grammatical formalism. Words have categories representing their syntactic role, which are either atomic, or functions from one category to another.

Phrase-structure grammars have a relatively small number of lexical categories types (e.g. POS-tags), and a large set of rules used to build a syntactic analysis of a complete sentence (e.g. an adjective and noun can combine into a noun). In contrast, CCG parsing has many lexical category types (we use 425), but a small set of combinatory rule types (we use 10 binary and 13 unary rule schemata). This means that, aside from the lexicon, the grammar is small enough to be hand-coded—which allows us, in this paper, to confine the entire statistical model to the lexicon.

CCG's generalized notion of constituency means that many derivations are possible for a given a set of lexical categories. However, most of these derivations will be semantically equivalent—for example, deriving the same dependency structures—in which case the actual choice of derivation is unimportant. Such ambiguity is often called *spurious*.

2.2 Existing CCG Parsing Models

The seminal C&C parser is by far the most popular choice of CCG parser (Clark and Curran, 2007). It showed that it was possible to parse to an expressive linguistic formalism with high speed and accuracy. The performance of the parser has enabled large-scale logic-based distributional research (Harrington, 2010; Lewis and Steedman, 2013a; Lewis and Steedman, 2013b; Reddy et al., 2014), and it is a key component of Boxer (Bos, 2008).

The C&C parser uses CKY chart parsing, with a log-linear model to rank parses. The vast number of possible parses means that computing the complete chart is impractical. To resolve this problem, a *supertagger* is first run over the sentence to prune the set of lexical categories considered by the parser for each word. The initial beam outputs an average of just 1.2 categories per word, rather than the 425 possible categories—making the standard CKY parsing algorithm very efficient. If the parser fails to find any analysis of the complete sentence with this set of supertags, the supertagger re-analyses the sentence with a more relaxed beam (*adaptive supertagging*).

2.3 A* Parsing

Klein and Manning (2003a) introduce A* parsing for PCFGs. The parser maintains a chart and an agenda, which is a priority queue of items to add to the chart. The agenda is sorted based on the items' inside probability, and a heuristic upper-bound on the outside probability—to give an upper bound on the probability of the complete parse. The chart is then expanded in best-first order, until a complete parse for the sentence is found.

Klein and Manning calculate an upper bound on the outside probability of a span based on a summary of the context. For example, the summary for the SX heuristic is the category of the span, and the number of words in the sentence before and after the span. The value of the heuristic is the probability of the best possible sentence meeting these restrictions. These probabilities are pre-computed for every non-terminal symbol and for every possible number of preceding and succeeding words, leading to large look-up tables.

Auli and Lopez (2011b) find that A* CCG parsing with this heuristic is very slow. However, they achieve a modest 15% speed improvement over CKY when A* is combined with adaptive supertagging. One reason is that the heuristic estimate is rather coarse, as it deals with the best possible outside context, rather than the actual sentence. We introduce a new heuristic which gives a tighter upper bound on the outside probability.

3 Model

3.1 Lexical Category Model

As input, our parser takes a distribution over all CCG lexical categories for each word in the sentence. These distributions are assigned using Lewis and Steedman (2014)'s semi-supervised supertagging model. The supertagger is a unigram log-linear classifier that uses features of the ± 3 word context window surrounding a word. The

key feature is word embeddings, initialized with the 50-dimensional embeddings trained in Turian et al. (2010), and fine-tuned during supervised training. The model also uses 2-character suffixes and capitalization features.

The use of word embeddings, which are trained on a large unlabelled corpus, allows the supertagger to generalize well to words not present in the labelled data. It does not use a POS-tagger, which avoids problems caused by POS-tagging errors.

Our methods could be applied to any supertagging model, but we find empirically that this model gives higher performance than the C&C supertagger.

3.2 Parsing Model

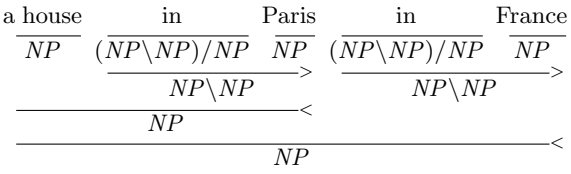
Let a CCG parse y of a sentence S be a list of lexical categories $c_1 \dots c_n$ and a derivation. If we assume all derivations licensed by our grammar are equally likely, and that lexical category assignments are conditionally independent given the sentence, we can compute the optimal parse $\hat{y}$ as:

$\hat{y} = argmax_y \prod_{i=1}^{n} p(c_i|S)$

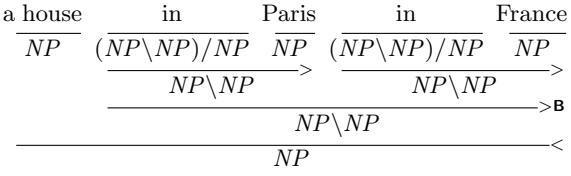
As discussed in Section 2.1, many derivations are possible given a sequence of lexical categories, some of which may be semantically distinct. However, our model will assign all of these an equal score, as they use the same sequence of lexical categories. Therefore we extend our model with a simple deterministic heuristic for ranking parses that use the same lexical categories. Given a set of derivations with equal probability, we output the one maximizing the sums of the length of all arcs in the corresponding dependency tree.

The effect of this heuristic is to prefer non-local attachments in cases of ambiguity, which we found worked better on development data than favouring local attachments. In cases of spurious ambiguity, all parses will have the same value of this heuristic, so one is chosen arbitrarily. For example, one of the parses in Figures 1a and 1b would be selected over the parse in Figure 1c.

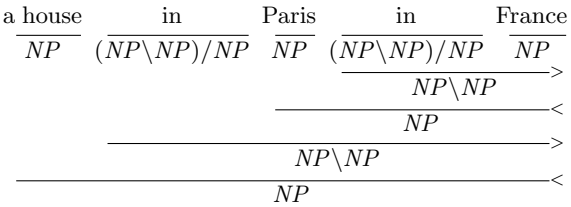
Of course, we could use any function of the parses in place of this heuristic, for example a head-dependency model. However, one aim of this paper is to demonstrate that an extremely simple parsing model can achieve high performance, so we leave more sophisticated alternatives to future work.



(a) A standard derivation of *a house in Paris in France*, with a dependency from *in France* to *house*



(b) A derivation of *a house in Paris in France*, which is spuriously equivalent to Figure 1a. A composition combinator is used to compose the predicates *in Paris* and *in France*, creating a constituent which creates dependencies to its argument from both *in Paris* and *in France*.



(c) A derivation of *a house in Paris in France*, which yields different dependencies to Figures 1a and 1b: here, there is a dependency from *in France* to *Paris*, not *house*.

Figure 1: Three CCG parses of *a house in Paris in France*, given the same set of supertags. The first two are spuriously equivalent, but the third is semantically distinct.

3.3 A* Search

For parsing, we use an A* search for the most-probable complete CCG derivation of a sentence. A key advantage of A* parsing over CKY parsing is that it does not require us to prune the search space first with a supertagger, allowing the parser to consider the complete distribution of 425 categories for each word (in contrast to an average of 3.57 categories per word considered by the C&C parser's most relaxed beam). This is possible because A* only searches for the Viterbi parse of a sentence, rather than building a complete chart with every possible category per word (another alternative, used by Hockenmaier (2003), is to use a highly aggressive beam search in the parser).

In A* parsing, items on the agenda are sorted by their *cost*; the product of their inside probability and an upper bound on their outside probability.

For a span $w_i \dots w_j$ with lexical categories $c_i \dots c_j$ in a sentence $S = w_1 \dots w_n$, the inside probability is simply: $\prod_{k=i}^{j} p(c_k|S)$

The factorization of our model lets us give the following upper-bound on the outside probability:

$$h(w_i \dots w_j) = \prod_{k=1}^{k<i} max_{c_k} p(c_k|S) \times \prod_{k=j+1}^{k \leq n} max_{c_k} p(c_k|S)$$

This heuristic assumes that all words outside the span will take their highest-probability supertag. Because the model is factored on lexical categories, this estimate is clearly an upper bound. As supertagging is over 90% accurate, the upper bound will often be exact, and in Section 4.3 we show empirically that it is extremely efficient. The values of the heuristic can be computed once for each sentence and cached.

To implement the preference for non-local attachment described in Section 3.2, if two agenda items have the same cost, the one with the longer dependencies is preferred.

Intuitively, the parser first attempts to find a parse for the sentence using the 1-best category for each word, by building as complete a chart as possible. If it fails to find a parse for the complete sentence, it adds one more supertag to the chart (choosing the most probable tag not already in the chart), and tries again. This strategy allows the parser to consider an unbounded number of categories for each word, as it does not build a complete chart with all supertags.

3.4 Grammar

Here, we describe the set of combinators and unary rules in the EASYCCG grammar. Because we do not have any probabilistic model of the derivation, all rules can apply with equal probability. This means that some care needs to be taken in designing the grammar to ensure that all the rules are generally applicable. We also try to limit spurious ambiguity, and build derivations which are compatible with the C&C parser's scripts for extracting dependencies (for evaluation). We describe the grammar in detail, to ensure replicability.

Our parser uses the following binary combinators from Steedman (2012): *forward application*, *backward application*, *forward composition*, *backward crossed composition*, *generalized forward composition*, *generalized backward crossed composition*. These combinators are posited to be linguistically universal. The generalized rules are generalized to degree 2. Following Steedman (2000) and Clark and Curran (2007), backward composition is blocked where the argument of the right-hand category is an N or NP. The unhelpful *[nb]* feature is ignored.

Initial	Result	Usage
N	NP	Bare noun phrases
NP	$S/(S\backslash NP)$	Type raising
NP	$(S\backslash NP)/((S\backslash NP)/NP)$	
PP	$(S\backslash NP)/((S\backslash NP)/PP)$	
$S_{pss}\backslash NP$	$NP\backslash NP$	Reduced relative clauses
$S_{ng}\backslash NP$	$NP\backslash NP$	
$S_{adj}\backslash NP$	$NP\backslash NP$	
$S_{to}\backslash NP$	$NP\backslash NP$	
$S_{to}\backslash NP$	$N\backslash N$	
S_{dcl}/NP	$NP\backslash NP$	
$S_{pss}\backslash NP$	S/S	VP Sentence Modifiers
$S_{ng}\backslash NP$	S/S	
$S_{to}\backslash NP$	S/S	

Table 1: Set of unary rules used by the parser.

As in the C&C parser, we add a special *Conjunction* rule:

$$\frac{Y \qquad X}{X\backslash X}>$$

Where $Y \in \{conj, comma, semicolon\}$. We block conjunctions where the right-hand category is type-raised, punctuation, N, or $NP\backslash NP$. This rule (and the restrictions) could be removed by changing CCGBank to analyse conjunctions with $(X\backslash X)/X$ categories.

We also add syntagmatic rules for removing any punctuation to the right, and for removing open-brackets and open-quotes to the left

The grammar also contains 13 unary rules, listed in Table 1. These rules were chosen based on their frequency in the training data, and their clear semantic interpretations.

Following Clark and Curran (2007), we also add a (switchable) constraint that only category combinations that have combined in the training data may combine in the test data. We found that this was necessary for evaluation, as the C&C conversion tool for extracting predicate-argument dependencies had relatively low coverage on the CCG derivations produced by our parser. While this restriction is theoretically inelegant, we found it did increase parsing speed without lowering lexi-

cal category accuracy.

We also use Eisner Normal Form Constraints (Eisner, 1996), and Hockenmaier and Bisk's (2010) Constraint 5, which automatically rule out certain spuriously equivalent derivations, improving parsing speed.

We add a hard constraint that the root category of the sentence must be a declarative sentence, a question, or a noun-phrase.

This grammar is smaller and cleaner than that used by the C&C parser, which uses 32 unary rules (some of which are semantically dubious, such as $S[dcl] \rightarrow NP\backslash NP$), and non-standard binary combinators such as merging two NPs into an NP. The C&C parser also has a large number of special case rules for handling punctuation. Our smaller grammar reduces the grammar constant, eases implementation, and simplifies the job of building downstream semantic parsers such as those of Bos (2008) or Lewis and Steedman (2013a) (which must implement semantic analogs of each syntactic rule).

3.5 Extracting Dependency Structures

The parsing model defined in Section 3.2 requires us to compute unlabelled dependency trees from CCG derivations (to prefer non-local attachments). It is simple to extract an unlabelled dependency tree from a CCG parse, by defining one argument of each binary rule instantiation to be the head. For forward application and (generalized) forward composition, we define the head to be the left argument, unless the left argument is an endocentric head-passing modifier category X/X. We do the inverse for the corresponding 'backward' combinators. For punctuation rules, the head is the argument which is not punctuation, and the head of a *Conjunction* rule is the right-hand argument.

The standard CCG parsing evaluation uses a different concept of dependencies, corresponding to the predicate-argument structure defined by CCGBank. These dependencies capture a deeper information—for example by assigning both *boy* and *girl* as subjects of *talk* in *a boy and a girl talked*. We extract these dependencies using the `generate` program supplied with the C&C parser.

3.6 Pruning

Our parsing model is able to efficiently and optimally search for the best parse. However, we found that over 80% of the run-time of our pipeline was spent during supertagging. Naively, the log-linear model needs to output a probability for each of the 425 categories. This is expensive both in terms of the number of dot products required, and the cost of building the initial priority-queue for the A* parsing agenda. It is also largely unnecessary—for example, periods at the end of sentences always have the same category, but our supertagger calculates a distribution over all possible categories.

Note that the motivation for introducing pruning here is fundamentally different from for the C&C pipeline. The C&C supertagger prunes the the categories so that the parser can build the complete set of derivations given those categories. In contrast, our parser can efficiently search large (or infinite) spaces of categories, but pruning is helpful for making supertagging itself more efficient, and for building the initial agenda.

We therefore implemented the following strategies to improve efficiency:

- Only allowing at most 50 categories per word. The C&C parser takes on average 1.27 tags per word (and an average of 3.57 at its loosest beam setting), so this restriction is a very mild one. Nevertheless, it considerably reduces the potential size of the agenda.

- Using a variable-width beam β which prunes categories less likely than β times the probability of the best category. We set $\beta = 0.00001$, which is two orders-of-magnitude smaller than the equivalent C&C beam. Again, this heuristic is useful for reducing the length of the agenda.

- Using a tag dictionary of possible categories for each word, so that weights are only calculated for a subset of the categories. Unlike the other methods, this approach does affect the probabilities which are calculated, as the normalizing constant is only computed for a subset of the categories. However, the probability mass contained in the pruned categories is small, and it only slightly decreases parsing accuracy. To build the tag dictionary, we parsed 42 million sentences of Wikipedia using our parser, and for all words occurring at least 500 times, we stored the set of observed word-category combinations. When parsing new sentences, these words are only allowed to occur with one of these categories.

Supertagger	Parser	CCGBank				Wikipedia			Bioinfer		
		F1 (cov)	COV	F1 (all)	Time	F1 (cov)	COV	F1 (all)	F1 (cov)	COV	F1 (all)
C&C	C&C	85.47	99.63	85.30	54s	81.19	99.0	80.64	76.08	97.2	74.88
EASYCCG	EASYCCG	83.37	99.96	83.37	13s	81.75	100	81.75	77.24	100	77.24
EASYCCG	C&C	86.14	99.96	86.11	69s	82.46	100	82.46	78.00	99.8	77.88

Table 2: Parsing F1-scores for labelled dependencies across a range of domains. F1 (cov) refers to results on sentences which the parser is able to parse, and F1 (all) gives results over all sentences. For the EASYCCG results, scores are only over parses where the C&C dependency extraction script was successful, which was 99.3% on CCGBank, 99.5% on Wikipedia, and 100% on Bioinfer.

4 Experiments

4.1 Experimental Setup

We trained our model on Sections 02-21 of CCGBank (Hockenmaier and Steedman, 2007), using Section 00 for development. For testing, we used Section 23 of CCGBank, a Wikipedia corpus annotated by Honnibal and Curran (2009), and the Bioinfer corpus of biomedical abstracts (Pyysalo et al., 2007). The latter two are out-of-domain, so are more challenging for the parsers.

We compare the performance of our model against both the C&C parser, and the system described in Lewis and Steedman (2014). This model uses the same supertagger as used in EASYCCG, but uses the C&C parser for parsing, using adaptive supertagging with the default values.

All timing experiments used the same 1.8Ghz AMD machine.

4.2 Parsing Accuracy

Results are shown in Table 2. Our parser performs competitively with a much more complex parsing model, and outperforms the C&C pipeline on both out-of-domain datasets. This result confirms our hypothesis that the majority of parsing decisions can be made accurately with a simple tagging model and a deterministic parser.

We see that the combination of the EASYCCG supertagger and the C&C parser achieves the best accuracy across all domains. This result shows that, unsurprisingly, there is some value to having a statistical model of the dependencies that the parser is evaluated on. However, the difference is not large, particularly out-of-domain, considering that a sophisticated and complex statistical parser is being compared with a deterministic one. Our parser is also far faster than this baseline.

It is interesting that the performance gap is much lower on out-of-domain datasets (2.8 points in domain, but only 0.65-0.75 out-of-domain), suggesting that much of the C&C parser's dependency model is domain specific, and does not generalize well to other domains.

	Speed (sentences/second)		
System	Tagger	Parser	Total
C&C	**343**	52	45
EASYCCG tagger + C&C parser	299	58	49
EASYCCG baseline	56	222	45
+Tag Dictionary	185	217	99
+Max 50 tags/word	238	345	141
+β=0.00001	299	**493**	**186**
EASYCCG — *null heuristic*	300	221	127

Table 3: Effect of our optimizations of parsing speed.

We also briefly experimented using the C&C supertagger (with a beam of $\beta = 10^{-5}$) with the EASYCCG parser. Performance was much worse, with an F-score of 79.63% on the 97.8% of sentences it parsed on CCGBank Section 23. This shows that our model is reliant on the accuracy of the supertagger.

4.3 Parsing Speed

CCG parsers have been used in distributional approaches to semantics (Lewis and Steedman, 2013a; Lewis and Steedman, 2013b), which benefit from large corpora. However, even though the C&C parser is relatively fast, it will still take over 40 CPU-days to parse the Gigaword corpus on our hardware, which is slow enough to be an obstacle to scaling distributional semantics to larger cor-

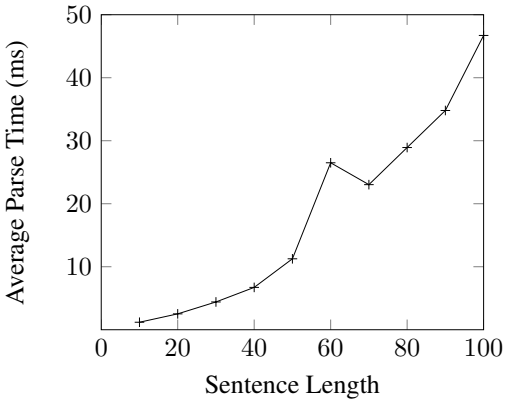


Figure 2: Average parse times in milliseconds, by sentence length.

pora such as ClueWeb. Therefore, it is important to be able to parse sentences at a high speed.

We measured parsing times on Section 23 of CCGBank (after developing against Section 00), using the optimizations described in Section 4.3. We also experimented with the *null heuristic*, which always estimates the outside probability as being 1.0. Times exclude the time taken to load models.

Results are shown in Table 3. The best EASYCCG model is roughly four times faster than the C&C parser[2]. Adding the tag dictionary caused accuracy to drop slightly from 83.46 to 83.37, and meant the parser failed to parse a single sentence in the test set ("*Among its provisions :*") but other changes did not affect accuracy. The pruning in the supertagger improves parsing speed, by limiting the length of the priority queue it builds for the agenda. Of course, we could use a backoff model to ensure full coverage (analogously to adaptive supertagging), but we leave that to future work. Using our A* heuristic doubles the speed of parsing (excluding supertagging).

To better understand the properties of our model, we also investigate how parsing time varies with sentence length. Unlike the cubic CKY algorithm typically used by chart parsers, our A* search potentially takes exponential time in the sentence length. For this experiment, we used the Sections 02-21 of CCGBank. Sentences were divided into bins of width 10, and we calculated the average parsing time for sentences in each bin.

Results are shown in Figure 2, and demonstrate that while parsing is highly efficient for sentences of up to 50 words (over 95% of CCGBank), it scales super-linearly with long sentences. In fact, Section 00 contains a sentence of 249 words, which took 37 *seconds* to parse (3 times longer than the other 1912 sentences put together). In practice, this scaling is unlikely to be problematic, as long sentences are typically filtered when processing large corpora.

4.4 Semantic Parsing

A major motivation for CCG parsing is to exploit its transparent interface to the semantics, allowing syntactic parsers to do much of the work of semantic parsers. Therefore, perhaps the most relevant measure of the performance of a CCG parser is its effect on the accuracy of downstream applications.

We experimented with a supervised version of Reddy et al. (2014)'s model for question-answering on Freebase (i.e. without using Reddy et al.'s lexicon derived from unlabelled text), using the WEBQUESTIONS dataset (Berant et al., 2013)[3]. The model learns to map CCG parses to database queries. We compare the performance of the QA system using both our parser and C&C, taking the 10-best parses from each parser for each sentence. Syntactic question parsing models were trained from the combination of 10 copies of Rimell and Clark (2008)'s question dataset and one copy of the CCGBank

The accuracy of Reddy et al. (2014)'s model varies significantly between iterations of the training data. Rather than tune the number of iterations, we instead measure the accuracy after each iteration. We experimented with the models' 1-best answers, and the oracle accuracy of their 100 best answers. The oracle accuracy gives a better indication of the performance of the parser, by mitigating errors caused by the semantic component.

Results are shown in Figure 3, and demonstrate that using EASYCCG can lead to better downstream performance than the C&C parser. The improvement is particularly large on oracle accuracy, increasing the upper bound on the performance of the semantic parser by around 4 points.

5 Related Work

CCG parsing has been the subject of much research. We have already described the C&C pars-

[2]It is worth noting that the C&C parser code is written in highly-optimized C++, compared to our simple Java implementation. It seems likely that our parser could be made substantially faster with a similar level of engineering effort.

[3]Using the *Business*, *Film* and *People* domains, with 1115 questions for training and 570 for testing.

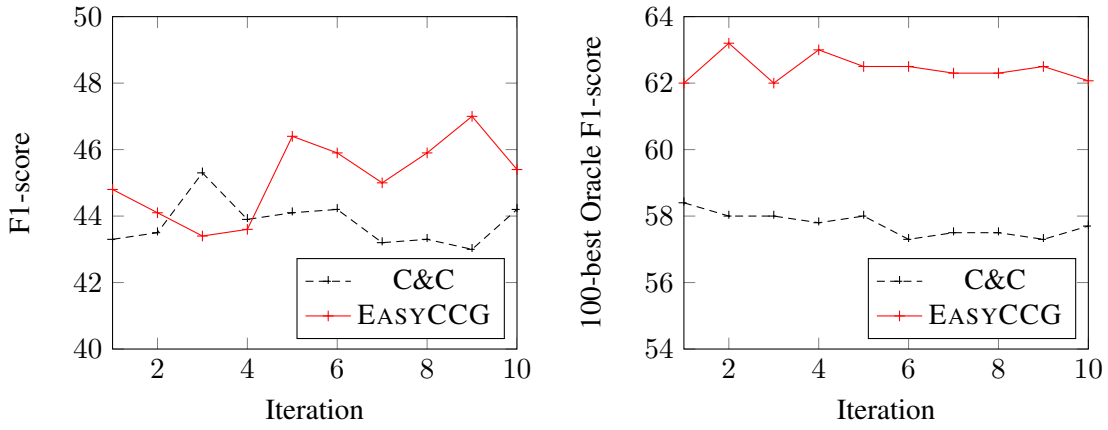

Figure 3: Question Answering accuracy per iteration of Reddy et al. (2014)'s supervised model.

ing model. Kummerfeld et al. (2010) showed that the speed of the C&C parser can be improved with domain-specific self-training—similar improvements may be possible applying this technique to our model. Auli and Lopez (2011a) have achieved the best CCG parsing accuracy, by allowing the parser and supertagger to perform joint inference (though there is a significant speed penalty). Auli and Lopez (2011b) were the first to use A* parsing for CCG, but their system is both much slower and less accurate than ours (due to a different model and a different A* heuristic). Krishnamurthy and Mitchell (2014) show how CCG parsing can be improved by jointly modelling the syntax and semantics. Fowler and Penn (2010) apply the Petrov parser to CCG, making a small improvement in accuracy over the C&C parser, at the cost of a 300-fold speed decrease. Zhang and Clark (2011) and Xu et al. (2014) explored shift-reduce CCG parsing, but despite the use of a linear-time algorithm, parsing speed in practice is significantly slower than the C&C parser.

Parsers based on supertagging models have previously been applied to other strongly lexicalized formalisms, such as to LTAG (Bangalore and Joshi, 1999) and to HPSG (Ninomiya et al., 2006). A major contribution of our work over these is showing that factoring models on lexical categories allows fast and exact A* parsing, without the need for beam search. Our parsing approach could be applied to any strongly lexicalized formalism.

Our work fits into a tradition of attempting to simplify complex models without sacrificing performance. Klein and Manning (2003b) showed that unlexicalized parsers were only slightly less accurate than their lexicalized counterparts. Collobert et al. (2011) showed how a range of NLP tagging tasks could be performed at high accuracy using a small feature set based on vector-space word embeddings. However, the extension of this work to phrase-structure parsing (Collobert, 2011) required a more complex model, and did not match the performance of traditional parsing techniques. We achieve state-of-the-art results using the same feature set and a simpler model by exploiting CCG's lexicalized nature, which makes it more natural to delegate parsing decisions to a tagging model.

Other parsing research has focused on building fast parsers for web-scale processing, typically using dependency grammars (e.g. Nivre (2003)). CCG has some advantages over dependency grammars, such as supporting surface-compositional semantics. The fastest dependency parsers use an *easy-first* strategy, in which edges are added greedily in order of their score, with $\mathcal{O}(nlog(n))$ complexity (Goldberg and Elhadad, 2010; Tratz and Hovy, 2011). This strategy is reminiscent of our A* search, which expands the chart in a best-first order. A* has higher asymptotic complexity, but finds a globally optimal solution.

6 Future Work

We believe that our model opens several interesting directions for future research.

One interesting angle would be to increase the amount of information in CCGBank's lexical entries, to further reduce the search space for the parser. For example, *PP* categories could be distinguished with the relevant preposition as a feature; punctuation and coordination could be given more detailed categories to avoid needing their own combinators, and slashes could be extended

with Baldridge and Kruijff (2003)'s multi-modal extensions to limit over-generation. Honnibal and Curran (2009) show how unary rules can be lexicalized in CCG. Such improvements may improve both the speed and accuracy of our model.

Because our parser is factored on a unigram tagging model, it can be trained from isolated annotated words, and does not require annotated parse trees or full sentences. Reducing the requirements for training data eases the task for human annotators. It may also make the model more amenable to semi-supervised approaches to CCG parsing, which have typically focused on extending the lexicon (Thomforde and Steedman, 2011; Deoskar et al., 2014). Finally, it may make it easier to convert other annotated resources, such as UCCA (Abend and Rappoport, 2013) or AMR (Banarescu et al., 2013), to CCG training data—as only specific words need to be converted, rather than full sentences.

Our model is weak at certain kinds of decisions, e.g. coordination-scope ambiguities or non-local attachments. Incorporating specific models for such decisions may improve accuracy, while still allowing fast and exact search—for example, we intend to try including Coppola et al. (2011)'s model for prepositional phrase attachment.

7 Conclusions

We have shown that a simple, principled, deterministic parser combined with a tagging model can parse an expressive linguistic formalism with high speed and accuracy. Although accuracy is not state-of-the-art on CCGBank, our model gives excellent performance on two out-of-domain datasets, and improves the accuracy of a question-answering system. We have shown that this model allows an efficient heuristic for A* parsing, which makes parsing extremely fast, and may enable logic-based distributional semantics to scale to larger corpora. Our methods are directly applicable to other lexicalized formalisms, such as LTAG, LFG and HPSG.

Acknowledgments

We would like to thank Tejaswini Deoskar, Bharat Ram Ambati, Michael Roth and the anonymous reviewers for helpful feedback on an earlier version of this paper, and Siva Reddy for running the semantic parsing experiments.

Abstract

We describe a new dependency parser for English tweets, TWEEBOPARSER. The parser builds on several contributions: new syntactic annotations for a corpus of tweets (TWEEBANK), with conventions informed by the domain; adaptations to a statistical parsing algorithm; and a new approach to exploiting out-of-domain Penn Treebank data. Our experiments show that the parser achieves over 80% unlabeled attachment accuracy on our new, high-quality test set and measure the benefit of our contributions.

Our dataset and parser can be found at http://www.ark.cs.cmu.edu/TweetNLP.

1 Introduction

In contrast to the edited, standardized language of traditional publications such as news reports, social media text closely represents language as it is used by people in their everyday lives. These informal texts, which account for ever larger proportions of written content, are of considerable interest to researchers, with applications such as sentiment analysis (Greene and Resnik, 2009; Kouloumpis et al., 2011). However, their often nonstandard content makes them challenging for traditional NLP tools. Among the tools currently available for tweets are a POS tagger (Gimpel et al., 2011; Owoputi et al., 2013) and a named entity recognizer (Ritter et al., 2011)—but not a parser.

Important steps have been taken. The English Web Treebank (Bies et al., 2012) represents an annotation effort on web text—which likely lies somewhere between newspaper text and social media messages in formality and care of editing—that was sufficient to support a shared task (Petrov and McDonald, 2012). Foster et al. (2011b) annotated a small test set of tweets to evaluate parsers trained on the Penn Treebank (Marcus et al., 1993), augmented using semi-supervision and in-domain data. Others, such as Soni et al. (2014), have used existing Penn Treebank–trained models on tweets.

In this work, we argue that the Penn Treebank approach to annotation—while well-matched to edited genres like newswire—is poorly suited to more informal genres. Our starting point is that rapid, small-scale annotation efforts performed by imperfectly-trained annotators should provide enough evidence to train an effective parser. We see this starting point as a necessity, given observations about the rapidly changing nature of tweets (Eisenstein, 2013), the attested difficulties of domain adaptation for parsing (Dredze et al., 2007), and the expense of creating Penn Treebank–style annotations (Marcus et al., 1993).

This paper presents TWEEBOPARSER, the first syntactic dependency parser designed explicitly for English tweets. We developed this parser following current best practices in empirical NLP: we annotate a corpus (TWEEBANK) and train the parameters of a statistical parsing algorithm. Our research contributions include:

- a survey of key challenges posed by syntactic analysis of tweets (by humans or machines) and decisions motivated by those challenges and by our limited annotation-resource scenario (§2);
- our annotation process and quantitative measures of the quality of the annotations (§3);
- adaptations to a statistical dependency parsing algorithm to make it fully compatible with the above, and also to exploit information from out-of-domain data cheaply and without a strong commitment (§4); and
- an experimental analysis of the parser's unlabeled attachment accuracy—which surpasses 80%—and contributions of various important components (§5).

The dataset and parser can be found at http://www.ark.cs.cmu.edu/TweetNLP.

2 Annotation Challenges

Before describing our annotated corpus of tweets (§3), we illustrate some of the challenges of syntactic analysis they present. These challenges motivate an approach to annotation that diverges significantly from conventional approaches to treebanking. Figure 1 presents a single example illustrating four of these: token selection, multiword expressions, multiple roots, and structure within noun phrases. We discuss each in turn.

2.1 Token Selection

Many elements in tweets have no syntactic function. These include, in many cases, hashtags, URLs, and emoticons. For example:

RT @justinbieber : now Hailee get a twitter

The retweet discourse marker, username, and colon should not, we argue, be included in the syntactic analysis. By contrast, consider:

Got #college admissions questions ? Ask them tonight during #CampusChat I'm looking forward to advice from @collegevisit http://bit.ly/cch0Tk

Here, both the hashtags and the at-mentioned username are syntactically part of the utterances, while the punctuation and the hyperlink are not. In the example of Figure 1, the unselected tokens include several punctuation tokens and the final token #believer, which marks the topic of the tweet.

Typically, dependency parsing evaluations ignore punctuation token attachment (Buchholz and Marsi, 2006), and we believe it is a waste of annotator (and parser) time to decide how to attach punctuation and other non-syntactic tokens. Ma et al. (2014) recently proposed to treat punctuation as context features rather than dependents, and found that this led to state-of-the-art performance in a transition-based parser. A small adaptation to our graph-based parsing approach, described in §4.2, allows a similar treatment.

Our approach to annotation (§3) forces annotators to explicitly select tokens that have a syntactic function. 75.6% tokens were selected by the annotators. Against the annotators' gold standard, we found that a simple rule-based filter for usernames, hashtags, punctuation, and retweet tokens achieves 95.2% (with gold-standard POS tags) and 95.1% (with automatic POS tags) average accuracy in the task of selecting tokens with a syntactic function in a ten-fold cross-validation experiment. To take context into account, we developed a first-order sequence model and found that it achieves 97.4% average accuracy (again, ten-fold cross-validated) with either gold-standard or automatic POS tags. Features include POS; shape features that recognize the retweet marker, hashtags, usernames, and hyperlinks; capitalization; and a binary feature for tokens that include punctuation. We trained the model using the structured perceptron (Collins, 2002).

2.2 Multiword Expressions

We consider multiword expressions (MWEs) of two kinds. The first, proper names, have been widely modeled for information extraction purposes, and even incorporated into parsing (Finkel and Manning, 2009). (An example found in Figure 1 is LA Times.) The second, lexical idioms, have been a "pain in the neck" for many years (Sag et al., 2002) and have recently received shallow treatment in NLP (Baldwin and Kim, 2010; Constant and Sigogne, 2011; Schneider et al., 2014). Constant et al. (2012), Green et al. (2012), Candito and Constant (2014), and Le Roux et al. (2014) considered MWEs in parsing. Figure 1 provides LA Times and All the Rage as examples.

Penn Treebank–style syntactic analysis (and dependency representations derived from it) does not give first-class treatment to this phenomenon, though there is precedent for marking multiword lexical units and certain kinds of idiomatic relationships (Hajič et al., 2012; Abeillé et al., 2003).[1]

We argue that internal analysis of MWEs is not critical for many downstream applications, and therefore annotators should not expend energy on developing and respecting conventions (or making arbitrary decisions) within syntactically opaque or idiosyncratic units. We therefore allow annotators to decide to group words as explicit MWEs, including: proper names (Justin Bieber, World Series), noncompositional or entrenched nominal compounds (belly button, grilled cheese), connectives (as well as), prepositions (out of), adverbials (so far), and idioms (giving up, make sure).

From an annotator's perspective, a MWE functions as a *single node* in the dependency parse, with no internal structure. For idioms whose internal syntax *is* easily characterized, the parse can be used to capture compositional structure, an at-

[1] The popular Stanford typed dependencies (de Marneffe and Manning, 2008) scheme includes a special dependency type for multiwords, though this is only applied to a small list.

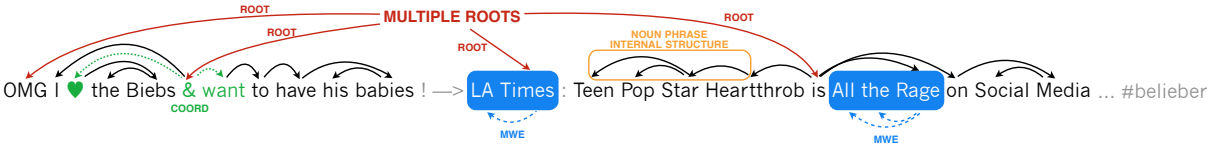

Figure 1: Parse tree for a (constructed) example illustrating annotation challenges discussed in §2. Colors highlight token selection (gray; §2.1), multiword expressions (blue; §2.2), multiple roots (red; §2.3), coordination (dotted arcs, green; §3.2), and noun phrase internal structure (orange; §2.4). The internal structure of multiword expressions (dashed arcs below the sentence) was predicted automatically by a parser, as described in §2.2.

tractive property from the perspective of semantic processing.

To allow training a fairly conventional statistical dependency parser from these annotations, we find it expedient to apply an automatic conversion to the MWE annotations, in the spirit of Johnson (1998). We apply an existing dependency parser, the first-order TurboParser (Martins et al., 2009) trained on the Penn Treebank, to parse each MWE independently, assigning structures like those for LA Times and All the Rage in Figure 1. Arcs involving the MWE in the annotation are then reconnected to the MWE-internal root, so that the resulting tree respects the original tokenization. The MWE-internal arcs are given a special label so that the transformation can be reversed and MWEs reconstructed from parser output.

2.3 Multiple Roots

For news text such as that found in the Penn Treebank, sentence segmentation is generally considered a very easy task (Reynar and Ratnaparkhi, 1997). Tweets, however, often contain multiple sentences or fragments, which we call "utterances," each with its own syntactic root disconnected from the others. The selected tokens in Figure 1 comprise four utterances.

Our approach to annotation allows multiple utterances to emerge directly from the connectedness properties of the graph implied by an annotator's decisions. Our parser allows multiple attachments to the "wall" symbol, so that multi-rooted analyses can be predicted.

2.4 Noun Phrase Internal Structure

A potentially important drawback of deriving dependency structures from phrase-structure annotations, as is typically done using the Penn Treebank, is that flat annotations lead to loss of information. This is especially notable for noun phrases in the Penn Treebank (Vadas and Curran, 2007). Consider Teen Pop Star Heartthrob in Figure 1; Penn Treebank conventions would label this as a single NP with four NN children and no internal structure. Dependency conversion tools would likely attach the first three words in the NP to Heartthrob. Direct dependency annotation (rather than phrase-structure annotation followed by automatic conversion) allows a richer treatment of such structures, which is potentially important for semantic analysis (Vecchi et al., 2013).

3 A Twitter Dependency Corpus

In this section, we describe the TWEEBANK corpus, highlighting data selection (§3.1), the annotation process (§3.2), important convention choices (§3.3), and measures of quality (§3.4).

3.1 Data Selection

We added manual dependency parses to 929 tweets (12,318 tokens) drawn from the POS-tagged Twitter corpus of Owoputi et al. (2013), which are tokenized and contain manually annotated POS tags.

Owoputi et al.'s data consists of two parts. The first, originally annotated by Gimpel et al. (2011), consists of tweets sampled from a particular day, October 27, 2010—this is known as OCT27. Due to concerns about overfitting to phenomena specific to that day (e.g., tweets about a particular sports game), Owoputi et al. (2013) created a new set of 547 tweets (DAILY547) consisting of one random English tweet per day from January 2011 through June 2012.

Our corpus is drawn roughly equally from OCT27 and DAILY547.[2] Despite its obvious temporal skew, there is no reason to believe this sample is otherwise biased; our experiments in §5 suggest that this property is important.

3.2 Annotation

Unlike a typical treebanking project, which may take years and involve thousands of person-hours of work by linguists, most of TWEEBANK was built in a day by two dozen annotators, most of whom had only cursory training in the annotation scheme.

[2]This results from a long-term goal to fully annotate both.

I'mmm** < meltiiinngggg
```

Figure 2: Examples of GFL annotations from the corpus.

Our annotators used the Graph Fragment Language (GFL), a text-based notation that facilitates keyboard entry of parses (Schneider et al., 2013). A Python Flask web application allows the annotator to validate and visualize each parse (Mordowanec et al., 2014). Some examples are shown in Figure 2. Note that all of the challenges in §2 are handled easily by GFL notation: "retweet" information, punctuation, and a URL are not selected by virtue of their exclusion from the GFL expression; in (2) went down is annotated as a MWE using GFL's square bracket notation; in (3) the tokens are grouped into two utterances whose roots are marked by the ** symbol.

Schneider et al.'s GFL offers some additional features, only some of which we made use of in this project. One important feature allows an annotator to leave the parse *underspecified* in some ways. We allowed our annotators to make use of this feature; however, we excluded from our training and testing data any parse that was incomplete (i.e., any parse that contained multiple disconnected fragments with no explicit root, excluding unselected tokens). Learning to parse from incomplete annotations is a fascinating topic explored in the past (Hwa, 2001; Pereira and Schabes, 1992) and, in the case of tweets, left for future work.

An important feature of GFL that we did use is special notation for coordination structures. For the coordination structure in Figure 1, for example, the notation is:

```
$a :: {♥ want} :: {&}
```

where `$a` creates a new node in the parse tree as it is visualized for the annotator, and this new node attaches to the syntactic parent of the conjoined structure, avoiding the classic forced choice between coordinator and conjunct as parent. For learning to parse, we transform GFL's coordination structures into specially-labeled dependency parses collapsing nodes like `$a` with the coordinator and labeling the attachments specially for postprocessing, following Schneider et al. (2013). In our evaluation (§5), these are treated like other attachments.

3.3 Annotation Conventions

A wide range of dependency conventions are in use; in many cases these are *conversion* conventions specifying how dependency trees can be derived from phrase-structure trees. For English, the most popular are due to Yamada and Matsumoto (2003) and de Marneffe and Manning (2008), known as "Yamada-Matsumoto" (YM) and "Stanford" dependencies, respectively. The main differences between them are in whether the auxiliary is the parent of the main verb (or vice versa) and whether the preposition or its argument heads a prepositional phrase (Elming et al., 2013).

A full discussion of our annotation conventions is out of scope. We largely followed the conventions suggested by Schneider et al. (2013), which in turn are close to those of YM. Auxiliary verbs are parents of main verbs, and prepositions are parents of their arguments. The key differences from YM are in coordination structures (discussed in §3.2; YM makes the first conjunct the head) and possessive structures, in which the possessor is the child of the clitic, which is the child of the semantic head, e.g., `the > king > 's > horses`.

3.4 Intrinsic Quality

Our approach to developing this initial corpus of syntactically annotated tweets was informed by an aversion to making the perfect the enemy of the good; that is, we sought enough data of sufficient quality to build a usable parser within a relatively short amount of time. If our research goals had been to develop a replicable process for annotation, more training and more quality control would have been called for. Under our budgeted time and annotator resources, this overhead was simply too costly. Nonetheless, we performed a few analyses that give a general picture of the quality of the annotations.

Inter-annotator agreement. 170 of the tweets were annotated by multiple users. By the *softComPrec* measure (Schneider et al., 2013),[3] the agreement rate on dependencies is above 90%.

Expert linguistic judgment. A linguist coauthor examined a stratified sample (balanced

[3] *softComPrec* is a generalization of attachment accuracy that handles unselected tokens and MWEs.

across annotators) of 60 annotations and rated their quality on a 5-point scale. 30 annotations were deemed to have "no obvious errors," 15 only minor errors, 3 a major error (i.e., clear violation of annotation guidelines),[4] 4 a major error and at least one minor error, and 8 as containing multiple major errors. Thus, 75% are judged as having no major errors. We found this encouraging, considering that this sample is skewed in favor of people who annotated less (including many of the less experienced and/or lower-proficiency annotators).

Pairwise ranking. For 170 of the doubly annotated tweets, an experienced annotator examined whether one or the other was markedly better. In 100 cases the two annotations were of comparable quality (neither was obviously better) and did not contain any obvious major errors. In only 7 pairs did both of the annotations contain a serious error.

Qualitatively, we found several unsurprising sources of error or disagreement, including embedded/subordinate clauses, subject-auxiliary inversion, predeterminers, and adverbial modifiers following a modal/auxiliary verb and a main verb. Clarification of the conventions, or even explicit rule-based checking in the validation step, might lead to quality improvements in further annotation efforts.

4 Parsing Algorithm

For parsing, we start with TurboParser, which is open-source and has been found to perform well on a range of parsing problems in different languages (Martins et al., 2013; Kong and Smith, 2014). The underlying model allows for flexible incorporation of new features and changes to specification in the output space. We briefly review the key ideas in TurboParser (§4.1), then describe decoder modifications required for our problem (§4.2). We then discuss features we added to TurboParser (§4.3).

4.1 TurboParser

Let an input sentence be denoted by x and the set of possible dependency parses for x be denoted by $\mathcal{Y}_x$. A generic linear scoring function based on a feature vector representation $\mathbf{g}$ is used in parsing algorithms that seek to find:

$$\text{parse}^*(x) = \arg\max_{y \in \mathcal{Y}_x} \mathbf{w}^\top \mathbf{g}(x, y) \quad (1)$$

The score is parameterized by a vector $\mathbf{w}$ of weights, which are learned from data (most commonly using MIRA, McDonald et al., 2005a).

The decomposition of the features into local "parts" is a critical choice affecting the computational difficulty of solving Eq. 1. The most aggressive decomposition leads to an "arc-factored" or "first-order" model, which permits exact, efficient solution of Eq. 1 using spanning tree algorithms (McDonald et al., 2005b) or, with a projectivity constraint, dynamic programming (Eisner, 1996).

Second- and third-order models have also been introduced, typically relying on approximations, since less-local features increase the computational cost, sometimes to the point of NP-hardness (McDonald and Satta, 2007). TurboParser attacks the parsing problem using a compact integer linear programming (ILP) representation of Eq. 1 (Martins et al., 2009), then employing alternating directions dual decomposition (AD^3; Martins et al., 2011). This enables inclusion of second-order features (e.g., on a word with its sibling or grandparent; Carreras, 2007) and third-order features (e.g., a word with its parent, grandparent, and a sibling, or with its parent and two siblings; Koo and Collins, 2010).

For a collection of (possibly overlapping) parts for input x, $\mathcal{S}_x$ (which includes the union of all parts of all trees in $\mathcal{Y}_x$), we will use the following notation. Let

$$\mathbf{g}(x, y) = \sum_{s \in \mathcal{S}_x} \mathbf{f}_s(x, y), \quad (2)$$

where $\mathbf{f}_s$ only considers part s and is nonzero only if s is present in y. In the ILP framework, each s has a corresponding binary variable z_s indicating whether part s is included in the output. A collection of constraints relating z_s define the set of feasible vectors $\mathbf{z}$ that correspond to valid outputs and enfore agreement between parts that overlap. Many different versions of these constraints have been studied (Riedel and Clarke, 2006; Smith and Eisner, 2008; Martins et al., 2009, 2010).

A key attraction of TurboParser is that many overlapping parts can be handled, making use of separate combinatorial algorithms for efficiently handling *subsets* of constraints. For example, the constraints that force $\mathbf{z}$ to encode a valid tree can be exploited within the framework by making calls

[4] What we deemed *major* errors included, for example, an incorrect dependency relation between an auxiliary verb and the main verb (like `ima > [have to]`). *Minor* errors included an incorrect attachment between two modifiers of the same head, as in `the > only > [grocery store]`—the correct annotation would have two attachments to a single head, i.e. `the > [grocery store] < only` (or equivalent).

to classic arborescence algorithms (Chu and Liu, 1965; Edmonds, 1967). As a result, when describing modifications to TurboParser, we need only to explain additional constraints and features imposed on *parts*.

4.2 Adapted Parse Parts

The first collection of parts we adapt are simple arcs, each consisting of an ordered pair of indices of words in x; $\text{arc}(p,c)$ corresponds to the attachment of x_c as a child of x_p (iff $z_{\text{arc}(p,c)} = 1$). Our representation explicitly excludes some tokens from being part of the syntactic analysis (§2.1); to handle this, we constrain $z_{\text{arc}(i,j)} = 0$ whenever x_i or x_j is excluded.

The implication is that excluded tokens are still "visible" to feature functions that involve other edges. For example, some conventional first-order features consider the tokens occurring *between* a parent and child. Even if a token plays no syntactic role of its own, it might still be informative about the syntactic relationships among other tokens. We note three alternative methods:

1. We might remove all unselected tokens from x before running the parser. In §5.6 we find this method to fare 1.7–2.3% worse than our modified decoding algorithm.
2. We might remove unselected tokens but use them to define new features, so that they still serve as evidence. This is the approach taken by Ma et al. (2014) for punctuation. We judge our simple modification to the decoding algorithm to be more expedient, and leave the translation of existing context-word features into that framework for future exploration.
3. We might incorporate the token selection decisions into the parser, performing joint inference for selection and parsing. The AD^3 algorithm within TurboParser is well-suited to this kind of extension: z-variables for each token's selection could be added, and similar scores to those of our token selection sequence model (§2.1) could be integrated into parsing. Given, however, that the sequence model achieves over 97% accuracy, and that perfect token selection would gain only 0.1–1% in parsing accuracy (reported in §5.5), we leave this option for future work as well.

For first-order models, the above change is all that is necessary. For second- and third-order models, TurboParser makes use of head automata, in particular "grand-sibling head automata" that assign scores to word tuples of x_g, its child x_p, and two of x_p's adjacent children, x_c and x'_c (Koo et al., 2010). The second-order models in our experiments include parts for $\text{sibling}(p,c,c')$ and $\text{grandparent}(p,c,g)$ and use the grand-sibling head automaton to reason about these together. Automata for an unselected x_p or x_g, and transitions that consider unselected tokens as children, are eliminated. In order to allow the scores to depend on unselected tokens between x_c and x'_c, we added the binned counts of unselected tokens (mostly punctuation) joint with the word form and POS tag of x_p and the POS tag of x_c and x'_c as features scored in the $\text{sibling}(p,c,c')$ part. The changes discussed above comprise the totality of adaptations we made to the TurboParser algorithm; we refer to them as "parsing adaptations" in the experiments.

4.3 Additional Features

Brown clusters. Owoputi et al. (2013) found that Brown et al. (1992) clusters served as excellent features in Twitter POS tagging. Others have found them useful in parsing (Koo et al., 2008) and other tasks (Turian et al., 2010). We therefore follow Koo et al. in incorporating Brown clusters as features, making use of the publicly available Twitter clusters from Owoputi et al.[5] We use 4 and 6 bit cluster representations to create features wherever POS tags are used, and full bit strings to create features wherever words were used.

Penn Treebank features. A potential danger of our choice to "start from scratch" in developing a dependency parser for Twitter is that the resulting annotation conventions, data, and desired output are very different from dependency parses derived from the Penn Treebank. Indeed, Foster et al. (2011a) took a very different approach, applying Penn Treebank conventions in annotation of a test dataset for evaluation of a parser trained using Penn Treebank trees. In §5.4, we replicate, for dependencies, their finding that a Penn Treebank–trained parser is hard to beat *on their dataset*, which was not designed to be topically representative of English Twitter. When we turn to a more realistic dataset like ours, we find the performance of the Penn Treebank–trained parser to be poor.

Nonetheless, it is hard to ignore such a large amount of high-quality syntactic data. We there-

[5] http://www.ark.cs.cmu.edu/TweetNLP/clusters/50mpaths2

fore opted for a simple, stacking-inspired incorporation of Penn Treebank information into our model.[6] We define a feature on every candidate arc whose value is the (quantized) score of the same arc under a first-order model trained on the Penn Treebank converted using head rules that are as close as possible to our conventions (discussed in more detail in §5.1). This lets a Penn Treebank model literally "weigh in" on the parse for a tweet, and lets the learning algorithm determine how much consideration it deserves.

5 Experiments

Our experiments quantify the contributions of various components of our approach.

5.1 Setup

We consider two test sets. The first, TEST-NEW, consists of 201 tweets from our corpus annotated by the most experienced of our annotators (one of whom is a co-author of this work). Given very limited data, we believe using the highest quality data for measuring performance, and lower-quality data for training, is a sensibly realistic choice.

Our second test set, TEST-FOSTER, is the dataset annotated by Foster et al. (2011b), which consists of 250 sentences. Recall that their corpus was annotated with phrase structures according to Penn Treebank conventions. Conversion to match our annotation conventions was carried out as follows:

1. We used the PennConverter tool with head rule options selected to approximate our annotation conventions as closely as possible.[7]
2. An experienced annotator manually modified the automatically converted trees by:
   (a) Performing token selection (§2.1) to remove the tokens which have no syntactic function.
   (b) Grouping MWEs (§2.2). Here, most of the MWEs are named entities such as Manchester United.
   (c) Attaching the roots of the utterance in tweets to the "wall" symbol (§2.3).[8]
   (d) Recovering the internal structure of the noun phrases.
   (e) Fixing a difference in conventions with respect to subject-auxiliary inversion.[9]

	TRAIN	TEST-NEW	TEST-FOSTER
tweets	717	201	$< 250^{\dagger}$
unique tweets	569	201	$< 250^{\dagger}$
tokens	9,310	2,839	2,841
selected tokens	7,015	2,158	2,366
types	3,566	1,461	1,230
utterances	1,473	429	337
multi-root tweets	398	123	60
MWEs	387	78	109

Table 1: Statistics of our datasets. (A tweet with k annotations in the training set is counted k times for the totals of tokens, utterances, etc.). †TEST-FOSTER contains 250 manually split sentences. The number of tweets should be smaller but is not recoverable from the data release.

We consider two training sets. TRAIN-NEW consists of the remaining 717 tweets from our corpus (§3) annotated by the rest of the annotators. Some of these tweets have annotations from multiple annotators; 11 annotations for tweets that also occurred in TEST-NEW were excluded. TRAIN-PTB is the conventional training set from the Penn Treebank (§2–21). The PennConverter tool was used to extract dependencies, with head rule options selected to approximate our annotation conventions as closely as possible (see footnote 7). The resulting annotations lack the same attention to noun phrase–internal structure (§2.4) and handle subject-auxiliary inversions differently than our data. Part-of-speech tags were coarsened to be compatible with the Twitter POS tags, using the mappings specified by Gimpel et al. (2011).

Statistics for the in-domain datasets are given in Table 1. As we can see in the table, more than half of the tweets in our corpus have multiple utterances. The out-of-vocabulary rate for our TRAIN/TEST-NEW split is 33.7% by token and 62.5% by type; for TRAIN/TEST-FOSTER it is 41.4% and 64.6% respectively. These are much higher than the 2.5% and 13.2% in the standard Penn Treebank split.

All evaluations here are on unlabeled attachment F_1 scores.[10] Our parser provides labels for coordination structures and MWEs (§2), but we do not present detailed evaluations of those due to space constraints.

[6] Stacking is a machine learning method where the predictions of one model are used to create features for another. The second model may be from a different family. Stacking has been found successful for dependency parsing by Nivre and McDonald (2008) and Martins et al. (2008). Johansson (2013) describes further advances that use path features.

[7] `http://nlp.cs.lth.se/software/treebank_converter`; run with `-rightBranching=false -coordStructure=prague -prepAsHead=true -posAsHead=true -subAsHead=true -imAsHead=true -whAsHead=false`.

[8] This was infrequent; their annotations split most multi-utterance tweets into separate sentence-instances.

[9] For example, in the sentence Is he driving, we attached he to driving while PennConverter attaches it to Is.

[10] Because of token selection, precision and recall may not be equal.

5.2 Preprocessing

Because some of the tweets in our test set were also in the training set of Owoputi et al. (2013), we retrained their POS tagger on all the annotated data they have minus the 201 tweets in our test set. Its tagging accuracy was 92.8% and 88.7% on TEST-NEW and TEST-FOSTER, respectively. The token selection model (§2.1) achieves 97.4% on TEST-NEW with gold or automatic POS tagging; and on TEST-FOSTER, 99.0% and 99.5% with gold and automatic POS tagging, respectively.

As noted in §4.3, Penn Treebank features were developed using a first-order TurboParser trained on TRAIN-PTB; Brown clusters were included in computing these Penn Treebank features if they were available in the parser to which the features (i.e. Brown clusters) were added.

5.3 Main Parser

The second-order TurboParser described in §4, trained on TRAIN-NEW (default hyperparameter values), achieves 80.9% unlabeled attachment accuracy on TEST-NEW and 76.1% on TEST-FOSTER. The experiments consider variations on this main approach, which is the version released as TWEEBOPARSER.

The discrepancy between the two test sets is easily explained: as noted in §3.1, the dataset from which our tweets are drawn was designed to be representative of English on Twitter. Foster et al. (2011b) selected tweets from Bermingham and Smeaton's (2010) corpus, which uses fifty predefined topics like politics, business, sports, and entertainment—in short, topics not unlike those found in the Penn Treebank. Relative to the Penn Treebank training set, the by-type out-of-vocabulary rates are 45.2% for TEST-NEW and only 21.6% for TEST-FOSTER (cf. 13.2% for the Penn Treebank test set).

Another mismatch is in the handling of utterances. In our corpus, utterance segmentation emerges from multi-rooted annotations (§2.3). Foster et al. (2011b) manually split each tweet into utterances and treat those as separate instances in their corpus, so that our model trained on often multi-rooted tweets from TRAIN is being tested only on single-rooted utterances.

5.4 Experiment: Which Training Set?

We consider the direct use of TRAIN-PTB instead of TRAIN-NEW. Table 2 reports the results on both test sets, with various options. "Baseline" is off-the-shelf second-order TurboParser. We consider augmenting it with Brown cluster features (§4.3; "+ Brown") and then also with the parsing adaptations of §4.2 ("+ Brown & PA"). Another choice is whether to modify the POS tags at test time; the modified version ("mod. POS") maps at-mentions to pronoun, and hashtags and URLs to noun.

	Unlabeled Attachment F_1 (%)	
	mod. POS	POS as-is
TEST-NEW		
Baseline	73.0	73.5
+ Brown	73.7	73.3
+ Brown & PA	72.9	73.1
TEST-FOSTER		
Baseline	76.3	75.2
+ Brown	75.5	76.7
+ Brown & PA	76.9	77.0

Table 2: Performance of second-order TurboParser trained on TRAIN-PTB, with various preprocessing options. The main parser (§5.3) achieves 80.9% and 76.1% on the two test sets, respectively; see §5.4 for discussion.

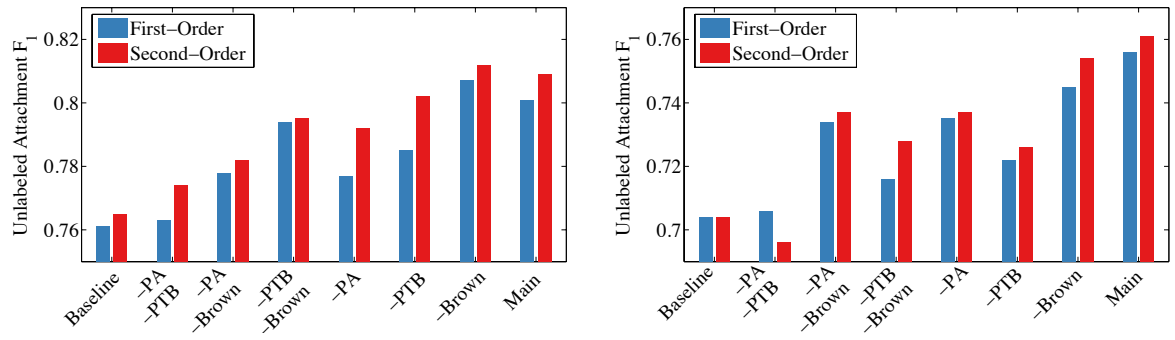
We note that comparing these scores to our main parser (§5.3) conflates three very important independent variables: the amount of training data (39,832 Penn Treebank sentences vs. 1,473 Twitter utterances), the annotation method, and the source of the data. However, we are encouraged that, on what we believe is the superior test set (TEST-NEW), our overall approach obtains a 7.8% gain with an order of magnitude less annotated data.

5.5 Experiment: Effect of Preprocessing

Table 3 (second block, italicized) shows the performance of the main parser on both test sets with gold-standard and automatic POS tagging and token selection. On TEST-NEW, with either gold-standard POS tags or gold-standard token selection, performance increases by 1.1%; with both, it increases by 2.3%. On TEST-FOSTER, token selection matters much less, but POS tagging accounts for a drop of more than 6%. This is consistent with Foster et al.'s finding: using a fine-grained Penn Treebank–trained POS tagger (achieving around 84% accuracy on Twitter), they saw 5–8% improvement in unlabeled dependency attachment accuracy using gold-standard POS tags.

5.6 Experiment: Ablations

We ablated each key element of our main parser—PTB features, Brown features, second order features and decoding, and the parsing adaptations of



(a) TEST-NEW (b) TEST-FOSTER

Figure 3: Feature ablations; these charts present the same scores shown in Table 3 and more variants of the first-order model.

	Unlabeled Attachment F_1 (%)	
	TEST-NEW	**TEST-FOSTER**
Main parser	80.9	**76.1**
Gold POS and TS	*83.2*	*82.8*
Gold POS, automatic TS	*82.0*	*82.3*
Automatic POS, gold TS	*82.0*	*76.2*
Single ablations:		
– PTB	80.2	72.6
– Brown	**81.2**	75.4
– 2nd order	80.1	75.6
– PA	79.2	73.7
Double ablations:		
– PTB, – Brown	79.5	72.8
– PTB, – 2nd order	78.5	72.2
– PTB, – PA	77.4	69.6
– Brown, – 2nd order	80.7	74.5
– Brown, – PA	78.2	73.7
– 2nd order, – PA	77.7	73.5
Baselines:		
Second order	76.5	70.4
First order	76.1	70.4

Table 3: Effects of gold-standard POS tagging and token selection (TS; §5.5) and of feature ablation (§5.6). The "baselines" are TurboParser without the parsing adaptations in §4.2 and without Penn Treebank or Brown features. The best result in each column is bolded. See also Figure 3.

§4.2—as well as each pair of these. These conditions use automatic POS tags and token selection. The "– PA" condition, which ablates parsing adaptations, is accomplished by deleting punctuation (in training and test data) and parsing using TurboParser's existing algorithm.

Results are shown in Table 3. Further results with first- and second-order TurboParsers are plotted in Figure 3. Notably, a 2–3% gain is obtained by modifying the parsing algorithm, and our stacking-inspired use of Penn Treebank data contributes in both cases, quite a lot on TEST-FOSTER (unsurprisingly given that test set's similarity to the Penn Treebank). More surprisingly, we find that Brown cluster features do not consistently improve performance, at least not as instantiated here, with our small training set.

6 Conclusion

We described TWEEBOPARSER, a dependency parser for English tweets that achieves over 80% unlabeled attachment score on a new, high-quality test set. This is on par with state-of-the-art reported results for news text in Turkish (77.6%; Koo et al., 2010) and Arabic (81.1%; Martins et al., 2011). Our contributions include important steps taken to build the parser: a consideration of the challenges of parsing tweets that informed our annotation process, the resulting new TWEEBANK corpus, adaptations to a statistical parsing algorithm, a new approach to exploiting data in a better-resourced domain (the Penn Treebank), and experimental analysis of the decisions we made. The dataset and parser can be found at `http://www.ark.cs.cmu.edu/TweetNLP`.

Abstract

Dependency parsing with high-order features results in a provably hard decoding problem. A lot of work has gone into developing powerful optimization methods for solving these combinatorial problems. In contrast, we explore, analyze, and demonstrate that a substantially simpler randomized greedy inference algorithm already suffices for near optimal parsing: a) we analytically quantify the number of local optima that the greedy method has to overcome in the context of first-order parsing; b) we show that, as a decoding algorithm, the greedy method surpasses dual decomposition in second-order parsing; c) we empirically demonstrate that our approach with up to third-order and global features outperforms the state-of-the-art dual decomposition and MCMC sampling methods when evaluated on 14 languages of non-projective CoNLL datasets.[1]

1 Introduction

Dependency parsing is typically guided by parameterized scoring functions that involve rich features exerting refined control over the choice of parse trees. As a consequence, finding the highest scoring parse tree is a provably hard combinatorial inference problem (McDonald and Pereira, 2006). Much of the recent work on parsing has focused on solving these problems using powerful optimization techniques. In this paper, we follow a different strategy, arguing that a much simpler inference strategy suffices. In fact, we demonstrate that a randomized greedy method of inference surpasses the state-of-the-art performance in dependency parsing.

Our choice of a randomized greedy algorithm for parsing follows from a successful track record of such methods in other hard combinatorial problems. These conceptually simple and intuitive algorithms have delivered competitive approximations across a broad class of NP-hard problems ranging from set cover (Hochbaum, 1982) to MAX-SAT (Resende et al., 1997). Their success is predicated on the observation that most realizations of problems are much easier to solve than the worst-cases. A simpler algorithm will therefore suffice in typical cases. Evidence is accumulating that parsing problems may exhibit similar properties. For instance, methods such as dual decomposition offer certificates of optimality when the highest scoring tree is found. Across languages, dual decomposition has shown to lead to a certificate of optimality for the vast majority of the sentences (Koo et al., 2010; Martins et al., 2011). These remarkable results suggest that, as a combinatorial problem, parsing appears simpler than its broader complexity class would suggest. Indeed, we show that a simpler inference algorithm already suffices for superior results.

In this paper, we introduce a randomized greedy algorithm that can be easily used with any rich scoring function. Starting with an initial tree drawn uniformly at random, the algorithm makes only local myopic changes to the parse tree in an attempt to climb the objective function. While a single run of the hill-climbing algorithm may indeed get stuck in a locally optimal solution, multiple random restarts can help to overcome this problem. The same algorithm is used both for learning the parameters of the scoring function as well as for parsing test sentences.

The success of a randomized greedy algorithm is tied to the number of local maxima in the search space. When the number is small, only a few restarts will suffice for the greedy algorithm to find the highest scoring parse. We provide an al-

gorithm for explicitly counting the number of local optima in the context of first-order parsing, and demonstrate that the number is typically quite small. Indeed, we find that a first-order parser trained with exact inference or using our randomized greedy algorithm delivers basically the same performance.

We hypothesize that parsing with high-order scoring functions exhibits similar properties. The main rationale is that, even in the presence of high-order features, the resulting scoring function remains first-order dominant. The performance of a simple arc-factored first-order parser is only a few percentage points behind higher-order parsers. The higher-order features in the scoring function offer additional refinement but only a few changes above and beyond the first-order result. As a consequence, most of the arc choices are already determined by a much simpler, polynomial time parser.

We use dual decomposition to show that the greedy method indeed succeeds as an inference algorithm even with higher-order scoring functions. In fact, with second-order features, regardless of which method was used for training, the randomized greedy method outperforms dual decomposition by finding higher scoring trees. For the sentences that dual decomposition is optimal (obtains a certificate), the greedy method finds the same solution in over 99% of the cases. Our simple inference algorithm is therefore likely to scale to higher-order parsing and we demonstrate empirically that this is indeed so.

We validate our claim by evaluating the method on the CoNLL dependency benchmark that comprises treebanks from 14 languages. Averaged across all languages, our method outperforms state-of-the-art parsers, including TurboParser (Martins et al., 2013) and our earlier sampling-based parser (Zhang et al., 2014). On seven languages, we report the best published results. The method is not sensitive to initialization. In fact, drawing the initial tree uniformly at random results in the same performance as when initialized from a trained first-order distribution. In contrast, sufficient randomization of the starting point is critical. Only a small number of restarts suffices for finding (near) optimal parse trees.

2 Related Work

Finding Optimal Structure in Parsing The use of rich-scoring functions in dependency parsing inevitably leads to the challenging combinatorial problem of finding the maximizing parse. In fact, McDonald and Pereira (2006) demonstrated that the task is provably NP-hard for non-projective second-order parsing. Not surprisingly, approximate inference has been at the center of parsing research. Examples of these approaches include easy-first parsing (Goldberg and Elhadad, 2010), inexact search (Johansson and Nugues, 2007; Zhang and Clark, 2008; Huang et al., 2012; Zhang et al., 2013), partial dynamic programming (Huang and Sagae, 2010) and dual decomposition (Koo et al., 2010; Martins et al., 2011).

Our work is most closely related to the MCMC sampling-based approaches (Nakagawa, 2007; Zhang et al., 2014). In our earlier work, we developed a method that learns to take guided stochastic steps towards a high-scoring parse (Zhang et al., 2014). In the heart of that technique are sophisticated samplers for traversing the space of trees. In this paper, we demonstrate that a substantially simpler approach that starts from a tree drawn from the uniform distribution and uses hill-climbing for parameter updates achieves similar or higher performance.

Another related greedy inference method has been used for non-projective dependency parsing (McDonald and Pereira, 2006). This method relies on hill-climbing to convert the highest scoring projective tree into its non-projective approximation. Our experiments demonstrate that when hill-climbing is employed as a primary learning mechanism for high-order parsing, it exhibits different properties: the distribution for initialization does not play a major role in the final outcome, while the use of restarts contributes significantly to the quality of the resulting tree.

Greedy Approximations for NP-hard Problems There is an expansive body of research on greedy approximations for NP-hard problems. Examples of NP-hard problems with successful greedy approximations include the traveling saleman problem problem (Held and Karp, 1970; Rego et al., 2011), the MAX-SAT problem (Mitchell et al., 1992; Resende et al., 1997) and vertex cover (Hochbaum, 1982). While some greedy methods have poor worst-case complexity, many

of them work remarkably well in practice. Despite the apparent simplicity of these algorithms, understanding their properties is challenging: often their "theoretical analyses are negative and inconclusive" (Amenta and Ziegler, 1999; Spielman and Teng, 2001). Identifying conditions under which approximations are provably optimal is an active area of research in computer science theory (Dumitrescu and Tóth, 2013; Jonsson et al., 2013).

In NLP, randomized and greedy approximations have been successfully used across multiple applications, including machine translation and language modeling (Brown et al., 1993; Ravi and Knight, 2010; Daumé III et al., 2009; Moore and Quirk, 2008; Deoras et al., 2011). In this paper, we study the properties of these approximations in the context of dependency parsing.

3 Method

3.1 Preliminaries

Let x be a sentence and $\mathcal{T}(x)$ be the set of possible dependency trees over the words in x. We use $y \in \mathcal{T}(x)$ to denote a dependency tree for x, and $y(m)$ to specify the head (parent) of the modifier word indexed by m in tree y. We also use m to denote the indexed word when there is no ambiguity. In addition, we define $\mathcal{T}(y, m)$ as the set of "neighboring trees" of y obtained by changing only the head of the modifier, i.e. $y(m)$.

The dependency trees are scored according to $S(x, y) = \theta \cdot \phi(x, y)$, where θ is a vector of parameters and $\phi(x, y)$ is a sparse feature vector representation of tree y for sentence x. In this work, $\phi(x, y)$ will include up to third-order features as well as a range of global features commonly used in re-ranking methods (Collins, 2000; Charniak and Johnson, 2005; Huang, 2008).

The parameters θ in the scoring function are estimated on the basis of a training set $D = \{(\hat{x}_i, \hat{y}_i)\}_{i=1}^{N}$ of sentences $\hat{x}_i$ and the corresponding gold (target) trees $\hat{y}_i$. We adopt a max-margin framework for this learning problem. Specifically, we aim to find parameter values that score the gold target trees higher than others:

$$\forall i \in \{1, \cdots, N\}, y \in \mathcal{T}(\hat{x}_i),$$
$$S(\hat{x}_i, \hat{y}_i) \geq S(\hat{x}_i, y) + \|\hat{y}_i - y\|_1 - \xi_i$$

where $\xi_i \geq 0$ is the slack variable (non-zero values are penalized against) and $\|\hat{y}_i - y\|_1$ is the hamming distance between the gold tree $\hat{y}_i$ and a candidate parse y.

In an online learning setup, parameters are updated successively after each sentence. Each update still requires us to find the "strongest violation", i.e., a candidate tree $\tilde{y}$ that scores higher than the gold tree $\hat{y}_i$:

$$\tilde{y} = \arg\max_{y \in \mathcal{T}(\hat{x}_i)} \{S(\hat{x}_i, y) + \|y - \hat{y}_i\|_1\}$$

The parameters are then revised so as to select against the offending $\tilde{y}$. Instead of a standard parameter update based on $\tilde{y}$ as in perceptron, stochastic gradient descent, or passive-aggressive updates, our implementation follows Lei et al. (2014) where the first-order parameters are broken up into a tensor. Each tensor component is updated successively in combination with the parameters corresponding to MST features (McDonald et al., 2005) and higher-order features (when included).[2]

3.2 Algorithm

During training and testing, the key combinatorial problem we must solve is that of decoding, i.e., finding the highest scoring tree $\tilde{y} \in \mathcal{T}(x)$ for each sentence x (or $\hat{x}_i$). In our notation,

$$\tilde{y} = \arg\max_{y \in \mathcal{T}(\hat{x}_i)} \{\theta \cdot \phi(\hat{x}_i, y) + \|y - \hat{y}_i\|_1\} \quad \text{(train)}$$

$$\tilde{y} = \arg\max_{y \in \mathcal{T}(x)} \{\theta \cdot \phi(x, y)\} \quad \text{(test)}$$

While the decoding problem with feature sets similar to ours has been shown to be NP-hard, many approximation algorithms work remarkably well. We commence with a motivating example.

Locality and Parsing One possible reason for why greedy or other approximation algorithms work well for dependency parsing is that typical sentences and therefore the learned scoring functions $S(x, y) = \theta \cdot \phi(x, y)$ are primarily "local". By this we mean that head-modifier decisions could be made largely without considering the surrounding structure (the context). For example, in English an adjective and a determiner are typically attached to the following noun.

We demonstrate the degree of locality in dependency parsing by comparing a first-order tree-based parser to the parser that predicts each head word independently of others. Note that the independent prediction of dependency arcs does not necessarily give rise to a tree. The parameters of

[2] We refer the readers to Lei et al. (2014) for more details about the tensor scoring function and the online update.

the two parsers, the independent prediction and a tree-based parser, are trained separately with the corresponding decoding algorithm but with the same feature set.

Table 1 shows that the accuracy of the independent prediction ranges from 79% to 93% on four CoNLL datasets. The results are on par with the first-order structured prediction model. This experiment reinforces the conclusion in Liang et al. (2008), where a local classifier was shown to achieve comparable accuracy to a sequential model (e.g. CRF) in POS tagging and named-entity recognition.

Hill-Climbing with Random Restarts We build here on the motivating example and explore greedy algorithms as generalizations of purely local decoding. Greedy algorithms break the decoding problem into a sequence of simple local steps, each required to improve the solution. In our case, simple local steps correspond to choosing the head for each modifier word.

We begin with a tree $y^{(0)}$, which can be a sample drawn uniformly from $\mathcal{T}(x)$ (Wilson, 1996). Our greedy algorithm then updates $y^{(t)}$ to a better tree $y^{(t+1)}$ by revising the head of one modifier word while maintaining the constraint that the resulting structure is a tree. The modifiers are considered in the bottom-up order relative to the current tree (the word furthest from the root is considered first). We provide an analysis to motivate this bottom-up update strategy in Section 4.1. The algorithm continues until the score can no longer be improved by changing the head of a single word. The resulting tree represents a locally optimal prediction relative to a single-arc greedy algorithm. Figure 1 gives the algorithm in pseudo-code.

There are many possible variations of the simple randomized greedy hill-climbing algorithm. First, the Wilson sampling algorithm (Wilson, 1996) can be naturally extended to obtain i.i.d. samples from any first-order distributions. Therefore, we could initialize the tree $y^{(0)}$ with a tree from a first-order parser, or draw the initial tree from a first-order distribution other than uniform. However, perhaps surprisingly, as we demonstrate later, little is lost with uniform initialization. Second, since a single run of randomized hill-climbing is relatively cheap and runs are independent to each other, it is easy to execute multiple runs independently in parallel. The final predicted tree is then simply the highest scoring tree across the multiple runs. We demonstrate that only a small number of parallel runs are necessary for near optimal prediction.

4 Analysis

4.1 First-Order Parsing

We provide here a firmer basis for why the randomized greedy algorithm can be expected to work. While the focus of the rest of the paper is on higher-order parsing, we limit ourselves in this subsection to first-order parsing. The reasons for this are threefold. First, a simple greedy algorithm is already not guaranteed a priori to work in the context of a first-order scoring function. The conclusions from this analysis are therefore likely to carry over to higher-order parsing scenarios as well. Second, a first-order arc-factored scoring provides us an easy way to ascertain when the randomized greedy algorithm indeed found the highest scoring tree. Finally, we are able to count the

Dataset	Average Len.	# of local optima at percentile			fraction of finding global optima (%)	
		50%	70%	90%	0 <Len.≤ 15	Len.> 15
Turkish	12.1	1	1	2	100	100
Slovene	15.9	2	20	3647	100	98.1
English	24.0	21	121	2443	100	99.3
Arabic	36.8	2	35	>10000	100	99.1

Table 2: The left part of the table shows the local optimum statistics of the first-order model. The sentences are sorted by the number of local optima. Columns 3 to 5 show the number of local optima of a sentence at different percentile of the sorted list. For example, on English 50% of the sentences have no more than 21 local optimum trees. The right part shows the fraction of finding global optima using 300 uniform restarts for each sentence.

number of locally optimal solutions for a greedy algorithm in the context of first-order parsing and can therefore relate this property to the success rates of the algorithm.

Reachability We begin by highlighting a basic property of trees, namely that single arc changes suffice for transforming any tree to any other tree in a small number of steps while maintaining that each intermediate structure is also a tree. In this sense, a target tree is reachable from any starting point using only single arc changes. More formally, let y be any starting tree and y' the desired target. Let $m_1, m_2, \cdots, m_n$ be the bottom-up list of words (modifiers) corresponding to tree y, where m_1 is the word furthest from the root. We can simply change each head $y(m_i)$ to that of $y'(m_i)$ in this order $i = 1, \ldots, n$. The bottom-up order guarantees that no cycle is introduced with respect to the remaining (yet unmodified) nodes of y. The fact that y' is a valid tree implies no cycle will appear with respect to the already modified nodes.

Note that, according to this property, any tree is reachable from any starting point using only k modifications, where k is the number of head differences, i.e. $k = |\{m : y(m) \neq y'(m)\}|$. The result also suggests that it may be helpful to perform the greedy steps in the bottom-up order, a suggestion that we follow in our implementation.

Broadly speaking, we have established that the greedy algorithm is not inherently limited by virtue of its basic steps. Of course, it is a different question whether the scoring function supports such local changes towards the correct target tree.

Locally Optimal Trees While greedy algorithms are notoriously prone to getting stuck in locally optimal solutions, we establish here that decoding with learned scoring functions involves only a small number of local optima. In our case, a local optimum corresponds to a tree y where no single change of head $y(m)$ results in a higher scoring tree. Clearly, the highest scoring tree is also a local optimum in this sense. If there were many such local optima, finding the one with the highest score would be challenging for a greedy algorithm, even with randomization.

We begin with a worst case analysis and estab-

Table 3: Decoding quality comparison between hill-climbing (HC) and dual decomposition (DD). Models are trained either with HC (left) or DD (right). s_{HC} denotes the score of the tree retrieved by HC and s_{DD} gives the analogous score for DD. The columns show the percentage of all test sentences for which one method succeeds in finding a higher or the same score. "Cert" column gives the percentage of sentences for which DD finds a certificate.

lish a tight upper bound on the number of local optima for a first-order scoring function.

Theorem 1 *For any first-order scoring function that factorizes into the sum of arc scores* $S(x, y) = \sum S_{arc}(y(m), m)$*: (a) the number of locally optimal trees is at most* 2^{n-1} *for* n *words; (b) this upper bound is tight.*[3]

While the number of possible dependency trees is $(n + 1)^{n-1}$ (Cayley's formula), the number of local optima is at most 2^{n-1}. This is still too many for longer sentences, suggesting that, in the worst case, a randomized greedy algorithm is unlikely to find the highest scoring tree. However, the scoring functions we learn for dependency parsing are considerably easier.

Average Case Analysis In contrast to the worst-case analysis above, we will count here the actual number of local optima *per sentence* for a first-order scoring function learned from data with the randomized greedy algorithm. Figure 2 provides pseudo-code for our counting algorithm. The algorithm is derived by tailoring the proof of Theorem 1 to each sentence.

Table 2 shows the empirical number of locally optimal trees estimated by our algorithm across 4 different languages. Decoding with trained scoring functions in the average case is clearly substantially easier than the worst case. For example, on the English test set more than 70% of the sentences have at most 121 locally optimal trees. Since the average sentence length is 24, the discrepancy between the typical number (e.g., 121) and the worst case (2^{24-1}) is substantial. As a result, only a small number of restarts is likely to suffice for finding optimal trees in practice.

Optimal Decoding We can easily verify whether the randomized greedy algorithm indeed succeeds in finding the highest scoring trees with a learned first-order scoring function. We have established above that there are typically only a small number of locally optimal trees. We would therefore expect the algorithm to work. We show the results in the second part of Table 2. For short sentences of length up to 15, our method finds the global optimum for all the test sentences. Success rates remain high even for longer test sentences.

4.2 Higher-Order Parsing

Exact decoding with high-order features is known to be provably hard (McDonald et al., 2005). We begin our analysis here with a second-order (sibling/grandparent) model, and compare our randomized hill-climbing (HC) method to dual decomposition (DD), re-implementing Koo et al. (2010). Table 3 compares decoding quality for the two methods across four languages. Overall, in 97.8% of the sentences, HC obtains the same score as DD, in 1.3% of the cases HC finds a higher scoring tree, and in 0.9% of cases DD results in a better tree. The results follow the same pattern regardless of which method was used to train the scoring function. The average rate of certificates for DD was 92%. In over 99% of these sentences, HC reaches the same optimum.

We expect that these observations about the success of HC carry over to other high-order parsing models for several reasons. First, a large number of arcs are pruned in the initial stage, considerably reducing the search space and minimizing the number of possible locally optimal trees. Second, many dependencies can be determined already with independent arc prediction (see our motivating example above), predictions that are readily achieved with a greedy algorithm. Finally, high-order features represent smaller refinements, i.e., suggest only a few changes above and beyond the dominant first-order scores. Greedy al-

[3] A proof sketch is given in Appendix.

gorithms are therefore likely to be able to leverage at least some of this potential. We demonstrate below that this is indeed so.

Our methods are trained within the max-margin framework. As a result, we are expected to find the highest scoring competing tree for each training sentence (the "strongest violation"). One may question therefore whether possible sub-optimal decoding for some training sentences (finding "a violation" rather than the "strongest violation") impacts the learned parser. To this end, Huang et al. (2012) have established that weaker violations do suffice for separable training sets.

5 Experimental Setup

Dataset and Evaluation Measures We evaluate our model on CoNLL dependency treebanks for 14 different languages (Buchholz and Marsi, 2006; Surdeanu et al., 2008), using standard training and testing splits. We use part-of-speech tags and the morphological information provided in the corpus. Following standard practice, we use Unlabeled Attachment Score (UAS) excluding punctuation (Koo et al., 2010; Martins et al., 2013) as the evaluation metric in all our experiments.

Baselines We compare our model with the TurboParser (Martins et al., 2013) and our earlier sampling-based parser (Zhang et al., 2014). For both parsers, we directly compare with the recent published results on the CoNLL datasets. We also compare our parser against the best published results for the individual languages in our datasets. This comparison set includes four additional parsers: Martins et al. (2011), Koo et al. (2010), Zhang et al. (2013) and our tensor-based parser (Lei et al., 2014).

Features We use the same feature templates as in our prior work (Zhang et al., 2014; Lei et al., 2014)[4]. Figure 3 shows the first- to third-order feature templates that we use in our model. For the global features we use right-branching, coordination, PP attachment, span length, neighbors, valency and non-projective arcs features.

Implementation Details Following standard practices, we train our model using the passive-aggressive online learning algorithm (MIRA) and parameter averaging (Crammer et al., 2006; Collins, 2002). By default we use an adaptive strategy for running the hill-climbing algorithm – for a given sentence we repeatedly run the algorithm in parallel[5] until the best tree does not change for $K = 300$ consecutive restarts. For each restart, by default we initialize the tree $y^{(0)}$ by sampling from the first-order distribution using the current learned parameter values (and first-order scores). We train our first-order and third-order model for 10 epochs and our full model for 20 epochs for all languages, and report the average performance across three independent runs.

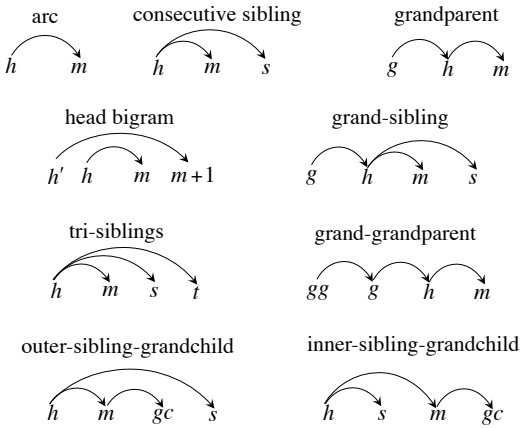

Figure 3: First- to third-order features.

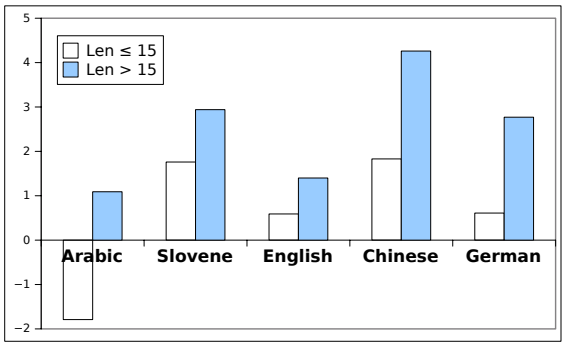

Figure 4: Absolute UAS improvement of our full model over the first-order model. Sentences in the test set are divided into 2 groups based on their lengths.

6 Results

Comparison with the Baselines Table 4 summarizes the results of our model, along with the state-of-the-art baselines. On average across 14 languages, our full model with the tensor component outperforms both TurboParser and the sampling-based parser. The direct comparison

[4]We refer the readers to Zhang et al. (2014) and Lei et al. (2014) for the detailed definition of each feature template.

[5]We use 8 threads in all the experiments.

Average	85.4	78.4	88.0	25.9	88.1	44.5

Table 5: Comparison between different initialization strategies: (a) MAP-1st: only the MAP tree of the first-order score; (b) Uniform: random trees are sampled from the uniform distribution; and (c) Rnd-1st: random trees are sampled from the first-order distribution. For each method, the table shows the average accuracy of the initial tree and the final parsing accuracy.

with TurboParser is achieved by restricting our model to third order features which still outperforms TurboParser (89.10% vs 88.72%). To compare against the sampling-based parser, we employ our model without the tensor component. The two models achieve a similar average performance (89.24% and 89.23% respectively). Since relative parsing performance depends on a target language, we also include comparison with the best published results. The model achieves the best published results for seven languages.

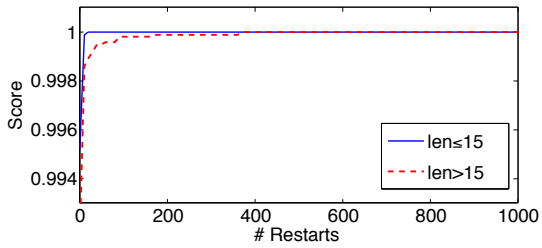
Another noteworthy comparison concerns first-order parsers. As Table 4 shows, the exact and approximate versions of the first-order parser deliver almost identical performance.

Impact of High-Order Features Table 4 shows that the model can effectively utilize high-order features. Comparing the average performance of the model variants, we see that the accuracy on the benchmark languages consistently improves when higher-order features are added. This characteristic of the randomized greedy parser is in line with findings about other state-of-the-art high-order parsers (Martins et al., 2013; Zhang et al., 2014). Figure 4 breaks down these gains based on the sentence length. As expected, on most languages high-order features are particularly helpful when parsing longer sentences.

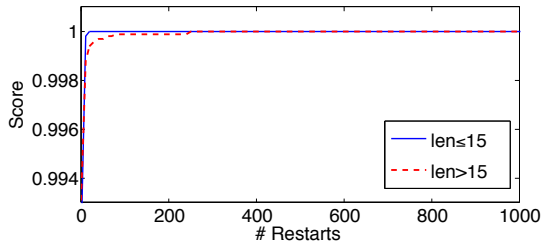
Impact of Initialization and Restarts Table 5 shows the impact of initialization on the model performance for several languages. We consider three strategies: the MAP estimate of the first-order score from the model, uniform sampling and sampling from the first-order distribution. The accuracy of initial trees varies greatly, ranging from 78.4% for the MAP estimate to 25.9% and 44.5% for the latter randomized strategies. However, the resulting parsing accuracy is not determined by the initial accuracy. In fact, the two sampling strategies result in almost identical parsing performance. While the first-order MAP estimate gives the best initial guess, the overall parsing accuracy of this method lags behind. This result demonstrates the importance of restarts – in contrast to the randomized strategies, the MAP initialization performs only a single run of hill-climbing.

	Length ≤ 15	Length > 15
Slovene	100	98.11
English	100	99.12

Table 6: Fractions (%) of the sentences that find the best solution among 3,000 restarts within the first 300 restarts.



(a) Slovene

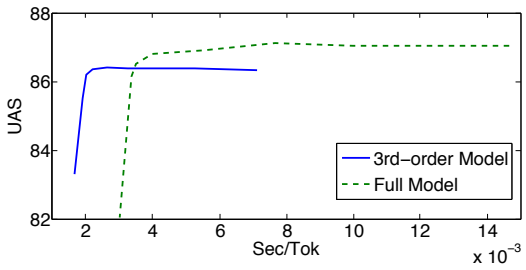


(b) English

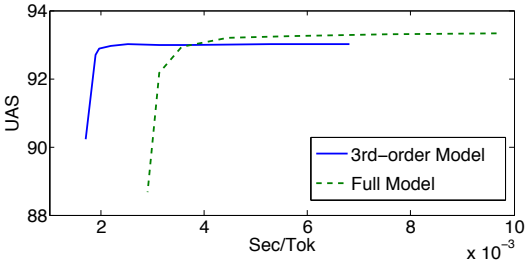
Figure 5: Convergence analysis on Slovene and English datasets. The graph shows the normalized score of the output tree as a function of the number of restarts. The score of each sentence is normalized by the highest score obtained for this sentence after 3,000 restarts. We only show the curves up to 1,000 restarts because they all reach convergence after around 500 restarts.

Convergence Properties Figure 5 shows the score of the trees retrieved by our full model with respect to the number of restarts, for short and long sentences in English and Slovene. To facilitate the comparison, we normalize the score of each sentence by the maximal score obtained for this sentence after 3,000 restarts. Overall, most sentences converge quickly. This view is also supported by Table 6 which shows the fraction of the sentences that converge within the first 300 restarts. We can see that all the short sentences (length up to 15) reach convergence within the allocated restarts. Perhaps surprisingly, more than 98% of the long sentences also converge within 300 restarts.

Decoding Speed As the number of restarts impacts the parsing accuracy, we can trade performance for speed. Figure 6 shows that the model



(a) Slovene



(b) English

Figure 6: Trade-off between performance and speed on Slovene and English datasets. The graph shows the accuracy as a function of decoding speed measured in second per token. Variations in decoding speed is achieved by changing the number of restarts.

achieves high performance with acceptable parsing speed. While various system implementation issues such as programming language and computational platform complicate a direct comparison with other parsing systems, our model delivers parsing time roughly comparable to other state-of-the-art graph-based systems (for example, TurboParser and MST parser) and the sampling-based parser.

7 Conclusions

We have shown that a simple, generally applicable randomized greedy algorithm for inference suffices to deliver state-of-the-art parsing performance. We argued that the effectiveness of such greedy algorithms is contingent on having a small number of local optima in the scoring function. By algorithmically counting the number of locally optimal solutions in the context of first-order parsing, we show that this number is indeed quite small. Moreover, we show that, as a decoding algorithm, the greedy method surpasses dual decomposition in second-order parsing. Finally, we empirically demonstrate that our approach with up to third-order and global features outperforms the state-of-the-art parsers when evaluated on 14 languages of

non-projective CoNLL datasets.

Appendix

We provide here a more detailed justification for the counting algorithm in Figure 2 and, by extension, a proof sketch of Theorem 1. The bullets below follow the operation of the algorithm.

- Whenever independent selection of the heads results in a valid tree, there is only 1 optimum (Lines 1&2 of the algorithm). Otherwise there must be a cycle C in y (Line 3 of the algorithm)
- We claim that any locally optimal tree y' of the graph $G = (V, E)$ must contain $|C| - 1$ arcs of the cycle $C \subseteq V$. This can be shown by contradiction. If y' contains less than $|C| - 1$ arcs of C, then (a) we can construct a tree y'' that contains $|C| - 1$ arcs; (b) the heads in y'' are strictly better than those in y' over the unused part of the cycle; (c) by reachability, there is a path $y' \rightarrow y''$ so y' cannot be a local optimum.
- Any locally optimal tree in G must select an arc in C and reassign it. The rest of the $|C|-1$ arcs will then result in a chain.
- By contracting cycle C we obtain a new graph G' of size $|G| - |C| + 1$ (Lines 5-11 of the algorithm). Easy to verify that (not shown): any local optimum in G' is a local optimum in G and vice versa.

The theorem follows as a corollary of these steps. To see this, let $F(G_m)$ be the number of local optima in the graph of size m:

$$F(G_m) \leq \max_{C \subseteq V(G)} \sum_i F(G^{(i)}_{m-c+1})$$

where $G^{(i)}_{m-c+1}$ is the graph (of size $m - c + 1$) created by selecting the i^{th} arc in cycle C and contracting G_m accordingly, and $c = |C|$ is the size of the cycle. Define $\hat{F}(m)$ as the upper bound of $F(G_m)$ for any graph of size m. By the above formula, we know that

$$\hat{F}(m) \leq \max_{2 \leq c < m} \hat{F}(m - c + 1) \times c$$

By solving for $\hat{F}(m)$ we get $\hat{F}(m) \leq 2^{m-2}$. Since $m = n+1$ for a sentence with n words, the upper-bound of local optima is 2^{n-1}.

To show the tightness, for any $n > 0$, create the graph G_{n+1} with arc scores $e_{ij} = e_{ji} = i$ for any $0 \leq i < j \leq n$. Note that $w_n \rightarrow w_{n-1} \rightarrow w_n$ forms the circle C of size 2, it can be shown by induction on n and $F(G_{n+1})$ that $F(G_{n+1}) = F(G_n) \times 2 = 2^{n-1}$.

A Unified Model for Word Sense Representation and Disambiguation

Abstract

Most word representation methods assume that each word owns a single semantic vector. This is usually problematic because lexical ambiguity is ubiquitous, which is also the problem to be resolved by word sense disambiguation. In this paper, we present a unified model for joint word sense representation and disambiguation, which will assign distinct representations for each word sense.[1] The basic idea is that both word sense representation (WSR) and word sense disambiguation (WSD) will benefit from each other: (1) high-quality WSR will capture rich information about words and senses, which should be helpful for WSD, and (2) high-quality WSD will provide reliable disambiguated corpora for learning better sense representations. Experimental results show that, our model improves the performance of contextual word similarity compared to existing WSR methods, outperforms state-of-the-art supervised methods on domain-specific WSD, and achieves competitive performance on coarse-grained all-words WSD.

1 Introduction

Word representation aims to build vectors for each word based on its context in a large corpus, usually capturing both semantic and syntactic information of words. These representations can be used as features or inputs, which are widely employed in information retrieval (Manning et al., 2008), document classification (Sebastiani, 2002) and other NLP tasks.

[1] Our sense representations can be downloaded at http://pan.baidu.com/s/1eQcPK8i.

Most word representation methods assume each word owns a single vector. However, this is usually problematic due to the homonymy and polysemy of many words. To remedy the issue, Reisinger and Mooney (2010) proposed a multi-prototype vector space model, where the contexts of each word are first clustered into groups, and then each cluster generates a distinct prototype vector for a word by averaging over all context vectors within the cluster. Huang et al. (2012) followed this idea, but introduced continuous distributed vectors based on probabilistic neural language models for word representations.

These cluster-based models conduct unsupervised word sense induction by clustering word contexts and, thus, suffer from the following issues:

- It is usually difficult for these cluster-based models to determine the number of clusters. Huang et al. (2012) simply cluster word contexts into static K clusters for each word, which is arbitrary and may introduce mistakes.
- These cluster-based models are typically offline , so they cannot be efficiently adapted to new senses, new words or new data.
- It is also troublesome to find the sense that a word prototype corresponds to; thus, these cluster-based models cannot be directly used to perform word sense disambiguation.

In reality, many large knowledge bases have been constructed with word senses available online, such as WordNet (Miller, 1995) and Wikipedia. Utilizing these knowledge bases to learn word representation and sense representation is a natural choice. In this paper, we present a unified model for both word sense representation and disambiguation based on these knowledge bases and large-scale text corpora. The unified model

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1025–1035,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

can (1) perform word sense disambiguation based on vector representations, and (2) learn continuous distributed vector representation for word and sense jointly.

The basic idea is that, the tasks of word sense representation (WSR) and word sense disambiguation (WSD) can benefit from each other: (1) high-quality WSR will capture rich semantic and syntactic information of words and senses, which should be helpful for WSD; (2) high-quality WSD will provide reliable disambiguated corpora for learning better sense representations.

By utilizing these knowledge bases, the problem mentioned above can be overcome:

- The number of senses of a word can be decided by the expert annotators or web users.
- When a new sense appears, our model can be easily applied to obtain a new sense representation.
- Every sense vector has a corresponding sense in these knowledge bases.

We conduct experiments to investigate the performance of our model for both WSR and WSD. We evaluate the performance of WSR using a contextual word similarity task, and results show that out model can significantly improve the correlation with human judgments compared to baselines. We further evaluate the performance on both domain-specific WSD and coarse-grained all-words WSD, and results show that our model yields performance competitive with state-of-the-art supervised approaches.

2 Methodology

We describe our method as a 3-stage process:

1. **Initializing word vectors and sense vectors.** Given large amounts of text data, we first use the Skip-gram model (Mikolov et al., 2013), a neural network based language model, to learn word vectors. Then, we assign vector representations for senses based on their definitions (e.g, glosses in WordNet).
2. **Performing word sense disambiguation.** Given word vectors and sense vectors, we propose two simple and efficient WSD algorithms to obtain more relevant occurrences for each sense.
3. **Learning sense vectors from relevant occurrences.** Based on the relevant occurrences of ambiguous words, we modify the training objective of Skip-gram to learn word vectors and sense vectors jointly. Then, we obtain the sense vectors directly from the model.

Before illustrating the three stages of our method in Sections 2.2, 2.3 and 2.4, we briefly introduce our sense inventory, WordNet, in Section 2.1. Note that, although our experiments will use the WordNet sense inventory, our model is not limited to this particular lexicon. Other knowledge bases containing word sense distinctions and definitions can also serve as input to our model.

2.1 WordNet

WordNet (Miller, 1995) is the most widely used computational lexicon of English where a concept is represented as a synonym set, or *synset*. The words in the same synset share a common meaning. Each synset has a textual definition, or gloss. Table 1 shows the synsets and the corresponding glosses of the two common senses of *bank*.

Before introducing the method in detail, we introduce the notations. The unlabeled texts are denoted as R, and the vocabulary of the texts is denoted as W. For a word w in W, w_{s_i} is the ith sense in WordNet WN. Each sense w_{s_i} has a gloss $gloss(w_{s_i})$ in WN. The word embedding of w is denoted as $vec(w)$, and the sense embedding of its ith sense w_{s_i} is denoted as $vec(w_{s_i})$.

2.2 Initializing Word Vectors and Sense Vectors

Initializing word vectors. First, we use Skip-gram to train the word vectors from large amounts of text data. We choose Skip-gram for its simplicity and effectiveness. The training objective of Skip-gram is to train word vector representations that are good at predicting its context in the same sentence (Mikolov et al., 2013).

More formally, given a sequence of training words w_1, w_2, w_3,...,w_T, the objective of Skip-gram is to maximize the average log probability

$$\frac{1}{T}\sum_{t=1}^{T}\left(\sum_{-k\leq j\leq k, j\neq 0}\log p(w_{t+j}|w_t)\right) \quad (1)$$

where k is the size of the training window. The inner summation spans from $-k$ to k to compute

Sense	Synset	Gloss
bank_{s_1}	bank	(sloping land (especially the slope beside a body of water)) "they pulled the canoe up on the bank"; "he sat on the bank of the river and watched the currents"
bank_{s_2}	depository institution, bank, banking concern, banking company	(a financial institution that accepts deposits and channels the money into lending activities) "he cashed a check at the bank"; "that bank holds the mortgage on my home"

Table 1: Example of a synset in WordNet.

the log probability of correctly predicting the word w_{t+j} given the word in the middle w_t. The outer summation covers all words in the training data.

The prediction task is performed via softmax, a multiclass classifier. There, we have

$$p(w_{t+j}|w_t) = \frac{\exp(vec'(w_{t+j})^\top vec(w_t))}{\sum_{w=1}^{W} \exp(vec'(w)^\top vec(w_t))} \quad (2)$$

where $vec(w)$ and $vec'(w)$ are the "input" and "output" vector representations of w. This formulation is impractical because the cost of computing $p(w_{t+j}|w_t)$ is proportional to W, which is often large($10^5 - 10^7$ terms).

Initializing sense vectors. After learning the word vectors using the Skip-gram model, we initialize the sense vectors based on the glosses of senses. The basic idea of the sense vector initialization is to represent the sense by using the similar words in the gloss. From the content words in the gloss, we select those words whose cosine similarities with the original word are larger than a similarity threshold δ. Formally, for each sense w_{s_i} in WN, we first define a candidate set from $gloss(w_{s_i})$

$$cand(w_{s_i}) = \{u|u \in gloss(w_{s_i}), u \neq w, \\ POS(u) \in CW, \cos(vec(w), vec(u)) > \delta\} \quad (3)$$

where $POS(u)$ is the part-of-speech tagging of the word u and CW is the set of all possible part-of-speech tags that content words could have. In this paper, CW contains the following tags: noun, verb, adjective and adverb.

Then the average of the word vectors in $cand(w_{s_i})$ is used as the initialization value of the sense vector $vec(w_{s_i})$.

$$vec(w_{s_i}) = \frac{1}{|cand(w_{s_i})|} \sum_{u \in cand(w_{s_i})} vec(u) \quad (4)$$

For example, in WordNet, the gloss of the sense bank_{s_1} is "sloping land (especially the slope beside a body of water)) they pulled the canoe up on the bank; he sat on the bank of the river and watched the currents". The gloss contains a definition of the sense and two examples of the sense. The content words and the cosine similarities with the word "bank" are listed as follows: (sloping, 0.12), (land, 0.21), (slope, 0.17), (body, 0.01), (water, 0.10), (pulled, 0.01), (canoe, 0.09), (sat, 0.06), (river, 0.43), (watch, -0.11), (currents, 0.01). If the threshold, δ, is set to 0.05, then $cand(\text{bank}_{s_1})$ is {sloping, land, slope, water, canoe, sat, river}. Then the average of the word vectors in $cand(\text{bank}_{s_i})$ is used as the initialization value of $vec(\text{bank}_{s_i})$.

2.3 Performing Word Sense Disambiguation.

One of the state-of-the-art WSD results can be obtained using exemplar models, i.e., the word meaning is modeled by using relevant occurrences only, rather than merging all of the occurrences into a single word vector (Erk and Pado, 2010). Inspired by this idea, we perform word sense disambiguation to obtain more relevant occurrences.

Here, we perform knowledge-based word sense disambiguation for training data on an all-words setting, i.e., we will disambiguate all of the content words in a sentence. Formally, the sentence S is a sequence of words (w_1,w_2,...,w_n), and we will identify a mapping M from words to senses such that $M(i) \in Senses_{WN}(w_i)$, where $Senses_{WN}(w_i)$ is the set of senses encoded in the WN for word w_i. For sentence S, there are $\prod_{i=1}^{n} |Sense_{WN}(w_i)|$ possible mapping answers, which are impractical to compute. Thus, we design two simple algorithms, L2R (left to right) algorithm and S2C (simple to complex) algorithm, for word sense disambiguation based on the sense vectors.

The main difference between L2R and S2C is

the order of words when performing word sense disambiguation. When given a sentence, the L2R algorithm disambiguates the words from left to right (the natural order of a sentence), whereas the S2C algorithm disambiguates the words with fewer senses first. The main idea of S2C algorithm is that the words with fewer senses are easier to disambiguate, and the disambiguation result can be helpful to disambiguate the words with more senses. Both of the algorithms have three steps:

Context vector initialization. Similar to the initialization of sense vectors, we use the average of all of the content words' vectors in a sentence as the initialization vector of context.

$$vec(context) = \frac{1}{|cand(S)|} \sum_{u \in cand(S)} vec(u) \quad (5)$$

where $cand(S)$ is the set of content words $cand(S) = \{u | u \in S, POS(u) \in CW\}$.

Ranking words. For L2R, we do nothing in this step. For S2C, we rank the words based on the ascending order of $|Senses_{WN}(w_i)|$.

Word sense disambiguation. For both L2R and S2C, we denote the order of words as L and perform word sense disambiguation according to L.

First, we skip a word if the word is not a content word or the word is monosemous ($|Senses_{WN}(w_i)| = 1$). Then, for each word in L, we can compute the cosine similarities between the context vector and its sense vectors. We choose the sense that yields the maximum cosine similarity as its disambiguation result. If the score margin between the maximum and the second maximum is larger than the threshold ε, we are confident with the disambiguation result of w_i and then use the sense vector to replace the word vector in the context vector. Thus, we obtain a more accurate context vector for other words that are still yet to be disambiguated.

For example, given a sentence "He sat on the bank of the lake", we first explain how S2C works. In the sentence, there are three content words, "sat", "bank" and "lake", to be disambiguated. First, the sum of the three word vectors is used as the initialization of the context vector. Then we rank the words by $|SensesWN(w_i)|$, in ascending order, that is, lake (3 senses), bank (10 senses), sat (10 senses). We first disambiguate the word "lake" based on the similarities between its sense vectors and context vector. If the score margin is larger than the threshold ε, then we are confident with this disambiguation result and replace the word vector with the sense vector to update the context vector. It would be helpful to disambiguate the next word, "bank". We repeat this process until all three words are disambiguated.

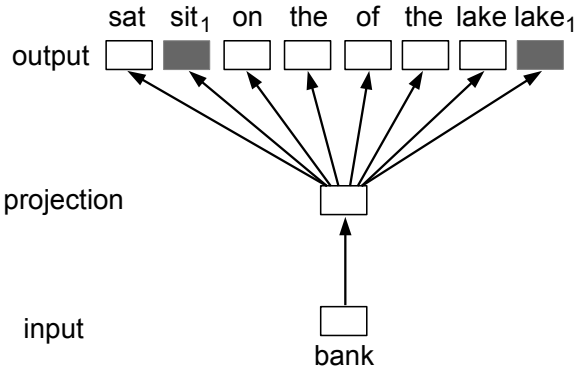

Figure 1: The architecture of our model. The training objective of Skip-gram is to train word vector representations that are not only good at predicting its context words but are also good at predicting its context words' senses. The center word "bank" is used to predict not only its context words but also the sense "sit$_1$" and "lake$_1$".

For L2R, the order of words to be disambiguated will be "sat", "bank" and "lake". In this time, when disambiguating "bank" (10 senses), we still don't know the sense of "lake" (3 senses).

2.4 Learning Sense Vectors from Relevant Occurrences.

Based on the disambiguation result, we modify the training objective of Skip-gram and train the sense vectors directly from the large-scale corpus. Our training objective is to train the vector representations that are not only good at predicting its context words but are also good at predicting its context words' senses. The architecture of our model is shown in Figure 1.

More formally, given the disambiguation result $M(w_1)$, $M(w_2)$, $M(w_3)$,...,$M(w_T)$, the training objective is modified to

$$\frac{1}{T}\sum_{t=1}^{T}\left(\sum_{j=-k}^{k}\log\{p(w_{t+j}|w_t)p(M(w_{t+j})|w_t)\}\right) \quad (6)$$

where k is the size of the training window. The inner summation spans from $-k$ to k to compute the log probability of correctly predicting the word w_{t+j} and the log probability of correctly predicting

the sense $M(w_{t+j})$ given the word in the middle w_t. The outer summation covers all words in the training data.

Because not all of the disambiguation results are correct, we only disambiguate the words that we are confident in. Similar to step 3 of our WSD algorithm, we only disambiguate words under the condition that the score margin between the maximum and the second maximum is larger than the score margin threshold, ε.

We also use the softmax function to define $p(w_{t+j}|w_t)$ and $p(M(w_{t+j})|w_t)$. Then, we use hierarchical softmax (Morin and Bengio, 2005) to greatly reduce the computational complexity and learn the sense vectors directly from the relevant occurrences.

3 Experiments

In this section, we first present the nearest neighbors of some words and their senses, showing that our sense vectors can capture the semantics of words. Then, we use three tasks to evaluate our unified model: a contextual word similarity task to evaluate our sense representations, and two standard WSD tasks to evaluate our knowledge-based WSD algorithm based on the sense vectors. Experimental results show that our model not only improves the correlation with human judgments on the contextual word similarity task but also outperforms state-of-the-art supervised WSD systems on domain-specific datasets and competes with them in a coarse-grained all-words setting.

We choose Wikipedia as the corpus to train the word vectors because of its wide coverage of topics and words usages. We use an English Wikipedia database dump from October 2013 [2], which includes roughly 3 million articles and 1 billion tokens. We use Wikipedia Extractor [3] to preprocess the Wikipedia pages and only save the content of the articles.

We use word2vec [4] to train Skip-gram. We use the default parameters of word2vec and the dimension of the vector representations is 200.

We use WordNet [5] as our sense inventory. The datasets for different tasks are tagged with different versions of WordNet. The version of WordNet is 1.7 for the domain-specific WSD task and 2.1 for the coarse-grained WSD task.

We use the S2C algorithm described in Section 2.3 to perform word sense disambiguation to obtain more relevant occurrences for each sense. We compare S2C and L2R on the coarse-grained WSD task in a all-words setting.

The experimental results of our model are obtained by setting the similarity threshold as $\delta = 0$ and the score margin threshold as $\varepsilon = 0.1$. The influence of parameters on our model can be found in Section 3.5.

Word or sense	Nearest neighbors
bank	banks, IDBI, CitiBank
bank_{s_1}	river, slope, Sooes
bank_{s_2}	mortgage, lending, loans
star	stars, stellar, trek
star_{s_1}	photosphere, radiation, gamma-rays
star_{s_2}	someone, skilled, genuinely
plant	plants, glavaticevo, herbaceous
plant_{s_1}	factories, machinery, manufacturing
plant_{s_2}	locomotion, organism, organisms

Table 2: Nearest neighbors of word vectors and sense vectors learned by our model based on cosine similarity. The subscript of each sense label corresponds to the index of the sense in WordNet. For example, bank_{s_2} is the second sense of the word bank in WordNet.

3.1 Examples for Sense Vectors

Table 2 shows the nearest neighbors of word vectors and sense vectors based on cosine similarity. We see that our sense representations can identify different meanings of a word, allowing our model to capture more semantic and syntactic relationships between words and senses. Note that each sense vector in our model corresponds to a sense in WordNet; thus, our sense vectors can be used to perform knowledge-based word sense disambiguation, whereas the vectors of cluster-based models cannot.

3.2 Contextual Word Similarity

Experimental setting. A standard dataset for evaluating a vector-space model is the WordSim-353 dataset (Finkelstein et al., 2001), which con-

[2] http://download.wikipedia.org.

[4] The code is available from https://code.google.com/p/word2vec/.

[5] http://wordnet.princeton.edu/.

Model	$\rho \times 100$
C&W-S	57.0
Huang-S	58.6
Huang-M AvgSim	62.8
Huang-M AvgSimC	65.7
Our Model-S	64.2
Our Model-M AvgSim	66.2
Our Model-M AvgSimC	**68.9**

Table 3: Spearman's ρ on the SCWS dataset. Our Model-S uses one representation per word to compute similarities, while Our Model-M uses one representation per sense to compute similarities. AvgSim calculates the similarity with each sense contributing equally, while AvgSimC weighs the sense according to the probability of the word choosing that sense in context c.

sists of 353 pairs of nouns. However, each pair of nouns in WordSim-353 is presented without context. This is problematic because the meanings of homonymous and polysemous words depend highly on the words' contexts. Thus we choose the Stanford's Contextual Word Similarities (SCWS) dataset from (Huang et al., 2012) [6]. The SCWS dataset contains 2003 pairs of words and each pair is associated with 10 human judgments on similarity on a scale from 0 to 10. In the SCWS dataset, each word in a pair has a sentential context.

In our experiments, the similarity between a pair of words (w, w') is computed as follows:

$$AvgSimC(w,w') = \frac{1}{MN}\sum_{i=1}^{M}\sum_{j=1}^{N} p(i|w,c)p(j|w',c')d(vec(w_{s_i}),vec(w'_{s_j})) \quad (7)$$

where $p(i|w,c)$ is the likelihood that word w chooses its ith sense given context c. $d(vec,vec')$ is a function computing the similarity between two vectors, and here we use cosine similarity.

Results and discussion. For evaluation, we compute the Spearman correlation between a model's computed similarity scores and human judgements. Table 3 shows our results compared to previous methods, including (Collobert and Weston, 2008)'s language model (C&W), and Huang's model which utilize the global context and multi-prototype to improve the word representations.

[6]The dataset can be downloaded at `http://ai.stanford.edu/~ehhuang/`.

From Table 3, we observe that:

- Our single-vector version outperforms Huang's single-vector version. This indicates that, by training the word vectors and sense vectors jointly, our model can better capture the semantic relationships between words and senses.
- With one representation per sense, our model can outperform the single-vector version without using context (66.2 vs. 64.2).
- Our model obtains the best performance (68.9) by using AvgSimC, which takes context into account.

3.3 Domain-Specific WSD

Experimental setting. We use Wikipedia as training data because of its wide coverage for specific domains. To test our performance on domain word sense disambiguation, we evaluated our system on the dataset published in (Koeling et al., 2005). This dataset consists of examples retrieved from the Sports and Finance sections of the Reuters corpus. 41 words related to the Sports and Finance domains were selected, with an average polysemy of 6.7 senses, ranging from 2 to 13 senses.

Approximately 100 examples for each word were annotated with senses from WordNet v.1.7 by three reviewers, yielding an inter-tagger agreement of 65%. (Koeling et al., 2005) did not clarify how to select the "correct" sense for each word, so we followed the work of (Agirre et al., 2009) and, used the sense chosen by the majority of taggers as the correct answer.

Baseline methods. As a baseline, we use the most frequent WordNet sense (MFS), as well as a random sense assignment. We also compare our results with four systems [7]: Static PageRank (Agirre et al., 2009), the k nearest neighbor algorithm (k-NN), Degree (Navigli and Lapata, 2010) and Personalized PageRank (Agirre et al., 2009).

Static PageRank applies traditional PageRank over the semantic graph based on WordNet and obtains a context-independent ranking of word senses.

k-NN is a widely used classification method, where neighbors are the k labeled examples most

[7]We compare only with those systems performing token-based WSD, i.e., disambiguating each instance of a target word separately.

Algorithm	Sports Recall	Finance Recall
Random BL	19.5	19.6
MFS BL	19.6	37.1
k-NN	30.3	43.4
Static PR	20.1	39.6
Personalized PR	35.6	46.9
Degree	42.0	47.8
Our Model	**57.3**	**60.6**

Table 4: Performance on the Sports and Finance sections of the dataset from (Koeling et al., 2005).

similar to the test example. The *k*-NN system is trained on SemCor (Miller et al., 1993), the largest publicly available annotated corpus.

Degree and Personalized PageRank are state-of-the-art systems that exploit WordNet to build a semantic graph and exploit the structural properties of the graph in order to choose the appropriate senses of words in context.

Results and discussion. Similar to other work on this dataset, we use recall (the ratio of correct sense labels to the total labels in the gold standard) as our evaluation measure. Table 4 shows the results of different WSD systems on the dataset, and the best results are shown in bold. The differences between other results and the best result in each column of the table are statistically significant at $p < 0.05$.

The results show that:

- Our model outperforms *k*-NN on the two domains by a large margin, supporting the findings from (Agirre et al., 2009) that knowledge-based systems perform better than supervised systems when evaluated across different domains.
- Our model also achieves better results than the state-of-the-art system (+15.3% recall on Sports and +12.8% recall on Finance against Degree). The reason for this is that when dealing with short sentences or context words that are not in WordNet, our model can still compute similarity based on the context vector and sense vectors, whereas Degree will have difficulty building the semantic graph.
- Moreover, our model achieves the best performance by only using the unlabeled text data and the definitions of senses, whereas other methods rely greatly on high-quality semantic relations or annotated data, which are hard to acquire.

Algorithm	Type	Nouns only F_1	All words F_1
Random BL	U	63.5	62.7
MFS BL	Semi	77.4	78.9
SUSSX-FR	Semi	81.1	77.0
NUS-PT	S	82.3	**82.5**
SSI	Semi	**84.1**	**83.2**
Degree	Semi	**85.5**	**81.7**
Our Model$_{L2R}$	U	79.2	73.9
Our Model$_{S2C}$	U	81.6	75.8
Our Model$_{L2R}$	Semi	82.5	79.6
Our Model$_{S2C}$	Semi	**85.3**	**82.6**

Table 5: Performance on Semeval-2007 coarse-grained all-words WSD. In the type column, U, Semi and S stand for unsupervised, semi-supervised and supervised, respectively. The differences between the results in bold in each column of the table are not statistically significant at $p < 0.05$.

3.4 Coarse-grained WSD

Experimental setting. We also evaluate our WSD model on the Semeval-2007 coarse-grained all-words WSD task (Navigli et al., 2007). There are multiple reasons that we perform experiments in a coarse-grained setting: first, it has been argued that the fine granularity of WordNet is one of the main obstacles to accurate WSD (cf. the discussion in (Navigli, 2009)); second, the training corpus of word representations is Wikipedia, which is quite different from WordNet.

Baseline methods. We compare our model with the best unsupervised system SUSSX-FR (Koeling and McCarthy, 2007), and the best supervised system, NUS-PT (Chan et al., 2007), participating in the Semeval-2007 coarse-grained all-words task. We also compare with SSI (Navigli and Velardi, 2005) and the state-of-the-art system Degree (Navigli and Lapata, 2010). We use different baseline methods for the two WSD tasks because we want to compare our model with the state-of-the-art systems that are applicable to different datasets and show that our WSD method can perform robustly in these different WSD tasks.

Results and discussion. We report our results in terms of F_1-measure on the Semeval-2007 coarse-grained all-words dataset (Navigli et al., 2007). Table 5 reports the results for nouns (1,108 words) and all words (2,269 words). The difference between unsupervised and semi-supervised methods is whether the method uses MFS as a back-off strategy.

We can see that the S2C algorithm outperforms the L2R algorithm no matter on the nouns subset or on the entire set. This indicates that words with fewer senses are easier to disambiguate, and it can be helpful to disambiguate the words with more senses.

On the nouns subset, our model yields comparable performance to SSI and Degree, and it outperforms NUS-PT and SUSSX-FR. Moreover, our unsupervised WSD method (S2C) beats the MFS baseline, which is notably a difficult competitor for knowledge-based systems.

On the entire set, our semi-supervised model is significantly better than SUSSX-FR, and it is comparable with SSI and Degree. In contrast to SSI, our model is simple and does not rely on a costly annotation effort to engineer the set of semantic relations.

Overall, our model achieves state-of-the-art performance on the Semeval-2007 coarse-grained all-words dataset compared to other systems, with a simple WSD algorithm that only relies on a large-scale unlabeled text corpora and a sense inventory.

3.5 Parameter Influence

We investigate the influence of parameters on our model with coarse-grained all-words WSD task. The parameters include the similarity threshold, δ, and the score margin threshold, ε.

Similarity threshold. In Table 6, we show the performance of domain WSD when the similarity threshold δ ranges from -0.1 to 0.3. The cosine similarity interval is [-1, 1], and we focus on the performance in the interval [-0.1, 0.3] for two reasons: first, no words are removed from glosses when $\delta < -0.1$; second, nearly half of the words are removed when $\delta > 0.3$ and the performance drops significantly for the WSD task. From table 6, we can see that our model achieves the best performance when $\delta = 0.0$.

Score margin threshold. In Table 7, we show the performance on the coarse-grained all-words WSD when the score margin threshold ε ranges from 0.0 to 0.3. When $\varepsilon = 0.0$, we use every disambiguation result to update the context vector. When $\varepsilon \neq 0$, we only use the confident disambiguation results to update the context vector if the score margin is larger than ε. Our model achieves the best performance when $\varepsilon = 0.1$.

Parameter	Nouns only	All words
$\delta = -0.10$	79.8	74.3
$\delta = -0.05$	81.0	74.6
$\delta = 0.00$	**81.6**	**75.8**
$\delta = 0.05$	81.3	75.4
$\delta = 0.10$	80.8	75.2
$\delta = 0.15$	80.0	75.0
$\delta = 0.20$	77.1	73.3
$\delta = 0.30$	75.0	72.1

Table 6: Evaluation results on the coarse-grained all-words WSD when the similarity threshold δ ranges from -0.1 to 0.3.

Parameter	Nouns only	All words
$\varepsilon = 0.00$	78.2	72.9
$\varepsilon = 0.05$	79.5	74.5
$\varepsilon = 0.10$	**81.6**	**75.8**
$\varepsilon = 0.15$	81.2	74.7
$\varepsilon = 0.20$	80.9	75.1
$\varepsilon = 0.25$	80.2	74.8
$\varepsilon = 0.30$	80.4	74.9

4 Related Work

4.1 Word Representations

Distributed representations for words were proposed in (Rumelhart et al., 1986) and have been successfully used in language models (Bengio et al., 2006; Mnih and Hinton, 2008) and many natural language processing tasks, such as word representation learning (Mikolov, 2012), named entity recognition (Turian et al., 2010), disambiguation (Collobert et al., 2011), parsing and tagging (Socher et al., 2011; Socher et al., 2013). They are very useful in NLP tasks because they can be used as inputs to learning algorithms or as extra word features in NLP systems. Hence, many NLP applications, such as keyword extraction (Li-

u et al., 2010; Liu et al., 2011b; Liu et al., 2012), social tag suggestion (Liu et al., 2011a) and text classification (Baker and McCallum, 1998), may also potentially benefit from distributed word representation. The main advantage is that the representations of similar words are close in vector space, which makes generalization to novel patterns easier and model estimation more robust.

Word representations are hard to train due to the computational complexity. Recently, (Mikolov et al., 2013) proposed two particular models, Skip-gram and CBOW, to learn word representations in large amounts of text data. The training objective of the CBOW model is to combine the representations of the surrounding words to predict the word in the middle, while the Skip-gram model's is to learn word representations that are good at predicting its context in the same sentence (Mikolov et al., 2013). Our paper uses the model architecture of Skip-gram.

Most of the previous vector-space models use one representation per word. This is problematic because many words have multiple senses. The multi-prototype approach has been widely studied. (Reisinger and Mooney, 2010) proposed the multi-prototype vector-space model. (Huang et al., 2012) used the multi-prototype models to learn the vector for different senses of a word. All of these models use the clustering of contexts as a word sense and can not be directly used in word sense disambiguation.

After our paper was submitted, we perceive the following recent advances: (Tian et al., 2014) proposed a probabilistic model for multi-prototype word representation. (Guo et al., 2014) explored bilingual resources to learn sense-specific word representation. (Neelakantan et al., 2014) proposed an efficient non-parametric model for multi-prototype word representation.

4.2 Knowledge-based WSD

The objective of word sense disambiguation (WSD) is to computationally identify the meaning of words in context (Navigli, 2009). There are two approaches of WSD that assign meaning of words from a fixed sense inventory, supervised and knowledge-based methods. Supervised approaches require large labeled training sets, which are time consuming to create. In this paper, we only focus on knowledge-based word sense disambiguation.

Knowledge-based approaches exploit knowledge resources (such as dictionaries, thesauri, ontologies, collocations, etc.) to determine the senses of words in context. However, it has been shown in (Cuadros and Rigau, 2006) that the amount of lexical and semantic information contained in such resources is typically insufficient for high-performance WSD. Much work has been presented to automatically extend existing resources, including automatically linking Wikipedia to WordNet to include full use of the first WordNet sense heuristic (Suchanek et al., 2008), a graph-based mapping of Wikipedia categories to WordNet synsets (Ponzetto and Navigli, 2009), and automatically mapping Wikipedia pages to WordNet synsets (Ponzetto and Navigli, 2010).

It was recently shown that word representations can capture semantic and syntactic information between words (Mikolov et al., 2013). Some researchers tried to incorporate WordNet senses in a neural model to learn better word representations (Bordes et al., 2011). In this paper, we have proposed a unified method for word sense representation and disambiguation to extend the information contained in the vector representations to the existing resources. Our method only requires a large amount of unlabeled text to train sense representations and a dictionary to provide the definitions of word meanings, which makes it easily applicable to other resources.

5 Conclusion

In this paper, we present a unified model for word sense representation and disambiguation that uses one representation per sense. Experimental results show that our model improves the performance of contextual word similarity compared to existing WSR methods, outperforms state-of-the-art supervised methods on domain-specific WSD, and achieves competitive performance on coarse-grained all-words WSD. Our model only requires large-scale unlabeled text corpora and a sense inventory for WSD, thus it can be easily applied to other corpora and tasks.

There are still several open problems that should be investigated further:

1. Because the senses of words change over time (new senses appear), we will incorporate cluster-based methods in our model to find senses that are not in the sense inventory.

2. We can explore other WSD methods based on sense vectors to improve our performance. For example, (Li et al., 2010) used LDA to perform data-driven WSD in a manner similar to our model. We may integrate the advantages of these models and our model together to build a more powerful WSD system.

3. To learn better sense vectors, we can exploit the semantic relations (such as the hypernym and hyponym relations defined in WordNet) between senses in our model.

Reducing Dimensions of Tensors in Type-Driven Distributional Semantics

Tamara Polajnar Luana Făgărăşan Stephen Clark

Abstract

Compositional distributional semantics is a subfield of Computational Linguistics which investigates methods for representing the meanings of phrases and sentences. In this paper, we explore implementations of a framework based on Combinatory Categorial Grammar (CCG), in which words with certain grammatical types have meanings represented by multi-linear maps (i.e. multi-dimensional arrays, or tensors). An obstacle to full implementation of the framework is the size of these tensors. We examine the performance of lower dimensional approximations of transitive verb tensors on a sentence plausibility/selectional preference task. We find that the matrices perform as well as, and sometimes even better than, full tensors, allowing a reduction in the number of parameters needed to model the framework.

1 Introduction

An emerging subfield of computational linguistics is concerned with learning compositional distributional representations of meaning (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Coecke et al., 2010; Grefenstette and Sadrzadeh, 2011; Clarke, 2012; Socher et al., 2012; Clark, 2013). The advantage of such representations lies in their potential to combine the benefits of distributional approachs to word meaning (Schütze, 1998; Turney and Pantel, 2010) with the more traditional compositional methods from formal semantics (Dowty et al., 1981). Distributional representations have the properties of robustness, learnability from data, ease of handling ambiguity, and the ability to represent gradations of meaning; whereas compositional models handle the unbounded nature of natural language, as well as providing established accounts of logical words, quantification, and inference.

One promising approach which attempts to combine elements of compositional and distributional semantics is by Coecke et al. (2010). The underlying idea is to take the type-driven approach from formal semantics — in particular the idea that the meanings of complex grammatical types should be represented as functions — and apply it to distributional representations. Since the mathematics of distributional semantics is provided by linear algebra, a natural set of functions to consider is the set of linear maps. Coecke et al. recognize that there is a natural correspondence from complex grammatical types to tensors (multi-linear maps), so that the meaning of an adjective, for example, is represented by a matrix (a 2nd-order tensor)[1] and the meaning of a transitive verb is represented by a 3rd-order tensor.

Coecke et al. use the grammar of pregroups as the syntactic machinery to construct distributional meaning representations, since both pregroups and vector spaces can be seen as examples of the same abstract structure, which leads to a particularly clean mathematical description of the compositional process. However, the approach applies more generally, for example to other forms of categorial grammar, such as Combinatory Categorial Grammar (Steedman, 2000; Maillard et al., 2014), and also to phrase-structure grammars in a way that a formal linguist would recognize (Baroni et al., 2014). Clark (2013) provides a description of the tensor-based framework aimed more at computational linguists, relying only on the mathematics of multi-linear algebra rather than the category theory used in Coecke et al. (2010). Section 2 repeats some of this description.

A major open question associated with the tensor-based semantic framework is how to learn

[1] This same insight lies behind the work of Baroni and Zamparelli (2010).

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1036–1046,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

the tensors representing the meanings of words with complex types, such as verbs and adjectives. The framework is essentially a compositional framework, providing a recipe for how to combine distributional representations, but leaving open what the underlying vector spaces are and how they can be acquired. One significant challenge is an engineering one: in a wide-coverage grammar, which is able to handle naturally occurring text, there will be a) a large lexicon with many word-category pairs requiring tensor representations; and b) many higher-order tensors with large numbers of parameters which need to be learned. In this paper we take a first step towards learning such representations, by learning tensors for transitive verbs.

One feature of the tensor-based framework is that it allows the meanings of words and phrases with different basic types, for example nouns and sentences, to live in different vector spaces. This means that the sentence space is task specific, and must be defined in advance. For example, to calculate sentence similarity, we would have to learn a vector space where distances between vectors representing the meanings of sentences reflect similarity scores assigned by human annotators.

In this paper we describe an initial investigation into the learning of word meanings with complex syntactic types, together with a simple sentence space. The space we consider is the "plausibility space" described by Clark (2013), together with sentences of the form subject-verb-object. This space is defined to distinguish semantically plausible sentences (e.g. *Animals eat plants*) from implausible ones (e.g. *Animals eat planets*). Plausibility can be either represented as a single continuous variable between 0 and 1, or as a two-dimensional probability distribution over the classes *plausible* ($\top$) and *implausible* ($\bot$). Whether we consider a one- or two-dimensional sentence space depends on the architecture of the logistic regression classifier that is used to learn the verb (Section 3).

We begin with this simple plausibility sentence space to determine if, in fact, the tensor-based representation can be learned to a sufficiently useful degree. Other simple sentence spaces which can perhaps be represented using one or two variables include a "sentence space" for the sentiment analysis task (Socher et al., 2013), where one variable represents positive sentiment and the other negative. We also expect that the insights gained from research on this task can be applied to more complex sentence spaces, for example a semantic similarity space which will require more than two variables.

2 Syntactic Types to Tensors

The syntactic type of a transitive verb in English is $(S\backslash NP)/NP$ (using notation from Steedman (2000)), meaning that a transitive verb is a function which takes an NP argument to the right, an NP argument to the left, and results in a sentence S. Such *categories* with slashes are *complex categories*; S and NP are *basic* or *atomic* categories. Interpreting such categories under the Coecke et al. framework is straightforward. First, for each atomic category there is a corresponding vector space; in this case the sentence space $\mathbf{S}$ and the noun space $\mathbf{N}$.[2] Hence the meaning of a noun or noun phrase, for example *people*, will be a vector in the noun space: $\overrightarrow{people} \in \mathbf{N}$. In order to obtain the meaning of a transitive verb, each slash is replaced with a tensor product operator, so that the meaning of *eat*, for example, is a 3rd-order tensor: $\overline{eat} \in \mathbf{S} \otimes \mathbf{N} \otimes \mathbf{N}$. Just as in the syntactic case, the meaning of a transitive verb is a function (a multi-linear map) which takes two noun vectors as arguments and returns a sentence vector.

Meanings combine using *tensor contraction*, which can be thought of as a multi-linear generalisation of matrix multiplication (Grefenstette, 2013). Consider first the adjective-noun case, for example *black cat*. The syntactic type of *black* is N/N; hence its meaning is a 2nd-order tensor (matrix): $\overline{black} \in \mathbf{N} \otimes \mathbf{N}$. In the syntax, N/N combines with N using the rule of forward application ($N/N \;\; N \Rightarrow N$), which is an instance of function application. Function application is also used in the tensor-based semantics, which, for a matrix and vector argument, corresponds to matrix multiplication.

Figure 1 shows how the syntactic types combine with a transitive verb, and the corresponding tensor-based semantic types. Note that, after the verb has combined with its object NP, the type of the verb phrase is $S\backslash NP$, with a corresponding meaning tensor (matrix) in $\mathbf{S} \otimes \mathbf{N}$. This matrix then combines with the subject vector, through

[2] In practice, for example using the CCG parser of Clark and Curran (2007), there will be additional atomic categories, such as PP, but not many more.

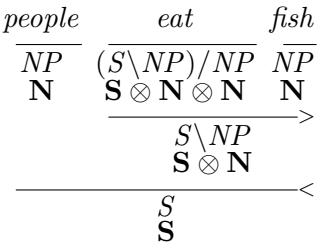

Figure 1: Syntactic reduction and tensor-based semantic types for a transitive verb sentence

matrix multiplication, to give a sentence vector.

In practice, using for example the wide-coverage grammar from CCGbank (Hockenmaier and Steedman, 2007), there will be many types with more than 3 slashes, with corresponding higher-order tensors. For example, a common category for a preposition is the following: $((S\backslash NP)\backslash(S\backslash NP))/NP$, which would be assigned to WITH in *eat* WITH *a fork*. (The way to read the syntactic type is as follows: *with* requires an NP argument to the right – *a fork* in this example – and then a verb phrase to the left – *eat* with type $S\backslash NP$ – resulting in a verb phrase $S\backslash NP$.) The corresponding meaning tensor lives in the tensor space $\mathbf{S}\otimes\mathbf{N}\otimes\mathbf{S}\otimes\mathbf{N}\otimes\mathbf{N}$, i.e. a 5th-order tensor. Categories with even more slashes are not uncommon, for example $((N/N)/(N/N))/((N/N)/(N/N))$. Clearly learning parameters for such tensors is highly challenging, and it is likely that lower dimensional approximations will be required.

3 Methods

In this paper we compare five different methods for modelling the type-driven semantic representation of subject-verb-object sentences. The tensor is a function that encodes the meaning of a verb. It takes two vectors from the K-dimensional noun space as input, and produces a representation of the sentence in the S-dimensional sentence space. In this paper, we consider a *plausibility space* where $\mathbf{S}$ is either a single variable or a two-dimensional space over two classes: *plausible* ($\top$) and *implausible* ($\bot$).

The first method (**Tensor**) follows Krishnamurthy and Mitchell (2013) by learning a tensor as parameters in a softmax classifier. We introduce three related methods (**2Mat**, **SKMat**, **KKMat**), all of which model the verb as a matrix or a pair of matrices (Figure 2). Table 1 gives the number of parameters for each method. **Tensor**, **2Mat**, and **SKMat** all have a two-dimensional $\mathbf{S}$ space, while **KKMat** produces a scalar value. In all of these learning-based methods the derivatives were obtained via the chain rule with respect to each set of parameters and gradient descent was performed using the Adagrad algorithm (Duchi et al., 2011).

	Tensor	**2Mat**	**SKMat**	**KKMat**	**DMat**
V	$2K^2$	$4K$	$2K$	K^2	K^2
Θ	4	8	4	0	0

Table 1: Number of parameters per method.

We also reimplement a distributional method (**DMat**), which was previously used in SVO experiments with the type-driven framework (Grefenstette and Sadrzadeh, 2011). While the other methods are trained as plausibility classifiers, in **DMat** we estimate the class boundary from cosine similarity via training data (see explanation below).

Tensor If subject (n_s) and object (n_o) nouns are K-dimensional vectors and the plausibility vector is S-dimensional with $S = 2$, we can learn the values of the $K \times K \times S$ tensor representing the verb as parameters (V) of a regression algorithm. To represent this space as a distribution over two classes ($\top$,$\bot$) we apply a sigmoid function (σ) to restrict the output to the [0,1] range and the softmax activation function (g) to balance the class probabilities. The full parameter set which needs to be optimised for is $\mathrm{B} = \{\mathrm{V}, \Theta\}$, where $\Theta = \{\theta_\top, \theta_\bot\}$ are the softmax parameters for the two classes. For each verb we optimise the KL-divergence $\mathcal{L}$ between the training labels t^i and classifier predictions using the following regularised objective:

$$O(\mathrm{B}) = \sum_{i=1}^{N} \mathcal{L}\left(t^i, g\left(\sigma\left(h_\mathrm{V}\left(n_s^i, n_o^i\right)\right), \Theta\right)\right) + \frac{\lambda}{2}||\mathrm{B}||^2 \quad (1)$$

where n_s^i and n_o^i are the subject and object of the training instance $i \in N$, and $h_\mathrm{V}\left(n_s^i, n_o^i\right) = (n_s^i)\mathrm{V}(n_o^i)^T$ describes tensor contraction. The function h_V is described diagrammatically in Figure 2-**(a)**, where the verb tensor parameters are drawn as a cube with the subject and object noun vectors as operands on either side. The output is a two-dimensional vector which is then transformed using the sigmoid and softmax functions.

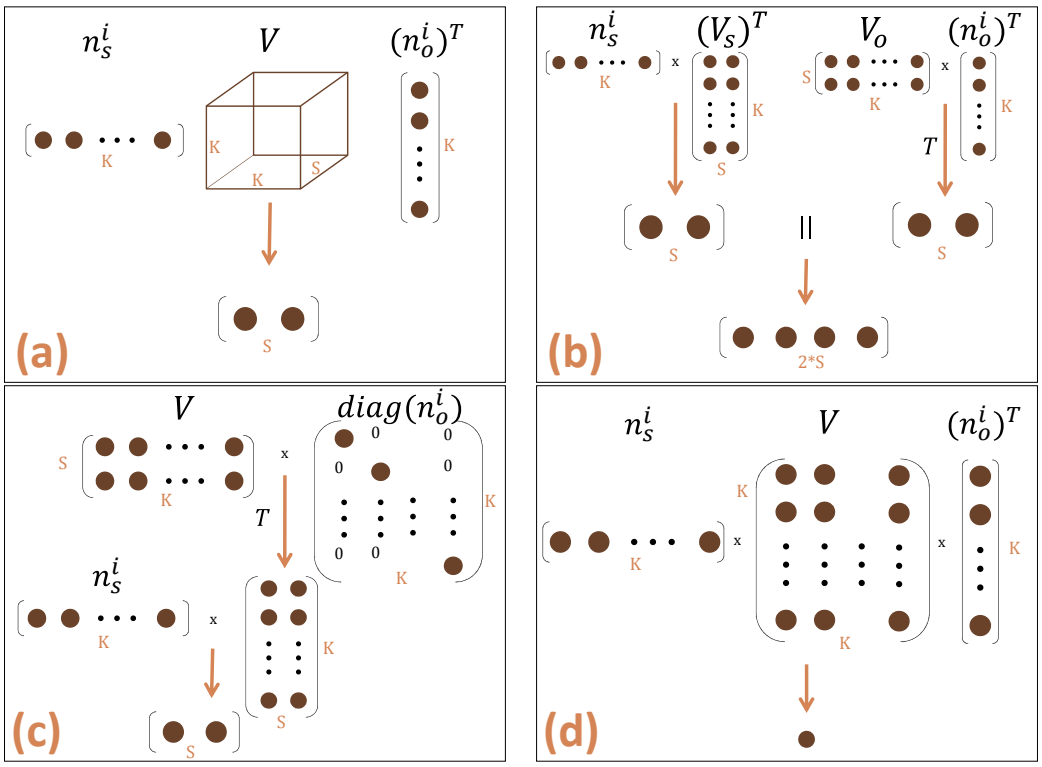

Figure 2: Illustrations of the h_{V} function for the regression-based methods **(a)-Tensor**, **(b)-2Mat**, **(c)-SKMat**, **(d)-KKMat**. The operation in **(a)** is tensor contraction, T denotes transpose, and $\times$ denotes matrix multiplication.

The gold-standard distribution over training labels is defined as $(1, 0)$ or $(0, 1)$, depending on whether the training instance is a positive (plausible) or negative (implausible) example. Tensor contraction is implemented using the Matlab Tensor Toolbox (Bader et al., 2012).

2Mat An alternative approach is to decouple the interaction between the object and subject by learning a pair of $S \times K$ ($S = 2$) matrices (V_s, V_o) for each of the input noun vectors (one matrix for the subject slot of the verb and one for the object slot). The resulting S-vectors are concatenated, after the subject and object nouns have been combined with their matrices, and combined with the softmax component to produce the output distribution. Therefore the objective function is the same as in Equation 1, but h_{V} is defined as:

$$h_{\mathrm{V}}\left(n_s^i, n_o^i\right) = \left((n_s^i)\mathrm{V}_s^T\right) || \left(\mathrm{V}_o(n_o^i)^T\right)^T$$

where $||$ represents vector concatenation. The intention is to test whether we can learn the verb without directly multiplying subject and object features, n_s^i and n_o^j. The function h_{V} is shown in Figure 2-**(b)**, where the verb tensor parameters are drawn as two $2 \times K$ matrices, one of which interacts with the subject and the other with the object noun vector. The output is a four-dimensional vector whose values are then restricted to [0,1] using the sigmoid function and then transformed into a two-dimensional distribution over the classes using the softmax function.

SKMat A third option for generating a sentence vector with $S = 2$ dimensions is to consider the verb as an $S \times K$ matrix. If we transform the object vector into a $K \times K$ matrix with the noun on the diagonal and zeroes elsewhere, we can combine the verb and object to produce a new $S \times K$ matrix, which is encoding the meaning of the verb phrase. We can then complete the sentence reduction by multiplying the subject vector with this verb phrase vector to produce an S-dimensional sentence vector. Formally, we define **SKMat** as:

$$h_{\mathrm{V}}\left(n_s^i, n_o^i\right) = n_s^i \left(\mathrm{V}diag(n_o^i)\right)^T$$

and use it in Equation 1. The function h_{V} is described in Figure 2-**(c)**, where the verb tensor parameters are drawn as a matrix, the subject as a vector, and the object as a diagonal ma-

trix. The graphic demonstrates the two-step combination and the intermediate $S \times K$ verb phrase matrix, as well as the the noun vector product that results in a two-dimensional vector which is then transformed using the sigmoid and softmax functions. Whilst the tensor method captures the interactions between all pairs of context features ($n_{si} \cdot n_{oj}$), **SKMat** only captures the interactions between matching features ($n_{si} \cdot n_{oi}$).

KKMat Given a two-class problem, such as plausibility classification, the softmax implementation is overparameterised because the class membership can be estimated with a single variable. To produce a scalar output, we can learn the parameters for a single $K \times K$ matrix (V) using standard logistic regression with the mean squared error cost function:

$$O(\mathrm{V}) = -\frac{1}{m}\left[\sum_{i=1}^{N} t^i \log h_{\mathrm{V}}\left(n_s^i, n_o^i\right) + (1-t^i)\log h_{\mathrm{V}}\left(n_s^i, n_o^i\right)\right]$$

where $h_{\mathrm{V}}\left(n_s^i, n_o^i\right) = (n_s^i)\mathrm{V}(n_o^i)^T$ and the objective is regularised: $O(\mathrm{V}) + \frac{\lambda}{2}||\mathrm{V}||^2$. This function is shown in Figure 2-**(d)**, where the verb parameters are shown as a matrix, while the subject and object are vectors. The output is a single scalar, which is then transformed with the sigmoid function. Values over 0.5 are considered plausible.

DMat The final method produces a scalar as in **KKMat**, but is distributional and based on corpus counts rather than regression-based. Grefenstette and Sadrzadeh (2011) introduced a corpus-based approach for generating a $K \times K$ matrix for each verb from an average of Kronecker products of the subject and object vectors from the positively labelled subset of the training data. The intuition is that, for example, the matrix for *eat* may have a high value for the contextual topic pair describing animate subjects and edible objects. To determine the plausibility of a new subject-object pair for a particular verb, we calculate the Kronecker product of the subject and object noun vectors for this pair, and compare the resulting matrix with the average verb matrix using cosine similarity.

For label prediction, we calculate the similarity between each of the training data pairs and the learned average matrix. Unlike for **KKmat**, the **class cutoff** is estimated at the break-even point of the receiver operator characteristic (ROC) generated by comparing the training labels with this cosine similarity value. The break-even point is when the true positive rate is equal to the false positive rate. In practice it would be more accurate to estimate the cutoff on a validation dataset, but some of the verbs have so few training instances that this was not possible.

4 Experiments

In order to examine the quality of learning we run several experiments where we compare the different methods. In these experiments we consider the **DMat** method as the baseline. Some of the experiments employ cross-validation, in particular five repetitions of 2-fold cross validation (5x2cv), which has been shown to be statistically more robust than the traditional 10-fold cross validation (Alpaydin, 1999; Ulaş et al., 2012). The results of 5x2cv experiments can be compared using the regular paired t-test, but the specially designed 5x2cv F-test has been proven to produce fewer statistical errors (Ulaş et al., 2012).

The performance was evaluated using the area under the ROC (AUC) and the F_1 measure (based on precision and recall over the plausible class). The AUC evaluates whether a method is ranking positive examples above negative ones, regardless of the class cutoff value. F_1 shows how accurately a method assigns the correct class label. Another way to interpret the results is to consider the AUC as the measure of the quality of the parameters in the verb matrix or tensor, while the F-score indicates how well the softmax, the sigmoid, and the **DMat** cutoff algorithm are estimating class participation.

Ex-1. In the first experiment, we compare the different transitive verb representations by running 5x2cv experiments on ten verbs chosen to cover a range of concreteness and frequency values (Section 4.2).

Ex-2. In the initial experiments we found that some models had low performance, so we applied the column normalisation technique, which is often used with regression learning to standardise the numerical range of features:

$$\vec{x} := \frac{\vec{x} - \min(\vec{x})}{\max(\vec{x}) - \min(\vec{x})} \qquad (2)$$

This preserves the relative values of features between training samples, while moving the values to the [0,1] range.

Ex-3. There are varying numbers of training examples for each of the verbs, so we repeated the 5x2cv with datasets of 52 training points for each verb, since this is the size of the smallest dataset of the verb CENSOR. The points were randomly sampled from the datasets used in the first experiment. Finally, the four verbs with the largest datasets were used to examine how the performance of the methods changes as the amount of training data increases. The 4,000 training samples were randomised and half were used for testing. We sampled between 10 and 1000 training triples from the other half (Figure 4).

4.1 Noun vectors

Distributional semantic models (Turney and Pantel, 2010) encode word meaning in a vector format by counting co-occurrences with other words within a specified context window. We constructed the vectors from the October 2013 dump of Wikipedia articles, which was tokenised using the Stanford NLP tools[3], lemmatised with the Morpha lemmatiser (Minnen et al., 2001), and parsed with the C&C parser (Clark and Curran, 2007). In this paper we use sentence boundaries to define context windows and the top 10,000 most frequent lemmatised words in the whole corpus (excluding stopwords) as context words. The raw co-occurrence counts are re-weighted using the standard tTest weighting scheme (Curran, 2004), where $f_{w_i c_j}$ is the number of times target noun w_i occurs with context word c_j:

$$tTest(\vec{w_i}, c_j) = \frac{p(w_i, c_j) - p(w_i)p(c_j)}{\sqrt{p(w_i)p(c_j)}} \quad (3)$$

where $p(w_i) = \frac{\sum_j f_{w_i c_j}}{\sum_k \sum_l f_{w_k c_l}}$, $p(c_j) = \frac{\sum_i f_{w_i c_j}}{\sum_k \sum_l f_{w_k c_l}}$, and $p(w_i, c_j) = \frac{f_{w_i c_j}}{\sum_k \sum_l f_{w_k c_l}}$.

Using all 10,000 context words would result in a large number of parameters for each verb tensor, and so we apply singular value decomposition (SVD) (Turney and Pantel, 2010) with 40 latent dimensions to the target-context word matrix. We use context selection (with $N = 140$) and row normalisation as described in Polajnar and Clark (2014) to markedly improve the performance of SVD on smaller dimensions (K) and enable us to train the verb tensors using very low-dimensional noun vectors. Performance of the noun vectors was measured on standard word similarity datasets and the results were comparable to those reported by Polajnar and Clark (2014).

Table 2: The 10 chosen verbs together with their concreteness scores. The number of positive SVO examples was capped at 2000. **Frequency** is the frequency of the verb in the GSN corpus.

4.2 Training data

In order to generate training data we made use of two large corpora: the Google Syntactic N-grams (GSN) (Goldberg and Orwant, 2013) and the Wikipedia October 2013 dump. We first chose ten transitive verbs with different concreteness scores (Brysbaert et al., 2013) and frequencies, in order to obtain a variety of verb types. Then the positive (plausible) SVO examples were extracted from the GSN corpus. More precisely, we collected all distinct syntactic trigrams of the form *nsubj ROOT dobj*, where the root of the phrase was one of our target verbs. We lemmatised the words using the NLTK[4] lemmatiser and filtered these examples to retain only the ones that contain nouns that also occur in Wikipedia, obtaining the counts reported in Table 2.

For every positive training example, we constructed a negative (implausible) one by replacing both the subject and the object with a *confounder*, using a standard technique from the selectional preference literature (Chambers and Jurafsky, 2010). A confounder was generated by choosing a random noun from the same frequency bucket as the original noun.[5] Frequency buckets of size 10 were constructed by collecting noun frequency counts from the Wikipedia corpus. For ex-

[4]http://nltk.org/

[5]Note that the random selection of the confounder could result in a plausible negative example by chance, but manual inspection of a subset of the data suggests this happens infrequently for those verbs which select strongly for their arguments, but more often for those verbs that don't.

ample, for the plausible triple *animal* EAT *plant*, we generate the implausible triple *mountain* EAT *product*. Some verbs were well represented in the corpus, so we used up to the top 2,000 most frequent triples for training.

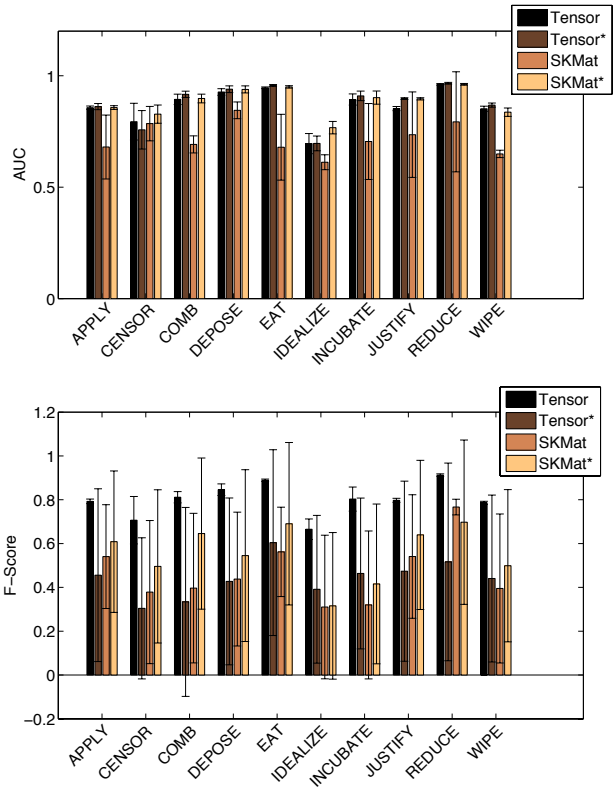

Figure 3: The effect of column normalisation (*) on **Tensor** and **SKMat**. Top table shows AUC and the bottom F_1-score, while the error bars indicate standard deviation.

5 Results

The results from **Ex-1** are summarised in Table 3. We can see that linear regression can lead to models that are able to distinguish between plausible and implausible SVO triples. The **Tensor** method outperforms **DMat**, which was previously shown to produce reasonable verb representations in related experiments (Grefenstette and Sadrzadeh, 2011). **2Mat** and **KKMat**, in turn, outperform **Tensor** demonstrating that it is possible to learn lower dimensional approximations of the tensor-based framework. **2Mat** is an appropriate approximation for functions with two inputs and a sentence space of any dimensionality, while **KKMat** is only appropriate for a single valued sentence space, such as the plausibility or sentiment space. Due to method variance and dataset size there are very few AUC results that are significantly better than **DMat** and even fewer that outperform **Tensor**. All methods perform poorly on the verb IDEALIZE, probably because it has the lowest concreteness value and is in one of the smallest datasets. This verb is also particularly difficult because it does not select strongly for either its subject or object, and so some of the pseudo-negative examples are in fact somewhat plausible (e.g. *town* IDEALIZE *authority* or *child* IDEALIZE *racehorse*). In general, this would indicate that more concrete verbs are easier to learn, as they have a clearer pattern of preferred property types, but there is no distinct correlation.

The results of the normalisation experiments (**Ex-2**) are shown in Table 4. We can see that the **SKMat** method, which performed poorly in **Ex-1** notably improves with normalisation. **Tensor** AUC scores also improve through normalisation, but the F-scores decrease. The rest of the methods, and in particular **DMat** are negatively affected by column normalisation. The results from **Ex-1** and **Ex-2** for **SKMat** and **Tensor** are summarised in

Figure 3. This figure also shows that AUC values have much lower variance, but that high variance in F-score leads to results that are not statistically significant.

When considering the size of the datasets (**Ex-3**), it would seem from Table 5 that **2Mat** is able to learn from less data than **DMat** or **Tensor**. While this may be true over a 5x2cv experiment on small data, Figure 4 shows that this view may be overly simplistic and that different training examples can influence learning. Analysis of errors shows that the baseline method mostly generates false negative errors (i.e. predicting implausible when the gold standard label is plausible). In contrast, **Tensor** produces almost equal numbers of false positives and false negatives, but sometimes produces false negatives with low frequency nouns (e.g. *bourgeoisie* IDEALIZE *work*), presumably because there is not enough information in the noun vector to decide on the correct class. It also produces some false positive errors when either of the nouns is plausible (but the triple is implausible), which would suggest results may be improved by training with data where only one noun is confounded or by treating negative data as possibly positive (Lee and Liu, 2003).

6 Discussion

Current methods which derive distributed representations for phrases, for example the work of Socher et al. (2012), typically use only matrix representations, and also assume that words, phrases and sentences all live in the same vector space. The tensor-based semantic framework is more flexible, in that it allows different spaces for different grammatical types, which results from it being tied more closely to a type-driven syntactic description; however, this flexibility comes at a cost, since there are many more paramaters to learn.

Various communities are beginning to recognize the additional power that tensor representations can provide, through the capturing of interactions that are difficult to represent with vectors and matrices (see e.g. (Ranzato et al., 2010; Sutskever et al., 2009; Van de Cruys et al., 2012)). Hierarchical recursive structures in language potentially represent a large number of such interactions – the obvious example for this paper being the interaction between a transitive verb's subject and object – and present a significant challenge for machine learning.

This paper is a practical extension of the work in Krishnamurthy and Mitchell (2013), which introduced learning of CCG-based function tensors with logistic regression on a compositional semantics task, but was implemented as a proof-of-concept with vectors of length 2 and on small, manually created datasets based on propositional

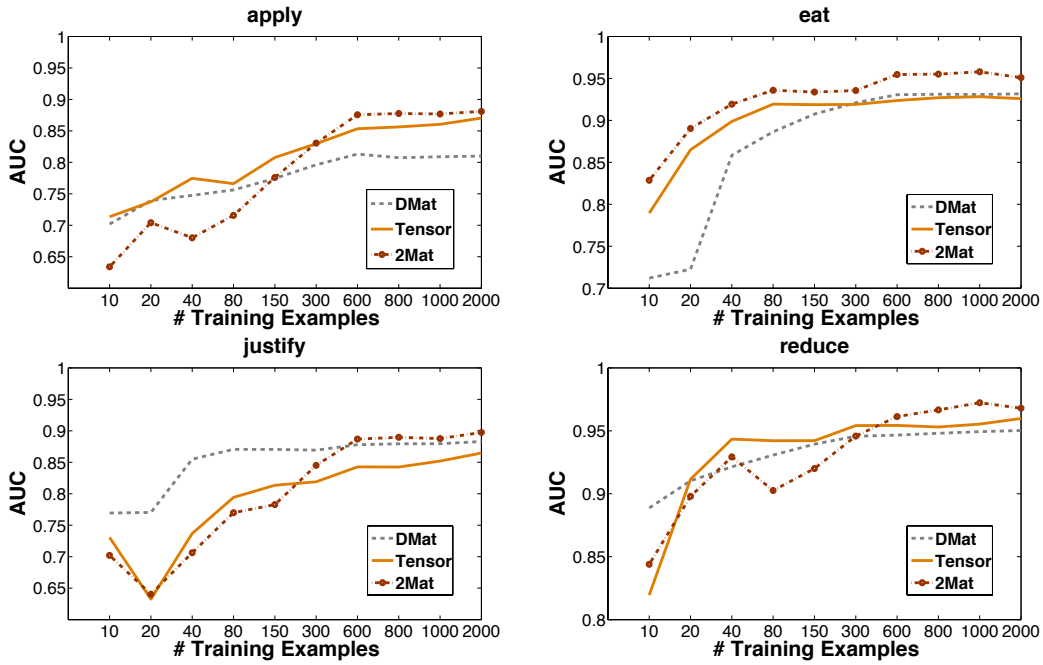

Figure 4: Comparison of **DMat**, **Tensor**, and **2Mat** methods as the number of training instances increases.

logic examples. Here, we go beyond this by learning tensors using corpus data and by deriving several different matrix representations for the verb in the subject-verb-object (SVO) sentence.

This work can also be thought of as applying neural network learning techniques to the classic problem of selectional preference acquisition, since the design of the pseudo-disambiguation experiments is taken from the literature on selectional preferences (Clark and Weir, 2002; Chambers and Jurafsky, 2010). We do not compare directly with methods from this literature, e.g. those based on WordNet (Resnik, 1996; Clark and Weir, 2002) or topic modelling techniques (Seaghdha, 2010), since our goal in this paper is not to extend the state-of-the-art in that area, but rather to use selectional preference acquisition as a test bed for the tensor-based semantic framework.

7 Conclusion

In this paper we introduced three dimensionally reduced representations of the transitive verb tensor defined in the type-driven framework for compositional distributional semantics (Coecke et al., 2010). In a comprehensive experiment on ten different verbs we find no significant difference between the full tensor representation and the reduced representations. The **SKMat** and **2Mat** representations have the lowest number of parameters and offer a promising avenue of research for more complex sentence structures and sentence spaces. **KKMat** and **DMat** also had high scores on some verbs, but these representations are applicable only in spaces where a single-value output is appropriate.

In experiments where we varied the amount of training data, we found that in general more concrete verbs can learn from less data. Low concreteness verbs require particular care with dataset design, since some of the seemingly random examples can be plausible. This problem may be circumvented by using semi-supervised learning techniques.

We also found that simple numerical techniques, such as column normalisation, can markedly alter the values and quality of learning. On our data, column normalisation has a side-effect of removing the negative values that were introduced by the use of tTest weighting measure. The use of the PPMI weighting scheme and non-negative matrix factorisation (NMF) (Grefenstette et al., 2013; Van de Cruys, 2010) could lead to a similar effect, and should be investigated. Further numerical techniques for improving the estimation of the class decision boundary, and consequently the F-score, will also constitute future work.

An Etymological Approach to Cross-Language Orthographic Similarity. Application on Romanian

Alina Maria Ciobanu, Liviu P. Dinu

alina.ciobanu@my.fmi.unibuc.ro, ldinu@fmi.unibuc.ro

Abstract

In this paper we propose a computational method for determining the orthographic similarity between Romanian and related languages. We account for etymons and cognates and we investigate not only the number of related words, but also their forms, quantifying orthographic similarities. The method we propose is adaptable to any language, as far as resources are available.

1 Introduction

Language relatedness and language change across space and time are two of the main questions of the historical and comparative linguistics (Rama and Borin, 2014). Many comparative methods have been used to establish relationships between languages, to determine language families and to reconstruct their proto-languages (Durie and Ross, 1996). If grouping of languages in linguistic families is generally accepted, the relationships between languages belonging to the same family are periodically investigated. In spite of the fact that linguistic literature abounds in claims of classification of natural languages, the degrees of similarity between languages are far from being certain. In many situations, the similarity of natural languages is a fairly vague notion, both linguists and non-linguists having intuitions about which languages are more similar to which others. McMahon and McMahon (2003) and Rama and Borin (2014) note that the computational historical linguistics did not receive much attention until the beginning of the 1990s, and argue for the necessity of development of quantitative and computational methods in this field.

1.1 Related Work

According to Campbell (2003), the methods based on comparisons of cognate lists and sound correspondences are the most popular approaches employed for establishing relationships between languages. Barbançon et al. (2013) emphasize the variety of computational methods used in this field, and state that the differences in datasets and approaches cause difficulties in the evaluation of the results regarding the reconstruction of the phylogenetic tree of languages. Linguistic phylogeny reconstruction proves especially useful in historical and comparative linguistics, as it enables the analysis of language evolution. Ringe et al. (2002) propose a computational method for evolutionary tree reconstruction based on a "perfect phylogeny" algorithm; using a Bayesian phylogeographic approach, Alekseyenko et al. (2012), continuing the work of Atkinson et al. (2005), model the expansion of the Indo-European language family and find support for the hypothesis which places its homeland in Anatolia; Atkinson and Gray (2006) analyze language divergence dates and argue for the usage of computational phylogenetic methods in the question of Indo-European age and origins. Using modified versions of Swadesh's lists[1], Dyen et al. (1992) investigate the classification of Indo-European languages by applying a lexicostatistical method.

The similarity of languages is interesting not only for historical and comparative linguistics, but for machine translation and language acquisition as well. Scannell (2006) and Hajič et al. (2000) argue for the possibility of obtaining a better translation quality using simple methods for very closely related languages. Koppel and Ordan (2011) study the impact of the distance between languages on the translation product and conclude that it is directly correlated with the ability to distinguish translations from a given source language from non-translated text. Some genetically related languages are so similar to each other, that

speakers of such languages are able to communicate without prior instruction (Gooskens, 2007). Gooskens et al. (2008) analyze several phonetic and lexical predictors and their conclusion is that lexical similarity can be seen as a predictor of language intelligibility. The impact of language similarities in the process of second language acquisition is argued by the contrastive analysis hypothesis, which claims that where similarities between the first and the second language occur, the acquisition would be easier compared with the situation in which there were differences between the two languages (Benati and VanPatten, 2011).

1.2 Our Approach

Although there are multiple aspects that are relevant in the study of language relatedness, such as the orthographic, phonetic, syntactic and semantic differences, in this paper we focus only on the orthographic similarity. The orthographic approach relies on the idea that sound changes leave traces in the orthography, and alphabetic character correspondences represent, to a fairly large extent, sound correspondences (Delmestri and Cristianini, 2010).

In this paper we propose an orthographic similarity method focused on etymons (direct sources of the words in a foreign language) and cognates (words in different languages having the same etymology and a common ancestor). In a broadly accepted sense, the higher the similarity degree between two languages, the closer they are.

One of our motivations is that when people encounter a language for the first time in written form, it is most likely that they can distinguish and individualize words which resemble words from their native language. These words are probably either inherited from their mother tongue (etymons), or have a common ancestor with the words in their language (cognates).

Our first goal is, given a corpus C, to automatically detect etymons and cognates. In Section 2 we propose a dictionary-based approach to automatically extract related words, and a method for computing the orthographic similarity of natural languages. Most of the traditional approaches in this field focus either on etymology detection or on cognate identification, most of them reporting results only on small sets of cognate pairs (usually manually determined lists of about 200 cognates, for which the cognate judgments are made by human experts (Rama and Borin, 2014)). Our approach implies a detailed investigation which accounts not only for the number of related words, as it is usually done in lexicostatistics (where the relationships between languages are determined based on the percentage of related words), but also for their forms, quantifying orthographic similarities. We employ three string similarity metrics for a finer-grained analysis, as related words in different languages do not have identical forms and their partial similarity implies different degrees of recognition and comprehensibility. For example, the Romanian word *lună* (*moon*) is closer to its Latin etymon *luna* than the word *bătrân* (*old*) to its etymon *veteranus*, and the Romanian word *vânt* (*wind*) is closer to its French cognate pair *vent* than the word *castel* (*castle*) to its cognate pair *château*.

In this paper we investigate the orthographic similarity between Romanian and related languages. Romanian is a Romance language, belonging to the Italic branch of the Indo-European language family, and is of particular interest regarding its geographic setting. It is surrounded by Slavic languages and its relationship with the big Romance kernel was difficult. Besides general typological comparisons that can be made between any two or more languages, Romanian can be studied based on comparisons of genetic and geographical nature, participating in numerous areally-based similarities that define the Balkan convergence area. Joseph (1999) states that, regarding the genetic relationships, Romanian can be studied in the context of those languages most closely related to it and that the well-studied Romance languages enable comparisons that might not be possible otherwise, within less well-documented families of languages. The position of Romanian within the Romance family is controversial (McMahon and McMahon, 2003): either marginal or more integrated within the group, depending on the versions of the cognate lists that are used in the analysis.

In Section 3.1 we apply our method on Romanian in different stages of its evolution, running our experiments on high-volume corpora from three historical periods: the period approximately between 1642 and 1743, the second half of 19th century (1870 - 1889), and the present period. In Section 3.2 we make use of a fourth corpus, Europarl, with a double goal: on the one hand, to check if degrees of similarity between Romanian

and other languages in the present period are consistent across two different corpora, and on the other hand, to investigate whether there are differences between the overall degrees of similarity obtained for the entire corpus and those obtained in various experiments at sentence level. The conclusions of our paper are outlined in Section 4.

2 Methodology and Algorithm

In this section we introduce a technique for determining the orthographic similarity of languages. In order to obtain accurate results, we investigate both etymons and cognates. First, we automatically identify etymons and cognates, then we measure the distances between related words, and finally we compute the overall degrees of similarity between pairs of languages. We also applied this method for investigating the mutual intelligibility of the Romance languages, and preliminary results are presented in (Ciobanu and Dinu, 2014b).

2.1 Similarity Method

Let $C = \{w_1, w_2, ..., w_{N_{words}}\}$ be a corpus in L_1 and let L_2 be a related language. We assume, without any loss of generality, that the elements of C are ordered such that $C_L = \{w_1, w_2, ..., w_{N_{lingua}}\}$ is the subset of C containing all the words that have an etymon or a cognate pair in L_2. We use the following notations: N_{words} is the number of token words in C, N_{lingua} is the number of token words in C_L, λ is the empty string and x_i is the etymon or cognate pair of w_i in L_2. Given a string distance Δ, we define the distance between L_1 and L_2 (non-metric distance), with frequency support from corpus C, as follows:

$$\Delta(L_1, L_2) = 1 - \frac{N_{lingua}}{N_{words}} + \frac{\sum_{i=1}^{N_{lingua}} \Delta(w_i, x_i)}{N_{words}} \quad (1)$$

Hence, the similarity between languages L_1 and L_2 is defined as follows:

$$Sim(L_1, L_2) = 1 - \Delta(L_1, L_2) \quad (2)$$

2.2 Algorithm

We present here the algorithm based on linguistic relationships detection and string similarity methods for determining the orthographic similarity between languages, with frequency support from corpora in the source language. This algorithm, represented in Figure 2, is applicable to any language. After a preprocessing phase, which is detailed in Subsection 2.2.1, we analyze words and begin by identifying their etymologies.

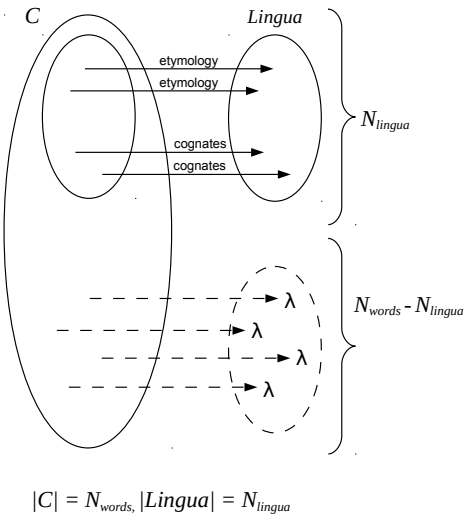

Figure 1: Schema for determining the orthographic similarity between related languages with frequency support from corpus *C*.

Corpus	#words		#stop words		#lemmas
	token	type	token	type	type
Parliament	22,469,290	162,399	14,451,178	214	40,065
Eminescu	870,828	65,742	565,396	212	21,456
Chronicles	253,786	28,936	170,582	193	8,189
RVR	2,464	2,464	124	124	2,252

Table 1: Statistics for the Romanian datasets.

2.2.1 Preprocessing

Given a corpus C, we start by preprocessing the text.

Step 1. Data Cleaning. We perform basic word segmentation, using whitespace and punctuation marks as delimiters and we lower-case all words. We remove from the datasets tokens that are irrelevant for our investigation, such as dates, numbers and non-textual annotations marked by non-alphanumeric characters.

Step 2. Stop Words Removal. We focus on analyzing word content and, in order to obtain relevant results, we remove stop words from the datasets. We use the lists of stop words for Romanian provided by the Apache Lucene[2] text search engine library. In Table 1 we list the total number of stop words from each corpus.

[2]http://lucene.apache.org

Step 3. Lemmatization. We use lemmas for identifying words' definitions in dictionaries and for computing adequate distances between words and their cognates or etymons. We use the Dexonline[3] machine-readable dictionary to lemmatize Romanian words.

Step 4. Diacritics Removal. Many words have undergone transformations by the augmentation of language-specific diacritics when entering a new language. From an orthographic perspective, the resemblance of words is higher between words without diacritics than between words with diacritics. For example, the orthographic distance is higher for the Romanian word *amiciţie* (*friendship*) and its French cognate pair *amitié* than for their corresponding forms without diacritics, *amicitie* and *amitie*. For this reason, in this step of our procedure we create two versions of each dataset, with and without diacritics, in order to further investigate the influence of the diacritics on the cross-language orthographic similarity. In Romanian, 5 diacritics are used today: *ă, î, â, ş, ţ*.

2.2.2 Relationships Identification

Step 1. Etymology Detection. For most words, etymological dictionaries offer a unique etymology, but when more options are possible for explaining a word's etymology (there are words whose etymology was and remains difficult to ascertain), dictionaries may provide multiple alternatives. For example, the Romanian word *parlament* (*parliament*) has a double etymology: French (with the etymon *parlement*) and Italian (with the etymon *parlamento*). We account for all the given etymological hypotheses, enabling our method to provide more accurate results.

For determining words' etymologies we use the Dexonline machine-readable dictionary, which is an aggregation of over 30 Romanian dictionaries. By parsing its definitions, we are able to automatically extract information regarding words' etymologies and etymons. The most frequently used pattern is shown below.

```
<abbr class="abbrev"
    title="limba language_name">
    language_abbreviation </abbr>
<b> origin_word </b>
```

As an example, we provide below an excerpt from a Dexonline entry which uses this pattern to specify the etymology of the Romanian word *capitol* (*chapter*), which has double etymology: Latin (with the etymon *capitulum*) and Italian (with the etymon *capitolo*).

```
<b> CAPÍTOL </b>
<abbr class="abbrev"
    title="limba italiana"> it. </abbr>
<b> capitolo </b>
<abbr class="abbrev"
    title="limba latina"> lat. </abbr>
<b> capitulum </b>
```

Step 2. Cognate Identification. Cognates are words in different languages having the same etymology and a common ancestor. The methods for cognate detection proposed so far are mostly based on orthographic/phonetic and semantic similarities (Kondrak, 2001; Frunza et al., 2005), but the term "cognates" is often used with a somewhat different meaning, denoting words with high orthographic/phonetic and cross-lingual meaning similarity, the condition of common etymology being left aside. We focus on etymology and we introduce an automatic strategy for detecting pairs of

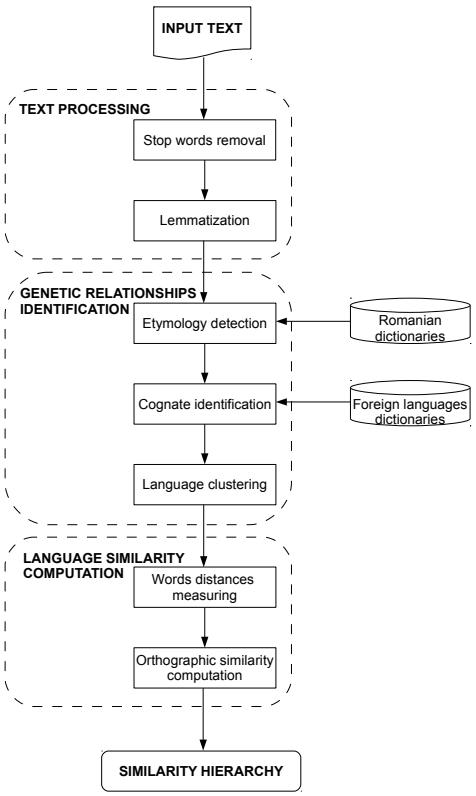

Figure 2: Algorithm for determining the orthographic similarity between related languages.

[3] http://dexonline.ro

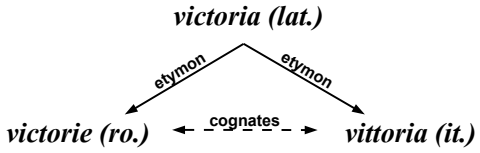

Figure 3: Word-etymon and cognate pairs.

cognates between two given languages, which enables the identification of all cognate pairs for the studied corpus.

Considering a set of words in a given language *L*, to identify the cognate pairs between *L* and a related language *L'*, we first determine the etymologies of the given words. Then we translate in *L'* all words without *L'* etymology. We consider cognate candidates pairs formed of input words and their translations. Using electronic dictionaries, we extract etymology-related information for the translated words. To identify cognates, we compare, for each pair of candidates, the etymologies and the etymons. If they match, we identify the words as being cognates.

In our previous work (Ciobanu and Dinu, 2014a) we applied this method on a Romanian dictionary, while here we extract cognates from Romanian corpora. We identify cognate pairs between Romanian and six other languages: Italian, French, Spanish, Portuguese, Turkish and English. We use electronic dictionaries[4] to extract etymology-related information and Google Translate[5] to translate Romanian words. We are restricted in our investigation by the available resources, but we plan to extend our method to other related languages as well. We selected these six languages for the following reason: the first four in our list are Romance languages, and our intuition is that there are numerous words in these languages which share a common ancestor with Romanian words. We investigate the cognate pairs for Turkish because many French words were imported in both Romanian and Turkish in the 19th century, and we believe that accounting for Romanian-Turkish cognates would provide a more accurate result for the similarity of these languages. As for English, we decided to investigate the cognate pairs for this language in order to analyze to what extent the influence of English on Romanian increases across time. In Table 2 we report the number of Romanian words having an etymon or a cognate pair in the six related languages.

Step 3. Evaluation. In order to evaluate our automatic method for extracting etymology-related information and for detecting related words, we excerpt a sample of 500 words for each of the considered languages (Romanian, French, Italian, Spanish, Portuguese, Turkish and English). The samples are drawn using a proportionate stratification sampling method with regard to the length of the lemmas in our datasets. We manually determine the etymologies of the words in the samples, and we compare these results with the automatically obtained etymologies. We compute the accuracy for etymology extraction for each language, and we obtain the following results: 95.8% accuracy for Romanian, 97.8% for Italian, 96.8% for French, 96.6% for Spanish, 97.0% for Portuguese, 96.0% for Turkish and, finally, 97.2% for English.

Language	Relationship	Corpus			
		Parliament	Eminescu	Chronicles	RVR
French	cognates	192,275	13,074	3,139	43
	etymons	15,665,865	484,668	89,946	1,203
Italian	cognates	1,660,588	40,491	2,743	100
	etymons	9,234,710	348,948	77,633	957
Spanish	cognates	4,616,528	119,627	9,942	355
	etymons	4,411,707	212,106	65,336	482
Portuguese	cognates	4,378,354	115,309	15,755	324
	etymons	3,477,285	156,908	55,991	435
Turkish	cognates	1,401,569	33,070	2,332	113
	etymons	331,863	24,115	11,985	69
English	cognates	4,347,302	146,377	21,966	296
	etymons	625,596	17,328	6,799	56

Table 2: Number of Romanian token words having etymons or cognate pairs in related languages.

2.2.3 Linguistic Distances

Various approaches have been previously employed for assessing the orthographic distance or similarity between related words. Their performance has been investigated and compared (Frunza et al., 2005; Rama and Borin, 2014), but a clear conclusion cannot be drawn with respect to which method is the most appropriate for a given task. We employ three metrics to determine the orthographic similarity between related words. In Subsection 3.1.2 we investigate to what extent the similarity scores computed with each of these metrics differ, and whether the differences are statistically significant. We use the following metrics:

[4] Italian: http://www.sapere.it/sapere/dizionari
French: http://www.cnrtl.fr
Spanish: http://lema.rae.es/drae
Portuguese: http://www.infopedia.pt/lingua-portuguesa
Turkish: http://www.nisanyansozluk.com
English: http://www.collinsdictionary.com

[5] http://translate.google.com

- **LCSR:** The longest common subsequence ratio (Melamed, 1995) is the longest common subsequence of two strings u and v divided by the length of the longer string. We subtract this value from 1, in order to obtain the distance between two words.

- **EDIT:** The edit distance (Levenshtein, 1965) counts the minimum number of operations (insertion, deletion and substitution) required to transform one string into another. We use a normalized version of the edit distance, dividing it by the length of the longer string.

- **RD:** The rank distance (Dinu and Dinu, 2005) is used to measure the similarity between two ranked lists. A ranking of a set of n objects can be represented as a permutation of the integers $1, 2, ..., n$. Let S be a set of ranking results, $\sigma \in S$. $\sigma(i)$ represents the rank of object i in the ranking result σ. The rank distance is computed as: $RD(\sigma, \tau) = \sum_{i=1}^{n} |\sigma(i) - \tau(i)|$. The ranks of the elements are assigned from bottom up, i.e. from n to 1, using the Borda count method (de Borda, 1781). The elements which do not occur in any of the rankings receive the rank 0. To extend the rank distance to strings, we index each occurrence of a given letter a with a_k, where k is the number of its previous occurrences, and then apply the rank distance on the new indexed strings, which become rankings in this situation. In order to normalize it, we divide the rank distance by the maximum possible distance between two strings u and v (Dinu and Sgarro, 2006): $\Delta_{max}(u, v) = |u|(|u|+1)/2+|v|(|v|+1)/2$.

3 Experiments and Results

In this section we present the results obtained by applying our method for determining orthographic similarity on Romanian datasets.

To our knowledge, only basic lexicostatistical methods (generally based on different dictionaries or versions of the representative vocabulary of Romanian) which compute the percentage of words with a given etymology have been applied for determining the relationships between Romanian and related languages. Because of the difficulty of setting the bounds between the basic lexicon and the remaining words, Graur (1968) uses in his experiments three concentric versions of the basic Romanian lexicon. Dinu (1996) reevaluates the etymology detection for the three versions of the basic Romanian lexicon and reclassifies the lexical material. He argues against grouping together all the words with Slavic origins, without differentiation between Old Slavic and languages such as Bulgarian, Russian, Ukrainian and Polish. Sala (1988) builds a version of the representative vocabulary of Romanian comprising 2588 words, which we use in our experiments as well.

3.1 Romanian Evolution

We apply our similarity method on high-volume Romanian corpora from three distinct historical periods of time, with different cultural, economical, political and social contexts. In Table 1 we report statistics for these corpora and for the basic Romanian lexicon.

3.1.1 Data

The first corpus consists of the transcription of the parliamentary debates held in the Romanian Parliament from 1996 to 2007 (Grozea, 2012). The second corpus consists of the publishing works of Mihai Eminescu (Eminescu, 1980 1985), the leading Romanian poet. His works provide an insightful description of the period between 1870 and 1889, with respect to its cultural, economical, social and political aspects, including some major events in the Romanian history. Many researchers consider that Eminescu had a crucial influence on Romanian, his contribution to modern language development being highly appreciated. The third corpus dates back to the period approximately between 1642 and 1743, the beginning period of the Romanian writing. Miron Costin, Grigore Ureche and Ion Neculce are Romanian chroniclers whose main works follow one another in creating one of the most detailed and valuable descriptions of Moldavia in that period, "Letopiseţul Ţării Moldovei". Along with them, Dimitrie Cantermir contributed to the early development of the Romanian writing, having written what is considered to be the first attempt at a socio-political novel ("Istoria Ieroglifică", 1703-1705). Their chronicles account for social, cultural, economical and political events with the purpose of recreating historical periods of time. We also use the basic Romanian lexicon (Sala, 1988), abbreviated RVR, for our experiments. The Dexonline machine-readable dictionary, which we use for determining the etymologies for the Romanian words, aggregates defini-

Table 3: Results for the Romanian datasets. In the *D* and *ND* columns we provide the average degrees of similarity for the datasets with and without diacritics. For languages for which we determine cognate pairs (besides etymons), we report both versions of the results, before and after cognate identification. In the *%words* column we provide the percentage of words having an etymon or a cognate pair in each language. The results are ordered according to the ranking of similarity for the corpus comprising the parliamentary debates after identifying cognates and with diacritics included.

tions from over 30 dictionaries ranging from 1927 to the present time and contains archaisms and obsolete words (which are marked accordingly); therefore, we are able to identify etymologies for words in all used corpora.

3.1.2 Results

In this subsection we present and analyze the main results drawn from our research. In Table 3 we list the output of our method for each corpus, with and without diacritics[6]. We report the similarity between Romanian and related languages, providing the average value of the three metrics used. In the *%words* column we provide, for each corpus, the percentage of words having an etymon or a cognate pair in a given language (the typical measure used in lexicostatistical comparison, i.e., the 0 distance function). The results for the Romanian datasets are plotted in Figure 4 and Figure 5.

Cognate Influence. Table 3 and Figure 4 present the gain obtained by cognate analysis. Accounting for cognates leads to an increase of similarity between Romanian and Spanish and Portuguese with almost 300%, and between Romanian and Italian with almost 20%. Another spectacular increase of closeness is for Turkish, which draws closer to Romanian with more than 500% by using the cognate gain. The degree of similarity is not given by the contribution of words inherited in Romanian from Turkish (about 1%), but by the pairs of shared cognates. Both Romanian and Turkish borrowed words from French massively towards the end of the 19th century. Thus, most pairs of Romanian-Turkish cognates have common French ancestors, and words in Romanian and Turkish which resemble are actually loans from the same French words. We also notice a significant increase in similarity between Romanian and English in the modern period. This increase is natural and probably arises for the similarity between English and most of the other languages as well. We notice that this increase is due preponderantly to the cognate pairs. Most of the Romanian-English cognates have a Romance common ancestor (78.4% Latin, 4.2% French, 3.4% Italian), and 11.8% have a Greek common ancestor, counted at lemma level on the corpus comprising the parliamentary debates.

Romanian Evolution. Some significant results can be observed in the evolution of Romanian: the degrees of similarity between Romanian and all the Romance languages has increased significantly from the Chronicles period until today. Besides them, German is the only language to which Romanian drew closer (a possible explanation might be the fact that, after the establishment of Germans

[6]The complete ranking of similarity is available online at http://nlp.unibuc.ro/resources/rosim.pdf.

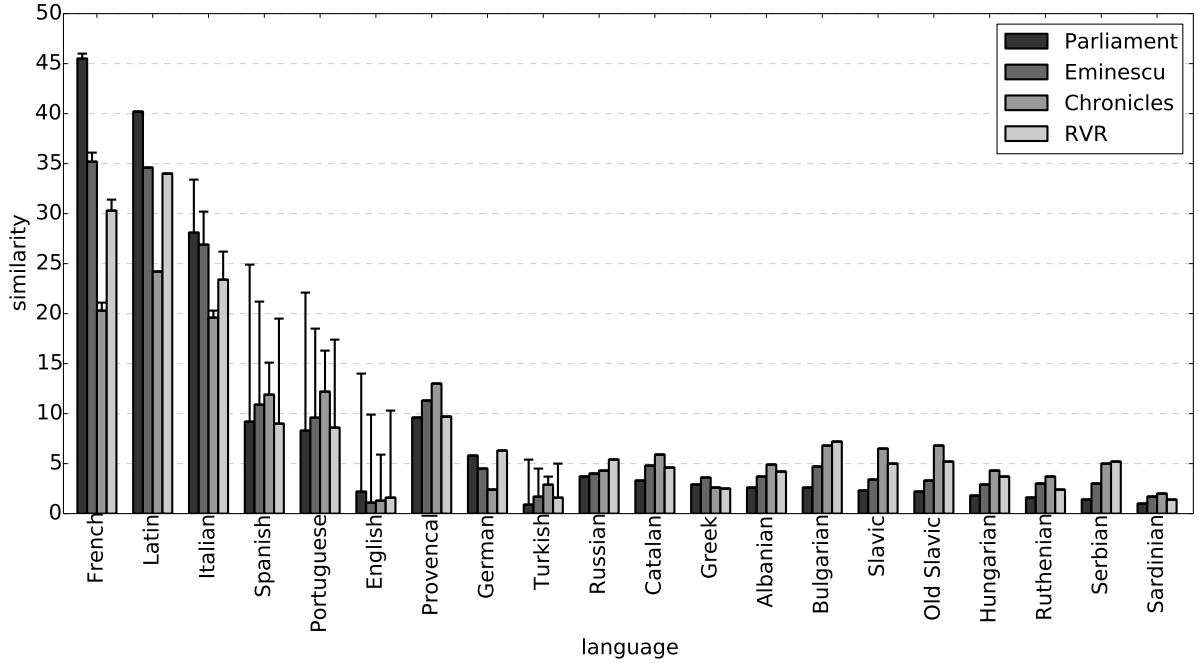

Figure 4: Degrees of similarity for the Romanian datasets. For French, Italian, Spanish, Portuguese, Turkish and English, the values obtained after the cognate identification phase are also plotted.

in Banat and Transylvania, many German words entered the basic Romanian lexicon). On the contrary, the similarity between Romanian and almost all the Slavic languages decreased in the same period. Russian is the only Slavic language which preserved its degree of similarity with Romanian (being, in the 2000s, the only Slavic language among the top 10 most closely related languages with Romanian, on the ninth position, with a degree of similarity of less than 4%). In the 18th and 19th centuries, the transition to the Latin alphabet and the desire to restore Romanian's Latin appearance contributed to the decrease of the Slavic influence (Gheţie, 1978). In fact, all Slavic influences in the 2000s sum up to 8.9%, in contrast with Latin influences, reaching 61.8%. Greek is the only language which reaches its peak regarding the similarity with Romanian in the 19th century (due to the brief Phanariot dominance in the 19th century). Therefore, Romanian preserved its Latin character all along, and the influence of the non-Latin languages on Romanian (overestimated in some works) was in fact not so significant. This fact supports Darwin's theory (Darwin, 1859), which states that the genealogy of languages is consistent with the genealogy of the nations (analyzed based on DNA similarity).

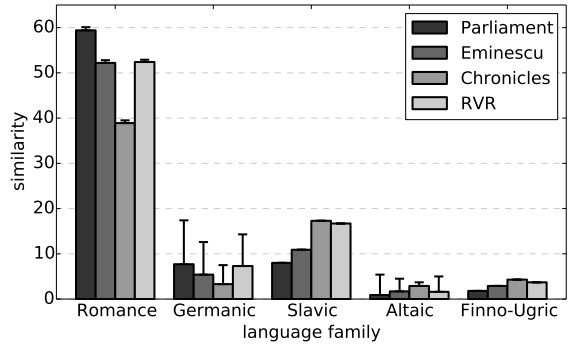

Figure 5: Degrees of similarity for the language families. Iranian and Baltic have a degree of similarity of less than 0.5.

Orthographic Metrics. In order to compare the similarity scores computed with the three metrics used, we conduct hypothesis tests (Sheskin, 2003) to determine whether the differences between the results obtained with each metric are statistically significant. We extract a sample of 5,000 words and we compute the pairwise differences between the similarity scores. Using the R v3.1.0 software environment for statistical computing (R Core Team, 2014), we perform the one-way ANOVA F-test, with the null hypothesis $\mathcal{H}_0$: $\mu_{EDIT} = \mu_{LCSR} = \mu_{RD}$ (where μ_Δ is the mean of the val-

ues computed with the Δ metric) and the alternative hypothesis $\mathcal{H}_a$: *not all* $\mu_{EDIT}, \mu_{LCSR}, \mu_{RD}$ *are equal*. Since the p-value of 2.88e-05 is much smaller than the 0.05 significance level, we have very strong evidence to reject the null hypothesis that the mean computed values for the three metrics are all equal. Further, we perform post-hoc comparisons applying pairwise t-tests with Bonferonni correction for the p-value, in order to analyze the differences between the metrics. For each pair of metrics, $p \ll 0.05$. The differences are statistically significant, but we notice that they are small. Applying a two-sampled t-test, we obtain a [0.012, 0.015] confidence interval for the mean difference between EDIT and LCSR, [0.015, 0.018] for EDIT and RD, and [0.001, 0.003] for RD and LCSR, at 95% confidence level. Moreover, computing Spearman's rank correlation coefficient for the rankings obtained by each metric for each dataset, we observe a very high correlation between them ($\rho > 0.98$ for each pair of variables). Thus, we conclude that reporting the average of the three metrics is relevant for our experiments, as differences are small and do not influence the ranking.

3.2 Europarl Experiments

We continue our investigation regarding the similarity of natural languages with two additional experiments. First, we want to see if degrees of similarity between Romanian and other languages in the present period are consistent across two different corpora. In the second experiment we are interested to see if there are differences between the overall degrees of similarity obtained for the entire corpus (the bag-of-words model) and those obtained in various experiments at sentence level. Our main corpus is Europarl (Koehn, 2005). More specifically, we use the portions larger than 2KB collected between 2007 and 2011 from the Romanian subcorpus of Europarl. The corpus is tokenized and sentence-aligned in 21 languages. For preprocessing this corpus, we discard all the transcribers' descriptions of the parliamentary sessions (such as "The President interrupted the speaker" or "The session was suspended at 19:30 and resumed at 21:00").

Exp. #1. In a first step, we apply the methodology described in Section 2 on the entire Europarl corpus for Romanian, using a bag-of-words model for the entire corpus, in which we account for the overall frequencies of the words. In this experiment, as in the previous ones, we cannot detect outliers, i.e., sentences which are unbalanced regarding the etymologies of the comprised words. For this reason, we conduct a second experiment which addresses this potential issue.

Exp. #2. We determine sentence-level orthographic similarity and we aggregate the results to compute the average values for the related languages. In this second experiment, we apply the methodology described in Section 2 for each sentence in the Europarl corpus for Romanian. For each sentence we obtain a ranking of related languages and, in order to obtain a ranking of similarity for the entire corpus, we compute the average degrees of similarity: for each related language, we sum up the degrees of similarity for all the sentences and divide this value by the number of sentences in the corpus.

Exp. #3. Because the interpretation of statistics derived from datasets that include outliers may be misleading, we compute the standard quartiles *Q1, Q2* and *Q3* (Sheskin, 2003) with regard to the length of the sentences. We use the interquartile range $IQR = Q3 - Q1$ to find outliers in the data. We consider outliers the observations that fall below the lower fence $LF = Q1 - 1.5(IQR)$ or above the upper fence $UF = Q3 + 1.5(IQR)$. We apply our methodology again only for the sentences having the length in the $[LF, UF]$ range.

Language	Exp. #1	Exp. #2	Exp. #3	Exp. #4
French	53.1	52.1	52.1	52.8
Latin	44.1	43.6	43.6	44.0
Italian	40.6	39.9	39.9	40.2
Portuguese	33.6	32.9	32.8	33.2
Spanish	27.6	27.3	27.3	26.8
English	16.0	15.7	15.7	15.1
Provencal	10.0	10.1	10.1	9.3
Turkish	6.3	6.2	6.1	5.7
German	5.9	5.8	5.8	5.3
Greek	4.4	4.3	4.3	3.8
Russian	4.2	4.1	4.1	3.6
Catalan	4.1	4.2	4.2	3.5
Old Slavic	3.1	3.2	3.2	2.7
Albanian	3.0	3.1	3.1	2.5
Bulgarian	2.9	2.9	2.9	2.2
Slavic	2.6	2.5	2.5	1.9
Hungarian	2.5	2.4	2.4	1.7
Ruthenian	2.1	2.1	2.1	1.3
Serbian	1.6	1.5	1.5	0.7
Sardinian	1.2	1.2	1.3	0.1

Table 4: Results for Europarl on the entire corpus (Exp. #1) and at sentence level (Exp. #2 - #4).

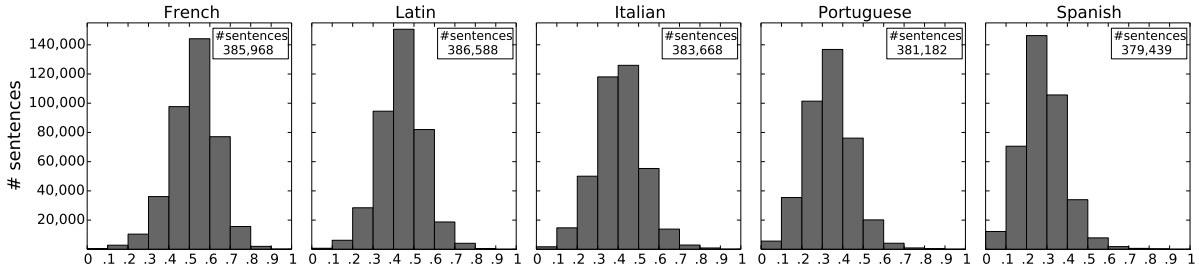

Figure 6: Distribution of the Romanian sentences in Europarl based on their similarity with the top 5 ranked languages. The OX axis represents the degree of similarity normalized to [0,1].

Exp. #4. As a last experiment, for each language L we consider as observations the degrees of similarity between Romanian and L, we discard outliers and we compute the average value of the observations inside the $[LF, UF]$ range. For each language, we determine the distribution of the sentences according to their similarity with the given language (the histograms for the top 5 languages are presented in Figure 6).

In Figure 7 we report the top 20 languages in the ranking of similarity for Europarl, emphasizing the gain obtained by identifying cognates. In Table 4 we report the similarity scores for the top 20 languages in the rankings of similarity for all the 4 experiments: overall similarity for the entire Europarl corpus (Exp. #1), sentence-level similarity (Exp. #2), similarity for the sentences having the length in the $[LF, UF]$ range (Exp. #3), and similarity for the sentences having the similarity between Romanian and each related language in the $[LF, UF]$ range (Exp. #4).

Some remarks are immediate. We observe that the differences between the values obtained for the entire corpus (Exp. #1) and those obtained in various experiments at sentence level (Exp. #2 - #4) are very small (an exception is Exp. #4, for languages whose degrees of similarity with Romanian are of less than 10%). We test the bag-of-words model on two corpora from the same period (the Parliament corpus and Europarl – in Exp. #1) and we notice that the results are consistent across different corpora (0.98 Spearman's ρ). The only significant difference is for Portuguese, which is closer to Romanian as measured on Europarl than on the Parliament corpus.

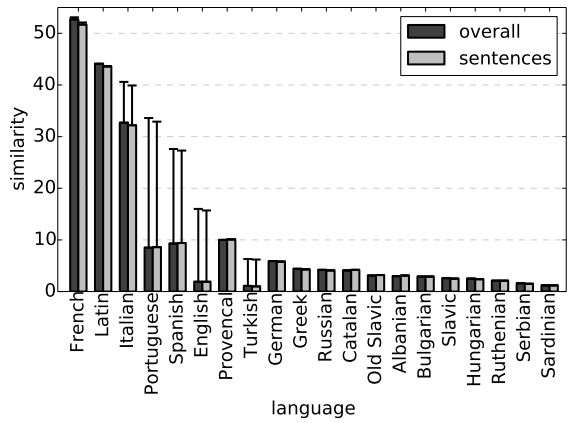

Figure 7: Degrees of similarity for Europarl.

4 Conclusions and Future Work

In this paper we proposed a computational method for determining cross-language orthographic similarity, with application on Romanian. We investigated etymons and cognates and we conducted a fine-grained analysis of the orthographic similarity between Romanian and related languages. Our results provide a new insight into the classification and evolution of Romanian. We plan to apply our similarity method on a corpus of spoken language, and to extend our analysis to other languages as well, as we gain access to available resources. We further intend to combine our orthographic approach with syntactic and semantic evidence for a wider perspective on language similarity.

Abstract

There is rising interest in vector-space word embeddings and their use in NLP, especially given recent methods for their fast estimation at very large scale. Nearly all this work, however, assumes a single vector per word type—ignoring polysemy and thus jeopardizing their usefulness for downstream tasks. We present an extension to the Skip-gram model that efficiently learns multiple embeddings per word type. It differs from recent related work by jointly performing word sense discrimination and embedding learning, by non-parametrically estimating the number of senses per word type, and by its efficiency and scalability. We present new state-of-the-art results in the word similarity in context task and demonstrate its scalability by training with one machine on a corpus of nearly 1 billion tokens in less than 6 hours.

1 Introduction

Representing words by dense, real-valued vector embeddings, also commonly called "distributed representations," helps address the curse of dimensionality and improve generalization because they can place near each other words having similar semantic and syntactic roles. This has been shown dramatically in state-of-the-art results on language modeling (Bengio et al, 2003; Mnih and Hinton, 2007) as well as improvements in other natural language processing tasks (Collobert and Weston, 2008; Turian et al, 2010). Substantial benefit arises when embeddings can be trained on large volumes of data. Hence the recent considerable interest in the CBOW and Skip-gram models of Mikolov et al (2013a); Mikolov et al (2013b)—relatively simple log-linear models that can be trained to produce high-quality word embeddings on the entirety of English Wikipedia text in less than half a day on one machine.

There is rising enthusiasm for applying these models to improve accuracy in natural language processing, much like Brown clusters (Brown et al, 1992) have become common input features for many tasks, such as named entity extraction (Miller et al, 2004; Ratinov and Roth, 2009) and parsing (Koo et al, 2008; Täckström et al, 2012). In comparison to Brown clusters, the vector embeddings have the advantages of substantially better scalability in their training, and intriguing potential for their continuous and multi-dimensional interrelations. In fact, Passos et al (2014) present new state-of-the-art results in CoNLL 2003 named entity extraction by directly inputting continuous vector embeddings obtained by a version of Skip-gram that injects supervision with lexicons. Similarly Bansal et al (2014) show results in dependency parsing using Skip-gram embeddings. They have also recently been applied to machine translation (Zou et al, 2013; Mikolov et al, 2013c).

A notable deficiency in this prior work is that each word type (*e.g.* the word string plant) has only one vector representation—polysemy and hononymy are ignored. This results in the word plant having an embedding that is approximately the average of its different contextual semantics relating to biology, placement, manufacturing and power generation. In moderately high-dimensional spaces a vector can be relatively "close" to multiple regions at a time, but this does not negate the unfortunate influence of the triangle inequality[2] here: words that are not synonyms but are synonymous with different senses of the same word will be pulled together. For example, pollen and refinery will be inappropriately pulled to a dis-

*The first two authors contributed equally to this paper.

[2]For distance d, $d(a,c) \leq d(a,b) + d(b,c)$.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1059–1069,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

tance not more than the sum of the distances plant–pollen and plant–refinery. Fitting the constraints of legitimate continuous gradations of semantics are challenge enough without the additional encumbrance of these illegitimate triangle inequalities.

Discovering embeddings for multiple senses per word type is the focus of work by Reisinger and Mooney (2010a) and Huang et al (2012). They both pre-cluster the contexts of a word type's tokens into discriminated senses, use the clusters to re-label the corpus' tokens according to sense, and then learn embeddings for these re-labeled words. The second paper improves upon the first by employing an earlier pass of non-discriminated embedding learning to obtain vectors used to represent the contexts. Note that by pre-clustering, these methods lose the opportunity to jointly learn the sense-discriminated vectors and the clustering. Other weaknesses include their fixed number of sense per word type, and the computational expense of the two-step process—the Huang et al (2012) method took one week of computation to learn multiple embeddings for a 6,000 subset of the 30,000 vocabulary on a corpus containing close to billion tokens.[3]

This paper presents a new method for learning vector-space embeddings for multiple senses per word type, designed to provide several advantages over previous approaches. (1) Sense-discriminated vectors are learned jointly with the assignment of token contexts to senses; thus we can use the emerging sense representation to more accurately perform the clustering. (2) A non-parametric variant of our method automatically discovers a varying number of senses per word type. (3) Efficient online joint training makes it fast and scalable. We refer to our method as *Multiple-sense Skip-gram*, or *MSSG*, and its non-parametric counterpart as *NP-MSSG*.

Our method builds on the Skip-gram model (Mikolov et al, 2013a), but maintains multiple vectors per word type. During online training with a particular token, we use the average of its context words' vectors to select the token's sense that is closest, and perform a gradient update on that sense. In the non-parametric version of our method, we build on *facility location* (Meyerson, 2001): a new cluster is created with probability proportional to the distance from the context to the nearest sense.

We present experimental results demonstrating the benefits of our approach. We show qualitative improvements over single-sense Skip-gram and Huang et al (2012), comparing against word neighbors from our parametric and non-parametric methods. We present quantitative results in three tasks. On both the SCWS and WordSim353 data sets our methods surpass the previous state-of-the-art. The Google Analogy task is not especially well-suited for word-sense evaluation since its lack of context makes selecting the sense difficult; however our method dramatically outperforms Huang et al (2012) on this task. Finally we also demonstrate scalabilty, learning multiple senses, training on nearly a billion tokens in less than 6 hours—a 27x improvement on Huang et al.

2 Related Work

Much prior work has focused on learning vector representations of words; here we will describe only those most relevant to understanding this paper. Our work is based on neural language models, proposed by Bengio et al (2003), which extend the traditional idea of n-gram language models by replacing the conditional probability table with a neural network, representing each word token by a small vector instead of an indicator variable, and estimating the parameters of the neural network and these vectors jointly. Since the Bengio et al (2003) model is quite expensive to train, much research has focused on optimizing it. Collobert and Weston (2008) replaces the max-likelihood character of the model with a max-margin approach, where the network is encouraged to score the correct n-grams higher than randomly chosen incorrect n-grams. Mnih and Hinton (2007) replaces the global normalization of the Bengio model with a tree-structured probability distribution, and also considers multiple positions for each word in the tree.

More relevantly, Mikolov et al (2013a) and Mikolov et al (2013b) propose extremely computationally efficient log-linear neural language models by removing the hidden layers of the neural networks and training from larger context windows with very aggressive subsampling. The goal of the models in Mikolov et al (2013a) and Mikolov et al (2013b) is not so much obtaining a low-perplexity language model as learning word representations which will be useful in

[3] Personal communication with authors Eric H. Huang and Richard Socher.

downstream tasks. Neural networks or log-linear models also do not appear to be necessary to learn high-quality word embeddings, as Dhillon and Ungar (2011) estimate word vector representations using Canonical Correlation Analysis (CCA).

Word vector representations or embeddings have been used in various NLP tasks such as named entity recognition (Neelakantan and Collins, 2014; Passos et al, 2014; Turian et al, 2010), dependency parsing (Bansal et al, 2014), chunking (Turian et al, 2010; Dhillon and Ungar, 2011), sentiment analysis (Maas et al, 2011), paraphrase detection (Socher et al, 2011) and learning representations of paragraphs and documents (Le and Mikolov, 2014). The word clusters obtained from Brown clustering (Brown et al, 1992) have similarly been used as features in named entity recognition (Miller et al, 2004; Ratinov and Roth, 2009) and dependency parsing (Koo et al, 2008), among other tasks.

There is considerably less prior work on learning multiple vector representations for the same word type. Reisinger and Mooney (2010a) introduce a method for constructing multiple sparse, high-dimensional vector representations of words. Huang et al (2012) extends this approach incorporating global document context to learn multiple dense, low-dimensional embeddings by using recursive neural networks. Both the methods perform word sense discrimination as a preprocessing step by clustering contexts for each word type, making training more expensive. While methods such as those described in Dhillon and Ungar (2011) and Reddy et al (2011) use token-specific representations of words as part of the learning algorithm, the final outputs are still one-to-one mappings between word types and word embeddings.

3 Background: Skip-gram model

The Skip-gram model learns word embeddings such that they are useful in predicting the surrounding words in a sentence. In the Skip-gram model, $v(w) \in R^d$ is the vector representation of the word $w \in W$, where W is the words vocabulary and d is the embedding dimensionality.

Given a pair of words (w_t, c), the probability that the word c is observed in the context of word w_t is given by,

$$P(D = 1|v(w_t), v(c)) = \frac{1}{1 + e^{-v(w_t)^T v(c)}} \quad (1)$$

The probability of not observing word c in the context of w_t is given by,

$$P(D = 0|v(w_t), v(c)) = 1 - P(D = 1|v(w_t), v(c))$$

Given a training set containing the sequence of word types $w_1, w_2, \ldots, w_T$, the word embeddings are learned by maximizing the following objective function:

$$J(\theta) = \sum_{(w_t, c_t) \in D^+} \sum_{c \in c_t} \log P(D = 1|v(w_t), v(c)) + \sum_{(w_t, c'_t) \in D^-} \sum_{c' \in c'_t} \log P(D = 0|v(w_t), v(c'))$$

where w_t is the t^{th} word in the training set, c_t is the set of observed context words of word w_t and c'_t is the set of randomly sampled, noisy context words for the word w_t. D^+ consists of the set of all observed word-context pairs (w_t, c_t) $(t = 1, 2 \ldots, T)$. D^- consists of pairs (w_t, c'_t) $(t = 1, 2 \ldots, T)$ where c'_t is the set of randomly sampled, noisy context words for the word w_t.

For each training word w_t, the set of context words $c_t = \{w_{t-R_t}, \ldots, w_{t-1}, w_{t+1}, \ldots, w_{t+R_t}\}$ includes R_t words to the left and right of the given word as shown in Figure 1. R_t is the window size considered for the word w_t uniformly randomly sampled from the set $\{1, 2, \ldots, N\}$, where N is the maximum context window size.

The set of noisy context words c'_t for the word w_t is constructed by randomly sampling S noisy context words for each word in the context c_t. The noisy context words are randomly sampled from the following distribution,

$$P(w) = \frac{p_{unigram}(w)^{3/4}}{Z} \quad (2)$$

where $p_{unigram}(w)$ is the unigram distribution of the words and Z is the normalization constant.

4 Multi-Sense Skip-gram (MSSG) model

To extend the Skip-gram model to learn multiple embeddings per word we follow previous work (Huang et al, 2012; Reisinger and Mooney, 2010a)

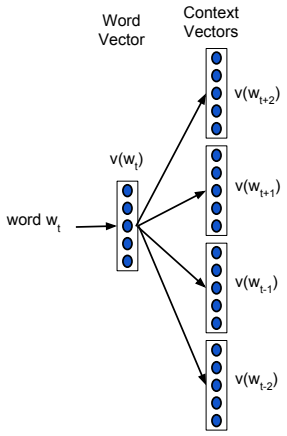

Figure 1: Architecture of the Skip-gram model with window size $R_t = 2$. Context c_t of word w_t consists of $w_{t-1}, w_{t-2}, w_{t+1}, w_{t+2}$.

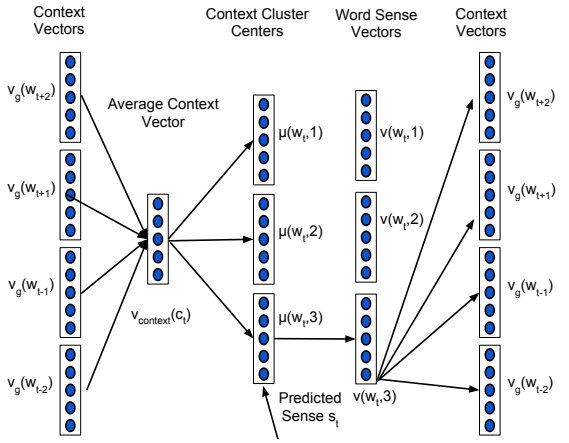

Figure 2: Architecture of Multi-Sense Skip-gram (MSSG) model with window size $R_t = 2$ and $K = 3$. Context c_t of word w_t consists of $w_{t-1}, w_{t-2}, w_{t+1}, w_{t+2}$. The sense is predicted by finding the cluster center of the context that is closest to the average of the context vectors.

and let each sense of word have its own embedding, and induce the senses by clustering the embeddings of the context words around each token. The vector representation of the context is the average of its context words' vectors. For every word type, we maintain clusters of its contexts and the sense of a word token is predicted as the cluster that is closest to its context representation. After predicting the sense of a word token, we perform a gradient update on the embedding of that sense. The crucial difference from previous approaches is that word sense discrimination and learning embeddings are performed jointly by predicting the sense of the word using the current parameter estimates.

In the MSSG model, each word $w \in W$ is associated with a global vector $v_g(w)$ and each sense of the word has an embedding (sense vector) $v_s(w,k)$ $(k = 1, 2, \ldots, K)$ and a context cluster with center $\mu(w,k)$ $(k = 1, 2, \ldots, K)$. The K sense vectors and the global vectors are of dimension d and K is a hyperparameter.

Consider the word w_t and let $c_t = \{w_{t-R_t}, \ldots, w_{t-1}, w_{t+1}, \ldots, w_{t+R_t}\}$ be the set of observed context words. The vector representation of the context is defined as the average of the global vector representation of the words in the context. Let $v_{context}(c_t) = \frac{1}{2*R_t} \sum_{c \in c_t} v_g(c)$ be the vector representation of the context c_t. We use the global vectors of the context words instead of its sense vectors to avoid the computational complexity associated with predicting the sense of the context words. We predict s_t, the sense of word w_t when observed with context c_t as the context cluster membership of the vector $v_{context}(c_t)$ as shown in Figure 2. More formally,

$$s_t = \underset{k=1,2,\ldots,K}{\arg\max}\ sim(\mu(w_t,k), v_{context}(c_t)) \quad (3)$$

The hard cluster assignment is similar to the k-means algorithm. The cluster center is the average of the vector representations of all the contexts which belong to that cluster. For sim we use cosine similarity in our experiments.

Here, the probability that the word c is observed in the context of word w_t given the sense of the word w_t is,

$$\begin{aligned} P(D=1|s_t, &v_s(w_t,1), \ldots, v_s(w_t,K), v_g(c)) \\ &= P(D=1|v_s(w_t,s_t), v_g(c)) \\ &= \frac{1}{1+e^{-v_s(w_t,s_t)^T v_g(c)}} \end{aligned}$$

The probability of not observing word c in the context of w_t given the sense of the word w_t is,

$$\begin{aligned} P(D=0|s_t, &v_s(w_t,1), \ldots, v_s(w_t,K), v_g(c)) \\ &= P(D=0|v_s(w_t,s_t), v_g(c)) \\ &= 1 - P(D=1|v_s(w_t,s_t), v_g(c)) \end{aligned}$$

Given a training set containing the sequence of word types $w_1, w_2, ..., w_T$, the word embeddings are learned by maximizing the following objective

Algorithm 1 Training Algorithm of MSSG model

Input: $w_1, w_2, ..., w_T$, d, K, N.
Initialize $v_s(w,k)$ and $v_g(w)$, $\forall w \in W, k \in \{1,\ldots,K\}$ randomly, $\mu(w,k)$ $\forall w \in W, k \in \{1,\ldots,K\}$ to 0.
for $t = 1, 2, \ldots, T$ **do**
    $R_t \sim \{1,\ldots,N\}$
    $c_t = \{w_{t-R_t},\ldots,w_{t-1},w_{t+1},\ldots,w_{t+R_t}\}$
    $v_{context}(c_t) = \frac{1}{2*R_t}\sum_{c\in c_t} v_g(c)$
    $s_t = \arg\max_{k=1,2,...,K}$ $\{$ $sim(\mu(w_t,k), v_{context}(c_t))\}$
    Update context cluster center $\mu(w_t, s_t)$ since context c_t is added to context cluster s_t of word w_t.
    $c'_t = Noisy\_Samples(c_t)$
    Gradient update on $v_s(w_t,s_t)$, global vectors of words in c_t and c'_t.
end for
Output: $v_s(w,k)$, $v_g(w)$ and context cluster centers $\mu(w,k)$, $\forall w \in W, k \in \{1,\ldots,K\}$

function:

$$J(\theta) = \sum_{(w_t,c_t)\in D^+}\sum_{c\in c_t}\log P(D=1|v_s(w_t,s_t),v_g(c)) + \sum_{(w_t,c'_t)\in D^-}\sum_{c'\in c'_t}\log P(D=0|v_s(w_t,s_t),v_g(c'))$$

where w_t is the t^{th} word in the sequence, c_t is the set of observed context words and c'_t is the set of noisy context words for the word w_t. D^+ and D^- are constructed in the same way as in the Skip-gram model.

After predicting the sense of word w_t, we update the embedding of the predicted sense for the word w_t ($v_s(w_t,s_t)$), the global vector of the words in the context and the global vector of the randomly sampled, noisy context words. The context cluster center of cluster s_t for the word w_t ($\mu(w_t,s_t)$) is updated since context c_t is added to the cluster s_t.

5 Non-Parametric MSSG model (NP-MSSG)

The MSSG model learns a fixed number of senses per word type. In this section, we describe a non-parametric version of MSSG, the NP-MSSG model, which learns varying number of senses per word type. Our approach is closely related to the online non-parametric clustering procedure described in Meyerson (2001). We create a new cluster (sense) for a word type with probability proportional to the distance of its context to the nearest cluster (sense).

Each word $w \in W$ is associated with sense vectors, context clusters and a global vector $v_g(w)$ as in the MSSG model. The number of senses for a word is unknown and is learned during training. Initially, the words do not have sense vectors and context clusters. We create the first sense vector and context cluster for each word on its first occurrence in the training data. After creating the first context cluster for a word, a new context cluster and a sense vector are created online during training when the word is observed with a context were the similarity between the vector representation of the context with every existing cluster center of the word is less than λ, where λ is a hyperparameter of the model.

Consider the word w_t and let $c_t = \{w_{t-R_t},\ldots,w_{t-1},w_{t+1},\ldots,w_{t+R_t}\}$ be the set of observed context words. The vector representation of the context is defined as the average of the global vector representation of the words in the context. Let $v_{context}(c_t) = \frac{1}{2*R_t}\sum_{c\in c_t} v_g(c)$ be the vector representation of the context c_t. Let $k(w_t)$ be the number of context clusters or the number of senses currently associated with word w_t. s_t, the sense of word w_t when $k(w_t) > 0$ is given by

$$s_t = \begin{cases} k(w_t)+1, & \text{if } \max_{k=1,2,...,k(w_t)}\{sim \\ & (\mu(w_t,k), v_{context}(c_t))\} < \lambda \\ k_{max}, & \text{otherwise} \end{cases} \quad (4)$$

where $\mu(w_t,k)$ is the cluster center of the k^{th} cluster of word w_t and $k_{max} = \arg\max_{k=1,2,...,k(w_t)} sim(\mu(w_t,k), v_{context}(c_t))$.

The cluster center is the average of the vector representations of all the contexts which belong to that cluster. If $s_t = k(w_t)+1$, a new context cluster and a new sense vector are created for the word w_t.

The NP-MSSG model and the MSSG model described previously differ only in the way word sense discrimination is performed. The objective function and the probabilistic model associated with observing a (word, context) pair given the sense of the word remain the same.

Model	Time (in hours)
Huang et al	168
MSSG 50d	1
MSSG-300d	6
NP-MSSG-50d	1.83
NP-MSSG-300d	5
Skip-gram-50d	0.33
Skip-gram-300d	1.5

Table 1: Training Time Results. First five model reported in the table are capable of learning multiple embeddings for each word and Skip-gram is capable of learning only single embedding for each word.

6 Experiments

To evaluate our algorithms we train embeddings using the same corpus and vocabulary as used in Huang et al (2012), which is the April 2010 snapshot of the Wikipedia corpus (Shaoul and Westbury, 2010). It contains approximately 2 million articles and 990 million tokens. In all our experiments we remove all the words with less than 20 occurrences and use a maximum context window (N) of length 5 (5 words before and after the word occurrence). We fix the number of senses (K) to be 3 for the MSSG model unless otherwise specified. Our hyperparameter values were selected by a small amount of manual exploration on a validation set. In NP-MSSG we set λ to -0.5. The Skip-gram model, MSSG and NP-MSSG models sample one noisy context word (S) for each of the observed context words. We train our models using AdaGrad stochastic gradient decent (Duchi et al, 2011) with initial learning rate set to 0.025. Similarly to Huang et al (2012), we don't use a regularization penalty.

Below we describe qualitative results, displaying the embeddings and the nearest neighbors of each word sense, and quantitative experiments in two benchmark word similarity tasks.

Table 1 shows time to train our models, compared with other models from previous work. All these times are from single-machine implementations running on similar-sized corpora. We see that our model shows significant improvement in the training time over the model in Huang et al (2012), being within well within an order-of-magnitude of the training time for Skip-gram models.

APPLE	
Skip-gram	blackberry, macintosh, acorn, pear, plum
MSSG	pear, honey, pumpkin, potato, nut microsoft, activision, sony, retail, gamestop macintosh, pc, ibm, iigs, chipsets

Table 2: Nearest neighbors of each sense of each word, by cosine similarity, for different algorithms. Note that the different senses closely correspond to intuitions regarding the senses of the given word types.

6.1 Nearest Neighbors

Table 2 shows qualitatively the results of discovering multiple senses by presenting the nearest neighbors associated with various embeddings. The nearest neighbors of a word are computed by comparing the cosine similarity between the embedding for each sense of the word and the context embeddings of all other words in the vocabulary. Note that each of the discovered senses are indeed semantically coherent, and that a reasonable number of senses are created by the non-parametric method. Table 3 shows the nearest neighbors of the word plant for Skip-gram, MSSG , NP-MSSG and Haung's model (Huang et al, 2012).

Skip-gram	plants, flowering, weed, fungus, biomass
MS -SG	plants, tubers, soil, seed, biomass refinery, reactor, coal-fired, factory, smelter asteraceae, fabaceae, arecaceae, lamiaceae, ericaceae
NP MS -SG	plants, seeds, pollen, fungal, fungus factory, manufacturing, refinery, bottling, steel fabaceae, legume, asteraceae, apiaceae, flowering power, coal-fired, hydro-power, hydroelectric, refinery
Hua -ng et al	insect, capable, food, solanaceous, subsurface robust, belong, pitcher, comprises, eagles food, animal, catching, catch, ecology, fly seafood, equipment, oil, dairy, manufacturer facility, expansion, corporation, camp, co. treatment, skin, mechanism, sugar, drug facility, theater, platform, structure, storage natural, blast, energy, hurl, power matter, physical, certain, expression, agents vine, mute, chalcedony, quandong, excrete

Table 3: Nearest Neighbors of the word *plant* for different models. We see that the discovered senses in both our models are more semantically coherent than Huang et al (2012) and NP-MSSG is able to learn reasonable number of senses.

6.2 Word Similarity

We evaluate our embeddings on two related datasets: the WordSim-353 (Finkelstein et al, 2001) dataset and the Contextual Word Similarities (SCWS) dataset Huang et al (2012).

WordSim-353 is a standard dataset for evaluating word vector representations. It consists of a list of pairs of word types, the similarity of which is rated in an integral scale from 1 to 10. Pairs include both monosemic and polysemic words. These scores to each word pairs are given without any contextual information, which makes them tricky to interpret.

To overcome this issue, Stanford's Contextual Word Similarities (SCWS) dataset was developed by Huang et al (2012). The dataset consists of 2003 word pairs and their sentential contexts. It consists of 1328 noun-noun pairs, 399 verb-verb pairs, 140 verb-noun, 97 adjective-adjective, 30 noun-adjective, 9 verb-adjective, and 241 same-word pairs. We evaluate and compare our embeddings on both WordSim-353 and SCWS word similarity corpus.

Since it is not trivial to deal with multiple embeddings per word, we consider the following similarity measures between words w and w' given their respective contexts c and c', where $P(w, c, k)$ is the probability that w takes the k^{th} sense given the context c, and $d(v_s(w, i), v_s(w', j))$ is the similarity measure between the given embeddings $v_s(w, i)$ and $v_s(w', j)$.

The avgSim metric,

$$\mathrm{avgSim}(w, w') = \frac{1}{K^2} \sum_{i=1}^{K} \sum_{j=1}^{K} d\left(v_s(w, i), v_s(w', j)\right),$$

computes the average similarity over all embeddings for each word, ignoring information from the context.

To address this, the $\mathrm{avgSimC}$ metric,

$$\mathrm{avgSimC}(w, w') = \sum_{j=1}^{K} \sum_{i=1}^{K} P(w, c, i) P(w', c', j) \times d\left(v_s(w, i), v_s(w', j)\right)$$

weighs the similarity between each pair of senses by how well does each sense fit the context at hand.

The $\mathrm{globalSim}$ metric uses each word's global context vector, ignoring the many senses:

$$\mathrm{globalSim}(w, w') = d\left(v_g(w), v_g(w')\right).$$

Finally, $\mathrm{localSim}$ metric selects a single sense for each word based independently on its context and computes the similarity by

$$\mathrm{localSim}(w, w') = d\left(v_s(w, k), v_s(w', k')\right),$$

where $k = \arg\max_i P(w, c, i)$ and $k' = \arg\max_j P(w', c', j)$ and $P(w, c, i)$ is the probability that w takes the i^{th} sense given context c. The probability of being in a cluster is calculated as the inverse of the cosine distance to the cluster center (Huang et al, 2012).

We report the Spearman correlation between a model's similarity scores and the human judgements in the datasets.

Table 5 shows the results on WordSim-353 task. C&W refers to the language model by Collobert and Weston (2008) and HLBL model is the method described in Mnih and Hinton (2007). On WordSim-353 task, we see that our model performs significantly better than the previous neural network model for learning multi-representations per word (Huang et al, 2012). Among the methods that learn low-dimensional and dense representations, our model performs slightly better than Skip-gram. Table 4 shows the results for the SCWS task. In this task, when the words are

Model	globalSim	avgSim	avgSimC	localSim
TF-IDF	26.3	-	-	-
Collobort & Weston-50d	57.0	-	-	-
Skip-gram-50d	63.4	-	-	-
Skip-gram-300d	65.2	-	-	-
Pruned TF-IDF	62.5	60.4	60.5	-
Huang et al-50d	58.6	62.8	65.7	26.1
MSSG-50d	62.1	64.2	66.9	49.17
MSSG-300d	65.3	67.2	**69.3**	57.26
NP-MSSG-50d	62.3	64.0	66.1	50.27
NP-MSSG-300d	**65.5**	**67.3**	69.1	**59.80**

Table 4: Experimental results in the SCWS task. The numbers are Spearmans correlation $\rho \times 100$ between each model's similarity judgments and the human judgments, in context. First three models learn only a single embedding per model and hence, avgSim, avgSimC and localSim are not reported for these models, as they'd be identical to globalSim. Both our parametric and non-parametric models outperform the baseline models, and our best model achieves a score of 69.3 in this task. NP-MSSG achieves the best results when globalSim, avgSim and localSim similarity measures are used. The best results according to each metric are in bold face.

Model	$\rho \times 100$
HLBL	33.2
C&W	55.3
Skip-gram-300d	70.4
Huang et al-G	22.8
Huang et al-M	64.2
MSSG 50d-G	60.6
MSSG 50d-M	63.2
MSSG 300d-G	69.2
MSSG 300d-M	**70.9**
NP-MSSG 50d-G	61.5
NP-MSSG 50d-M	62.4
NP-MSSG 300d-G	69.1
NP-MSSG 300d-M	68.6
Pruned TF-IDF	73.4
ESA	75
Tiered TF-IDF	76.9

Table 5: Results on the WordSim-353 dataset. The table shows the Spearmans correlation ρ between the model's similarities and human judgments. G indicates the globalSim similarity measure and M indicates avgSim measure.The best results among models that learn low-dimensional and dense representations are in bold face. Pruned TF-IDF (Reisinger and Mooney, 2010a), ESA (Gabrilovich and Markovitch, 2007) and Tiered TF-IDF (Reisinger and Mooney, 2010b) construct spare, high-dimensional representations.

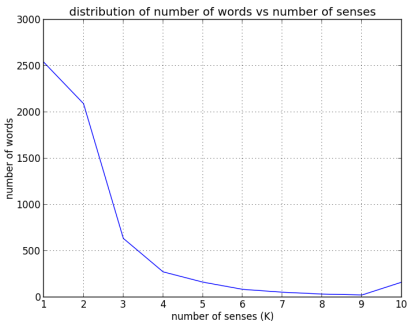

Figure 3: The plot shows the distribution of number of senses learned per word type in NP-MSSG model

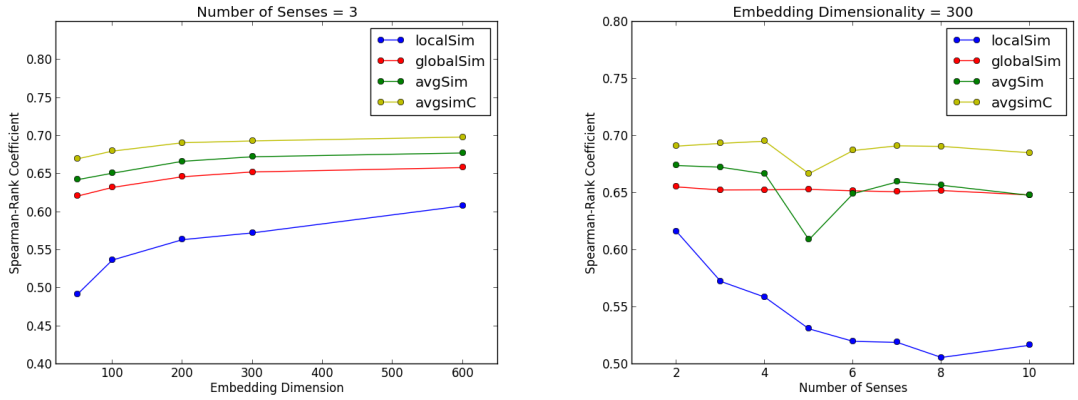
given with their context, our model achieves new state-of-the-art results on SCWS as shown in the Table-4. The previous state-of-art model (Huang et al, 2012) on this task achieves 65.7% using the avgSimC measure, while the MSSG model achieves the best score of 69.3% on this task. The results on the other metrics are similar. For a fixed embedding dimension, the model by Huang et al (2012) has more parameters than our model since it uses a hidden layer. The results show that our model performs better than Huang et al (2012) even when both the models use 50 dimensional vectors and the performance of our model improves as we increase the number of dimensions to 300.

We evaluate the models in a word analogy task



(a) (b)

Figure 4: Figures (a) and (b) show the effect of varying embedding dimensionality and number of senses respectively of the MSSG Model on the SCWS task.

Model	Task	Sim	$\rho \times 100$
Skip-gram	WS-353	globalSim	70.4
MSSG	WS-353	globalSim	68.4
MSSG	WS-353	avgSim	**71.2**
NP MSSG	WS-353	globalSim	68.3
NP MSSG	WS-353	avgSim	69.66
MSSG	SCWS	localSim	59.3
MSSG	SCWS	globalSim	64.7
MSSG	SCWS	avgSim	67.2
MSSG	SCWS	avgSimC	**69.2**
NP MSSG	SCWS	localSim	60.11
NP MSSG	SCWS	globalSim	65.3
NP MSSG	SCWS	avgSim	67
NP MSSG	SCWS	avgSimC	68.6

Table 6: Experiment results on WordSim-353 and SCWS Task. Multiple Embeddings are learned for top 30,000 most frequent words in the vocabulary. The embedding dimension size is 300 for all the models for this task. The number of senses for MSSG model is 3.

introduced by Mikolov et al (2013a) where both MSSG and NP-MSSG models achieve 64% accuracy compared to 12% accuracy by Huang et al (2012). Skip-gram which is the state-of-art model for this task achieves 67% accuracy.

Figure 3 shows the distribution of number of senses learned per word type in the NP-MSSG model. We learn the multiple embeddings for the same set of approximately 6000 words that were used in Huang et al (2012) for all our experiments to ensure fair comparision. These approximately 6000 words were choosen by Huang et al. mainly from the top 30,00 frequent words in the vocabulary. This selection was likely made to avoid the noise of learning multiple senses for infrequent words. However, our method is robust to noise, which can be seen by the good performance of our model that learns multiple embeddings for the top 30,000 most frequent words. We found that even by learning multiple embeddings for the top 30,000 most frequent words in the vocubulary, MSSG model still achieves state-of-art result on SCWS task with an avgSimC score of 69.2 as shown in Table 6.

7 Conclusion

We present an extension to the Skip-gram model that efficiently learns multiple embeddings per word type. The model jointly performs word sense discrimination and embedding learning, and non-parametrically estimates the number of senses per word type. Our method achieves new state-of-the-art results in the word similarity in context task and learns multiple senses, training on close to billion tokens in less than 6 hours. The global vectors, sense vectors and cluster centers of our model and code for learning them are available at `https://people.cs.umass.edu/~arvind/emnlp2014wordvectors`. In future work we plan to use the multiple embeddings per word type in downstream NLP tasks.

Tailor knowledge graph for query understanding: linking intent topics by propagation

Shi Zhao

Abstract

Knowledge graphs are recently used for enriching query representations in an entity-aware way for the rich facts organized around entities in it. However, few of the methods pay attention to non-entity words and clicked websites in queries, which also help conveying user intent. In this paper, we tackle the problem of intent understanding with innovatively representing entity words, refiners and clicked urls as *intent topics* in a unified knowledge graph based framework, in a way to exploit and expand knowledge graph which we call 'tailor'. We collaboratively exploit global knowledge in knowledge graphs and local contexts in query log to initialize intent representation, then propagate the enriched features in a graph consisting of intent topics using an unsupervised algorithm. The experiments prove intent topics with knowledge graph enriched features significantly enhance intent understanding.

1 Introduction

Query understanding is the process of generating a representation which characterizes a user's search intent (Croft et al., 2010), which is of vital importance for information retrieval. However, users are remarkably laconic in describing their information needs due to anomalous state of knowledge (Belkin et al., 1982), resulting in vague and underspecified queries, which makes it especially difficult to understand and locate what they intended for in mountains of web data. The problem is often significantly compounded that people convey their intent rather in a series of behaviors called a search session than a single query, leaving a wealth of clues including query reformulations, page visits, dwell times, etc. What's more, as entities are taking center stage (Yin and Shah, 2010), string-level or phrase-level modeling of intent soon hits the bottleneck, calling for an entity-aware perspective.

Knowledge repositories, better known as knowledge graphs, such as Wikipedia, DBpedia and Freebase, have been recently utilized for enhancing query understanding for the large amounts of world knowledge they've harvested about entities and facts. A widely accepted way to use knowledge graph is tying queries with it by annotating entities in them, also known as entity linking.

However, information need is conveyed through more than entities. Quite a few non-entity words, aka refiners or modifiers, as well as many urls are barely included in knowledge graph, while they play an irreplaceable role in intent understanding. For example, a user may query *toyota*, *volvo* or just enter *car soup, cars for sale* and click *www.carsoup.com*, which should be encoded in a form that we could perceive their closeness in intent. That's why at-a-glance info cards about merely recognized entity in the query are far from enough and previous methods disregarding refiners and urls are too limited to cover queries in majority.

We move one step further to tailor knowledge graph for representing more than entity words. We collect refiners and clicked urls along with entity words and model intents they represent using knowledge graph based features. We use Freebase[1], one of the largest available knowledge graph, in our work and our method can be easily generalized to other knowledge repositories.

We put up an idea of *intent topic* which can be query words or urls, whether mean an entity or not, representing an atomic information need. We identify them with *intent features* by exploiting global knowledge in Freebase and local con-

texts in query sessions. Notice the new concept here is distinguished from *query intent* or *query facet* in previous literature for it is in a holistic view, not specifically meaning subtopics around a certain query.

Our intuitive observations as follows inspire us to represent intent features with topics and domains in knowledge graph and propagate the enriched features in the intent topic graph.

1) Query words and urls within the same session tend to indicate the same query intent.
2) Intent topics sharing similar query intent often relate to similar topics in knowledge graph.
3) Knowledge graph domains sketch the query intent briefly.

Observation 1 indicates domain coherency within sessions is a good starting point to generate intent features, along with Observation 2 and 3 lay the basis of proximity that the propagation rely on.

To the best of our knowledge, we're the first to represent intent behind entity words, refiners and urls in a unified knowledge graph based framework, in a way to exploit and expand knowledge graph which we call 'tailor'.

Our contributions include:

- An innovative and unified framework to represent intent topics, whether they can directly link to an entity in knowledge graph or not.
- A novel algorithm to generate a specified intent topic graph, which enables learning intent features in an unsupervised propagation method.
- With intent topic graph we can better understand user intent conducting session-based contextualization and potentially find highly-related intent topic.

The rest of the paper is organized as follows. Section 2 tells our methods to map queries to Freebase and initialize intent features. Section 3 is about how we model intent topics in a unified graph and the propagation framework to learn intent features. We provide experiments and analysis in Section 4. Related work and conclusions are presented at the end of the paper.

2 Labeling intent topic nodes with Freebase-enriched features

In Freebase, facts around a certain topic and multi-faceted intents they reflect is more like a global domain distribution, what facet do users exactly intend for is difficult to locate until in a specified context, namely a query session.

We take a line in query log as a *query*, exhibiting an interaction with the search engine, including query words and page clicks. And a sequence of queries with a certain time interval constitute a *session*, completely conveying an information need.

In existing knowledge graph, only a small part of urls are contained in views of web pages beyond number online. Even for query words, we can merely get access to some of them, which we call *entity words* and the rest *refiners*. To avoid misunderstanding, the url intent topics in the following will specially refer to the clicks without directly matched concepts in knowledge graph, otherwise they'll be taken as entity intent topic.

In this section, we propose a framework of knowledge graph enriched representation of intent topics, the following propagation in Section3 bases on it.

2.1 Freebase as a knowledge graph

Freebase has over 39 million concepts, aka topics, about real-world entities like people, places and things stored as *nodes* in a graph. They're linked to each other with annotated egdes named as *property*. These *edges* actually represent *facts*. There are over a billion such facts or relations that make up the graph and they're all available for free. Properties are grouped into types, types are grouped into domains, which gives a broad view of knowledge in addtion to specific topics.

We can tap into Freebase through dump data or API[2]. In our work, we retrieve related Freebase topics with relevance scores for entity words via Freebase search API, which is based on combination of topic's inbound and outbound link counts in Freebase and Wikipedia as well as a popularity score computed by Google, and all the facts about a given topic through Freebase topic API. We use $\mathbb{T} = \{t_1, t_2, ...t_n\}$, $\mathbb{D} = \{d_1, d_2, ...d_n\}$ to denote all Freebase topics and domains used in our work.

2.2 Enriching entities and queries with Freebase

We represent a query's candidate intent topics by three sets, E_q, R_q, C_q, where E_q includes entity words and clicks which have equivalents in Freebase, R_q the refiner words and C_q the rest clicks.

[2]http://developers.google.com/freebase/

Global knowledge in Freebase can directly enrich each e in E_q with Freebase topics represented in vector $\mathbf{t}^e$, for each candidate topic there's a Freebase domain distribution vector $\mathbf{d}^t$. As for the rest in R_q and C_q, they can learn features in later propagation process.

For any topic t_i in $\mathbf{t}^e$, the relevance of entity words e and knowledge graph topic t_i is estimated as follows:

$$\mathbf{t}_i^e = \frac{RelevanceScore(e, t_i)}{\max_{t_j \in \mathbb{T}} RelevanceScore(e, t_j)} \quad (1)$$

And the domain vector $\mathbf{d}^{t_i}$ for t_i is:

$$\mathbf{d}_j^{t_i} = \frac{pr(d_j|t_i)}{\sum_{d_k \in \mathbb{D}} pr(d_k|t_i)} \quad (2)$$

$$pr(d_j|t_i) = \frac{\#\ of\ links\ of\ t_i\ in\ domain\ d_j}{\#\ of\ all\ links\ in\ domain\ d_j} \quad (3)$$

Then we'll get a knowledge graph enriched intent description of the query by combining that of e, r, c.

$$\mathbf{t}_i^q = \sum_{e \in E_q} \mathbf{t}_i^e w_q(e) + \sum_{r \in R_q} \mathbf{t}_i^r w_q(r) + \sum_{c \in C_q} \mathbf{t}_i^c w_q(c) \quad (4)$$

$$w_q(e) = NCount_q(e)\varphi(e) \quad (5)$$

Here $\mathbf{t}^e$ $\mathbf{t}^r$ $\mathbf{t}^c$ correspond to the topic vector of each entity, refiner and click respectively. The weight indicates how dominant it is in conveying intent in the query. It is in proportion to the normalized count as well as each occurrence's quality denoted by $\varphi(e)$. Such as for entity words in Equation (5), the quality $\varphi(e)$ can be estimated with the help of entity linking methods, which describes the probability of e as a candidate reference. That for clicks and refiners will be explained later.

The query's domain feature can be calculated as follows:

$$\mathbf{d}_i^q = \frac{\sum_{t_j \in \mathbb{T}} \mathbf{d}_i^{t_j} \mathbf{t}_j^q}{\sum_{d_k \in \mathbb{D}} \sum_{t_j \in \mathbb{T}} \mathbf{d}_k^{t_j} \mathbf{t}_j^q} \quad (6)$$

It describes the probability of query q in domain d_i, in which $\mathbf{t}_j^q$ can be calculated by Equation (4) and $\mathbf{d}_i^{t_j}$ via facts around topic t_j by Equation (2).

2.3 Contextualized intent depiction of sessions

The aforesaid enriched features we get about queries rely heavily on global knowledge in Freebase, reflecting prior distribution in the feature space. In this part, we derive a contextualized description of session intent in a local view by aggregating all the global knowledge we get about the session's queries. The ambiguity of a single query can be alleviated by looking at the dominant domain within the session.

The intent features $\mathbf{t}^s$ and $\mathbf{d}^s$ of session s can be represented by computations on its query set $Q_s = \{q_1, q_2, ...q_n\}$ with time-order decay.

$$\mathbf{t}_i^s = \frac{\sum_{q \in Q_s} \mathbf{t}_i^q \alpha^{rank(q)}}{\sum_{t_j \in \mathbb{T}} \sum_{q \in Q_s} \mathbf{t}_j^q \alpha^{rank(q)}} \quad (7)$$

where we put an exponential decay controlled by decay factor α. We get domain feature the same way as Equation (6).

We'll put up an unsupervised method of learning knowledge graph based intent representation of refiners and clicks in the following part.

3 Propagating intent features in the intent topic graph

In this section, our idea is to characterize entities, refiners and urls uniformly as intent topics, tailoring knowledge graph to intent topic graph so as to enrich representations by propagation.

3.1 Modeling intent topic graph

As in last section, with $\mathbf{d}^s$ featuring the context, candidate intent topics in sessions can make intent topic nodes now. We use the concept *intent topic* to stress words with local contexts tell a specified information need, thus making a node. Taking entity word *fl* as an example, it can be recognized as the topic *Florida* in Freebase, while the intent behind it can hardly be mapped to a single intent topic, such as *travel* domain in *hollywood fl*, *education* domain in *community college in florida*, and *florida department of health* actually convey intent in *government* domain.

So each intent topic node is identified with its name string and Freebase-enriched intent features $\mathbf{t}$ and $\mathbf{d}$. They're directly linked by co-occurring in the same line in the query log and implicitly related via intent features similarities, so that constitute a large graph $G =< V, E, W >$, where $\forall w \in W$ denotes an explicit edge weight and $\forall v \in V$ an intent topic. With intent topics and their relations modeled in a graph, we can better understand the query space so as to find the intended query faster. We realize it by aggregating massive sessions.

The implicit intent similarity $ISim$ of any node pair n and v can be encoded as follows.

$$ISim_{n,v} = \beta SSim_{n,v} + \gamma DSim_{n,v} + \eta TSim_{n,v} \tag{8}$$

where $SSim$ denotes the names' string similarity, $DSim$ the similarity of their domain feature and $TSim$ the topic vector similarity, with β, γ and η controlling the weight. The parameters may vary due to different scenarios. We just provide a framework of modeling nodes' intent features, which actually mirror their proximity in query intent.

To put it in more details, we use jaccard similarity for name shinglings and cosine similarity for domain and topic vector. As query log induced intent topic graph is of considerable large size, the pair-wise similarity is computationally prohibitive, hence we use Local Sensitive Hash (Indyk and Motwani, 1998) for each similarity metric so as to compute $ISim$ just in candidate set. We use random hyperplane based hash family proposed in (Charikar, 2002) and set the hash code dimension and hash table numbers empirically to ensure the number of nodes falling into each bucket is relatively stable.

3.2 Merging nodes

Although our idea of specifying intent topics by context better models the multi-facets of queries, it obviously also brings a sparse issue. For example, in one session user query *beep lyrics* and click *www.lyricsandsongs.com*, *lyrics* is tagged with the song *beep* and the musician *Pussycat Dolls*, in another scenario *lyrics* occurs with the song *what you know* and url *www.dapslyrics.com*, intents behind these two nodes are so similar that they should come into one, otherwise connections between the two intent-coherent urls may be lost.

To avoid that, we conduct a merge process to integrate nodes with exactly the same names and contexts into one, combing linked nodes and intent features together.

For a set of nearly duplicate nodes ω the calculation of new node's features can be written as:

$$\hat{\mathbf{t}} = \frac{\sum_{u \in \omega} \mathbf{t}^u}{|\omega|} \tag{9}$$

$$\hat{\mathbf{d}} = \frac{\sum_{u \in \omega} \mathbf{d}^u}{|\omega|} \tag{10}$$

In other words, we gather candidate nodes retrieved by LSH and then calculate $ISim$ for them with η setting to 0. Only node pairs with $ISim$ higher than a merge threshold θ can be seen as duplicates. The merge process is summarized in Algorithm 1.

Algorithm 1: Merging similar nodes

Input: $G =< V, E, W >, \beta, \gamma, \eta, \theta$
Output: $\hat{G} =< \hat{V}, \hat{E}, \hat{W} >$
begin
  Initialize $\Omega \leftarrow \varnothing$
  for $v \in V$ **do**
    Find dupset ω_v with $ISim_{\beta,\gamma,\eta}$
    if $\exists u \in V, \omega_u \in \Omega$ *and* $\omega_v \cap \omega_u \neq \varnothing$ **then**
      $\omega_v \leftarrow \omega_v \cup \omega_u$
      Remove ω_u from Ω
    Add ω_v to Ω
  for $\omega \in \Omega$ **do**
    Merge nodes in ω into new node $\hat{v}$
    Update G with replacing nodes in ω with $\hat{v}$

3.3 Label propagation

We utilize knowledge graph induced intent features instead of manually labels as constraints to conduct label propagation(Zhu and Ghahramani, 2002). The idea is that node labels are propagated to nearby nodes via weighted edges until convergence, as highly weighted edges indicate high probability of sharing labels.

Nodes in our work have soft labels, where each dimension of intent features denotes a label, such as a topic or domain of knowledge graph. As described in aforesaid observations, it is intuitively reasonable to propagate on the basis of explicit edges and implicit intent similarities. We illustrate the propagation with topic feature, that of domain feature is similar.

We use matrix $\mathbf{Y}^t \in \mathbb{R}^{|V|*|\mathbb{T}|}$ to denote the intent topic graph's initial topic feature labels, with element $\mathbf{Y}^t_{ik}$ indicating node v_i's relevance to t_k, wherer $t_k \in \mathbb{T}$. $\mathbf{Y}^t$ is initialized based on the results of the feature enriching step in Section 2, with no manually-labelled instances needed in our model. As only part of nodes can directly map to Freebase topics, those are initialized as labelled nodes, then propagate $\mathbf{t}$ to their linked neighbors. The number of unlabelled data is written as u, while that of labelled data l and the total number of nodes N.

The transition matrix T indicates the impact of nodes on each other. Note that here the w_{ij} can be replaced by other similarity measures such as $ISim$ in Section 3.2.

$$T_{ij} = \frac{w_{ij}}{\sum_{k=1}^{N} w_{kj}} \tag{11}$$

Let D denote an $N \times N$ diagonal matrix with $d_{ii} = \sum_j T_{ij}$. Then we can get a normalized version of transition matrix $P = D^{-1}T$.

The normalized transition matrix can be split into 4 sub-matrices.

$$P = \begin{bmatrix} P_{ll} & P_{lu} \\ P_{ul} & P_{uu} \end{bmatrix} \tag{12}$$

At each step, we propagate and clamp the labelled data and repeat until Y converges, the propagation step can be written as:

$$\hat{Y_u} = P_{uu}Y_u + P_{ul}Y_l \tag{13}$$

As is shown in (Zhu and Ghahramani, 2002; Zhu et al., 2003) the solution to the propagation converges to:

$$\hat{Y_u} = (I - P_{uu})^{-1}P_{ul}Y_l \tag{14}$$

3.4 The propagation framework for intent features

We carry the propagation in an iterative process illustrated in Algorithm 2.

Algorithm 2: Intent feature propagation

Input: G, Y_l^t,Y_l^d
Output: $\hat{G}$, $\hat{Y}_u^t$, $\hat{Y}_u^d$
Initialize Y_l^t Y^d with results of Section2
repeat
  Merge similar nodes according to Algorithm 1
  Compute matrix P
  repeat
    $\hat{Y}_u^t = P_{uu}Y_u^t + P_{ul}Y_l^t$
  until *Convergence*;
  Recompute $\hat{P}$ with $\hat{Y}^t$
  repeat
    $\hat{Y}_u^d = \hat{P}_{uu}Y_u^d + \hat{P}_{ul}Y_l^d$
  until *Convergence*;
until *no dups*;

Since intent features include both domain vector and topic vector, we propagate them in an alternating way. At first we label nodes as described in Section 2, though missing refiners' and some urls' intent features, they are just used for initialization. Then we propagate Freebase topic features based on explicit edge weights, so that more nodes in intent topic graph have topic features now. Then fetching the learned topic features, we reinput it into domain feature propagation, which means we recalculate the transition matrix combining the implicit learned $TSim$ into edge weight, then propagate domain vector of labelled nodes through the graph. At each iteration, we first update Y^t, then input it to update Y^d, therefore merge near duplicate intent topics to update the whole graph.

4 Experiments

4.1 Data preparation

4.1.1 Search logs

We use AOL search log data for experiments. It includes 20 million web queries collected covering 500K users over three months in 2006.

Table 1: The query set

# of sessions	35140
# of queries	271127
# of users	21378
# of urls	63019

We preprocess the query log by keeping urls occurring more than 3 times and queries with 2 to 40 characters, then extract sessions considering 25 minutes duration. While user session segmentation can be improved with more sophisticated algorithms, this simple low-cost heuristic performs adequately for our purposes. We then move on to map queries to Freebase and empirically filter sessions that are less entity-centric. We use an annotation tool especially for short text (Ferragina and Scaiella, 2012) called Tagme[3] to recognize entities and observe only 16% of all the queries are exactly an entity itself, which means most of queries do have refiner words to convey information need. To ensure the precision of recognized entities, we set a significant threshold and bottom line threshold , queries should have at least one recognized entity with a likelihood above significant level, and those below bottom line are ignored. They are 0.19 and 0.05 in our work, which may vary with entity recognition method. The normalized

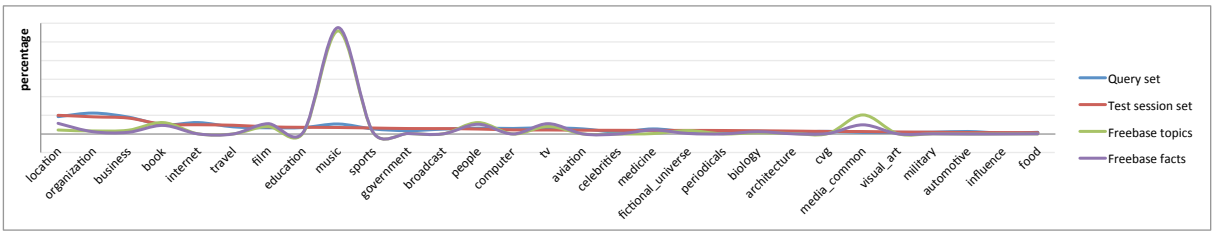

Figure 1: Unbalanced domain distributions in Freebase comparing against query set. Only domains with top proportions are shown.

Table 2: Examples of labelled intent topic nodes with learned feature

Intent topic nodes	Original in Freebase	After propagation	Annotation
travel.yahoo.com	Yahoo! Travel (internet, 0.87), (projects, 0.13)	(location, 0.13), (travel, 0.11), (organization, 0.08), (business, 0.08) ...	Yahoo! Travel offers travel guides, booking and reservation services.
map quest www.mapquest.com	MapQuest (organization, 0.6), (book, 0.4)	(location, 0.13), (organization, 0.09), (travel, 0.09), (automotive, 0.06)...	MapQuest is an American free online web mapping service.

likelihood is used as $w_q(e)$. Then we drop sessions where tagged entity words weight less than refiners as well as the ones with too many entity words spotted indicating disperse intents. For each recognized entity, only Freebase topics with relevance over 0.3 are kept. The query set we finally get is shown in Table 1.

4.1.2 Freebase

To enrich query representations, we collect a subset of Freebase including more than 7 millions facts and 4 millions topics in total which also contain 150 thousand topical equivalent websites, though less than 3% urls in query set are covered.

The facts and entities in Freebase is rather unbalanced across domains especially against that of recoginized entities in query set as shown in Figure 1. Thus the original global knowledge we use about domain distribution may cause bias, which makes *tailoring* necessary for intent understanding.

For both generality and precision, we keep most of Freebase domains except several extreme incomplete ones, instead of retaining a small number of *representative* domains like many researchers do (Li et al., 2013; Yu et al., 2014; Lin et al., 2012). But generality comes at a price that some domains are confusing and mixed used which we then choose to merge, like celebrities and people, periodicals and books, tv and broadcast, etc. We finally keep 50 of all 76 domains.

4.2 Intent topic graph

4.2.1 Building the graph

We leverage both Freebase and search sessions to enrich intent topics. We set α to 0.9 in calculation of session's intent features. After labeling the session log, we roughly make a graph with 335206 intent topic nodes, 119364 of them have been labelled with Freebase topic feature, others only have domain feature. Then we conduct a merge process with β set to 0.7, γ to 0.3 and θ to 0.75 in order to merge nodes with duplicate names and similar contexts. We find 46659 duplicate sets covering 140768 nodes. Then we ignore nodes with few links and rare names to reduce sparsity. Finally we've got a graph of 209351 intent topics to initialize the propagation, including 78932 labelled nodes. The merge and propagation progress get converged in less than 4 rounds.

We'll further evaluate the graph with case study and a session intent understanding task.

4.2.2 Case Study

We demonstrate intent features are good interpretations for query intent, whether they're labelled in Section 2 or learned by propagation in Section 3.

We can see in Table 2 that as nodes' original

types in Freebase are not proper for describing intent, the intent features they get after propagation tend to be more explainable, such as the travel site often co-occurs with city names, tourist attractions, hotels and so on, thus indicating its intent in travel and location domain.

Table 3 shows examples which have no equivalents in Freebase. Although some of them may be accessible in other ontologies, we only take them as examples to show our propagation method makes it possible to depict intents behind urls and words in a knowledge graph based way while beyond the capacity of knowledge graph.

4.3 Session intent understanding task

4.3.1 Experiment Setup

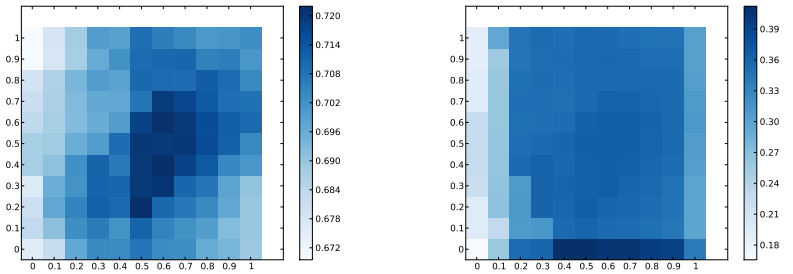
The evaluation of query understanding has long been a challenging task. To judge whether the concepts in query are successfully recognized seems too straightforward, and it can hardly be considered *understanding* the intent until the big idea about what *kind* of topics users emphasis is captured, which can be briefly sketched by distribution across Freebase domains. Also it is difficult to translate results of previous log analysis methods into knowledge graph domain information, thus hardly fit into our evaluation schema. We take popularity-based method as baseline.

We have few choices but to tag ground truth ourselves for intent understanding evaluation.

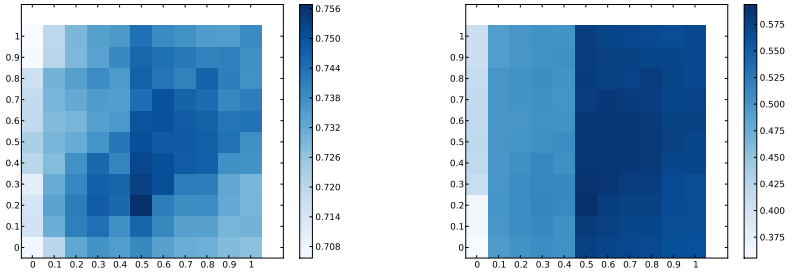
We randomly select 150 sessions as test set, the domain distribution of which agrees with the whole query set as shown in Figure 1. As mastering meanings of all Freebase domains is too challenging, we ask 5 accessors to describe each session's intent broadly with a few natural language terms, then an expert familiar with Freebase schema translates the words into matched Freebase domains. Each test session is tagged by 2 accessors and 1 expert, we choose to use the tags of the cases in which the accessors reached agreement as the gold stantard. For example, if accessors tag session intent as pictures, then experts can translate it into Freebase visual art domain. Each session has 1$\sim$4 tags and 1.6 tags in average. The tags cover 30 domains.

For each session, we derive the local intent domain vector $\mathbf{d}^s$ following the method in Section 2. Here we simply set quality function $\varphi(r)$ to a constant λ^r for all refiners and $\varphi(c)$ to λ^c for all clicks, we'll dive into more specialized weighting method in future work. λ^r and λ^c are parameters to control impact of different kinds of intent topics. Based on whether to exploit global intent features of non-entity words, we compare four variations against one baseline.

- Popularity-based (GP). We use domains' frequency in the query set as a baseline.
- Entity-based (E). We only use entity nodes' original intent features without propagation.
- Entity+Clicks (EC). Both intent features of entity words and clicks are used, controlled with λ^c.
- Entity+Refiners (ER). Intent features of entity words and refiner words are used, refiners' impact is controlled by λ^r.
- Entity+Clicks+Refiners (ECR). All intent topics are combined, controlled by λ^c, λ^r.



(a) $MAP@5$ (b) $GMAP@5$



(c) $MAP@10$ (d) $GMAP@10$

Figure 2: The impact of $\lambda^r$and λ^c on ECR methods in four metrics, with vertical axis indicating λ^r, horizontal axis as λ^c. The first column on the left denotes ER method, while the bottom row the EC method.

4.3.2 Evaluation metrics

We use each approach to rank domains according to its derived weight, then compare it with golden standard set. It can be evaluated using Mean Average Precision (MAP), Geometric MAP and Precision@K. We use GMAP because it is more robust to outliers than the arithmetic mean.

For test set of size N, the MAP and GMAP can be calculated as follows:

$$MAP@k = \frac{1}{N}\sum_{i=1}^{N} AP_i@k \tag{15}$$

$$GMAP@k = \sqrt[N]{\prod_{i=1}^{N} AP_i@k} \tag{16}$$

4.3.3 Results and analysis

We first study impact of parameters λ^r and λ^c, which is shown in Figure 2.

It roughly demonstrates different combinations of parameters' impact on ECR methods, performance is evaluated in four metrics, with deeper color indicating better result.

Best results comes with a λ^c larger than λ^r in all four subfigures. This trend seems more obvious in (d) where right part with larger λ^c get better results. Also, deeper colors around diagonal line in (a) (c) indicate a more balanced combination of refiners and urls are more likely to enhance intent understanding. Thus we conclude clicks has a weak advantage over refiners in improving the result, while combining both with proper parameters can get the best result.

When comparing between MAP and GMAP, we can see while GMAP stays a high value when amplifying the impact of clicks, MAP changes with the variation of λ^r for better or worse. As GMAP is a more robust metric, we can then infer that increasing weight of refiners could bring more outliers, implying refiners' intent features are more susceptible to noise.

Then we use ER with $\lambda^r = 0.5$ as ER^{opt}, EC with $\lambda^c = 0.5$ as EC^{opt} and ECR with $\lambda^r = 0.2, \lambda^c = 0.5$ as ECR^{opt}.

Figure 3 clearly shows the superior performance of our model, especially at top positions. Table 4 shows the detailed comparisons between different methods. We can see our knowledge graph based intent representations perform well in session intent understanding. And refiners' and clicks' intent features which we learn by propagation con-

tribute a lot to improve naive entity-based method, which do validate an complment effect of their learned intent features.

5 Related Work

5.1 Query intent understanding

Query intent or search intent has been studied intensively from various views.

A popular paradigm is to label several intents for each query, also called facets subgoals and subtopics in the literature, manully or by mining methods and then do classification (Hu et al., 2009; Li et al., 2008) based on that. Manually intent schemas range from 3 top level (Broder, 2002) to fine-grained subcatogories (Rose and Levinson, 2004) and taxonomy (Yin and Shah, 2010). Intent tasks in NTCIR-10 (Sakai et al., 2013) also provide subtopic pools made by accessors.

Another view of intent is more generic, mining or learning search intents without any kind of pre-defined intent category and clustering method is often used. Methods including (Sadikov et al., 2010; Yamamoto et al., 2012; Cheung and Li, 2012) cast intent as represented by a pattern or template consisting of a sequence of semantic concepts or lexical items. (Tan et al., 2012) encode intent in language models, aware of long-lasting interests. (Ren et al., 2014) uses an unsupervised heterogeneous clustering. (Yin and Shah, 2010) capture generic intents around a certain named entities and model their relationships in a tree taxonomy and (Wang et al., 2009) mine broad latent modifiers of intent aspect , which are similar to our motivation, while we model more than intent phrases, but intent topics. We do not split queries into clusters or subtopics relevant to the original query to indicate a intent, but link them in an graph with intent feature similarity, weakly or strongly, in a holistical view.

On the other hand, previous research can be categorized by what kind of resources they rely on. Quite an amount of work leverage query logs (Jiang et al., 2013), including query reformulations (Radlinski et al., 2010), click-through data (Li et al., 2008). There are also works using sponsered data (Yamamoto et al., 2012) and interactive data (Ruotsalo et al., 2013). The new trend of integrating knowledge graph will be discussed next.

5.2 Knowledge graph on intent understanding

Instead of summarizing queries into concepts by clustering, recently there appears a tendency to use concpets from knowledge graph resources. Some researchers manage to build entity graph from queries (Bordino et al., 2013a) (Bordino et al., 2013b; Yu et al., 2014), some in a structure view, interpret quries into knowledge base fit template (Pound et al., 2012; Li et al., 2013). (Pantel et al., 2012) models latent intent to mine entity type distributions. (Ren et al., 2014) utilizes knowledge graph resources in a hetrogeneous view. (Lin et al., 2012) also pays attention to refiners, but restricted to limited domains, while our method is more general.

6 Conclusion

In this paper, we tailor knowledge graph to represent query intent behind entity words, refiners and clicked urls in a unified framework, taking them as intent topic nodes connected in a large graph. We manage to get a contextualized intent depiction exploiting global knowledge in Freebase, then propagate the feature to cover more intent topics. We show in experiments the knowledge graph enriched representation is reasonable and explainable, and the intents feature of refiners and clicks can better enhance intent understanding than methods simply relying on entities.

There are several directions for future work, including using both types and domains in Freebase schema, diving into refiners and looking for a proper weighting method, developing a query recommendation framework based on the intent topic graph and user interest modeling.

Acknowledgments

We sincerely thank all the anonymous reviewers for their valuable comments, which have helped to improve this paper greatly. This work is supported by NSFC with Grant No.61370054, and 973 Program with Grant No.2014CB340405.

Queries as a Source of Lexicalized Commonsense Knowledge

Abstract

The role of Web search queries has been demonstrated in the extraction of attributes of instances and classes, or of sets of related instances and their class labels. This paper explores the acquisition of open-domain commonsense knowledge, usually available as factual knowledge, from Web search queries. Similarly to previous work in open-domain information extraction, knowledge extracted from text - in this case, from queries - takes the form of lexicalized assertions associated with open-domain classes. Experimental results indicate that facts extracted from queries complement, and have competitive accuracy levels relative to, facts extracted from Web documents by previous methods.

1 Introduction

Motivation: Open-domain information extraction methods (Etzioni et al., 2005; Pennacchiotti and Pantel, 2009; Wang and Cohen, 2009; Kozareva and Hovy, 2010; Wu et al., 2012) aim at distilling text into knowledge assertions about classes, instances and relations among them (Etzioni et al., 2011). Ideally, the assertions would complement or expand upon knowledge available in popular, human-created resources such as Wikipedia (Remy, 2002) and Freebase (Bollacker et al., 2008), reducing costs and scalability issues associated with manual editing, curation and maintenance of knowledge.

Candidate knowledge assertions extracted from text for various instances and classes (Banko et al., 2007; Cafarella et al., 2008; Wu and Weld, 2010) must satisfy several constraints in order to be useful. First, their boundaries must be correctly identified within the larger context (e.g., a document sentence) from which they are extracted. In practice, this is a challenge with arbitrary Web documents, where even instances and class labels that are complex nouns, and thus still shorter than candidate assertions, are difficult to precisely detect and pick out from surrounding text (Downey et al., 2007). This causes the extraction of assertions like *companies* may *"be in the process"*, *hurricanes* may *"run from june"*, or *video games* may *"make people"* (Fader et al., 2011). Second, the assertions must be correctly associated with their corresponding instance or class. In practice, tagging and parsing errors over documents of arbitrary quality may cause the extracted assertions to be associated with the wrong instances or classes. Examples are *video games* may *"watch movies"*, or *video games* may *"read a book"*. Third, the assertions, even if true, must refer to relevant properties or facts, rather than to statements of little or no practical interest to anyone. In practice, relevant properties may be difficult to distinguish from uninteresting statements in Web documents. Consequently, assertions extracted from Web documents include the facts that *companies* may *"say in a statement"*, or that *hurricanes* may *"be just around the corner"* or may *"be in effect"*.

Contributions: This paper explores the use of Web search queries, as opposed to Web documents, as a textual source from which knowledge pertaining to open-domain classes can be extracted. Previous explorations of the role of queries in information extraction include the acquisition of attributes of instances (Alfonseca et al., 2010) and of classes (Van Durme and Paşca, 2008); the acquisition of sets of related

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1081–1091,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

instances (Sekine and Suzuki, 2007; Jain and Pennacchiotti, 2010) and their class labels (Van Durme and Paşca, 2008; Pantel et al., 2012); the disambiguation of instances mentioned in queries relative to entries in external knowledge repositories (Pantel and Fuxman, 2011) and its application in query expansion (Dalton et al., 2014); and the extraction of the most salient of the instances mentioned in a given Web document (Gamon et al., 2013). In comparison, this paper shows that queries also lend themselves to the acquisition of factual knowledge beyond attributes, like the facts that *companies* may *"buy back stock"*, *hurricanes* may *"need warm water"*, and *video games* may *"come out on tuesdays"*.

To extract knowledge assertions for diverse classes of interest to Web users, the method applies simple extraction patterns to queries. The presence of the source queries, from which the assertions are extracted, is in itself deemed evidence that the Web users who submitted the queries find the assertions to be relevant and not just random statements. Experimental results indicate that knowledge assertions extracted from queries complement, and have competitive accuracy levels relative to, knowledge extracted from Web documents by previous methods.

2 Extraction from Queries

Queries as Knowledge: Users tend to formulate their Web search queries based on knowledge that they already possess at the time of the search (Paşca, 2007). Therefore, search queries play two roles simultaneously: in addition to requesting new information, they indirectly convey knowledge in the process.

A fact corresponds to a property that, together with other properties, help define the semantics of the class and its interaction with other classes. The extraction of factual knowledge from queries starts from the intuition that, if a fact F is relevant for a class C, then users are likely to ask for various aspects of the fact F, in the context of the class C. If *companies* may *"pay dividends"* or *"get audited"*, and such properties are relatively prominent for *companies*, then users eventually submit queries to inquire about the facts.

Often, queries will be simple concatenations of keywords: *"companies pay dividends"* or perhaps *"company dividends"*, *"audit companies"*. Since there are no restrictions on the linguistic structure

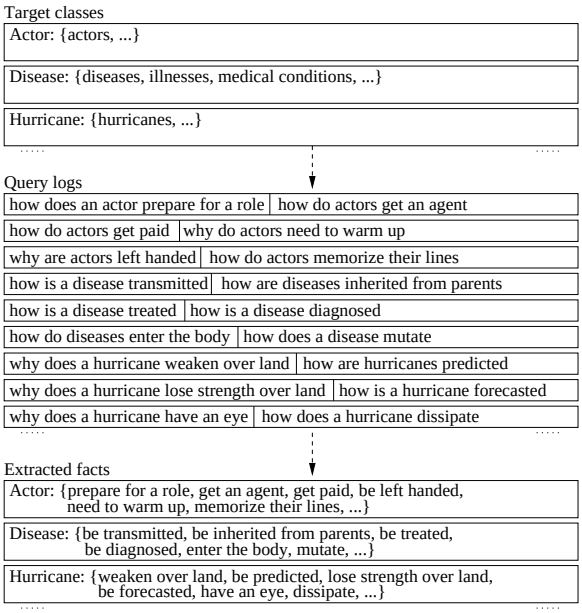

Figure 1: Overview of extraction of knowledge from Web search queries

of keyword-based queries, extracting facts from such queries would be difficult. But if queries are restricted to fact-seeking questions, the expected format of the questions makes it easier to identify the likely boundaries of the class and the fact mentioned in the queries. Queries such as *"why does a (company)$_C$ (pay dividends)$_F$"* and *"how do (companies)$_C$ (get audited)$_F$"*, follow the linguistic structure, even if minimal, imposed by formulating the query as a question. This allows one to approximate the location of the class C, possibly towards the beginning of the query; the start of the fact F, possibly as the verb immediately following the class; and the end of the fact, which possibly coincides with the end of the query.

Acquisition from Queries: The extraction method proposed in this paper takes as input a set of target classes, each of which is available as a set of class descriptors, i.e., phrases that describe the class. It also has access to a set of anonymized queries. As illustrated in Figure 1, the method selects queries that contain a class descriptor and what is deemed to be likely a fact. It outputs ranked lists of facts for each class. The extraction consists in several stages: 1) the selection of a subset of queries that refer to a class in a form that suggests the queries inquire about a fact of the class; 2) the extraction of facts, from query fragments that describe the property of interest to users submitting the queries; and 3) the aggregation and

ranking of facts of a class.

Extraction Patterns: In order to determine whether a query contains a fact for a class, the query is matched against the extraction patterns from Table 1.

The use of targeted patterns in relation extraction has been suggested before (Hearst, 1992; Fader et al., 2011; Mesquita et al., 2013). Specifically, in (Tokunaga et al., 2005), the patterns *"A of D"* or *"what is the A of D"* extract noun-phrase A attributes from queries and documents, for phrase descriptors D of the class. In our case, the patterns are constructed such that they match questions that likely inquire about the reason why, or manner in which, a relevant fact F may hold for a class C. For example, the first pattern from Table 1 matches the queries *"why does a company pay dividends"* and *"why do video games come out on tuesdays"*. These queries seek explanations for why certain properties may hold for *companies* and *video games* respectively.

A class C can be mentioned in queries through lexicalized, phrase descriptors D that capture its meaning. The descriptors D of the class C may be available as non-disambiguated items, i.e., as strings (*companies*, *firms*, *businesses*, *video games*); or as disambiguated items, that is, as pointers to knowledge base entries with a disambiguated meaning (*Company*, *Video Game*). In the first case, the matching of a query fragment, on one hand, to the portion of an extraction pattern corresponding to the class C, on the other hand, consists in simple string matching with one of the descriptors D specified for C. In the second case, the matching requires that the disambiguation of the query fragment, in the context of the query, matches the desired disambiguated meaning of C from the pattern. The subset of queries matching any of the extraction patterns, for any descriptor D of a class C, are the queries that contribute to extracting facts of the class C.

If a pattern from Table 1 employs a form of the auxiliary verb *"be"*, the extracted facts are modified by having the verb *"be"* inserted at their beginning. For example, the fact *"be stored sideways"* is extracted from the query *"why is wine stored sideways"*. In all patterns, the candidate fact is required to start with a verb that acts as the predicate of the query.

Ranking of Facts: Facts of a class C are aggregated from facts of individual class descriptors D.

Extraction Pattern → Examples of Matched Queries
why [does|did|do] [a|an|the|<nothing>] D F → why does a (company)$_D$ (pay dividends)$_F$ → why do (planes)$_D$ (take longer to fly west than east)$_F$ → why do (video games)$_D$ (come out on tuesdays)$_F$
why [is|was|were] [a|an|the|<nothing>] D F → why are (cars)$_D$ (made of steel)$_F$ → why is a (newspaper)$_D$ (written in columns)$_F$ → why is (wine)$_D$ (stored sideways)$_F$
how [does|did|do] [a|an|the|<nothing>] D F → how does a (company)$_D$ (use financial statements)$_F$ → how does (food)$_D$ (get absorbed)$_F$ → how do (stadiums)$_D$ (get cleaned)$_F$
how [is|was|were] [a|an|the|<nothing>] D F → how are (hurricanes)$_D$ (predicted)$_F$ → how is a (treaty)$_D$ (ratified)$_F$ → how is a (cell phone)$_D$ (unlocked)$_F$

Table 1: The extraction patterns match queries likely to inquire about facts of a class (D=a phrase acting as a class descriptor; F=a sequence of tokens whose first token is the head verb of the query)

A fact F is deemed more relevant for C if the fact is extracted for more of the descriptors D of the class C, and for fewer descriptors D that do not belong to the class C. Concretely, the score of a fact for a class is the lower bound of the Wilson score interval (Brown et al., 2001):

$$Score(F, C) = LowBound(Wilson(N_+, N_-))$$

where:

- the number of positive observations N_+ is the number of queries for which the fact A is extracted for some descriptor D of the class C, $|\{Query(D, A)\}_{D \in C}|$; and
- the number of negative observations N_- is the number of queries for which the fact F is extracted for some descriptors D outside of the class C, $|\{Query(D, A)\}_{D \notin C}|$.

The scores are internally computed at 95% confidence. Facts of each class are ranked in decreasing order of their scores. In case of ties, facts are ranked in decreasing order of the frequency sum of the source queries from which the facts are extracted.

3 Experimental Setting

Textual Data Sources: The experiments rely on a random sample of around 1 billion fully-anonymized Web search queries in English. The sample is drawn from queries submitted to a general-purpose Web search engine. Each query is available independently from other queries, and is accompanied by its frequency of occurrence in

Target Class (class descriptors to be looked up in queries)	
Actor (actors)	Mountain (mountains)
Aircraft (planes)	Movie (movies)
Award (awards)	NationalPark (national parks)
Battle (battles)	NbaTeam (nba teams)
Car (cars)	Newspaper (newspapers)
CartoonChar (cartoon characters)	Painter (painters)
CellPhone (cell phones)	ProgLanguage (programming languages)
ChemicalElem (elements)	Religion (religions)
City (cities)	River (rivers)
Company (companies)	SearchEngine (search engines)
Country (countries)	SkyBody (celestial bodies)
Currency (currencies)	Skyscraper (skyscrapers)
DigitalCamera (digital cameras)	SoccerClub (soccer teams)
Disease (diseases)	SportEvent (sport events)
Drug (drugs)	Stadium (stadiums)
Empire (empires)	TerroristGroup (terrorist groups)
Flower (flowers)	Treaty (treaties)
Food (foods)	University (universities)
Holiday (holidays)	VideoGame (video games)
Hurricane (hurricanes)	Wine (wines)

Table 2: Set of 40 target classes used in the evaluation of extracted facts

the query logs.

Target Classes: Table 2 shows the set of 40 target classes for evaluating the extracted facts. Similar evaluation strategies were followed in previous work (Paşca, 2007). As illustrated earlier in Figure 1, a target class consists in a small set of phrase descriptors. The phrase descriptors are selected such that they best approximate the meaning of the class. In general, the descriptors can be selected and expanded with any strategy from any source. One such possible source might be synonym sets from WordNet (Fellbaum, 1998). Following a stricter strategy, the sets of descriptors in our experiments contain only one phrase each, manually selected to match the target class. Examples are the sets of phrase descriptors {*actors*} for the class *Actor* and {*nba teams*} for *NbaTeam*. The occurrence of a descriptor (*nba teams*) in a query (*"how do nba teams make money"*) is deemed equivalent to a mention of the corresponding class (*NbaTeam*) in that query. Each set of descriptors of a class is then expanded (not shown in Table 2), to also include the singular forms of the descriptors (e.g., *nba team* for *nba teams*). Further inclusion of additional descriptors would increase the coverage of the extracted facts.

Experimental Runs: The baseline run R_D is the extraction method introduced in (Fader et al., 2011). The method produces triples of an instance or a class, a text fragment capturing a fact, and another instance or class. In these experiments, the second and third elements of each triple are concatenated together, giving pairs of an instance or a class, and a fact applying to it. The baseline run is applied to around 500 million Web documents in English. [1] In addition to the baseline run, the method introduced in this paper constitutes the second experimental run R_Q. Facts extracted by the two experimental runs are directly comparable: both are text snippets extracted from the respective sources of text - documents in the case of R_D, or queries in the case of R_Q.

Parameter Settings: Queries that match any of the extraction patterns from Table 1 are syntactically parsed (Petrov et al., 2010), in order to verify that the first token of an extracted fact is the head verb of the query. Extracted facts that do not satisfy the constraint are discarded. A positive side effect of doing so is to avoid extraction from some of the particularly subjective queries. For example, facts extracted from the queries *"why is (A) evil"* or *"why is (B) ugly"*, where *(A)* and *(B)* are the name of a company and actress respectively, are discarded.

4 Evaluation Results

Accuracy: The measurement of recall requires knowledge of the complete set of items (in our case, facts) to be extracted. Unfortunately, this number is often unavailable in information extraction tasks in general (Hasegawa et al., 2004), and fact extraction in particular. Indeed, the manual enumeration of all facts of each target class, to measure recall, is unfeasible. Therefore, the evaluation focuses on the assessment of accuracy.

Following evaluation methodology from prior work (Paşca, 2007), the top 50 facts, from a ranked lists extracted for each target class, are manually assigned correctness labels. A fact is marked as *vital*, if it must be present among representative facts of the class; *okay*, if it provides useful but non-essential information; and *wrong*, if it is incorrect (Paşca, 2007). For example, the facts *"run on kerosene"*, *"be delayed"* and *"fly wiki"* are annotated as *vital*, *okay* and *wrong* respectively for the class *Aircraft*. To compute the precision score

[1] At the time when the experiments were conducted, the facts were extracted by the baseline run from English documents in the ClueWeb collection, and were accessible at http://reverb.cs.washington.edu.

Target Class: Sample of Extracted Facts (with Source Queries)	Target Class: Sample of Extracted Facts (with Source Queries)
Actor (may): prepare for a role (how does an actor prepare for a role), get an agent (how do actors get an agent), do love scenes (how do actors do love scenes), get paid (how do actors get paid), be left handed (why are actors left handed), need to warm up (why do actors need to warm up)	Car (may): backfire (why does a car backfire), burn oil (why do cars burn oil), pull to the right (why do cars pull to the right), pull to the left (why does a car pull to the left), catch on fire (how does a car catch on fire), run hot (why do cars run hot), get repossessed (why do cars get repossessed)
Company (may): buy back stock (how does a company buy back stock), go public (why does a company go public), buy back shares (why do companies buy back shares), incorporate in delaware (why do companies incorporate in delaware), pay dividends (why does a company pay dividends), merge (how do companies merge)	Disease (may): be transmitted (how is a disease transmitted), be inherited from parents (how are diseases inherited from parents), affect natural selection (how do diseases affect natural selection), be treated (how is a disease treated), affect the conquest of the americas (how did diseases affect the conquest of the americas), be diagnosed (how is a disease diagnosed)
Hurricane (may): weaken over land (why does a hurricane weaken over land), be predicted (how are hurricanes predicted), lose strength over land (why does a hurricane lose strength over land), have an eye (why does a hurricane have an eye), be forecasted (how is a hurricane forecasted), dissipate (how does a hurricane dissipate), lose strength (how do hurricanes lose strength)	NbaTeam (may): make money (how does an nba team make money), communicate to win (how does an nba team communicate to win), want expiring contracts (why do nba teams want expiring contracts), make the playoffs (how do nba teams make the playoffs), get their names (how do nba teams get their names), do sign and trades (why do nba teams do sign and trades), lose money (how do nba teams lose money)

Table 4: Relative accuracy of facts extracted from documents in run R_D, vs. facts extracted from queries in run R_Q

over a set of facts, the correctness labels are converted to numeric values: *vital* to 1.0, *okay* to 0.5, and *wrong* to 0.0. Precision is the sum of the correctness values of the facts, divided by the number of facts. Table 3 shows a sample of facts extracted from queries by run R_Q, which are judged to be *vital* or *okay*.

Table 4 provides a comparison of precision at ranks 10, 20 and 50, for each of the 40 target classes and as an average over all target classes. The scores vary from one class to another and between the two runs, for example 0.22 (R_D) and 0.73 (R_Q) for the class *Currency* at rank 50, but 0.77 (R_D) and 0.59 (R_Q) for *Treaty*. Run R_Q fails to extract any facts for two of the target classes, *SkyBody* and *SportEvent*. Therefore, it receives no credit for those classes during the computation of precision.

Over all target classes, run R_Q is superior to run R_D, with relative precision boosts of 65% (0.71 vs. 0.43) at rank 10, 67% at rank 20, and 65% at rank 50. The results show that facts extracted from

Run: [Ranked Facts Extracted from Text for a Sample of Classes]
Class: Actor (may):
R_D: [do a great job, get the part, play their roles, play their parts, play their characters, be on a theatre, die aged 81, be all great, deliver their lines, portray their characters, take on a role, be best known for his role, play the role of god, be people, give great performances, bring the characters to life, wear a mask, be the one, have chemistry, turn director, read the script, ..]
R_Q: [prepare for a role, get an agent, do love scenes, get paid, be left handed, need to warm up, get started, get paid so much, memorize their lines, get ripped so fast, remember their lines, make themselves cry, learn their lines, jump out of a window in times square, lose weight so fast, play dead, be paid, kiss, remember lines, memorize lines, get discovered, get paid for movies, go uncredited, say break a leg, get their start, have perfect skin, become actors, ..]
Class: Car (may):
R_D: [get a tax write-off, can be more competitive than airline rates, be in good condition, be first for second hand cars, be in the shop, relocate to a usa firm, be in motion, come to a stop, hire companies, be in great shape, be for sale, hire service from spain, ride home, be on fire, use the autos.com, come to a halt, catch fire, be on road, be on display, go on sale, hit a tree, be available for delivery, stop in front, be a necessity, go off the road, pull out in front, hire services, run out of gas, ..]
R_Q: [backfire, burn oil, save ostriches from extinction, pull to the right, pull to the left, catch on fire, run hot, sputter, get repossessed, have a top speed, be called a car, have gears, get impounded, be called cars, go to auction, called whip, made of steel, get hot in the sun, shake at high speed, changed america, totaled, cut out, cut off while driving, fail emissions, protect from lightning, run rich, lose oil, become electrically charged, cut off, flip over, know tire pressure, have a maximum speed, require premium gas, shake at high speeds, stall out, cause acid rain, fog up, get stuck in park, need an oil change, ..]
Class: Company (may):
R_D: [say in a statement, specialize in local moves, be in the process, go out of business, have been in business, be in business, do business, file for bankruptcy, make money, be on track, say in a press release, be a place, have cut back on health insurance, state in a press release, be on the verge, save money, be in talks, have helped thousands of consumers, reduce costs, go bust, be in the midst, say in a release, be founded in 1999, be in trouble, be founded in 2000, be losing money, ..]
R_Q: [buy back stock, go public, buy back shares, incorporate in delaware, pay dividends, merge, go global, go international, use financial statements, verify education, expand internationally, go green, verify employment, need a website, choose to form as a corporation, do market research, go private, diversify, go into administration, get on angies list, pay dividend, struck off, buy back their shares, get audited, need a mission statement, repurchase common stock, spin off, get listed on the nyse, create value, distribute dividends, need a strategic plan, ..]
Class: Mountain (may):
R_D: [spot fever, meet the sea, be covered with snow, be covered in snow, be the place, come into view, be on fire, be fun, fly fishing, be volcano, be moved out of their places, enjoy the exhilaration, meet the ocean, be available for hire, keep their secrets, win the mwc in 2010, ..]
R_Q: [affect rainfall, affect the climate of an area, affect climate, be measured, be formed, be created, be made, grow, affect weather, have snow on top, affect solar radiation, affect temperature, be formed ks2, affect the weather, be built, affect people, look blue, tops cold, affect neighboring climates, be formed video, help shape the development of greek civilization, be made for kids, occur, affect the climate, be formed, be formed wikipedia, have roots, affect precipitation, exist, affect life on earth, be formed kids, float in avatar, erode, have snow on the top, affect the political character of greece, help rain form, ..]

Table 5: Comparative top facts extracted for a sample of classes from documents (R_D) or queries (R_Q)

queries have higher levels of accuracy.

Facts from Documents vs. Queries: Table 5 compares the top facts extracted by the two experimental runs for a sample of target classes. Most commonly, erroneous facts are extracted by run R_D due to the extraction of relatively uninteresting properties (a *Company* may *"say in a statement"* or *"be in the process"*). Other errors in R_D are caused by wrong boundary detection of facts within documents (a *Company* may *"be in the midst"*), or by the association of a fact with the wrong instance or class (a *Car* may *"hire companies"* or *"hire services"*).

As for facts extracted by run R_Q, they are sometimes too informal, due to the more conversational nature of queries when compared to documents. Queries may suggest that a *Car* may *"know tire pressure"*. Occasionally, similarly to facts from documents, they have wrong boundaries (a *Mountain* may *"be made for kids"* or *"be formed wikipedia"*); and they may correspond to less interesting, or too specific, properties (a *Company* may *"incorporate in delaware"*). Lastly, queries may appear to be questions, but occasionally they really are not. An example is the query *"why did the actor jump out of the window in times square"*, which may refer to a joke. When such queries match one of the extraction patterns, they produce wrong facts. Overall, Table 5 corroborates the scores from Table 4. It suggests that a) facts extracted by either R_D or R_Q still need refinement, before they can capture essential characteristics of the respective classes and nothing else; and b) facts extracted in run R_Q have higher quality than facts extracted in run R_D. Indeed, because fact-seeking queries inquire about the value (or reason, or manner) of some relations of an instance, the facts themselves tend to be more relevant than facts extracted from arbitrary document sentences.

An issue related to facts extracted from text

is their ability to capture the kind of "obvious" commonsense knowledge (Zang et al., 2013) that would be essential for machine-driven reasoning. If it is obvious that *"teachers give lectures"*, how likely is it for such information to be explicitly stated in documents or, even more interestingly, inquired about in queries? Anecdotal evidence gathered during experimentation suggests that queries do produce many commonsense facts, perhaps even surprisingly so given that a) queries tend to be shorter and grammatically simpler than document sentences; and b) the patterns in Table 1 are relatively more restrictive than the patterns used in (Fader et al., 2011). Indeed, the patterns in Table 1, when applied to queries like *"why do teachers give homework"*, *"why do teachers give grades"*, actually produce commonsense knowledge that *teachers* give *homework*, *grades* (to their students). In fact, the quality of equivalent facts extracted from documents in (Fader et al., 2011) may be lower. Concretely, facts extracted in (Fader et al., 2011) state that what *teachers* give is *students*, *class*, *homework* and *feedback*, in this order. The first two of these extractions are errors, likely caused by the incorrect detection of complex entities and their inter-dependencies in document sentences (Downey et al., 2007).

A necessary condition for the usefulness of extracted facts is that the source text contain consistent, true information. But both documents and queries may contain contradictory or false information, whether due to unsupported conjectures, unintended errors or systematic campaigns that fall under the scope of adversarial information retrieval (Castillo and Davison, 2011). The phenomena potentially affect prior work on Web-based open-domain extraction, and potentially affect the quality of facts extracted from queries in this paper. For example, facts extracted from queries like *"why do companies like obamacare"* and *"why do companies hate obamacare"* would be inconsistent, if not incorrect.

Occasionally, facts extracted from the two text sources refer to the same properties. For example, a *VideoGame* may *"be good for the hand-eye coordination"*, according to documents; and may *"improve hand eye coordination"*, according to queries. Nevertheless, facts derived from queries likely serve as a complement, rather than replacement, of facts from documents. In particular, facts extracted from queries make no attempt to isolate the value of the respective properties, whereas facts extracted from documents usually do.

Stricter Comparison of Data Sources: In the experiments described so far, distinct sets of patterns are applied in the experimental runs to documents vs. queries. More precisely, run R_D applies the patterns introduced in (Fader et al., 2011) to document sentences, whereas run R_Q the patterns shown in Table 1 to queries. To more accurately gauge the role of queries vs. documents in extracting facts from unstructured text, additional experiments isolate the effect of extracting facts from different types of data sources. For this purpose, the same set of patterns from Table 1 is matched against the sentences from around 500 million Web documents. The patterns are applied to document sentences converted to lowercase, similarly to how they are applied to queries. This corresponds to a new experimental run R_{DS}, which employs the same patterns as the earlier run R_Q but runs over document sentences instead of queries.

As an average over the target classes, the precision of facts extracted by run R_{DS} is 0.50, 0.47 and 0.44 at ranks 10, 20 and 50 respectively. Two conclusions can be drawn from comparing these scores with the average scores from the earlier Table 4. First, the average precision of run R_{DS} is higher than for run R_D. In other words, when extracting from document sentences in R_{DS} and R_D, the patterns proposed in our method give fewer and more accurate facts than the patterns from (Fader et al., 2011). Second, although R_{DS} is more accurate than R_D, it is less accurate than run R_Q. Note that, among the top 50 facts extracted for each target class by runs R_{DS} and R_Q, an average of 13% of the facts are extracted by both runs. There are several phenomena contributing to the difference in precision. While inherently noisy, queries tend to be more compact, and therefore more focused. In comparison, document sentences matching the patterns are often more convoluted (e.g., *"who do cities keep building stadiums despite study after study showing they do not make money"*, or *"how does a company go from low associate satisfaction to #15 on the fortune 100 best list in the midst of a crippling recession"*). Furthermore, both queries and sentences may not be useful questions from which relevant facts can be extracted, even when they match the extraction patterns. However, anecdotal evidence suggests

that this happens more frequently with document sentences than with queries. Examples include document sentences extracted from sites aggregating jokes (*"why did the cell phone ask to see the psychologist"*). The results confirm that queries represent an intriguing resource for fact extraction, providing a useful complement to document sentences for the purpose of extracting facts.

Quantitative Results: From the set of queries used as input in run R_Q, 3.8% of all queries start with *why* or *how*. In turn, 13.6% of them match one of the extraction patterns from Table 1, and therefore produce a candidate fact in R_Q. In the case of run R_{DS}, 18.7% of the document sentences that start with *why* or *how* match one of the patterns from Table 1.

Choice of Extraction Patterns: The sets of patterns sometimes employed in relation extraction from documents (Hearst, 1992) occasionally benefit from the addition of new patterns, or the refinement into more specific patterns (Kozareva et al., 2008). Similarly, the set of patterns proposed in Table 1, which targets the extraction of facts from queries, is neither exhaustive nor final. Other patterns beyond *why* and *how* may prove useful, whether they rely on relatively less frequent *when* and *where* queries, or extract relations containing underspecified arguments from *who* or *what* queries.

When applied to queries in run R_Q, the *how* patterns from Table 1 match 3.3 times more queries than the *why* patterns.

In separate experiments, *why* vs. *how* patterns from Table 1 are temporarily disabled. The ratio of facts extracted on average per target class in run R_Q diminishes from 100% (with both patterns) to 30% (with *why* only) or 70% (with *how* only). Overall, no difference in accuracy is observed over facts extracted by *why* vs. *how* patterns.

Choice of Phrase Descriptors: A separate experiment investigates the impact of expanding the sets of phrase descriptors associated with each target class. Among many possible strategies, each set of phrase descriptors associated with a target class is expanded automatically, using WordNet and distributional similarities. For this purpose, for each target class, the set of synonyms and hyponyms of all senses, if any, available in WordNet for each phrase descriptor is intersected with the set of the 50 most distributionally similar phrases, if any, available for each phrase descriptor. The original set of phrase descriptors of each target class is then expanded, to include the phrases from the intersected set, if any.

A repository of distributionally similar phrases is collected in advance following (Lin and Wu, 2009; Pantel et al., 2009), from a sample of around 200 million Web documents. Their intersection with phrases collected from WordNet aims at reducing the noise associated with expansion solely from either source. For example, for the class *Actor*, the set of phrases {*player*, *worker*, *heavy*, *plant*, *actress*, *comedian*, *film star*, ..} is collected from WordNet for the descriptor *actors*. The set is intersected with the set of phrases {*film stars*, *performers*, *comedians*, *actresses*, ..} most distributionally similar to *actors*. Examples of sets of phrase descriptors after expansion are {*actors*, *actresses*, *comedians*, *players*, *film stars*, ..}, for the class *Actor*; and {*battles*, *naval battles*, *fights*, *skirmishes*, *struggles*, ..}, for *Battle*.

On average, the sets of phrase descriptors associated with each target class contains 2 vs. 11 phrases, before vs. after expansion. Some of the sets of phrase descriptors, such as for the target classes *CartoonChar* and *DigitalCamera*, remain unchanged after expansion. As expected, expansion may introduce noisy phrase descriptors, such as *players* for *Actor*, or *diets* for *Food*. The presence of noisy phrase descriptors lowers the precision of the extracted facts. After expansion, the precision scores of R_Q, as an average over all target classes, become smaller by 6% (0.71 vs. 0.67), at rank 10; 6% (0.67 vs. 0.63), at rank 20; and 7% (0.63 vs. 0.59), at rank 50. Expansion also affects relative coverage, increasing the average number of facts extracted by R_Q per target class by more than twice (i.e., by a factor of 2.6).

Redundant Facts: Due to lexical variation in the source text fragments, some of the extracted facts may be near-duplicates of one another. In general, the phenomenon affects facts extracted from text by previous methods (Van Durme and Paşca, 2008; Etzioni et al., 2011; Fader et al., 2011). In particular, it affects facts extracted from both documents or queries in our experiments. For example, the facts extracted from documents for *Actor* include *"play their roles"*, *"play their parts"*, *"play their characters"* and *"portrayed their characters"*. Separately, the facts *"memorize their lines"*, *"remember their lines"* and *"learn their lines"* are extracted from queries for the class

Actor. The automatic detection of equivalent facts would increase the usefulness of facts extracted from text in general, and of facts extracted by the method presented here in particular.

5 Related Work

A variety of methods address the more general task of acquisition of open-domain relations from text, e.g., (Banko et al., 2007; Carlson et al., 2010; Wu and Weld, 2010; Fader et al., 2011; Lao et al., 2011; Mausam et al., 2012; Lopez de Lacalle and Lapata, 2013). In general, relations extracted from document sentences (e.g., *"Claude Monet was born in Paris"*) are tuples of an argument (*claude monet*), a text fragment acting as the lexicalized relation (*was born in*), and another argument (*paris*) (cf. (Banko et al., 2007; Fader et al., 2011; Mausam et al., 2012)). For convenience, the relation and second argument may be concatenated into a fact applying to the first argument, as in *"was born in paris"* for *claude monet*. Relatively shallow tools like part of speech taggers, or more complex tools like semantic taggers (Van Durme et al., 2008; Van Durme et al., 2009) can be employed in order to extract relations from document sentences. The former choice scales better to Web documents of arbitrary quality, whereas the latter could be more accurate over high-quality documents such as news articles (Mesquita et al., 2013). In both cases, document sentences mentioning an instance or a class may refer to properties of the instance that people other than the author of the document are less likely to inquire about. Consequently, even top-ranked extracted relations occasionally include less informative ones, such as *"come into view"* for *mount rainier*, *"be on the table"* for *madeira wine*, or *"allow for features"* for *javascript* (Fader et al., 2011).

Data available within Web documents, from which relations are extracted in previous work, includes unstructured (Banko et al., 2007; Fader et al., 2011), structured (Raju et al., 2008) and semi-structured text (Yoshinaga and Torisawa, 2007; Pasupat and Liang, 2014), layout formatting tags (Wong et al., 2008), itemized lists or tables (Cafarella et al., 2008). Another source is human-compiled resources (Wu and Weld, 2010) including infoboxes and category labels (Nastase and Strube, 2008; Hoffart et al., 2013; Wang et al., 2013; Flati et al., 2014) in Wikipedia, or topics and relations in Freebase (Weston et al., 2013; Yao and Van Durme, 2014).

Whether Web search queries are a useful textual data source for open-domain information extraction has been investigated in several tasks. Examples are collecting unlabeled sets of similar instances (Jain and Pennacchiotti, 2010), extracting attributes of instances (Alfonseca et al., 2010; Paşca, 2014), identifying mentions in queries of instances defined in a manually-created resource (Pantel et al., 2012), and extracting the most salient of the instances mentioned within Web documents (Gamon et al., 2013).

Other previous work shares the intuition that the submission of Web search queries is influenced by, and indicative of, various relations. Relations are loosely defined, either by approximating them via distributional similarities (Alfonseca et al., 2009), or by exploring the acquisition of untyped, similarity-based relations from query logs (Baeza-Yates and Tiberi, 2007). In both cases, the computed relations hold among full-length queries. Untyped relations can also be identified among query terms for the purpose of query reformulation (Wang and Zhai, 2008). More generally, the choice of query substitutions may reveal various relations among full queries or query terms (Jones et al., 2006), but requires individual queries to be connected to one another via query sessions or via search-result click-through data.

6 Conclusion

Anonymized search queries submitted by Web users represent requests for knowledge. Collectively, they can also be seen as informal, lexicalized knowledge assertions. By asking about a property of some class, fact-seeking queries implicitly assert the relevance of the property for the class.

Since Web search queries refer to properties that Web users are collectively interested in, factual knowledge extracted from queries tends to be more relevant than facts extracted from arbitrary documents using previous methods. Current work explores the extraction of facts from implicit rather than explicit fact-seeking questions, that is, from queries that do not start with a question prefix; and the combination of queries as a source of more accurate facts, and documents as a source of more numerous facts.

Abstract

Question Answering over Linked Data (QALD) aims to evaluate a question answering system over structured data, the key objective of which is to translate questions posed using natural language into structured queries. This technique can help common users to directly access open-structured knowledge on the Web and, accordingly, has attracted much attention. To this end, we propose a novel method using first-order logic. We formulate the knowledge for resolving the ambiguities in the main three steps of QALD (phrase detection, phrase-to-semantic-item mapping and semantic item grouping) as first-order logic clauses in a Markov Logic Network. All clauses can then produce interacted effects in a unified framework and can jointly resolve all ambiguities. Moreover, our method adopts a pattern-learning strategy for semantic item grouping. In this way, our method can cover more text expressions and answer more questions than previous methods using manually designed patterns. The experimental results using open benchmarks demonstrate the effectiveness of the proposed method.

1 Introduction

With the rapid development of the Web of Data, many RDF datasets have been published as Linked Data (Bizer et al., 2009), such as DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008) and YAGO (Suchanek et al., 2007). The growing amount of Linked Data contains a wealth of knowledge, including entities, classes and relations. Moreover, these linked data usually have complex structures and are highly heterogeneous. As a result, there are gaps for users regarding access. Although a few experts can write queries using structured languages (such as SPARQL) based on their needs, this skill cannot be easily utilized by common users (Christina and Freitas, 2014). Thus, providing user-friendly, simple interfaces to access these linked data becomes increasingly more urgent.

Because of this, question answering over linked data (QALD) (Walter et al., 2012) has recently received much interest, and most studies on this topic have focused on translating natural language questions into structured queries (Freitas and Curry, 2014; Yahya et al., 2012; Unger et al., 2012; Shekarpour et al., 2013; Yahya et al., 2013; Bao et al., 2014; Zou et al., 2014). For example, with respect to the question

"Which software has been developed by organizations founded in California, USA?",

the aim is to automatically convert this utterance into an SPARQL query that contains the following *subject-property-object (SPO)* triple format: ⟨**?url rdf:type dbo:Software, ?url dbo:developer ?x1, ?x1 rdf:type dbo:Company, ?x1 dbo:foundationPlace dbr:California**⟩[1].

To fulfill this objective, existing systems (Lopez et al., 2006; Unger et al., 2012; Yahya et al., 2012; Zou et al., 2014) usually adopt a pipeline framework that contains four major steps: 1) decomposing the question and detecting phrases, 2) mapping the detected phrases into semantic items of Linked Data, 3) grouping the mapped semantic items into semantic triples, and 4) generating the correct SPARQL query.

However, completing these four steps and constructing such a structured query is not easy. The first three steps mentioned above are subject to the

*Shizhu He and Kang Liu have equal contribution to this work.

[1]The prefixes in semantic items indicate the source of their vocabularies.

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

problem of ambiguity, which is the major challenge in QALD. Using the question mentioned above as an example, we can choose *California* or *California, USA* when detecting phrases, the phrase *California* can be mapped to the entity **California_State** or **California_Film**, and the class **Software** (mapped from the phrase *software*) can be matched with the first argument of the relation **producer** or **developer** (these two relations can be mapped from the phrase *developed*). Previous methods (Lopez et al., 2006; Lehmann et al., 2012; Freitas and Curry, 2014) have usually performed disambiguation at each step only, and the subsequent step was performed based on the disambiguation results in the previous step(s). However, we argue that the three steps mentioned above have mutual effects. In the previous example, the phrase *founded in (verb)* can be mapped to the entities (**Founding_of_Rome** and **Founder_(company)**), classes (**Company** and **Department**) or relations (**foundedBy** and **foundationPlace**). If we know that the phrase *California* can refer to the entity **California_State**, and which can be the second argument of the relation **foundationPlace**, together with a *verb* phrase being more likely to be mapped to *Relation*, we should map the phrase *founded in* to **foundationPlace** in this question. **Thus, we aim to determine if joint disambiguation is better than individual disambiguation.** (**Question One**)

In addition, previous systems usually employed manually designed patterns to extract predicate-argument structures that are used to guide the disambiguation process in the three steps mentioned above (Yahya et al., 2012; Unger et al., 2012; Zou et al., 2014). For example, (Yahya et al., 2012) used only three dependency patterns to group the mapped semantic items into semantic triples. Nevertheless, these three manually designed patterns miss many cases because of the diversity of the question expressions. We gathered statistics on 144 questions and found that the macro-average F1 and micro-average F1 of the three patterns[2] used in (Yahya et al., 2012) are only 62.8 and 66.2%, respectively. Furthermore, these specially designed patterns may not be valid with variations in domains or languages. **Therefore, another important question arises: can we automatically learn rules or patterns to achieve the same objective?** (**Question Two**)

Focusing on the two problems mentioned above, this paper proposes a novel algorithm based on a learning framework, Markov Logic Networks (MLNs) (Richardson and Domingos, 2006), to learn a joint model for constructing structured queries from natural language utterances. MLN is a statistical relational learning framework that combines first-order logic and Markov networks. The appealing property of MLN is that it is readily interpretable by humans and that it is a natural framework for performing joint learning. We formulate the knowledge for resolving the ambiguities in the main three steps of QALD (phrase detection, phrase-to-semantic-item mapping and semantic item grouping) as first-order logic clauses in an MLN. In the framework of MLN, all clauses will produce interacted effects that jointly resolve all problems into a unified process. In this way, the result in each step can be globally optimized. Moreover, in contrast to previous methods, we adopt a learning strategy to automatically learn the patterns for semantic item grouping. We design several meta patterns as opposed to the specific patterns. In addition, these meta patterns are formulated as the first-order logic formulas in the MLN. The specific patterns can be generated by these meta patterns based on the training data. The model will learn the weights of each clause to determine the most effective patterns for semantic triple construction. In this way, with little effort, our approach can cover more semantic expressions and answer more questions than previous methods, which depend on manually designed patterns.

We evaluate the proposed method using several benchmarks (QALD-1, QALD-3, QALD-4). The experimental results demonstrate the advantage of the joint disambiguation process mentioned above. They also prove that our approach, employing MLN to automatically learn the patterns of semantic triple grouping, is effective. Our system can answer more questions and obtain better performance than the traditional methods based on manually designed heuristic rules.

2 Background

2.1 Linked Data Sources

Linked Data consist of many relational data, which are usually inter-linked as subject-property-object (*SPO*) triple statements (such as using the **owl:sameAs** relation). In this paper, we mainly use

[2]They are 1) verbs and their arguments, 2) adjectives and their arguments and 3) propositionally modified tokens and objects of prepositions.

Subject(Arg1)	Relation(Property)	Object(Arg2)
ProgrammingLanguage	subClassOf	Software
Java_(programming_language)	type	Software
Java_(programming_language)	developer	Oracle_Corporation
Oracle_Corporation	foundationPlace	California_(State)
foundationPlace	domain	Organisation
California_(State)	label	"California"
California_(1977_film)	label	"California"
Oracle_Corporation	numEmployees	118119(xsd:integer)

Figure 1: Sample knowledge base facts.

DBpedia[3] and some classes from Yago[4]. These knowledge bases (*KBs*) are composed of many ontological and instance statements, and all statements are expressed by *SPO* triple facts. Figure 1 shows some triple fact samples from DBpedia.

Each fact is composed of three **semantic items**. A semantic item can be an entity (**California_(State)**, **Oracle_Corporation**, etc.), a class (**Software**, **Organisation**, etc.) or a relation (called a property or predicate in some occasions). Some entities are literals including strings, numbers and dates (**118119(xsd:integer)**, etc.). Relations contain standard Semantic Web relations (**subClassOf**, **type**, **domain** and **label**) and ontological relations (**developer**, **foundationPlace** and **numEmployees**).

2.2 Task Statement

Given a knowledge base (*KB*), our objective is to translate a natural language question q_{NL} into a formal language query q_{FL} that targets the semantic vocabularies given by the *KB*, and the query q_{FL} should capture the user information needs expressed by q_{NL}.

Following (Yahya et al., 2012), we focus on the factoid questions, and the answers to such questions are an entity or a set of entities. We ignore the questions that need the aggregation[5] (max/min, etc.) and negation operations. That is, we generate queries that consist of a plentiful number of triple patterns, which are multiple conjunctions of *SPO* search conditions.

3 Framework

Figure 2 shows the entire framework of our system for translating a question into a formal SPARQL query. The first three steps address the input question through 1) Phrase Detection (detecting possible phrases), 2) Phrase Mapping (mapping all phrase candidates to the corresponding semantic items), and 3) Feature Extraction (extracting the linguistic features and semantic item features from the question and the Linked Data, respectively). As a result, a space of candidates is constructed, including possible phrases, mapped semantic items and the possible argument match relations among them. Next, the fourth step (Inference) formulates the joint disambiguation as a generalized inference task. We employ rich features and constraints (including hard and soft constraints) to infer a joint decision through an MLN. Finally, with the inference results, we can construct a semantic item query graph and generate an executable SPARQL query. In the following subsection, we demonstrate each step in detail.

1) Phrase detection. In this step, we detect phrases (sequences of tokens) that probably indicate semantic items in the *KB*. We do not use a named entity recognizer (NER) because of its low coverage. We perform testing on two commonly used question corpora, QALD-3 and free917[6], using the Stanford NER tool[7]. The results demonstrate that only 51.5 and 23.8% of the NEs are correctly recognized, respectively. To avoid missing useful phrases, we retain all n-grams as phrase candidates, and then use some rules to filter them. The rules include the following: the span length must be less than 4 (accepting that all contiguous tokens are capitalizations), the POS tag of the start token must be *jj*, *nn*, *rb* and *vb*, all contiguous capitalization tokens must not be split, etc. For instance, *software*, *developed by*, *organizations*, *founded in* and *California* are detected in the example of the first section.

2) Phrase mapping. After the phrases are detected, each phrase can be mapped to the corresponding semantic item in *KB* (entity, class and relation). For example, *software* is mapped to **dbo:Software**, **dbo:developer**, etc., and *California* is mapped to **dbr:California**, **dbr:California_(wine)**, etc. For different types of semantic items, we use different techniques. For mapping phrases to entities, considering that the entities in DBpedia and Wikipedia are consistent, we employ anchor, redirection and disambiguation information from Wikipedia. For mapping phrases to classes, considering that classes have lexical variation, especially synonyms, e.g., **dbo:Film** can be mapped

[3]http://dbpedia.org/

[4]http://www.mpi-inf.mpg.de/yago-naga/yago/

[5]We can address the *count* query questions, which will be explained in Section 3.

[6]http://www.cis.temple.edu/∼yates/open-sem-parsing/index.html

[7]http://nlp.stanford.edu/software/CRF-NER.shtml

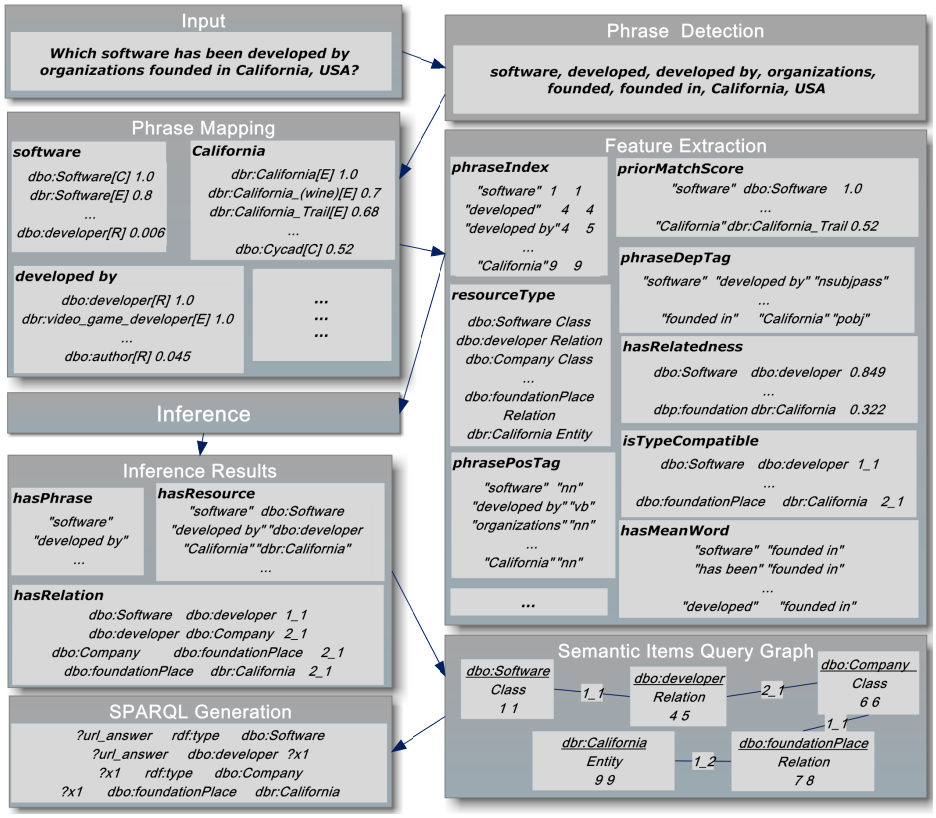

Figure 2: Framework of our system.

from *film*, *movie* and *show*, we compute the similarity between the phrase and the class in the *KB* with the *word2vec* tool[8]. The *word2vec* tool computes fixed-length vector representations of words with a recurrent-neural-network based language model (Mikolov et al., 2010). The similarity scoring methods are introduced in Section 4.2. Then, the top-N most similar classes for each phrase are returned. For mapping phrases to relations, we employ the resources from PATTY (Nakashole et al., 2012) and ReVerb (Fader et al., 2011). Specifically, we first compute the associations between the ontological relations in DBpedia and the relation patterns in PATTY and ReVerb through instance alignments as in (Berant et al., 2013). Next, if a detected phrase is matched to some relation pattern, the corresponding ontological relations in DBpedia will be returned as a candidate. This step only generates candidates for every possible mapping, and the decision of the best selection will be performed in the next step.

3) Feature extraction and joint inference. There exist ambiguities in phrase detection and in mapping phrases to semantic items. This step focuses on addressing these ambiguities and determining the argument match relations among the mapped semantic items. This is the core component of our system, and it performs disambiguation in a unified manner. First, feature extraction is performed to prepare a rich number of features from the input question and from the *KB*. Next, the disambiguation is performed in a joint fashion with a Markov Logic Network. Detailed information will be presented in Section 4.

4) Semantic item query graph construction. Based on the inference results, we construct a query graph. The vertices contain the following: the detected phrase, the token span indexes of the phrases, the mapped semantic items and their types. The edge indicates the argument match relation between two semantic items. For example, we use ***1_2*** to indicate that the first argument of an item matches the second argument of another item[9]. The right bottom in Figure 2 shows an example of this.

5) Query generation. The SPARQL queries require the grouped triples of semantic items. Thus, in this step, we convert a query graph into multiple joined semantic triples. Three interconnected semantic items, whereby it must

[8]https://code.google.com/p/word2vec/

[9]The other marks will be introduced in Section 4.2.

be ensured that the middle item is a ***relation***, are converted into a semantic triple (multiple joined facts containing variables). For example, the query graph $[$**dbo:Book[Class]** $\underset{\longleftrightarrow}{1\_2}$ **dbo:author[Relation]** $\underset{\longleftrightarrow}{1\_1}$ **dbr:Danielle_Steel[Entity]**$]$ is converted into $\langle$**?x rdf:type dbo:Book, dbr:Danielle dbo:author ?x**$\rangle$, and $[$**dbo:populationTotal[Relation]** $\underset{\longleftrightarrow}{1\_2}$ **dbo:capital[Relation]** $\underset{\longleftrightarrow}{1\_1}$ **dbr:Australia[Entity]**$]$[10] is converted into $\langle$**?x1 dbo:populationTotal ?answer, ?x1 dbo:capital dbr:Australia**$\rangle$. If the query graph only contains one vertex that indicates a class ***ClassURI***, we generate $\langle$**?x rdf:type ClassURI**$\rangle$. If the query graph only contains two connected vertexes, we append a variable to bind the missing match argument of the semantic item.

The final SPARQL query is constructed by joining the semantic item triples based on the corresponding SPARQL template. We divide the questions into three types: **Yes/No**, **Normal** and **Number**. Yes/No questions use the ***ASK WHERE*** template. Normal questions use the ***SELECT ?url WHERE*** template. Number questions first use the normal question template, and if they cannot obtain a correct answer (a valid numeric value), we use the ***SELECT COUNT(?url) WHERE*** template to generate a query again. For instance, we construct the SPARQL query ***SELECT(?url) WHERE***{ ***?url rdf:type dbo:Software. ?url dbo:developer ?x1. ?x1 rdf:type dbo:Company. ?x1 dbo:foundationPlace dbr:California.***} for this example.

4 Joint Disambiguation with MLN

In this section, we present our method for question answering over linked data using a Markov Logic Network (MLN). In the following subsections, we first briefly describe the MLN. Then, we present the predicates and the first-order logic formulas used in the model.

4.1 Markov Logic Networks

Markov logic networks combine Markov networks with first-order logic in a probabilistic framework (Richardson and Domingos, 2006). An MLN $\mathcal{M}$ consists of several weighted formulas $\{(\phi_i, w_i)\}_i$, where ϕ_i is a first order formula and w_i is the penalty (the formula's weight). In contrast to the first-order logic, whereby a formula represents a hard constraint, these logic formulas are relaxed and can be violated with penalties in the MLN. Each formula ϕ_i consists of a set of first-order predicates, logical connectors and variables. These weighted formulas define a probability distribution over a possible world. Let $\mathbf{y}$ denote a possible world. Then $p(\mathbf{y})$ is defined as follows:

$$p(\mathbf{y}) = \frac{1}{Z} exp\left(\sum_{(\phi_i, w_i)\in\mathcal{M}} w_i \sum_{\mathbf{c}\in C^{n_{\phi_i}}} f_{\mathbf{c}}^{\phi_i}(\mathbf{y})\right),$$

where each c is a binding of the free variables in ϕ_i to constants; $f_{\mathbf{c}}^{\phi_i}$ is a binary feature function that returns 1 if the ground formula that we obtain through replacing the free variables in ϕ_i with the constants in $\mathbf{c}$ under the given possible world $\mathbf{y}$ is true and is 0 otherwise; and $C^{n_{\phi_i}}$ is the set of all possible bindings for the free variables in ϕ_i. Z is a normalized constant. The Markov network corresponds to this distribution, where nodes represent ground atoms and factors represent ground formulas.

4.2 Predicates

In the MLN, we design several predicates to resolve the ambiguities in phrase detection, mapping phrases to semantic items and semantic item grouping. Specifically, we design a hidden predicate *hasPhrase(i)* to indicate that the *i*-th candidate phrase has been chosen. The predicate *hasResource(i,j)* indicates that the *i*-th phrase is mapped to the *j*-th semantic item. The predicate *hasRelation(j,k,rr)* indicates that the *j*-th semantic item and the *k*-th semantic item should be grouped together with the argument-match-type *rr*. Note that we define four argument match types between two semantic items: *1_1*, *1_2*, *2_1* and *2_2*. Here, the argument match type *t_s* denotes that the *t*-th argument of the first semantic item corresponds to the *s*-th argument of the second semantic item[11]. The detailed illustration is shown in Table 1.

Type	Example	Question
1_1	*dbo:height 1_1 dbr:Michael_Jordan*	*How tall is Michael Jordan?*
1_2	*dbo:River 1_2 dbo:crosses*	*Which river does the Brooklyn Bridge cross?*
2_1	*dbo:creator 2_1 dbr:Walt_Disney*	*Which television shows were created by Walt Disney?*
2_2	*dbo:birthPlace 2_2 dbo:capital*	*Which actors were born in the capital of American?*

Table 1: Examples of the argument match types.

[10] This corresponds to the question "*How many people live in the capital of Australia?*"

[11] The *2*-nd argument is corresponding to the object argument of the relation, and the *1*-st argument is corresponding with the subject argument of the relation and the entity (including the class) itself.

Describing the attributes of phrases and relation between two phrases	
phraseIndex(p, i, j)	The start and end position of phrase *p* in question.
phrasePosTag(p, pt)	The POS tag of the head word in phrase *p*.
phraseDepTag(p, q, dt)	The dependency path tags between phrase *p* and *q*.
phraseDepOne (p, q)	If there is only one tag in the dependency path, the predicate is true.
hasMeanWord (p, q)	If there is any one meaning word in the dependency path of two phrases, the predicate is true.
Describing the attributes of semantic item and the mappings between phrases and semantic items	
resourceType(r, rt)	The type of semantic item r. Types of semantic items include *Entity*, *Class* and *Relation*
priorMatchScore(p, r, s)	The prior score of phrase *p* mapping to semantic item *r*.
Describing the attributes of relation between two semantic items in a knowledge base	
hasRelatedness(p, q, s)	The semantic coherence of semantic items.
isTypeCompatible(p, q, rr)	If the semantic items *p* are type-compatible with the semantic items *q*, the predicate is true.
hasQueryResult(s, p, o, rr1, rr2)	If the triple pattern consisting of semantic items *s*, *p*, *o* and argument-match-types *rr1* and *rr2* have query results, the predicate is true.

Table 2: Descriptions of observed predicates.

Moreover, we define a set of observed predicates to describe the properties of phrases, semantic items, relations between phrases and relations between semantic items. The observed predicates and descriptions are shown in Table 2.

Previous methods usually designed some heuristic patterns to group semantic items, which usually employed a human-designed syntactic path between two phrases to determine their relations. In contrast, we collect all the tokens in the dependency path between two phrases as possible patterns. The predicates *phraseDepTag* and *hasMeanWord* are designed to indicate the possible patterns. Note that if these tokens only contain POS tags *dt|in|wdt|to|cc|ex|pos|wp* or *stop words*, the value of the predicate *hasMeanWord* is false; otherwise, it is true. In this way, our system is expected to cover more question expressions. Moreover, the SPARQL endpoint is used to verify the type compatibility of two semantic items and if one triple pattern can obtain query results.

The predicate *hasRelatedness* needs to compute the coherence score between two semantic items. Following (Yahya et al., 2012), we use the Jaccard coefficient (Jaccard, 1908) based on the inlinks between two semantic items.

The predicate *priorMatchScore* assigns a prior score when mapping a phrase to a semantic item. We use different methods to compute this score according to different semantic item types. For entities, we use a normalized score based on the frequencies of a phrase referring to an entity. For classes and relations, we use different methods. We first define the following three similarity metrics: a) s_1: The Levenshtein distance score (Navarro, 2001) between the labels of the semantic item and the phrase; b) s_2: The word embedding (Mikolov et al., 2010) score, which measures the similarity between two phrases and is the maximum cosine value of the words' word embeddings between two phrases; and c) s_3: the instance overlap score, which is computed using the Jaccard coefficient of the instance overlap. All scores are normalized to produce a comparable scores in the interval of (0, 1). The final prior scores for mapping phrases to classes and relations are $\gamma s_1 + (1-\gamma)s_2$ and $\alpha s_1 + \beta s_2 + (1-\alpha-\beta)s_3$, respectively. The parameters are set to empirical values[12].

4.3 Formulas

According to these predicates, we design several first-order logic formulas for joint disambiguation. As mentioned in the first section, these formulas represent the meta patterns. The concrete patterns can be generated through these meta patterns with training data. Specifically, we use two types of formulas for the joint decisions: *Boolean* and *Weighted* formulas. *Boolean* formulas are hard constraints, which must be satisfied by all of the ground atoms in the final inference results. *Weighted* formulas are soft constraints, which can be violated with some penalties.

4.3.1 Boolean Formulas (Hard Constraints)

Table 3 lists the Boolean formulas used in this work. The "_" notation in the formulas indicates an arbitrary constant. The "$|f|$" notation expresses the number of true grounded atoms in the formula f. These formulas express the following constraints:

hf1: If a phrase is chosen, then it must have a mapped semantic item;

hf2: If a semantic item is chosen, then its mapped phrase must be chosen;

hf3: A phrase can be mapped to at most one semantic item;

hf4: If the phrase is not chosen, then its mapped

Table 4: Descriptions of weighted formulas.

semantic item should not be chosen;

hf5: If a semantic item is chosen, then it should have at least one argument match relation with other semantic items;

hf6: Two semantic items have at most one argument match relation;

hf7: If an argument match relation for two semantic items is chosen, then they must be chosen;

hf8: Each of two chosen phrases must not overlap;

hf9, ***hf10***, ***hf11***, ***hf12***: The semantic item with type *Entity* and *Class* should not have a second argument that matches with others;

hf13: The chosen argument match relation for two sematic items must be type compatible.

4.3.2 Weighted Formulas (Soft Constraints)

Table 4 lists the weighted formulas used in this work. The "+" notation in the formulas indicates that each constant of the logic variable should be weighted separately. Those formulas express the following properties in joint decisions:

sf1, ***sf2***: The larger the score of the phrase mapping to a semantic item, the more likely the corresponding phrase and semantic item should been chosen;

sf3: There are some associations between the POS tags of phase and the types of mapped semantic items;

sf4, ***sf5***, ***sf6***: There are some associations between the dependency tags in the dependency pattern path of two phases and the types of argument match relations of two mapped semantic items;

sh7: The larger the relatedness of two semantic items, the more likely they have an argument match relation;

sf8: If the triple pattern has query results, these semantic items should have corresponding argument match relations.

5 Experiments

5.1 Dataset & Evaluation Metrics

We use the following three collections of questions from the QALD[13] task for question answering over linked data: QALD-1, QALD-3 and QALD-4. The generated SPARQL queries are evaluated on Linked Data from DBpedia and YAGO using a Virtuoso engine[14]. A typical example question from the QALD benchmark is *"Which books written by Kerouac were published by Viking Press?"*. As mentioned in Section 2.2, our system is not designed to answer questions that contain numbers, date comparisons and aggregation operations such as *group by* or *order by*. Therefore, we remove these types of questions and retain 110 questions from the QALD-4 training set for generating the specific formulas and for training their weights in MLN. We test our system using 37, 75 and 26 questions from the training set of QALD-1[15], and the testing set of QALD-3 and QALD-4 respectively. We use #T, #Q and #A to indicate the total

[13] www.sc.cit-ec.uni-bielefeld.de/qald/

[14] https://github.com/openlink/virtuoso-opensource

[15] We use the training set because we try to make a fair comparison with (Yahya et al., 2012).

number of questions in the testing set, the number of questions we could address and the number of questions answered correct, respectively. We select Precision ($P = \frac{\#A}{\#Q}$), Recall ($R = \frac{\#A}{\#T}$), and F1-score ($F1 = \frac{2 \cdot P \cdot R}{P+R}$) as the evaluation metrics. To assess the effectiveness of the disambiguation process in the MLN, we computed the overall quality measures by precision and recall with the manually obtained results.

5.2 Experimental Configurations

The Stanford dependency parser (De Marneffe et al., 2006) is used for extracting features from the dependency parse trees. We use the toolkit *thebeast*[16] to learn the weights of the formulas and to perform the MAP inference. The inference algorithm uses a cutting plane approach. In addition, for the parameter learning, we set all initial weights to zero and use an online learning algorithm with MIRA update rules to update the weights of the formulas. The number of iterations for the training and testing are set to 10 and 200, respectively.

5.3 Results and Discussion

5.3.1 The Effect of Joint Learning

To demonstrate the advantages of our joint learning, we design a pipeline system for comparison, which independently performs phrase detection, phrase mapping, and semantic item grouping by removing the unrelated formulas in MLN. For example, the formulas[17] related to the predicates *hasResource* and *hasRelation* are removed when detecting phrases in questions.

Table 5 shows the results, where **Joint** denotes the proposed method with joint inference and **Pipeline** denotes the compared method performing each step independently. We perform a comparison with the question answering results of QALD (QA), and comparisons at each of the following steps: PD (phrase detection), PM (phrase mapping) and MG (mapped semantic items grouping). From the results, we observe that our method answers over half of the questions. Moreover, our joint model based on MLN can obtain better performance in question answering compared to the pipeline system. We also observe that Joint exhibits better performance than Pipeline in most steps, except for MG in QALD-3. We believe this is because the three tasks (phrase detection, phrase mapping, and semantic item grouping) are connected with each other. Each step can provide useful information for the other two tasks. Therefore, performing joint inference can effectively improve the performance. Finally, we observe that the former task usually produces better results than the subsequent tasks (phrase detection exhibits a better performance than phrase mapping, and phrase mapping exhibits a better performance than semantic item grouping). The main reason is that the latter subtask is more complex than the former task. The decisions of the latter subtask strongly rely on the former results even though they have interacted effects.

5.3.2 The Effect of Pattern Learning

Table 6 shows a comparison of our system with *DEANNA* (Yahya et al., 2012), which is based on a joint disambiguation model but which employs hand-written patterns in its system. Because *DEANNA* only reports its results of the QALD-1 dataset, we do not show the results for QALD-3 and QALD-4 for equity. From the results, we can see that our system solved more questions and exhibited a better performance than did *DEANNA*. One of the greatest strengths of our system is that the learning system can address more questions than hand-written pattern rules.

System	#T	#Q	#A	P	R	F1
DEANNA (Yahya et al., 2012)	50	27	13	0.48	0.26	0.33
Ours	50	37	20	0.54	0.4	0.46

Table 6: Comparisons with *DEANNA* using the QALD-1 test questions.

Compared to the ILP (Integer Linear Programming) used in (Yahya et al., 2012) for joint disambiguation, we argue that there are two major differences to our method. 1) Our method is a data-driven approach that can learn effective patterns or rules for the task. Therefore, it exhibits more robustness and adaptability for various *KBs*. 2) We design several meta rules in MLN as opposed to specific ones. The specific rules can be generated by these meta rules based on the training data. By contrast, the traditional approach using ILP needs to set specific rules in advance, which requires more intensive labor than our approach.

To further illustrate the effectiveness of our pattern-learning strategy, we show the weights of the learned patterns corresponding to formula *sf3* in the MLN, as shown in Table 7. From the table,

[16] http://code.google.com/p/thebeast

[17] including entire formulas, excluding *hf8* and *sf1*

Benchmark	PD			PM			MG			QA

Table 5: The performance of joint learning on three benchmark datasets.

we can see that *nn*[18] is more likely mapped to *Entity*[19] than to *Class* and *Relation*, and *vb* is most likely mapped to *Relation*. This proves that our model can learn effective and reasonable patterns for QALD.

POS tag of Phrase	type of mapped Item	Weight
nn	*Entity*	2.11
nn	*Class*	0.243
nn	*Relation*	0.335
vb	*Relation*	0.517
wp	*Class*	0.143
wr	*Class*	0.025

Table 7: Sample weights of formulas, corresponding with formula *sf3*.

5.3.3 Comparison to the state of the art

To illustrate the effectiveness of the proposed method, we perform comparisons to the state-of-the-art methods. Table 8 shows the results using QALD-3 and QALD-4. These systems are the participants in the QALD evaluation campaigns. From the results, we can see that our system outperforms most systems at a competitive performance. They further prove the effectiveness of the proposed method.

Test set	System	#T	#Q	#A	P	R	F1
QALD-3	CASIA (He et al., 2013)	99	52	29	0.56	0.3	0.38
	Scalewelis (Joris and Ferré, 2013)	99	70	32	0.46	0.32	0.38
	RTV (Cristina et al., 2013)	99	55	30	0.55	0.3	0.39
	Intui2 (Corina, 2013)	99	99	28	0.28	28	0.28
	SWIP (Pradel et al., 2013)	99	21	15	0.71	0.15	0.25

	RO FII	50	50	6	0.12	0.12	0.12
	Ours	50	26	15	0.58	0.3	0.4

Table 8: Comparisons with state-of-the-art systems using the QALD benchmark.

[18]The POS tag of the head word in the phrase

[19]The type of semantic item

[20]Because the QALD-4 conference does not start until after submission, we have no citation for the state-of-the-art systems in QALD-4. The results can be found at http://greententacle.techfak.uni-bielefeld.de/ cunger/qald.

5.3.4 The Effect of Different Formulas

To determine which formulas are more useful for QALD, we evaluate the performance of the proposed method with different predicate sets. We subtract one weighted formula from the original sets at a time, except retaining the first two formulas *sf1* and *sf2* for basic inference. Because of space limitations, only the results using QALD-3 testing set are shown in Table 9.

From the results, we can observe that removing some formulas can boost the performance on some single tasks, but employing all formulas can produce the best performance. This illustrates that solely resolving the steps in QALD (phrase detection, phrase mapping, semantic items grouping) can obtain local results, and that making joint inference is necessary and useful.

6 Related Work

Our proposed method is related to two lines of work: *Question Answering over Knowledge bases* and *Markov Logic Networks*.

Question answering over knowledge bases has attracted a substantial amount of interest over a long period of time. The initial attempts included BaseBall (Green Jr et al., 1961) and Lunar (Woods, 1977). However, these systems were mostly limited to closed domains due to a lack of knowledge resources. With the rapid development of structured data, such as DBpedia, Freebase and Yago, the need for providing user-friendly interface to these data has become increasingly urgent. Keyword (Elbassuoni and Blanco, 2011) and semantic (Pound et al., 2010) searches are limited to their ability to specify the relations among the different keywords.

The open topic progress has also been pushed by the QALD evaluation campaigns (Walter et al., 2012). Lopez et al. (2011) gave a comprehensive survey in this research area. The authors developed the *PowerAqua* system (Lopez et al., 2006) to

-sf8	0.927	0.927	0.927	0.868	0.908	0.888	0.639	0.807	0.713	0.83	0.893	0.861

Table 9: Performance comparisons of different weighted formulas evaluated using the QALD-3 question set.

answer questions on large, heterogeneous datasets. For questions containing quantifiers, comparatives or superlatives, Unger et al. (2012) translated *NL* to *FL* using several SPARQL templates and using a set of heuristic rules mapping phrases to semantic items. The system most similar to ours is *DEANNA* (Yahya et al., 2012). However, *DEANNA* extracts predicate-argument structures from the questions using three hand-written patterns. Our system jointly learns these mappings and extractions completely from scratch.

Recently, the Semantic Parsing (SP) community targeted this problem from limited domains (Tang and Mooney, 2001; Liang et al., 2013) to open domains (Cai and Yates, 2013; Berant et al., 2013). The methods in semantic parsing answer questions by first converting natural language utterances into meaningful representations (e.g., the lambda calculus) and subsequently executing the formal logical forms over *KBs*. Compared to deriving the complete logical representation, our method aims to parse a question into a limited logic form with the semantic item query, which we believe is more appropriate for answering factoid questions.

Markov Logic Networks have been widely used in NLP tasks. Huang (2012) applied MLN to compress sentences by formulating the task as a word/phrase deletion problem. Fahrni and Strube (2012) jointly disambiguated and clustered concepts using MLN. MLN has also been used in coreference resolution (Song et al., 2012). For the task of identifying subjective text segments and of extracting their corresponding explanations from product reviews, Zhang et al. (2013) modeled these segments with MLN. To discover logical knowledge for deep question answering, Liu (2012) used MLN to resolve the inconsistencies of multiple knowledge bases.

Meza-Ruiz and Riedel (2009) employed MLN for Semantic Role Labeling (SRL). They jointly performed the following tasks for a sentence: predicate identification, frame disambiguation, argument identification and argument classification. The semantic analysis of SRL solely rested on the lexical level, but our analysis focuses on the knowledge-base level and aims to obtain an executable query and to support natural language inference.

7 Conclusions and Future Work

For the task of QALD, we present a joint learning framework for phrase detection, phrase mapping and semantic item grouping. The novelty of our method lies in the fact that we perform joint inference and pattern learning for all subtasks in QALD using first-order logic. Our experimental results demonstrate the effectiveness of the proposed method.

In the future, we plan to address the following limitations that still exist in the current system: a) numerous hand-labeled data are required for training the MLN, and we could use a latent form of semantic item query graphs (Liang et al., 2013); b) more robust solutions can be developed to find the implicit relations in questions; c) our system can be scaled up to large-scale open-domain knowledge bases (Fader et al., 2013; Yao and Van Durme, 2014); and d) the learning system has the advantage of being easily adapted to new settings, and we plan to extend it to other domains and languages (Liang and Potts, 2014).

Abstract

Much recent work focuses on formal interpretation of natural question utterances, with the goal of executing the resulting structured queries on knowledge graphs (KGs) such as Freebase. Here we address two limitations of this approach when applied to open-domain, entity-oriented Web queries. First, Web queries are rarely well-formed questions. They are "telegraphic", with missing verbs, prepositions, clauses, case and phrase clues. Second, the KG is always incomplete, unable to directly answer many queries. We propose a novel technique to segment a telegraphic query and assign a coarse-grained purpose to each segment: a base entity e_1, a relation type r, a target entity type t_2, and contextual words s. The query seeks entity $e_2 \in t_2$ where $r(e_1, e_2)$ holds, further evidenced by schema-agnostic words s. Query segmentation is integrated with the KG and an unstructured corpus where mentions of entities have been linked to the KG. We do not trust the best or any specific query segmentation. Instead, evidence in favor of candidate e_2s are aggregated across several segmentations. Extensive experiments on the ClueWeb corpus and parts of Freebase as our KG, using over a thousand telegraphic queries adapted from TREC, INEX, and WebQuestions, show the efficacy of our approach. For one benchmark, MAP improves from 0.2–0.29 (competitive baselines) to 0.42 (our system). NDCG@10 improves from 0.29–0.36 to 0.54.

*Work done as Masters student at IIT Bombay

1 Introduction

A majority of Web queries mention an entity or type (Lin et al., 2012), as users increasingly explore the Web of objects using Web search. To better support entity-oriented queries, commercial Web search engines are rapidly building up large catalogs of types, entities and relations, popularly called a "knowledge graph" (KG) (Gallagher, 2012). Despite these advances, robust, Web-scale, open-domain, entity-oriented search faces many challenges. Here, we focus on two.

1.1 "Telegraphic" queries

First, the surface utterances of entity-oriented Web queries are dramatically different from TREC- or Watson-style factoid question answering (QA), where questions are grammatically well-formed. Web queries are usually "telegraphic": they are short, rarely use function words, punctuations or clausal structure, and use relatively flexible word orders. E.g., the natural utterance "on the bank of which river is the Hermitage Museum located" may be translated to the telegraphic Web query hermitage museum river bank. Even on well-formed question utterances, 50% of interpretation failures are contributed by parsing or structural matching failures (Kwiatkowski et al., 2013). Telegraphic utterances will generally be even more challenging.

Consequently, whereas TREC-QA/NLP-style research has focused on parsing and precise interpretation of a well-formed query sentence to a strongly structured (typically graph-oriented) query language (Kasneci et al., 2008; Pound et al., 2012; Yahya et al., 2012; Berant et al., 2013; Kwiatkowski et al., 2013), the Web search and information retrieval (IR) community has focused on telegraphic queries (Guo et al., 2009; Sarkas et al., 2010; Li et al., 2011; Pantel et al., 2012; Lin et al., 2012; Sawant and Chakrabarti, 2013). In terms of target schema richness, these efforts may

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1104–1114,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

appear more modest. The act of query 'interpretation' is mainly a segmentation of query tokens by *purpose*. In the example above, one may report segments "Hermitage Museum" (a located artifact or named entity), and "river bank" (the target type). This is reminiscent of record segmentation in information extraction (IE). Over well-formed utterances, IE baselines are quite competitive (Yao and Van Durme, 2014). But here, we are interested exclusively in telegraphic queries.

1.2 Incomplete knowledge graph

The second problem is that the KG is always work in progress (Pereira, 2013), and connections found within nodes of the KG, between the KG and the query, or the KG and unstructured text, are often incomplete or erroneous. E.g., Wikipedia is considered tiny, and Freebase rather small, compared to what is needed to answer all but the "head" queries. Google's Freebase annotations (Gabrilovich et al., 2013) on ClueWeb (ClueWeb09, 2009) number fewer than 15 per page to ensure precision. Fewer than 2% are to entities in Freebase but not in Wikipedia.

It may also be difficult to harness the KG for answering certain queries. E.g., answering the query fastest odi century batsman, the intent of which is to find the batsman holding the record for the fastest century in One Day International (ODI) cricket, may be too difficult for most KG-only systems, but may be answered quite effectively by a system that also utilizes evidence from unstructured text.

There is a clear need for a "pay-as-you-go" architecture that involves both the corpus and KG. A query easily served by a curated KG should give accurate results, but it is desirable to have a *graceful interpolation* supported by the corpus: e.g., if the relation $r(e_1, e_2)$ is not directly evidenced in the KG, but strongly hinted in the corpus, we still want to use this for ranking.

1.3 Our contributions

Here, we make progress beyond the above frontier of prior work in the following significant ways. We present a new architecture for structural interpretation of a telegraphic query into these segments (some may be empty):

- Mention/s $\widehat{e_1}$ of an entity e_1,
- Mention $\widehat{r}$ of a relation type r,
- Mention $\widehat{t_2}$ of a target type t_2, and
- Other contextual matching words s (sometimes called *selectors*),

with the simultaneous intent of finding and ranking entities $e_2 \in t_2$, such that $r(e_1, e_2)$ is likely to hold, evidenced near the matching words in unstructured text.

Given the short, telegraphic query utterances, we limit our scope to at most one relation mention, unlike the complex mapping of clauses in well-formed questions to twig and join style queries (e.g., "find an actor whose spouse was an Italian bookwriter"). On the other hand, we need to deal with the unhelpful input, as well as consolidate the KG with the corpus for ranking candidate e_2s. Despite the modest specification, our query template is quite expressive, covering a wide range of entity-oriented queries (Yih et al., 2014).

We present a novel discriminative graphical model to capture the entity ranking inference task, with query segmentation as a by-product. Extensive experiments with over a thousand entity-seeking telegraphic queries using the ClueWeb09 corpus and a subset of Freebase show that we can accurately predict the segmentation and intent of telegraphic relational queries, and simultaneously rank candidate responses with high accuracy. We also present evidence that the KG and corpus have synergistic salutary effects on accuracy.

§2 explores related work in more detail. §3 gives some examples fitting our query template, explains why interpreting some of them is nontrivial, and sets up notation. §4 presents our core technical contributions. §5 presents experiments. Data can be accessed at `http://bit.ly/Spva49` and `http://bit.ly/WSpxvr`.

2 Related work

The NLP/QA community has traditionally assumed that question utterances are grammatically well-formed, from which precise clause structure, ground constants, variables, and connective relations can be inferred via semantic parsing (Kasneci et al., 2008; Pound et al., 2012; Yahya et al., 2012; Berant et al., 2013; Kwiatkowski et al., 2013) and translated to lambda expressions (Liang, 2013) or SPARQL style queries (Kasneci et al., 2008), with elaborate schema knowledge. Such approaches are often correlated with the assumption that all usable knowledge has been curated into a KG. The query is first translated to a structured form and then "executed" on the KG. A

large corpus may be used to build relation expression models (Yao and Van Durme, 2014), but not as supporting evidence for target entities.

In contrast, the Web and IR community generally assumes a free-form query that is often telegraphic (Guo et al., 2009; Sarkas et al., 2010; Li et al., 2011). Queries being far more noisy, the goal of structure discovery is more modest, and often takes the form of a segmentation of the query regarded as a token sequence, assigning a broad *purpose* (Pantel et al., 2012; Lin et al., 2012) to each segment, mapping them probabilistically to a relatively loose schema, and ranking responses in conjunction with segmentations (Sawant and Chakrabarti, 2013). To maintain quality in the face of noisy input, these approaches often additionally exploit clicks (Li et al., 2011) or a corpus that has been annotated with entity mentions (Cheng and Chang, 2010; Li et al., 2010). The corpus provides contextual snippets for queries where the KG fails, preventing the systems from falling off the "structure cliff" (Pereira, 2013).

Our work advances the capabilities of the latter class of approaches, bringing them closer to the depth of the former, while handling telegraphic queries and retaining the advantage of corpus evidence over and above the KG. Very recently, (Yao et al., 2014) have concluded that for current benchmarks, deep parsing and shallow information extraction give comparable interpretation accuracy. The very recent work of (Yih et al., 2014) is similar in spirit to ours, but they do not unify segmentation and answer inference, along with corpus evidence, like we do.

3 Notation and examples

We use e_1, r, t_2, e_2 to represent abstract nodes and edges (MIDs in case of Freebase) from the KG, and $\widehat{e_1}, \widehat{r}, \widehat{t_2}$ to represent their textual mentions or hints, if any, in the query. s is a set of uninterpreted textual tokens in the query that are used to match and collect corpus contexts that lend evidence to candidate entities.

Figure 1 shows some telegraphic queries with possible segmentation into the above parts. Consider another example: dave navarro first band. 'Band' is a hint for type `/music/musical_group`, so it comprises $\widehat{t_2}$. Dave Navarro is an entity, with mention words 'dave navarro' comprising $\widehat{e_1}$. $\widehat{r}$ is made up of 'band', and represents the relation `/music/group_member/membership`. Finally, the word first cannot be mapped to any simple KG artifact, so are relegated to s (which makes the corpus a critical part of answer inference). We use s and $\widehat{s}$ interchangeably.

Generally, there will be enough noise and uncertainty that the search system should try out several of the most promising segmentations as shown in Figure 1. The accuracy of any specific segmentation is expected to be low in such adversarial settings. Therefore, support for an answer entity is aggregated over several segmentations. The expectation is that by considering multiple interpretations, the system will choose the entity with best supporting evidence from corpus and knowledge base.

4 Our Approach

Telegraphic queries are usually short, so we enumerate query token spans (with some restrictions, similar to beam search) to propose segmentations (§4.1). Candidate response entities are lined up for each interpretation, and then scored in a global model along with query segmentations (§4.2). §4.3 describes how model parameters are trained.

1: **input:** query token sequence q
2: initialize segmentations $\mathcal{I} = \varnothing$
3: $\mathcal{E}_1$ = (entity, mention) pairs from linker
4: **for all** $(e_1, \widehat{e_1}) \in \mathcal{E}_1$ **do**
5: assign label E_1 to mention tokens $\widehat{e_1}$
6: **for all** contiguous span $v \subset q \setminus \widehat{e_1}$ **do**
7: label each word $w \in v$ as T_2R
8: label other words $w \in q \setminus \widehat{e_1} \setminus v$ as S
9: add segments (E_1, T_2R, S) to $\mathcal{I}$
10: **end for**
11: **end for**
12: **return** candidate segmentations $\mathcal{I}$

Figure 2: Generating candidate query segmentations.

4.1 Generating candidate query segmentations

Each query token can have four labels, E_1, T_2, R, S, corresponding to the mentions of the base entity, target type, connecting relation, and context words. We found that segments hinting at T_2 and R frequently overlapped (e.g., 'author' in the query zhivago author). In our implementation, we simplified to three labels, E_1, T_2R, S, where tokens labeled T_2R are involved with both t_2 and r, the proposed structured target type and connecting relation. Another reasonable assumption was that the base entity mention and type/relation mentions are contiguous token spans, whereas context words can be scattered in multiple segments.

Figure 2 shows how candidate segmentations are generated. For step 3, we use TagMe (Ferragina and Scaiella, 2010), an entity linker backed by an entity gazette derived from our KG.

4.2 Graphical model

Based on the previous discussion, we assume that an entity-seeking query q is a sequence of tokens $q_1, q_2, \ldots$, and this can be partitioned into different kinds of subsequences, corresponding to e_1, r, t_2 and s, and denoted by a structured (vector) labeling $z = z_1, z_2, \ldots$. Given sequences q and z, we can separate out (possibly empty) token segments $\widehat{e_1}(q,z)$, $\widehat{t_2}(q,z)$, $\widehat{r}(q,z)$, and $\widehat{s}(q,z)$.

A query segmentation z becomes plausible in conjunction with proposals for e_1, r, t_2 and e_2 from the KG. The probability $\Pr(z, e_1, r, t_2, e_2|q)$ is modeled as proportional to the product of several potentials (Koller and Friedman, 2009) in a graphical model. In subsequent subsections, we will present the design of specific potentials.

- $\Psi_R(q,z,r)$ denotes the compatibility between the relation hint segment $\widehat{r}(q,z)$ and a proposed relation type r in the KG (§4.2.1).
- $\Psi_{T_2}(q,z,t_2)$ denotes the compatibility between the type hint segment $\widehat{t_2}(q,z)$ and a proposed target entity type t_2 in the KG (§4.2.2).
- $\Psi_{E_1,R,E_2,S}(q,z,e_1,r,e_2)$ is a novel corpus-based evidence potential that measures how strongly e_1 and e_2 appear in corpus snippets in the proximity of words in $\widehat{s}(q,z)$, and apparently related by relation type r (§4.2.3).
- $\Psi_{E_1}(q,z,e_1)$ denotes the compatibility between the query segment $\widehat{e_1}(q,z)$ and entity e_1 that it purportedly mentions (§4.2.4).
- $\Psi_S(q,z)$ denotes selector compatibility. Selectors are a fallback label, so this is pinned arbitrarily to 1; other potentials are balanced against this base value.
- $\Psi_{E_1,R,E_2}(e_1,r,e_2)$ is A if the relation $r(e_1,e_2)$ exists in the KG, and is $B > 0$ otherwise, for tuned/learnt constants $A > B > 0$. Note that this is a soft constraint ($B > 0$); if the KG is incomplete, the corpus may be able to supplement the required information.
- $\Psi_{E_2,T_2}(e_2,t_2)$ is 1 if e_2 belongs to t_2 and zero otherwise. In other words, candidate e_2s must be proposed to be instances of the proposed t_2 — this is a hard constraint, but can be softened if desired, like Ψ_{E_1,R,E_2}.

Figure 3 shows the relevant variable states as circled nodes, and the potentials as square factor nodes. To rank candidate entities e_2, we pin the node E_2 to each entity in turn. With E_2 pinned, we perform a MAP inference over all other hidden variables and note the score of e_2 as the product of the above potentials maximized over choices of all other variables: score$(e_2) =$

$$\begin{aligned}\max_{z,t_2,r,e_1} & \Psi_{T_2}(q,z,t_2)\Psi_R(q,z,r) \\ & \Psi_{E_1}(q,z,e_1)\Psi_S(q,z) \\ & \Psi_{E_2,T_2}(e_2,t_2)\Psi_{E_1,R,E_2}(e_1,r,e_2) \\ & \Psi_{E_1,R,E_2,S}(q,z,e_1,r,e_2). \qquad (1)\end{aligned}$$

We rank candidate e_2s by decreasing score, which is estimated by max-product message-passing (Koller and Friedman, 2009).

As noted earlier, any of the relation/type, or query entity partitions may be empty. To handle

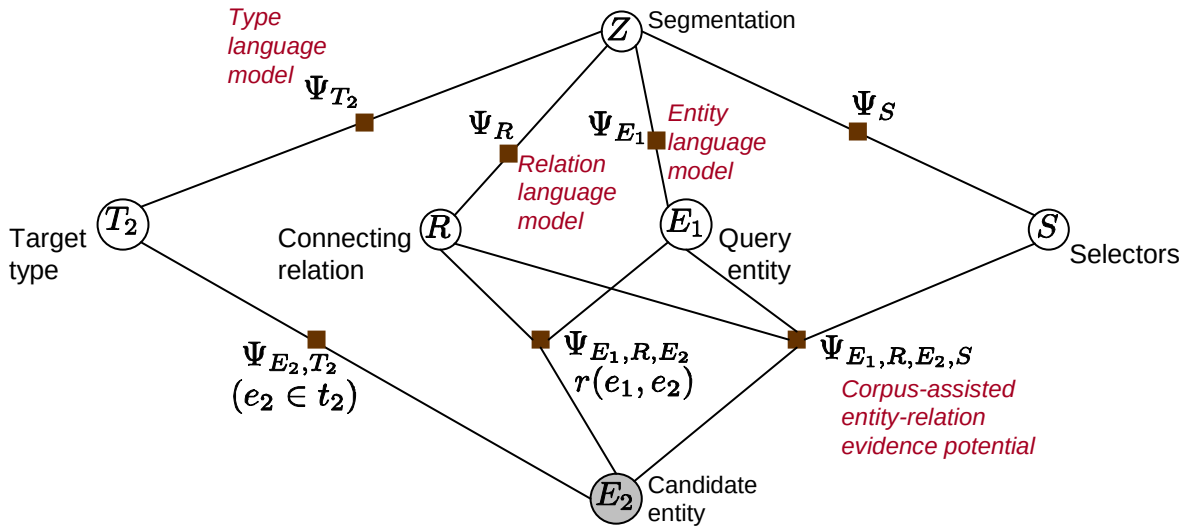

Figure 3: Graphical model for query segmentation and entity scoring. Factors/potentials are shown as squares. A candidate e_2 is observed and scored using equation (1). Query q is also observed but not shown to reduce clutter; most potentials depend on it.

this case, we allow each of the entity, relation or target type nodes in the graphical to take the value $\perp$ or 'null'. To support this, the value of the factor between the query segmentation node Z and $\Psi_{E1}(q, z, e_1)$, $\Psi_{T2}(q, z, t_2)$, and $\Psi_R(q, z, r)$) are set to suitable low values.

Next, we will describe the detailed design of some of the key potentials introduced above.

4.2.1 Relation language model for Ψ_R

Potential $\Psi_R(q, z, r)$ captures the compatibility between $\widehat{r}(q, z)$ and the proposed relation r. E.g., if the query is steve jobs death reason, and $\widehat{r}$ is (correctly chosen as) death reason, then the correct candidate r is `/people/deceased_person/cause_of_death`. An incorrect r is `/people/deceased_person/place_of_death`. An incorrect z may lead to $\widehat{r}(q, z)$ being jobs death.

Using corpus: Considerable variation may exist in how r is represented textually in a query. The relation language model needs to build a bridge between the formal r and the textual $\widehat{r}$, so that (un)likely r's have (small) large potential. Many approaches (Berant et al., 2013; Berant and Liang, 2014; Kwiatkowski et al., 2013; Yih et al., 2014) to this problem have been intensely studied recently. Given our need to process billions of Web pages efficiently, we chose a pattern-based approach (Nakashole et al., 2012): with each r, discover the most strongly associated phrase patterns from a reference corpus, then mark these patterns into much larger payload corpus.

We started with the 2000 (out of approximately 14000) most frequent relation types in Freebase, and the ClueWeb09 corpus annotated with Freebase entities (Gabrilovich et al., 2013). For each triple instance of each relation type, we located all corpus sentences that mentioned both participating entities. We made the crude assumption that if $r(e_1, e_2)$ holds and e_1, e_2 co-occur in a sentence then this sentence is evidence of the relationship. Each such sentence is parsed to obtain a dependency graph using the Malt Parser (Hall et al., 2014). Words in the path connecting the entities are joined together and added to a candidate phrase dictionary, provided the path is at most three hops. (Inspection suggested that longer dependency paths mostly arise out of noisy sentences or botched parses.) 30% of the sentences were thus retained. Finally, we defined

$$\Psi_R(q, z, r) = \frac{n(r, \widehat{r}(q, z))}{\sum_{p'} n(r, p')}, \qquad (2)$$

where p' ranges over all phrases that are known to hint at r, and $n(r, p)$ denotes the number of sentences where the phrase p occurred in the dependency path between the entities participating in relation r.

Assuming entity co-occurrence implies evidence is admittedly simplistic. However, the primary function of the relation model is to retrieve top-k relations that are compatible with the type/s

of e_1 and the given relation hint. Moreover, the remaining noise is further mitigated by the collective scoring in the graphical model. While we may miss relations if they are expressed in the query through obscure hints, allowing the relation to be $\perp$ acts as a safety net.

Using Freebase relation names: As mentioned earlier, queries may express relations differently as compared to the corpus. A relation model based solely on corpus annotations may not be able to bridge that gap effectively, particularly so, because of sparsity of corpus annotations or the rarity of Freebase triples in ClueWeb. E.g., for the Freebase relation `/people/person/profession`, we found very few annotated sentences. One way to address this problem is to utilize relation type names in Freebase to map hints to relation types. Thus, in addition to the corpus-derived relation model, we also built a language model that used Freebase relation type names as lemmas. E.g., the word 'profession' would contribute to the relation type `/people/person/profession`.

Our relation models are admittedly simple. This is mainly because telegraphic queries may express relations very differently from natural language text. As it is difficult to ensure precision of query interpretation stage, our models are geared towards recall. The system generates a large number of interpretations and relies on signals from the corpus and KG to bring forth correct interpretations.

4.2.2 Type language model for Ψ_{T_2}

Similar to the relation language model, we need a type language model to measure compatibility between t_2 and $\widehat{t_2}(q, z)$. Estimating the target entity type, without over-generalizing or over-specifying it, has always been important for QA. E.g., when $\widehat{t_2}$ is 'city', a good type language model should prefer t_2 as `/location/citytown` over `/location/location` while avoiding `/location/es_autonomous_city`.

A catalog like Freebase suggests a straightforward method to collect a type language model. Each type is described by one or more phrases through the link `/common/topic/alias`. We can collect these into a micro-'document' and use a standard Dirichlet-smoothed language model from IR (Zhai, 2008). In Freebase, an entity node (e.g., Einstein, `/m/0jcx`) may be linked to a type node (e.g. `/base/scientist/physicist`) using an edge with label `/type/object/type`.

But relation types provide additional clues to types of the endpoint entities. Freebase relation types have the form `/x/y/z`, where `x` is the domain of the relation, and `y` and `z` are string representations of the type of the entities participating in the relation. E.g., the (directed) relation type `/location/country/capital` connects from from `/location/country` to `/location/citytown`. Therefore, "capital" can be added to the set of descriptive phrases of entity type `/location/citytown`.

It is important to note that while we use Freebase link nomenclature for relation and type language models, our models are not incompatible with other catalogs. Indeed, most catalogs have established ways of deriving language models that describe their various structures. For example, most YAGO types are derived from WordNet synsets with associated phrasal descriptions (lemmas). YAGO relations also have readable names such as actedIn, isMarriedTo, etc. which can be used to estimate language models. DBPedia relations are mostly derived from (meaningfully) named attributes taken from infoboxes, hence they can be used directly. Furthermore, others (Wu and Weld, 2007) have shown how to associate language models with such relations.

4.2.3 Snippet scoring

The factor $\Psi_{E_1,R,E_2,S}(q, z, e_1, r, e_2)$ should be large if many snippets contain a mention of e_1 and e_2, relation r, and many high-signal words from s. Recall that we begin with a corpus annotated with entity mentions. Our corpus is not directly annotated with relation mentions. Therefore, we get from relations to documents via high-confidence phrases. Snippets are retrieved using a combined entity + word index, and scored for a given e_1, r, e_2, and selectors $\widehat{s}(q, z)$.

Given that relation phrases may be noisy and that their occurrence in the snippet may not necessarily mean that the given relation is being expressed, we need a scoring function that is cognizant of the roles of relation phrases and entities occurring in the snippets. In a basic version, $e_1, p, e_2, \widehat{s}$ are used to probe a combined entity+word index to collect high scoring snippets, with the score being adapted from BM25. The second, refined scoring function used a RankSVM-

style (Joachims, 2002) optimization.

$$\min_{\lambda,\xi} \|\lambda\|^2 + C\sum_{e^+,e^-} \xi_{e^+,e^-} \quad \text{s.t.}$$
$$\forall e^+, e^- : \quad \lambda \cdot f(q, D_{e^+}, e^+) + \xi_{e^+,e^-} \geq \lambda \cdot f(q, D_{e^-}, e^-) + 1. \tag{3}$$

where e^+ and e^- are positive and negative entities for the query q and $f(q, D_e, e)$ represents the feature map for the set of snippets D_e belonging to entity e. The assumption here is that all snippets containing e^+ are "positive" snippets for the query. f consolidates various signals like the number of snippets where e occurs near query entity e_1 and a relation phrase, or the number of snippets with high proportion of query IDF, hinting that e is a positive entity for the given query. A partial list of features used for snippet scoring is given in Figure 4.

Number of snippets with distance(e_2, $\widehat{e_1}$) $< k_1$ (k_1 = 5, 10)
Number of snippets with distance(e_2, relation phrase) $< k_2$ (k_2 = 3, 6)
Number of snippets with relation $r = \perp$
Number of snippets with relation phrases as prepositions
Number of snippets covering fraction of query IDF $> k_3$ (k_3 = 0.2, 0.4, 0.6, 0.8)

Figure 4: Sample features used for learning weights λ to score snippets.

4.2.4 Query entity model

Potential $\Psi_{E_1}(q, z, e_1)$ captures the compatibility between $\widehat{e_1}(q, z)$ (i.e., the words that mention e_1) and the claimed entity e_1 mentioned in the query. We used the TagMe entity linker (Ferragina and Scaiella, 2010) for annotating entities in queries. TagMe annotates the query with Wikipedia entities, which we map to Freebase, and use the annotation confidence scores as the potential $\Psi_{E_1}(q, z, e_1)$.

4.3 Discriminative parameter training with latent variables

We first set the potentials in (1) as explained in §4.2 (henceforth called 'Unoptimized'), and got encouraging accuracy. Then we rewrote each potential as

$$\Psi_\bullet(\cdots) = \exp\big(w_\bullet \cdot \phi_\bullet(\cdots)\big) \tag{4}$$
$$\text{or} \quad \log \textstyle\prod_\bullet \Psi_\bullet(\cdots) = \sum_\bullet w_\bullet \cdot \phi_\bullet(\cdots),$$

with $w_\bullet$ being a weight vector for a specific potential $\bullet$, and $\phi_\bullet$ being a corresponding feature vector. During inference, we seek to maximize

$$\max_{q,z,e_1,t_2,r} w \cdot \phi(q, z, e_1, t_2, r, e_2), \tag{5}$$

for a fixed w, to find the score of each candidate entity e_2. Here all $w_\bullet$ and $\phi_\bullet$ have been collected into unified weight and feature vectors w, ϕ. During training of w, we are given pairs of correct and incorrect answer entities e_2^+, e_2^-, and we wish to satisfy constraints of the form

$$\max_{q,z,e_1,t_2,r} w \cdot \phi(q, z, e_1, t_2, r, e_2^+) + \xi \geq 1 + \max_{q,z,e_1,t_2,r} w \cdot \phi(q, z, e_1, t_2, r, e_2^-), \tag{6}$$

because collecting e_2^+, e_2^- pairs is less work than supervising with values of z, e_1, t_2, r, e_2 for each query. Similar distant supervision problems were posed via bundle method by (Bergeron et al., 2008), and (Yu and Joachims, 2009), who used CCCP (Yuille and Rangarajan, 2006). These are equivalent in our setting. We use the CCCP style, and augment the objective with an additional entropy term as in (Sawant and Chakrabarti, 2013). We call this LVDT (latent variable discriminative training) in §5.

5 Experiments

5.1 Testbed

Corpus and knowledge graph: We used the ClueWeb09B (ClueWeb09, 2009) corpus containing 50 million Web documents. This corpus was annotated by Google with Freebase entities (Gabrilovich et al., 2013). The average page contains 15 entity annotations from Freebase. We used the Freebase KG and its links to Wikipedia.

Queries: We report on two sets of entity-seeking queries. A sample of about 800 well-formed queries from WebQuestions (Berant et al., 2013) were converted to telegraphic utterances (such as would be typed into commercial search engines) by volunteers familiar with Web search. We call this WQT (WebQuestions, telegraphic). Queries are accompanied by ground truth entities. The second data set, TREC-INEX, from (Sawant and Chakrabarti, 2013) has about 700 queries sampled from TREC and INEX, available at `http://bit.ly/WSpxvr`. These come with well-formed and telegraphic utterances, as well as ground truth entities.

There are some notable differences between these query sets. For WQT, queries were generated by using Google's query suggestions interface. Volunteers were asked to find answers using single Freebase pages. Therefore, by construction, queries retained can be answered using the Freebase KG alone, with a simple $r(e_1, ?)$ form. In contrast, TREC-INEX queries provide a balanced mix of t_2 and r hints in the queries, and direct answers from triples is relatively less available.

5.2 Implementation details

On an average, the pseudocode in Figure 2 generated 13 segmentations per query, with longer queries generating more segmentations than shorter ones.

We used an MG4J (Boldi and Vigna, 2005) based query processor, written in Java, over entity and word indices on ClueWeb09B. The index supplies snippets with a specified maximum width, containing a mention of some entity and satisfying a WAND (Broder et al., 2003) predicate over words in $\widehat{s}$. In case of phrases in the query, the WAND threshold was computed by adding the IDF of constituent words. The index returned about 330,000 snippets on average for WAND threshold of 0.6.

We retained the top 200 candidate entities from the corpus; increasing this horizon did not give benefits. We also considered as candidates for e_2 those entities that are adjacent to e_1 in the KG via top-scoring r candidates. In order to generate supporting snippets for an interpretation containing entity annotation e, we need to match e with Google's corpus annotations. However, relying solely on corpus annotations fails to retrieve many potential evidence snippets, because entity annotations are sparse. Therefore we probed the token index with the textual mention of e_1 in the query; this improved recall.

We also investigated the feasibility of our proposals for interactive search. There are three major processes involved in answering a query - generating potential interpretations, collecting/scoring snippets, and inference (MAP for Unoptimized and $w\phi(\cdot)$ for LVDT). For the WQT dataset, average time per query for each stage was approximately - 0.2, 16.6 and 1.3 seconds respectively. Our (Java) code did not optimize the bottleneck at all; only 10 hosts and no clever load balancing were used. We believe commercial search engines can cut this down to less than a second.

5.3 Research questions

In the rest of this section we will address these questions:

- For telegraphic queries, is our entity-relation-type-selector segmentation better than the type-selector segmentation of (Sawant and Chakrabarti, 2013)?
- When semantic parsers (Berant et al., 2013; Kwiatkowski et al., 2013) are subjected to telegraphic queries, how do they perform compared to our proposal?
- Are the KG and corpus really complementary as regards their support of accurate ranking of candidate entities?
- Is the prediction of r and t_2 from our approach better than a greedy assignment based on local language models?

We also discuss anecdotes of successes and failures of various systems.

5.4 Benefits of relation in addition to type

Figure 5 shows entity-ranking MAP, MRR, and NDCG@10 (n@10) for two data sets and various systems. "No interpretation" is an IR baseline without any KG. Type+selector is our implementation of (Sawant and Chakrabarti, 2013). Unoptimized and LVDT both beat "no interpretation" and "type+selector" by wide margins. (Boldface implies best performing formulation.) There are two notable differences between S&C and our work. First, S&C do not use the knowledge graph (KG) and rely on a noisy corpus. This means S&C fails to answer queries whose answers are found only in KG. This can be seen from WQT results; they perform only slightly better than the baseline. Second, even for queries that can be answered through the corpus alone, S&C miss out on two important signals that the query may provide - namely the query entity and the relation. Our framework not only provides a way to use a curated and high precision knowledge graph but also attempts to provide more reachability to corpus by the use of relational phrases.

In case of TREC-INEX, LVDT improves upon the unoptimized graphical model, where for WQT, it does not. Preliminary inspection suggests this is because WQT has noisy and incomplete ground truth, and LVDT trains to the noise; a non-convex

Dataset	Formulation	map	mrr	n@10
TREC -INEX	No interpretation	.205	.215	.292
	Type+selector	.292	.306	.356
	Unoptimized	.409	.419	.502
	LVDT	**.419**	**.436**	**.541**
WQT	No interpretation	.080	.095	.131
	Type+selector	.116	.152	.201
	Unoptimized	**.377**	**.401**	**.474**
	LVDT	.295	.323	.406

Figure 5: 'Entity-relation-type-selector' segmentation yields better accuracy than 'type-selector' segmentation.

objective makes matters worse. The bias in our unoptimized model circumvents training noise.

5.5 Comparison with semantic parsers

For TREC-INEX, both unoptimized and LVDT beat SEMPRE (Berant et al., 2013) convincingly, whether it is trained with Free917 or WebQuestions (Figure 6).

SEMPRE's relatively poor performance, in this case, is explained by its complete reliance on the knowledge graph. As discussed previously, the TREC-INEX dataset contains a sizable proportion of queries that may be difficult to answer using a KG alone. When SEMPRE is compared with our systems with a telegraphic sample of WebQuestions (WQT), results are mixed. Our Unoptimized model still compares favorably to SEMPRE, but with slimmer gains. As before, LVDT falls behind.

Dataset	Formulation	map	mrr	n@10
TREC -INEX	SEMPRE(Free917)	.154	.159	.186
	SEMPRE(WQ)	.197	.208	.247
	Unoptimized	.409	.419	.502
	LVDT	**.419**	**.436**	**.541**
WQT	SEMPRE(Free917)	.229	.255	.285
	SEMPRE(WQ)	.374	**.406**	.449
	Unoptimized	**.377**	.401	**.474**
	Jacana	.239	.256	.329
	LVDT	.295	.323	.406

Figure 6: Comparison with semantic parsers.

Our smaller gains over SEMPRE in case of WebQuestions is explained by how WebQuestions was assembled (Berant et al., 2013). Although Google's query suggestions gave an eclectic pool, only those queries survived that could be answered using a single Freebase page, which effectively reduced the role of a corpus. In fact, a large fraction of WQT queries cannot be answered well using the corpus alone, because FACC1 annotations are too sparse and rarely cover common nouns and phrases such as 'democracy' or 'drug overdose' which are needed for some WQT queries.

For WQT, our system also compares favorably with Jacana (Yao and Van Durme, 2014). Given that they subject their input to natural langauge parsing, their relatively poor performance is not unsurprsing.

5.6 Complementary benefits of KG & corpus

Figure 7 shows the synergy between the corpus and the KG. In all cases and for all metrics, using the corpus and KG together gives superior performance to using any of them alone. However, it is instructive that in case of TREC-INEX, corpus-only is better than KG-only, whereas this is reversed for WQT, which also supports the above argument.

Data	Formulation	map	mrr	n@10
TREC-INEX	Unoptimized (KG)	.201	.209	.241
	Unoptimized (Corpus)	.381	.388	.471
	Unoptimized (Both)	**.409**	**.419**	**.502**
	LVDT (KG only)	.255	.264	.293
	LVDT (Corpus)	.267	.272	.315
	LVDT (Both)	**.419**	**.436**	**.541**
WQT	Unoptimized (KG)	.329	.343	.394
	Unoptimized (Corpus)	.188	.228	.291
	Unoptimized (Both)	**.377**	**.401**	**.474**
	LVDT (KG only)	.257	.281	.345
	LVDT (Corpus only)	.170	.210	.280
	LVDT (Both)	**.295**	**.323**	**.406**

Figure 7: Synergy between KB and corpus.

5.7 Collective vs. greedy segmentation

To judge the quality of interpretations, we asked paid volunteers to annotate queries with an appropriate relation and type, and compared them with the interpretations associated with top-ranked entities. Results in Figure 8 indicate that in spite of noisy relation and type language models, our formulations produce high quality interpretations through collective inference.

Figure 9 demonstrates the benefit of collective inference over greedy segmentation followed by

Formulation	Type	Relation	Type/Rel
Unoptimized (top 1)	23	49	60
Unoptimized (top 5)	29	57	68
LVDT (top 1)	25	52	61
LVDT (top 5)	33	61	69

Figure 8: Fraction of queries (%) with correct interpretations of t_2, r, and t_2 or r, on TREC-INEX.

evaluation. Collective inference boosts absolute MAP by as much as 0.2.

Dataset	Formulation	map	mrr	n@10
TREC -INEX	Unoptimized (greedy)	.343	.347	.432
	Unoptimized	.409	.419	.502
	LVDT (greedy)	205	.214	.259
	LVDT	**.419**	.436	.541
WQT	Unoptimized (greedy)	.246	.271	.335
	Unoptimized	.377	.401	.474
	LVDT (greedy)	.212	.246	.317
	LVDT	.295	.323	.406

Figure 9: Collective vs. greedy segmentation

5.8 Discussion

Closer scrutiny revealed that collective inference often overcame errors in earlier stages to produce a correct ranking over answer entities. E.g., for the query automobile company makes spider the entity disambiguation stage fails to identify the car Alfa Romeo Spider (`/m/08ys39`). However, the interpretation stage recovers from the error and segments the query with Automobile (`/m/0k4j`) as the query entity e_1, `/organization/organization` and `/business/industry/companies` as target type t_2 and relation r respectively (from the relation/type hint 'company'), and *spider* as selector to arrive at the correct answer Alfa Romeo (`/m/09c50`). The corpus features also play a crucial role for queries which may not be accurately represented with an appropriate logical formula. For the query meg ryan bookstore movie, the textual patterns for the relation `ActedIn` in conjunction with the selector word 'bookstore' correctly identifies the answer entity You've Got Mail (`/m/014zwb`).

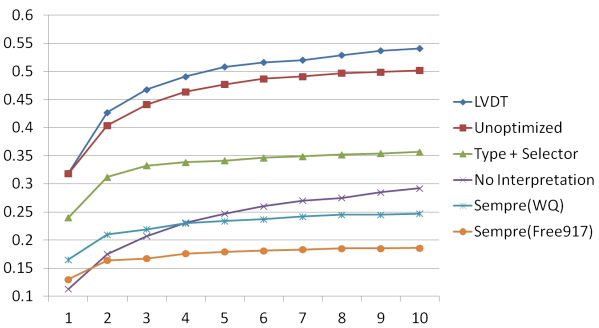

Figure 10: Comparison of various approaches for NDCG at rank 1 to 10, TREC-INEX dataset

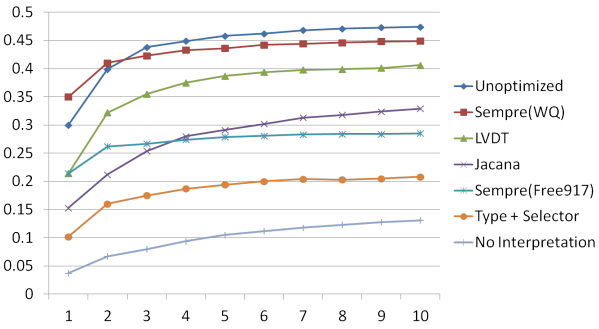

Figure 11: Comparison of various approaches for NDCG at rank 1 to 10, WQT dataset

We also analyzed samples of queries where our system did not perform particularly well. We observed that one of the recurring themes of these queries was that their answer entities had very little corpus support, and the type/relation hint mapped to too many or no candidate type/relations. For example, in the query south africa political system, the relevant type/relation hint 'political system' could not be mapped to `/government/form_of_government` and `/location/country/form_of_government` respectively.

6 Conclusion and future work

We presented a technique to partition telegraphic entity-seeking queries into functional segments and to rank answer entities accordingly. While our results are favorable compared to strong prior art, further improvements may result from relaxing our model to recognize multiple e_1s and rs. It may also help to deploy more sophisticated paraphrasing models (Berant and Liang, 2014) or word embeddings (Yih et al., 2014) for relation hints. It would also be interesting to supplement entity-linked corpora and curated KGs with extracted triples (Fader et al., 2014). Another possibility is to apply the ideas presented here to well-formed questions.

Abstract

Estimating questions' difficulty levels is an important task in community question answering (CQA) services. Previous studies propose to solve this problem based on the question-user comparisons extracted from the question answering threads. However, they suffer from data sparseness problem as each question only gets a limited number of comparisons. Moreover, they cannot handle newly posted questions which get no comparisons. In this paper, we propose a novel question difficulty estimation approach called Regularized Competition Model (RCM), which naturally combines question-user comparisons and questions' textual descriptions into a unified framework. By incorporating textual information, RCM can effectively deal with data sparseness problem. We further employ a K-Nearest Neighbor approach to estimate difficulty levels of newly posted questions, again by leveraging textual similarities. Experiments on two publicly available data sets show that for both well-resolved and newly-posted questions, RCM performs the estimation task significantly better than existing methods, demonstrating the advantage of incorporating textual information. More interestingly, we observe that RCM might provide an automatic way to quantitatively measure the knowledge levels of words.

1 Introduction

Recent years have seen rapid growth in community question answering (CQA) services. They have been widely used in various scenarios, including general information seeking on the web[1], knowledge exchange in professional communities[2], and question answering in massive open online courses (MOOCs)[3], to name a few.

An important research problem in CQA is how to automatically estimate the difficulty levels of questions, i.e., *question difficulty estimation* (QDE). QDE can benefit many applications. Examples include 1) Question routing. Routing questions to appropriate answerers can help obtain quick and high-quality answers (Li and King, 2010; Zhou et al., 2009). Ackerman and McDonald (1996) have demonstrated that routing questions by matching question difficulty level with answerer expertise level will make better use of answerers' time and expertise. This is even more important for enterprise question answering and MOOCs question answering, where human resources are expensive. 2) Incentive mechanism design. Nam et al. (2009) have found that winning point awards offered by reputation systems is a driving factor for user participation in CQA services. Assigning higher point awards to more difficult questions will significantly improve user participation and satisfaction. 3) Linguistics analysis. Researchers in computational linguistics are always interested in investigating the correlation between language and knowledge, to see how the language reflects one's knowledge (Church, 2011). As we will show in Section 5.4, QDE provides an automatic way to quantitatively measure the knowledge levels of words.

Liu et al. (2013) have done the pioneer work on QDE, by leveraging question-user comparisons extracted from the question answering threads. Specifically, they assumed that the difficulty level of a question is higher than the expertise level of the asker (i.e. the user who asked the question), but lower than that of the best answerer (i.e. the user who provided the best answer). A TrueSkill al-

gorithm (Herbrich et al., 2006) was further adopted to estimate question difficulty levels as well as user expertise levels from the pairwise comparisons among them. To our knowledge, it is the only existing work on QDE. Yang et al. (2008) have proposed a similar idea, but their work focuses on a different task, i.e., estimating difficulty levels of tasks in crowdsourcing contest services.

There are two major drawbacks of previous methods: 1) *data sparseness problem* and 2) *cold-start problem*. By the former, we mean that under the framework of previous work, each question is compared only twice with the users (once with the asker and the other with the best answerer), which might not provide enough information and contaminate the estimation accuracy. By the latter, we mean that previous work only deals with well-resolved questions which have received the best answers, but cannot handle newly posted questions with no answers received. In many real-world applications such as question routing and incentive mechanism design, however, it is usually required that the difficulty level of a question is known instantly after it is posted.

To address the drawbacks, we propose further exploiting questions' textual descriptions (e.g., title, body, and tags) to perform QDE. Preliminary observations have shown that a question's difficulty level can be indicated by its textual description (Liu et al., 2013). We take advantage of the observations, and assume that if two questions are close in their textual descriptions, they will also be close in their difficulty levels, i.e., the *smoothness assumption*. We employ manifold regularization (Belkin et al., 2006) to characterize the assumption. Manifold regularization is a well-known technique to preserve local invariance in manifold learning algorithms, i.e., nearby points are likely to have similar embeddings (Belkin and Niyogi, 2001). Then, we propose a novel Regularized Competition Model (RCM), which formalizes QDE as minimizing a loss on question-user comparisons with manifold regularization on questions' textual descriptions. As the smoothness assumption offers extra information for inferring question difficulty levels, incorporating it will effectively deal with data sparsity. Finally, we adopt a K-Nearest Neighbor approach (Cover and Hart, 1967) to perform cold-start estimation, again by leveraging the smoothness assumption.

Experiments on two publicly available data sets collected from Stack Overflow show that 1) RCM performs significantly better than existing methods in the QDE task for both well-resolved and cold-start questions. 2) The performance of RCM is insensitive to the particular choice of the term weighting schema (determines how a question's textual description is represented) and the similarity measure (determines how the textual similarity between two questions is measured). The results demonstrate the advantage of incorporating textual information for QDE. Qualitative analysis further reveals that RCM might provide an automatic way to quantitatively measure the knowledge levels of words.

The main contributions of this paper include: 1) We take fully advantage of questions' textual descriptions to address data sparseness problem and cold-start problem which previous QDE methods suffer from. To our knowledge, it is the first time that textual information is introduced in QDE. 2) We propose a novel QDE method that naturally combines question-user comparisons and questions' textual descriptions into a unified framework. The proposed method performs QDE significantly better than existing methods. 3) We demonstrate the practicability of estimating difficulty levels of cold-start questions purely based on their textual descriptions, making various applications feasible in practice. As far as we know, it is the first work that considers cold-start estimation. 4) We explore how a word's knowledge level can be automatically measured by RCM.

The rest of the paper is structured as follows. Section 2 describes the problem formulation and the motivation of RCM. Section 3 presents the details of RCM. Section 4 discusses cold-start estimation. Section 5 reports experiments and results. Section 6 reviews related work. Section 7 concludes the paper and discusses future work.

2 Preliminaries

2.1 Problem Formulation

A CQA service provides a platform where people can ask questions and seek answers from others. Given a CQA portal, consider a specific category where questions on the same topic are asked and answered, e.g., the "C++ programming" category of Stack Overflow. When an asker u_a posts a question q in the category, there will be several answerers to answer the question. Among all the received answers, a best one will be chosen

by the asker or voted by the community. The answerer who provides the best answer is called the best answerer u_b. The other answerers are denoted by $O = \{u_{o_1}, u_{o_2}, \cdots, u_{o_M}\}$. A question answering thread (QA thread) is represented as a quadruplet (q, u_a, u_b, O). Collecting all such QA threads in the category, we get M users and N questions, denoted by $\mathcal{U} = \{u_1, u_2, \cdots, u_M\}$ and $\mathcal{Q} = \{q_1, q_2, \cdots, q_N\}$ respectively. Each user u_m is associated with an expertise score θ_m, representing his/her expertise level. A larger θ_m indicates a higher expertise level of the user. Each question q_n is associated with a difficulty score β_n, representing its difficulty level. A larger β_n indicates a higher difficulty level of the question. Difficulty scores (as well as expertise scores) are assumed to be comparable with each other in the specified category. Besides, each question q_n has a textual description, and is represented as a V-dimensional term vector $\boldsymbol{d}_n$, where V is the vocabulary size.

The *question difficulty estimation* (QDE) task aims to automatically learn the question difficulty scores (β_n's) by utilizing the QA threads $\mathcal{T} = \{(q, u_a, u_b, O) : q \in \mathcal{Q}\}$ as well as the question descriptions $\mathcal{D} = \{\boldsymbol{d}_1, \boldsymbol{d}_2, \cdots, \boldsymbol{d}_N\}$ in the specified category. Note that in Section 2 and Section 3, we consider estimating difficulty scores of resolved questions, i.e., questions with the best answers selected or voted. Estimating difficulty scores of unresolved questions, e.g., newly posted ones, will be discussed in Section 4.

2.2 Competition-based Methods

Liu et al. (2013) have proposed a competition-based method for QDE. The key idea is to 1) extract pairwise competitions from the QA threads and 2) estimate question difficulty scores based on extracted competitions.

To extract pairwise competitions, it is assumed that question difficulty scores and user expertise scores are expressed on the same scale. Given a QA thread (q, u_a, u_b, O), it is further assumed that:

Assumption 1 (pairwise comparison assumption) *The difficulty score of question q is higher than the expertise score of the asker u_a, but lower than that of the best answerer u_b. Moreover, the expertise score of the best answerer u_b is higher than that of the asker u_a, as well as any answerer in O.*[4]

[4]The difficulty score of question q is not assumed to be lower than the expertise score of any answerer in O, since such a user may just happen to see the question and respond to it, rather than knowing the answer well.

Given the assumption, there are $(|O| + 3)$ pairwise competitions extracted from the QA thread, including 1) one competition between the question q and the asker u_a, 2) one competition between the question q and the best answerer u_b, 3) one competition between the best answerer u_b and the asker u_a, and 4) $|O|$ competitions between the best answerer u_b and each of the answerers in O. The question q is the winner of the first competition, and the best answerer u_b is the winner of the remaining $(|O| + 2)$ competitions. These pairwise competitions are denoted by

$$C_q = \{u_a \prec q, q \prec u_b, u_a \prec u_b, u_{o_1} \prec u_b, \cdots, u_{o_M} \prec u_b\},$$

where $i \prec j$ means that competitor j beats competitor i in a competition. Let

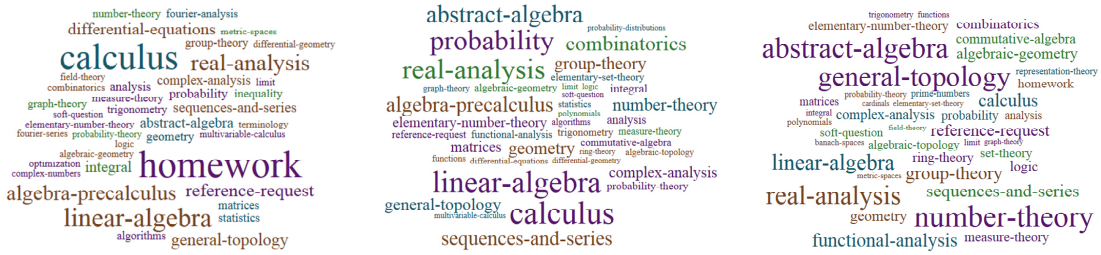
$$C = \bigcup_{q \in \mathcal{Q}} C_q \tag{1}$$

be the set containing all the pairwise competitions extracted from $\mathcal{T}$.

Given the competition set C, Liu et al. (2013) further adopted a TrueSkill algorithm (Herbrich et al., 2006) to learn the competitors' skill levels (i.e. the question difficulty scores and the user expertise scores). TrueSkill assumes that the practical skill level of each competitor follows a normal distribution $N\left(\mu, \sigma^2\right)$, where μ is the average skill level and σ is the estimation uncertainty. Then it updates the estimations in an online mode: for a newly observed competition with its win-loss result, 1) increase the average skill level of the winner, 2) decrease the average skill level of the loser, and 3) shrink the uncertainties of both competitors as more data has been observed. Yang et al. (2008) have proposed a similar competition-based method to estimate tasks' difficulty levels in crowdsourcing contest services, by leveraging PageRank (Page et al., 1999) algorithm.

2.3 Motivating Discussions

The methods introduced above estimate competitors' skill levels based solely on the pairwise competitions among them. The more competitions a competitor participates in, the more accurate the estimation will be. However, according to the pairwise comparison assumption (Assumption 1), each question participates in only two competitions, one with the asker and the other with the best answerer. Hence, there might be no enough information to accurately infer its difficulty score. We call this the *data sparseness problem*.



(a) Low difficulty. (b) Medium difficulty. (c) High difficulty.

Figure 1: Tag clouds of SO/Math questions with different difficulty levels.

Taking advantage of additional metadata has been demonstrated to be an effective way of dealing with data sparsity in various applications such as collaborative filtering (Claypool et al., 1999; Schein et al., 2002) and personalized search (Dou et al., 2007; Sugiyama et al., 2004). The rationale behind is to bridge the gap among users/items by leveraging their similarities based on the metadata. As for QDE, preliminary observations have shown that a question's difficulty level can be indicated by its textual description (Liu et al., 2013). As an example, consider the QA threads in the "mathematics" category of Stack Overflow. Divide the questions into three groups: 1) low difficulty, 2) medium difficulty, and 3) high difficulty, according to their difficulty scores estimated by TrueSkill. Figure 1 visualizes the frequency distribution of tags in each group, where the size of each tag is in proportion to its frequency in the group. The results indicate that the tags associated with the questions do have the ability to reflect the questions' difficulty levels, e.g., low difficulty questions usually have tags such as "homework" and "calculus", while high difficulty ones usually have tags such as "general topology" and "number theory". We further calculate the Pearson correlation coefficient (Rodgers and Nicewander, 1988) between 1) the gap between the averaged difficulty scores in each two groups and 2) the Euclidean distance between the aggregated textual descriptions in each two groups . The result is $r = 0.6424$, implying that the difficulty gap is positively correlated with the textual distance. In other words, the more similar two questions' textual descriptions are, the more close their difficulty levels are. Therefore, we take the textual information to bridge the difficulty gap among questions, by assuming that

Assumption 2 (smoothness assumption) *If two questions q_i and q_j are close in their textual descriptions $\boldsymbol{d}_i$ and $\boldsymbol{d}_j$, they will also be close in their difficulty scores β_i and β_j.*

The smoothness assumption brings us additional information about question difficulty scores by inferring textual similarities. It serves as a supplement to the pairwise competitions, and might help address the data sparseness problem which previous methods suffer from.

3 Modeling Text Similarities for QDE

This section presents a novel Regularized Competition Model (RCM) for QDE, which combines the pairwise competitions and the textual descriptions into a unified framework. RCM can alleviate the data sparseness problem and perform more accurate estimation.

3.1 Regularized Competition Model

We start with several notations. As question difficulty scores can be directly compared with user expertise scores, we take questions as pseudo users. Let $\bar{\boldsymbol{\theta}} \in \mathbb{R}^{M+N}$ denote the skill levels (i.e. the expertise scores and the difficulty scores) of all the (pseudo) users:

$$\bar{\theta}_i = \begin{cases} \theta_i, & 1 \le i \le M, \\ \beta_{i-M}, & M < i \le M+N, \end{cases}$$

where $\bar{\theta}_i$ is the i-th entry of $\bar{\boldsymbol{\theta}}$. The first M entries are the user expertise scores, denoted by $\bar{\boldsymbol{\theta}}_u \in \mathbb{R}^M$. The last N entries are the question difficulty scores, denoted by $\bar{\boldsymbol{\theta}}_q \in \mathbb{R}^N$. Let $\bar{\theta}_i^{(u)}$ and $\bar{\theta}_i^{(q)}$ denote the i-th entries of $\bar{\boldsymbol{\theta}}_u$ and $\bar{\boldsymbol{\theta}}_q$ respectively.

Exploiting Pairwise Competitions. We define a loss on each pairwise competition $i \prec j$:

$$\ell\left(\bar{\theta}_i, \bar{\theta}_j\right) = \max\left(0, \delta - \left(\bar{\theta}_j - \bar{\theta}_i\right)\right)^p, \qquad (2)$$

where p is either 1 or 2. The loss is defined on the skill gap between the two competitors, i.e., $\bar{\theta}_j - \bar{\theta}_i$,

measuring the inconsistency between the expected outcome and the actual outcome. If the gap is larger than a predefined threshold δ, competitor j would probably beat competitor i in the competition, which coincides with the actual outcome. Then the loss will be zero. Otherwise, there is a higher chance that competitor j loses the competition, which goes against the actual outcome. Then the loss will be greater than zero. The smaller the gap is, the higher the chance of inconsistency becomes, and the greater the loss will be. Note that the threshold δ can take any positive value since we do not pose a norm constraint on $\bar{\boldsymbol{\theta}}$.[5] Without loss of generality we take $\delta = 1$ throughout this paper. As we will show in Section 3.2, the loss defined in Eq. (2) has some similarity with the SVM loss (Chapelle, 2007). We name it hinge loss when $p = 1$, and quadratic loss when $p = 2$.

Given the competition set C, estimating skill levels of (pseudo) users then amounts to solving the following optimization problem:

$$\min_{\bar{\boldsymbol{\theta}}} \sum_{(i \prec j) \in C} \ell\left(\bar{\theta}_i, \bar{\theta}_j\right) + \frac{\lambda_1}{2} \bar{\boldsymbol{\theta}}^T \bar{\boldsymbol{\theta}}, \tag{3}$$

where the first term is the empirical loss measuring the total inconsistency; the second term is a regularizer to prevent overfitting; and $\lambda_1 \geq 0$ is a trade-off coefficient. It is also a competition-based QDE method, called Competition Model (CM).

Exploiting Question Descriptions. Manifold regularization is a well-known technique used in manifold learning algorithms to preserve local invariance, i.e., nearby points are likely to have similar embeddings (Belkin and Niyogi, 2001). In QDE, the smoothness assumption expresses similar "invariance", i.e., nearby questions (in terms of textual similarities) are likely to have similar difficulty scores. Hence, we characterize the assumption with the following manifold regularizer:

$$\begin{aligned} \mathcal{R} &= \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} \left(\bar{\theta}_i^{(q)} - \bar{\theta}_j^{(q)}\right)^2 w_{ij} \\ &= \bar{\boldsymbol{\theta}}_q^T \mathbf{D} \bar{\boldsymbol{\theta}}_q - \bar{\boldsymbol{\theta}}_q^T \mathbf{W} \bar{\boldsymbol{\theta}}_q = \bar{\boldsymbol{\theta}}_q^T \mathbf{L} \bar{\boldsymbol{\theta}}_q, \end{aligned} \tag{4}$$

where w_{ij} is the textual similarity between question i and question j; $\mathbf{W} \in \mathbb{R}^{N \times N}$ is the similarity matrix with the (i, j)-th entry being w_{ij}; $\mathbf{D} \in \mathbb{R}^{N \times N}$ is a diagonal matrix with the i-th entry on the diagonal being $d_{ii} = \sum_{j=1}^{N} w_{ij}$; and $\mathbf{L} = \mathbf{D} - \mathbf{W} \in \mathbb{R}^{N \times N}$ is the graph Laplacian (Chung, 1997). Minimizing $\mathcal{R}$ results in the smoothness assumption: for any questions i and j, if their textual similarity w_{ij} is high, the difficulty gap $\left(\bar{\theta}_i^{(q)} - \bar{\theta}_j^{(q)}\right)^2$ will be small.

A Hybrid Method. Combining Eq. (3) and Eq. (4), we obtain RCM, which amounts to the following optimization problem:

$$\min_{\bar{\boldsymbol{\theta}}} \sum_{(i \prec j) \in C} \ell\left(\bar{\theta}_i, \bar{\theta}_j\right) + \frac{\lambda_1}{2} \bar{\boldsymbol{\theta}}^T \bar{\boldsymbol{\theta}} + \frac{\lambda_2}{2} \bar{\boldsymbol{\theta}}_q^T \mathbf{L} \bar{\boldsymbol{\theta}}_q. \tag{5}$$

Here $\lambda_2 \geq 0$ is also a trade-off coefficient. The advantages of RCM include 1) It naturally formalizes QDE as minimizing a manifold regularized loss function, which seamlessly integrates both the pairwise competitions and the textual descriptions. 2) By incorporating textual information, it can address the data sparseness problem which previous methods suffer from, and perform significantly better in the QDE task.

3.2 Learning Algorithm

Redefine the k-th pairwise competition (assumed to be carried out between competitors i and j) as $(\boldsymbol{x}_k, y_k)$. $\boldsymbol{x}_k \in \mathbb{R}^{M+N}$ indicates the competitors:

$$x_i^{(k)} = 1, x_j^{(k)} = -1, \text{and } x_l^{(k)} = 0 \text{ for any } l \neq i, j,$$

where $x_l^{(k)}$ is the l-th entry of $\boldsymbol{x}_k$. $y_k \in \{1, -1\}$ is the outcome: if competitor i beats competitor j, $y_k = 1$; otherwise, $y_k = -1$. The objective in Eq. (5) can then be rewritten as

$$\mathcal{L}\left(\bar{\boldsymbol{\theta}}\right) = \sum_{k=1}^{|C|} \max\left(0, 1 - y_k \left(\bar{\boldsymbol{\theta}}^T \boldsymbol{x}_k\right)\right)^p + \frac{1}{2} \bar{\boldsymbol{\theta}}^T \mathbf{Z} \bar{\boldsymbol{\theta}},$$

where $\mathbf{z} = \begin{pmatrix} \lambda_1 \mathbf{I}_M & \mathbf{0} \\ \mathbf{0} & \lambda_1 \mathbf{I}_N + \lambda_2 \mathbf{L} \end{pmatrix}$ is a block matrix; $\mathbf{I}_M \in \mathbb{R}^{M \times M}$ and $\mathbf{I}_N \in \mathbb{R}^{N \times N}$ are identity matrices; $p = 1$ corresponds to the hinge loss, and $p = 2$ the quadratic loss. It is clear that the loss defined in Eq. (2) has the same format as the SVM loss.

The objective $\mathcal{L}$ is differentiable for the quadratic loss but non-differentiable for the hinge loss. We employ a subgradient method (Boyd et al., 2003) to solve the optimization problem. The algorithm starts at a point $\bar{\boldsymbol{\theta}}_0$ and, as many iterations as needed, moves from $\bar{\boldsymbol{\theta}}_t$ to $\bar{\boldsymbol{\theta}}_{t+1}$ in the direction of the negative subgradient:

$$\bar{\boldsymbol{\theta}}_{t+1} = \bar{\boldsymbol{\theta}}_t - \gamma_t \nabla \mathcal{L}\left(\bar{\boldsymbol{\theta}}_t\right),$$

[5] Given any $\bar{\theta}_i$, $\bar{\theta}_j$, and δ, there always exists a linear transformation which keeps the sign of $\left(\delta - \left(\bar{\theta}_j - \bar{\theta}_i\right)\right)$ unchanged.

Algorithm 1 Regularized Competition Model

Require: competition set C and description set $\mathcal{D}$
1: $\bar{\boldsymbol{\theta}}_0 \leftarrow \mathbf{1}$
2: **for** $t = 0 : T-1$ **do**
3: $\quad \mathcal{K}_t \leftarrow \left\{k : 1 - y_k\left(\bar{\boldsymbol{\theta}}_t^T \boldsymbol{x}_k\right) > 0\right\}$
4: $\quad \nabla\mathcal{L}\left(\bar{\boldsymbol{\theta}}_t\right) \leftarrow$ calculated by Eq. (6)
5: $\quad \bar{\boldsymbol{\theta}}_{t+1} \leftarrow \bar{\boldsymbol{\theta}}_t - \gamma_t \nabla\mathcal{L}\left(\bar{\boldsymbol{\theta}}_t\right)$
6: $\quad \boldsymbol{\Theta}_{t+1} \leftarrow \left\{\bar{\boldsymbol{\theta}}_0, \bar{\boldsymbol{\theta}}_1, \cdots, \bar{\boldsymbol{\theta}}_{t+1}\right\}$
7: $\quad \bar{\boldsymbol{\theta}}_{t+1} \leftarrow \arg\min_{\bar{\boldsymbol{\theta}} \in \boldsymbol{\Theta}_{t+1}} \mathcal{L}\left(\bar{\boldsymbol{\theta}}\right)$
8: **end for**
9: **return** $\bar{\boldsymbol{\theta}}_T$

where $\gamma_t > 0$ is the learning rate. The subgradient is calculated as

$$\nabla\mathcal{L}\left(\bar{\boldsymbol{\theta}}_t\right) = \begin{cases} \mathbf{Z}\bar{\boldsymbol{\theta}}_t - \sum\limits_{k\in\mathcal{K}_t} y_k \boldsymbol{x}_k, & p=1, \\ \mathbf{Z}\bar{\boldsymbol{\theta}}_t + 2\sum\limits_{k\in\mathcal{K}_t} \boldsymbol{x}_k \boldsymbol{x}_k^T \bar{\boldsymbol{\theta}}_t - 2\sum\limits_{k\in\mathcal{K}_t} y_k \boldsymbol{x}_k, & p=2, \end{cases} \quad (6)$$

where $\mathcal{K}_t = \left\{k : 1 - y_k\left(\bar{\boldsymbol{\theta}}_t^T \boldsymbol{x}_k\right) > 0\right\}$. As it is not always a descent method, we keep track of the best point found so far (Boyd et al., 2003):

$$\bar{\boldsymbol{\theta}}_{t+1} = \arg\min_{\bar{\boldsymbol{\theta}} \in \boldsymbol{\Theta}_{t+1}} \mathcal{L}\left(\bar{\boldsymbol{\theta}}\right),$$

where $\boldsymbol{\Theta}_{t+1} = \left\{\bar{\boldsymbol{\theta}}_0, \bar{\boldsymbol{\theta}}_1, \cdots, \bar{\boldsymbol{\theta}}_{t+1}\right\}$. The whole procedure is summarized in Algorithm 1.

Convergence. For constant learning rate (i.e., $\gamma_t = \gamma$), Algorithm 1 is guaranteed to converge to within some range of the optimal value, i.e.,

$$\lim_{t\to\infty} \mathcal{L}\left(\bar{\boldsymbol{\theta}}_t\right) - \mathcal{L}^* < \epsilon,$$

where $\mathcal{L}^*$ denotes the minimum of $\mathcal{L}(\cdot)$, and ϵ is a constant defined by the learning rate γ. For more details, please refer to (Boyd et al., 2003). During our experiments, we set the iteration number as $T = 1000$ and the learning rate as $\gamma_t = 0.001$, and convergence was observed.

Complexity. For both the hinge loss and the quadratic loss, the time complexity (per iteration) and the space complexity of RCM are both $O\left(|C| + \eta N^2\right)$. Here, $|C|$ is the total number of competitions, M and N are the numbers of users and questions respectively, and η is the ratio of non-zero entries in the graph Laplacian $\mathbf{L}$.[6] In the analysis, we have assumed that $M \ll \eta N^2$ and $N \ll \eta N^2$.

[6]Owing to the sparse nature of questions' textual descriptions, the graph Laplacian $\mathbf{L}$ is usually sparse, with about 70% entries being zero according to our experiments.

4 Cold-Start Estimation

Previous sections discussed estimating difficulty scores of resolved questions, from which pairwise competitions could be extracted. However, for newly posted questions without any answers received, no competitions could be extracted and none of the above methods work. We call it the *cold-start problem*.

We heuristically apply a K-Nearest Neighbor (KNN) approach (Cover and Hart, 1967) to cold-start estimation, again by leveraging the smoothness assumption. The key idea is to propagate difficulty scores from well-resolved questions to cold-start ones according to their textual similarities. Specifically, suppose that there exists a set of well-resolved questions whose difficulty scores have already been estimated by a QDE method. Given a cold-start question q^*, we first pick K well-resolved questions that are closest to q^* in textual descriptions, referred to as the nearest neighbors. The difficulty score of question q^* is then predicted as the averaged difficulty scores of its nearest neighbors. The KNN method bridges the gap between cold-start and well-resolved questions by inferring their textual similarities, and might effectively deal with the cold-start problem.

5 Experiments

We have conducted experiments to test the effectiveness of RCM in estimating difficulty scores of both well-resolved and cold-start questions. Moreover, we have explored how a word's difficulty level can be quantitatively measured by RCM.

5.1 Experimental Settings

Data Sets. We obtained a publicly available data set of Stack Overflow between July 31, 2008 and August 1, 2012[7], containing QA threads in various categories. We considered the categories of "C++ programming" and "mathematics", and randomly sampled about 10,000 QA threads from each category, denoted by SO/CPP and SO/Math respectively. For each question, we took the title and body fields as its textual description. For both data sets, stop words in a standard list[8] and words whose total frequencies are less than 10 were removed. Table 1 gives the statistics of the data sets.

[7]http://blog.stackoverflow.com/category/cc-wiki-dump/

[8]http://jmlr.org/papers/volume5/lewis04a/a11-smart-stop-list/english.stop

	# users	# questions	# competitions	# words
SO/CPP	14,884	10,164	50,043	2,208
SO/Math	6,564	10,528	40,396	2,009

Table 1: Statistics of the data sets.

For evaluation, we randomly sampled 600 question pairs from each data set, and asked annotators to compare the difficulty levels of the questions in each pair. We had two graduate students majoring in computer science annotate the SO/CPP questions, and two majoring in mathematics annotate the SO/Math questions. For each question, only the title, body, and tags were exposed to the annotators. Given a question pair (q_1, q_2), the annotators were asked to give one of the three labels: $q_1 \succ q_2$, $q_2 \succ q_1$, or $q_1 = q_2$, which respectively means that question q_1 has a higher, lower, or equal difficulty level compared with question q_2. We used Cohen's kappa coefficient (Cohen, 1960) to measure the inter-annotator agreement. The result is $\kappa = 0.7533$ on SO/CPP and $\kappa = 0.8017$ on SO/Math, indicating that the inter-annotator agreement is quite substantial on both data sets. After removing the question pairs with inconsistent labels, we got 521 annotated SO/CPP question pairs and 539 annotated SO/Math question pairs.

We further randomly split the annotated question pairs into development/test/cold-start sets, with the ratio of 2:2:1. The first two sets were used to evaluate the methods in estimating difficulty scores of resolved questions. Specifically, the development set was used for parameter tuning and the test set was used for evaluation. The last set was used to evaluate the methods in cold-start estimation, and the questions in this set were excluded from the learning process of RCM as well as any baseline method.

Baseline Methods. We considered three baseline methods: PageRank (PR), TrueSkill (TS), and CM, which are based solely on the pairwise competitions.

- PR first constructs a competitor graph, by creating an edge from competitor i to competitor j if j beats i in a competition. A PageRank algorithm (Page et al., 1999) is then utilized to estimate the relative importance of the nodes, i.e., question difficulty scores and user expertise scores. The damping factor was set from 0.1 to 0.9 in steps of 0.1.
- TS has been applied to QDE by Liu et al. (2013). We set the model parameters in the same way as they suggested.
- CM performs QDE by solving Eq. (3). We set λ_1 in $\{0, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1\}$.

We compared RCM with the above baseline methods. In RCM, both parameters λ_1 and λ_2 were set in $\{0, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1\}$.

Evaluation Metric. We employed accuracy (ACC) as the evaluation metric:

$$\text{ACC} = \frac{\text{\# correctly judged question pairs}}{\text{\# all question pairs}}.$$

A question pair is regarded as correctly judged if the relative difficulty ranking given by an estimation method is consistent with that given by the annotators. The higher the accuracy is, the better a method performs.

5.2 Estimation for Resolved Questions

The first experiment tested the methods in estimating difficulty scores of resolved questions.

Estimation Accuracies. We first compared the estimation accuracies of PR, TS, CM, and RCM on the test sets of SO/CPP and SO/Math, obtained with the best parameter settings determined by the development sets. Table 2 gives the results, where "H" denotes the hinge loss and "Q" the quadratic loss. In RCM, to calculate the graph Laplacian $\mathbf{L}$, we adopted Boolean term weighting schema and took Jaccard coefficient as the similarity measure. From the results, we can see that 1) RCM performs significantly better than the baseline methods on both data sets (t-test, p-value < 0.05), demonstrating the advantage of exploiting questions' textual descriptions for QDE. 2) The improvements of RCM over the baseline methods on SO/Math are greater than those on SO/CPP, indicating that the textual descriptions of the SO/Math questions are more powerful in reflecting their difficulty levels. The reason is that the SO/Math questions are much more heterogeneous, belonging to various subfields of mathematics. The difficulty gaps among different subfields are sometimes obvious (e.g., a question in topology in general has a higher difficulty level than a question in linear algebra), making the textual descriptions more powerful in distinguishing the difficulty levels.

Graph Laplacian Variants. We further investigated the performances of different term weighting schemas and similarity measures in the graph

	PR	TS	CM		RCM	
			H	Q	H	Q
SO/CPP	0.5876	0.6134	0.6340	0.6753	**0.7371**	0.7268
SO/Math	0.6067	0.6109	0.6527	0.6820	**0.7699**	**0.7699**

Table 2: ACC of different methods for well-resolved questions.

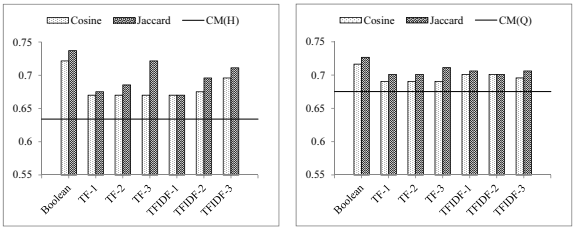
Notation	Definition
Boolean	$v(w,q) = \begin{cases} 1, & \text{if word } w \text{ occurs in question } q \\ 0, & \text{otherwise} \end{cases}$
TF-1	$v(w,q) = f(w,q)$, the number of occurrences
TF-2	$v(w,q) = \log(f(w,q)+1)$
TF-3	$v(w,q) = 0.5 + \frac{0.5 \times f(w,q)}{\max\{f(w,q) : w \in q\}}$
TFIDF-1	$v(w,q) = \text{TF-1} \times \log \frac{\lvert Q \rvert}{\lvert\{q \in Q : w \in q\}\rvert}$
TFIDF-2	$v(w,q) = \text{TF-2} \times \log \frac{\lvert Q \rvert}{\lvert\{q \in Q : w \in q\}\rvert}$
TFIDF-3	$v(w,q) = \text{TF-3} \times \log \frac{\lvert Q \rvert}{\lvert\{q \in Q : w \in q\}\rvert}$
Cosine	$\text{Sim}(\boldsymbol{d}_1, \boldsymbol{d}_2) = \frac{\boldsymbol{d}_1^T \boldsymbol{d}_2}{\lVert\boldsymbol{d}_1\rVert \times \lVert\boldsymbol{d}_2\rVert} \in [0,1]$
Jaccard	$\text{Sim}(\boldsymbol{d}_1, \boldsymbol{d}_2) = \frac{\boldsymbol{d}_1^T \boldsymbol{d}_2}{\lVert\boldsymbol{d}_1\rVert^2 + \lVert\boldsymbol{d}_2\rVert^2 - \lVert\boldsymbol{d}_1\rVert \times \lVert\boldsymbol{d}_2\rVert} \in [0,1]$

Table 3: Different term weighting schemas and similarity measures.

Laplacian. The term weighting schema determines how a question's textual description is represented. We explored a Boolean schema, three TF schemas, and three TFIDF schemas (Salton and Buckley, 1988). The similarity measure determines how the textual similarity between two questions is calculated. We explored the Cosine similarity and the Jaccard coefficient (Huang, 2008). Detailed descriptions are given in Table 3.

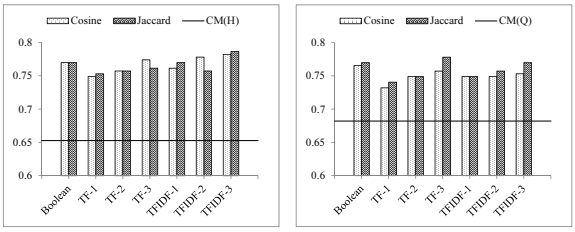
Figure 2 and Figure 3 show the estimation accuracies of the RCM variants on the test sets of SO/CPP and SO/Math respectively, again obtained with the best parameter settings determined by the development sets. The performance of CM is also given (the straight lines in the figures).[9] From the results, we can see that 1) All the RCM variants can improve over CM on both data sets, and most of the improvements are significant (t-test, p-value < 0.05). This further demonstrates that the effectiveness of incorporating textual descriptions is not affected by the particular choice of the term weighting schema or similarity measure. 2) Boolean term weighting schema performs the best, considering different similarity measures, loss types, and data sets collectively. 3) Jaccard

[9]CM performs better than PR and TS on both data sets.



(a) Hinge loss. (b) Quadratic loss.

Figure 2: ACC of RCM variants for well-resolved questions on SO/CPP.



(a) Hinge loss. (b) Quadratic loss.

Figure 3: ACC of RCM variants for well-resolved questions on SO/Math.

coefficient performs as well as Cosine similarity on SO/Math, but almost consistently better on SO/CPP. Throughout the experiments, we adopted Boolean term weighting schema and Jaccard coefficient to calculate the graph Laplacian.

5.3 Estimation for Cold-Start Questions

The second experiment tested the methods in estimating difficulty scores of cold-start questions. We employed Boolean term weighting schema to represent a cold-start question, and utilized Jaccard Coefficient to select its nearest neighbors.

Figure 4 and Figure 5 list the cold-start estimation accuracies of different methods on SO/CPP and SO/Math respectively, with different K values (the number of nearest neighbors). As the accuracy oscillates drastically with a K value smaller than 11 on SO/CPP and smaller than 6 on SO/Math, we report the results with $K \in [11, 20]$ on SO/CPP and $K \in [6, 15]$ on SO/Math. The averaged (over different K values) cold-start estimation accuracies are further given in Table 4. All the results are reported on the cold-start sets, with the optimal parameter settings adopted in Section 5.2. From the results, we can see that 1) Cold-start estimation is possible, and can achieve a considerably high accuracy by choosing a proper method (e.g. RCM), making applications such as better question routing and better incentive mechanism

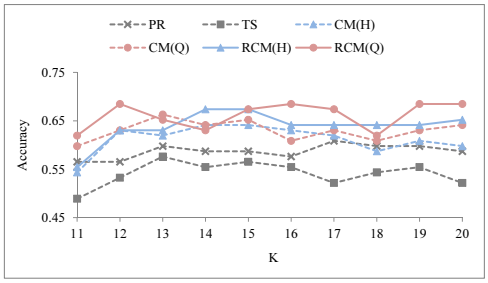


Figure 4: ACC of different methods for cold-start questions on SO/CPP.

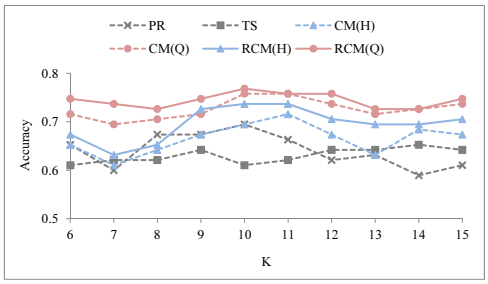

Figure 5: ACC of different methods for cold-start questions on SO/Math.

design feasible in practice. 2) As the value of K varies, RCM (the red/blue solid line) performs almost consistently better than CM with the same loss type (the red/blue dotted line), as well as PR and TS (the gray dotted lines), showing the advantages of RCM in the cold-start estimation. 3) The cold-start estimation accuracies on SO/Math are higher than those on SO/CPP, again demonstrating that the textual descriptions of the SO/Math questions are more powerful in reflecting their difficulty levels. This is consistent with the phenomenon observed in Section 5.2.

5.4 Difficulty Levels of Words

The third experiment explored how a word's difficulty level can be measured by RCM automatically and quantitatively.

On both SO/CPP and SO/Math, we evenly split the range of question difficulty scores (estimated by RCM) into 10 buckets, and assigned questions to the buckets according to their difficulty scores. A larger bucket ID indicates a higher difficulty level. Then, given a word w, we calculated its frequency in each bucket as follows:

$$f_i(w) = \frac{\text{\# questions in bucket } i \text{ where } w \text{ occurs}}{\text{\# all questions in bucket } i}.$$

To make the frequency meaningful, buckets with less than 50 questions were discarded. We picked

	PR	TS	CM		RCM	
			H	Q	H	Q
SO/CPP	0.5870	0.5413	0.6120	0.6304	0.6380	**0.6609**
SO/Math	0.6411	0.6305	0.6653	0.7263	0.6958	**0.7442**

Table 4: Averaged ACC of different methods for cold-start questions.

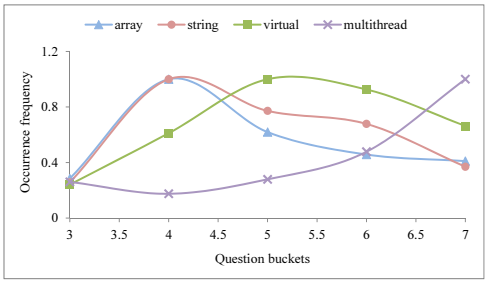

Figure 6: Frequencies of different words in the buckets on SO/CPP.

four words from each data set as examples. Their normalized frequencies in different buckets are shown in Figure 6 and Figure 7. On SO/CPP, we can observe that "array" and "string" occur most frequently in questions with lower difficulty levels, "virtual" higher, and "multithread" the highest. It coincides with the intuition: "array" and "string" are usually related to some basic concepts in programming language, while "virtual" and "multithread" usually discuss more advanced topics. Similar phenomena can be observed on SO/Math. The results indicate that RCM might provide an automatic way to measure the difficulty levels of words.

6 Related Work

QDE is relevant to the problem of estimating task difficulty levels and user expertise levels in crowdsourcing services (Yang et al., 2008; Whitehill et al., 2009). Studies on this problem fall into two categories: 1) binary response based and 2) partially ordered response based. In the first category, binary responses (i.e. whether the solution provided by a user is correct or not) are observed, and techniques based on item response theory are further employed (Whitehill et al., 2009; Welinder et al., 2010; Zhou et al., 2012). In the second category, partially ordered responses (i.e. which of the two given solutions is better) are observed, and pairwise comparison based methods are further adopted (Yang et al., 2008; Liu et al., 2013). QDE belongs to the latter.

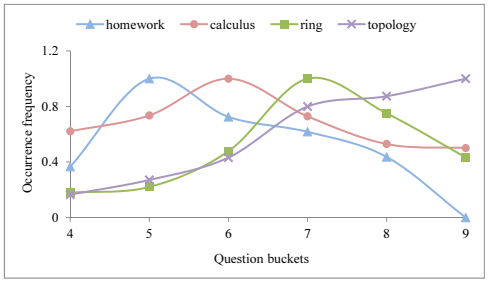

Figure 7: Frequencies of different words in the buckets on SO/Math.

The most relevant work to ours is a pairwise comparison based approach proposed by Liu et al. (2013) to estimate question difficulty levels in C-QA services. They have also demonstrated that a similar approach can be utilized to estimate user expertise levels (Liu et al., 2011). Yang et al. (2008) and Chen et al. (2013) have also proposed pairwise comparison based methods, for task difficulty estimation and rank aggregation in crowdsourcing settings. Our work differs from previous pairwise comparison based methods in that it further utilizes textual information, formalized as a manifold regularizer.

Manifold regularization is a geometrically motivated framework for machine learning, enforcing the learning model to be smooth w.r.t. the geometrical structure of data (Belkin et al., 2006). Within the framework, dimensionality reduction (Belkin and Niyogi, 2001; Cai et al., 2008) and semi-supervised learning (Zhou et al., 2004; Zhu and Lafferty, 2005) algorithms have been constructed. In dimensionality reduction, manifold regularization is utilized to guarantee that nearby points will have similar low-dimensional representations (Cai et al., 2008), while in semi-supervised learning it is utilized to ensure that nearby points will have similar labels (Zhou et al., 2004). In our work, we assume that nearby questions (in terms of textual similarities) will have similar difficulty levels.

Predicting reading difficulty levels of text is also a relevant problem (Collins-Thompson and Callan, 2004; Schwarm and Ostendorf, 2005). It is a key to automatically finding materials at appreciate reading levels for students, and also helps in personalized web search (Collins-Thompson et al., 2011). In the task of predicting reading difficulty levels, documents targeting different grade levels are taken as ground truth, which can be easily obtained from the web. However, there is no naturally annotated data for our QDE task on the web. Other related problems include query difficulty estimation for search engines (Carmel et al., 2006; Yom-Tov et al., 2005) and question difficulty estimation for automatic question answering systems (Lange et al., 2004). In these tasks, query/question difficulty is system-oriented and irrelevant with human knowledge, which is a different setting from ours.

7 Conclusion and Future Work

In this paper, we have proposed a novel method for estimating question difficulty levels in CQA services, called Regularized Competition Model (RCM). It takes fully advantage of questions' textual descriptions besides question-user comparisons, and thus can effectively deal with data sparsity and perform more accurate estimation. A K-Nearest Neighbor approach is further adopted to estimate difficulty levels of cold-start questions. Experiments on two publicly available data sets show that RCM performs significantly better than existing methods in the estimation task, for both well-resolved and cold-start questions, demonstrating the advantage of incorporating textual information. It is also observed that RCM might automatically measure the knowledge levels of words.

As future work, we plan to 1) Enhance the efficiency and scalability of RCM. The complexity analysis in Section 3.2 indicates that storing and processing the graph Laplacian is a bottleneck of RCM. We would like to investigate how to deal with the bottleneck, e.g., via parallel or distributed computing. 2) Apply RCM to non-technical domains. For non-technical domains such as the "news and events" category of Yahoo! Answers, there might be no strongly distinct notions of "experts" and "non-experts", and it might be more difficult to distinguish between "hard questions" and "easy questions". It is worthy investigating whether RCM still works on such domains.

Vote Prediction on Comments in Social Polls

Abstract

A poll consists of a question and a set of predefined answers from which voters can select. We present the new problem of vote prediction on comments, which involves determining which of these answers a voter selected given a comment she wrote after voting. To address this task, we exploit not only the information extracted from the comments but also extra-textual information such as user demographic information and inter-comment constraints. In an evaluation involving nearly one million comments collected from the popular SodaHead social polling website, we show that a vote prediction system that exploits only textual information can be improved significantly when extended with extra-textual information.

1 Introduction

We introduce in this paper a new opinion mining task, *vote prediction* on comments in social polls. Recall that a poll consists of a question accompanied by a set of predefined answers. A user who votes on the question will choose one of these answers and will be prompted to enter a comment giving an explanation of why she chose the answer. Given a poll and a user comment written in response to it, the task of *vote prediction* seeks to determine which predefined answer was chosen by the author of the comment.

A solution to the vote prediction problem would contribute significantly to our understanding of the underlying attitudes of individual social polling website users. This understanding could be exploited for tasks such as improving user experience or directed advertising; if we can predict how a user will vote on a question, we can make more accurate guesses about what kind of content/ads related to the question the user would like to see. Unfortunately, a major difficulty of vote prediction arises from the casual nature of discussion in social media. A comment often contains insufficient information for inferring the user's vote, or in some cases may even be entirely absent.

In light of this difficulty, we exploit two additional types of information in the prediction process. First, we employ demographic features derived from user profiles. Demographic features may be broadly useful for other opinion mining tasks such as stance classification (Somasundaran and Wiebe, 2010), as many social media websites like CreateDebate[1] allow users to create profiles with similar demographic information. Previous work has attempted to predict such latent features (e.g., Rao and Yarowsky (2010), Burger et al. (2011)) rather than employing them for opinion mining tasks.

Second, we exploit inter-comment constraints to help us perform joint inference over votes on different questions. Note that previous work on debate stance recognition has also employed constraints to improve the inference process. Specifically, in stance prediction, it is typical to employ so-called author constraints (e.g., Thomas et al. (2006), Bansal et al. (2008), Walker et al. (2012a), Hasan and Ng (2013)), which specify that two documents written by the same author for the same topic should have the same stance. However, in vote prediction, author constraints are not useful because a user is not permitted to cast more than one vote per question, unlike in stance prediction, where users may engage in a debate and therefore post more than once per debate topic. Consequently, we propose two new types of constraints for exploiting inter topic user voting patterns. One constraint involves pairs of authors and the other involves pairs of questions. These constraints are also potentially useful for other opin-

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ion mining tasks involving social media, as social media sites typically allow users to comment on multiple topics. Note that enforcing constraints involving two questions is by no means trivial, as the possible class values associated with the two comments may not necessarily be the same.

Another contribution of our work lies in our adaptation of the label propagation algorithm (Zhu and Ghahramani, 2002) to enforce constraints for vote prediction. Recall that existing stance classification approaches enforce constraints using minimum cut (Thomas et al., 2006), integer linear programming (Lu et al., 2012), and loopy belief propagation (Burfoot et al., 2011). Our decision to employ label propagation stems in part from the inability of loopy belief propagation and integer linear programming to efficiently process the nearly one million comments we have, and in part from the inability of the traditional two-way minimum cut algorithm to handle multiclass classification. It is worth noting, however, that other variations of the label propagation algorithm have been proposed for unrelated NLP tasks such as automatically harvesting temporal facts from the web (e.g., Wang et al. (2011) and Wang et al. (2012)).

While we are the first to address the vote prediction task, other researchers have previously used social media to predict the outcomes of various events, primarily by analyzing Twitter data. For example, Tumasjan et al. (2010) and Gayo-Avello et al. (2011) performed the related task of predicting the outcomes of elections. Rather than predicting election outcomes, O'Connor et al. (2010) focused on finding correlations between measures derived from tweets and the outcomes of political events like elections and polls. Finally, Asur and Huberman (2010) predicted movies' box office success. These tasks contrast with our task of vote prediction in that they are concerned with aggregate measures such as the fraction of the vote each candidate or party will win in an election or how much money a movie will make at the box office, whereas vote prediction is concerned with predicting how individual people will vote on a much wider variety of news/political topics.

2 Corpus

SodaHead[2] is a social polling website where users vote on and ask questions about a wide variety of topics ranging from the serious (e.g., "Should the U.S. raise the minimum wage?") to the silly (e.g "What is your favorite kind of pie?"). Whenever a user votes on one of these questions, choosing one of a set of predefined answers, she is prompted to enter a comment giving an explanation of why she chose the answer she did. Our corpus[3] consists of all the comments[4] users posted under all featured questions in the News & Politics category of the SodaHead website between March 12, 2008 and August 21, 2013.

This dataset consists of a total of 997,379 comments over 4,803 different questions, so an average of 208 comments are written in response to each question. The length of an average comment is 49 words. As Table 1 illustrates, these questions may have more than two possible answers, with an average question having 2.4 possible answers.

Each SodaHead user has her own profile that contains demographic information about her. As we can see from Table 2, many users choose to provide only some information about themselves, leaving many of the demographic fields blank. 108,462 users posted at least one comment in our corpus, with an average user commenting on 9.2 of our questions.

3 Baseline Systems

To perform our experiments, we first split our comments into three sets, a test set for evaluating performance, a training set for training classifiers, and a development set for tuning parameters. In order to ensure that the comparisons of our experiments are valid, we construct our test set using the same 20% of comments in the dataset regardless of experiment. Since our goal is to plot a learning curve illustrating how our various vote prediction systems perform given different amounts of training and development data, we vary the size of our training and development sets across experiments so that in the smallest experiment, together they comprise 25% of the remaining (non-test) comments, and in the largest experiment, they com-

[2] http://www.sodahead.com

[3] http://www.hlt.utdallas.edu/%7epersingq/SocialPolls/ is the distribution site for our corpus. We preserve user anonymity by replacing the original id of each user with a random number in our corpus.

[4] A "comment" is the text a user posted when submitting her vote on a question. It does not include posts not associated with a vote (such as responses to other posts) or votes where the user chose not to enter a comment. Thus, there is a one-to-one relationship between comments in votes in our dataset. The vote associated with a comment is always known.

Question	Vote	Comment
Who Won Round Two of the Presidential Debate?	Barack Obama	Binders full of women. That is all.
	Mitt Romney	Obama is inept and a liar. We can't survive 4 more years of his crazy crap.
What's the Best Way to Read a Magazine?	in print	Upside down like Luna Lovegood.
	online	Print costs money. It also doesn't have a Search function.
	on a tablet device	since sooooo many people have tablet devices why read it as print or online?
	on a smartphone	Clicked in print!!! Aargh

Table 1: Sample questions and comments. All of the pre-defined answers for these questions are represented by one comment.

User ID	3479864	3189372
Age	25-34	
Smoker		No
Drinker		No
Income		
Sexual Orientation		Straight
Relationship Status		Single
Political Views	Conservative	Moderate
Ethnicity		
Looking For		
Career Industry		
Children		Undecided
Education		High School
Gender	Female	Male
Religious Views	Other	Christian
Employment Status		
Weight Type		

Table 2: Sample user profiles.

prise 100% of the remaining comments. For each experiment, we maintain a ratio of three training comments to one development comment.

Recall that each comment in our dataset is written in response to a particular question. For each test comment, our goal is to predict the user's answer to the question given the text of her comment. One of the major inherent difficulties of our task is that it consists not of one, but of 4,803 separate multiclass classification problems (one for each question). As a result, our approach to the problem necessarily has to be somewhat generic, as it would be too time-consuming to develop an appropriate feature set for each question.

3.1 Baseline 1

Our first baseline's (B_1) approach employs 4,803 multiclass classifiers (one for each question). Each classifier is trained on one question's training set, representing each comment using only a bias feature. Each of our classifiers is trained using MALLET's (McCallum, 2002) implementation of maximum entropy (ME) classification. This is equivalent to merely counting the number of training set comments that voted for each possible answer, selecting the most frequent answer, then applying this label to all the comments in the test set. This majority baseline serves primarily to tell us how well our more sophisticated baseline performs.

3.2 Baseline 2

Our second baseline (B_2) is constructed in exactly the same way as B_1 except that each classifier is trained using both a bias feature and a standard set of feature types described below.

3.2.1 Features

Since the questions in our dataset come from the News & Politics category of the SodaHead website, many of the questions' topics are political. For that reason, it makes sense to use features which have been shown to work well on other political classification problems. We therefore base our feature set on that used by Walker et al. (2012b) for political debate classification. Our features are described below.

N-grams. Unigrams have been shown to perform well in ideological debates (Somasundaran and Wiebe, 2010), so we therefore present our classifiers with lemmatized unigram, bigram, and trigram features. We normalize the n-gram feature vector to unit length to avoid giving undue influence to longer comments.

Cue Words. Based on other work (Fox Tree and Schrock, 1999; Fox Tree and Schrock, 2002; Groen et al., 2010; Walker et al., 2012b), we also present our classifiers with features representing the first lemmatized unigram, bigram, and trigram appearing in each comment. These may be useful in our task when, for example, a user's comment begins with or entirely consists of a restatement of the answer she chose. So if the possible answers for a given question are "Yes" and "No", a user might write in her comment "Yes. Because ...", and this would make the "CueWord:Yes" feature useful for classifying this comment.

Emotion Frequency. For each word in a comment, we used the NRC Emotion Word Lexicon

(Mohammad and Yang, 2011) to discover if the word conveys any emotion. Then, for each emotion or sentiment covered by the lexicon (anger, anticipation, disgust, fear, joy, sadness, surprise, trust, positive, or negative) e_i, we construct a feature e_i:$\frac{C(e_i)}{total}$ describing how much of the comment consists of words conveying emotion e_i, where $C(e_i)$ is the count of words in the comment bearing emotion e_i and $total$ is the number of words in the comment. To understand why this feature may be useful, consider the question "Does Sarah Palin deserve VP?" We suspect that users who post comments laden with words associated with positive emotions like joy are more likely to vote "Yes" because the positive emotions imply they are happy about a Sarah Palin vice presidency. Similarly, users who post comments laden with negative emotions like anger might be more likely to vote "No".

Dependencies. We use the Stanford Parser (de Marneffe et al., 2006) to extract a set of dependencies from each comment. For an example of how dependencies might help in our task, consider the second comment in Table 1. From this comment, we can extract the dependency triple dependency:(nsubj,inept,obama), which indicates that the user who wrote it does not like Obama and is therefore more likely to have voted for Romney in the question. Dependency feature vectors are normalized to unit length.

Emotion Dependencies. To form an emotion dependency feature, we take a regular dependency feature and replace each of its words where possible with the emotion it evokes as determined by the NRC Emotion Word Lexicon. Thus from the dependency:(nsubj,inept,obama) example above, we would generate three features: emotiondependency:(nsubj,anger,obama), emotiondependency:(nsubj,disgust,obama), and emotiondependency:(nsubj,negative,obama). These features help generalize dependencies, and this is useful because predictive features like emotiondependency:(nsubj,negative,obama) appear frequently in the comments for this question, but dependency:(nsubj,inept,obama) does not. Emotion Dependency feature vectors are normalized to unit length.

Post Information. Features under this category just calculate some basic statistics about a comment. These features may be useful because, for example, the question "Most Scandalous Politicians of 2008– Who deserves the title?" has six possible answers, each except the last naming a particular well-known politician. The last choice is "The most scandalous politician of 2008 is ..." and the user is expected to name a politician in her comment. It would make sense for users choosing this option to have written longer responses since they have to name and possibly explain their choice to users who might not necessarily know who their chosen politician is.

3.2.2 Feature Selection

Because some of the feature types (n-grams, cue words, dependencies, and emotion dependencies) described in the previous subsection are expected to generate a large number of non-predictive features, we trim some of the most irrelevant features out of the feature set to avoid memory problems. Therefore, following Yang and Pedersen (1997), for each question we calculate the information gain of each feature of these types on the training set. We then remove those features having the lowest information gain as well as those features occurring less than ten times in the dataset. Early experiments showed that 1,000 was a reasonable number of features to keep, so for all experiments we keep only the top 1,000 features of these types. Note that we do not apply feature selection to emotion frequency or post information features, as each of these sets consists of a small number of real-valued features.

4 Demographic Features

As mentioned in the introduction, a major difficulty inherent to our problem is that in many cases a comment contains insufficient information for inferring the underlying vote. Aside from being short, the comments shown in Table 1 are typical of comments found in the dataset. Some comments are like the first and third in the table, requiring some obscure bit of world knowledge to understand what the writer is saying. Others like the fourth only explain why the user did not choose a particular answer, which is always potentially useful, but sufficient only if the comment excludes every other possible choice.

Because it is difficult to tell how a user voted given her comment, we exploit the demographic information users provide in their profiles as an additional source of information. Since many of the questions in our dataset deal with politics, we anticipate that information about things

such as whether a comment was written by a conservative or progressive user would be useful for predicting the answers of many comments. For each comment, we encode demographic information as features in the following way. For each field in the user's profile shown in Table 2 (aside from user ID), we construct a feature of the form F_i:V_i if the user filled in field F_i with value V_i. Thus, any comment made by user 3479864 would include the features Age:25−34, PoliticalViews:Conservative, Gender:Female, and Religion:Other.

Here is an example of a comment whose predicted vote gets corrected by adding demographic features to our system. For the question, "LPGA Decides to Allow Transgender Competitors: Good or Bad Move for Golf?", user 2252750 writes, "LPGA ...can let monkeys play if they wish....nobody gives a rip... bark". Of the three possible answers for this question, "Good move", "Bad move", and "Undecided", our baseline system without demographics believes that user 2252750 probably voted for the third, as "nobody gives a rip" makes him sound apathetic toward the issue. However, our demographic system notices that his profile contains "Religion:Christian", and users with this demographic attribute choose "Bad Move" 64% of the time. Thus, demographic features allowed our system to correctly predict his vote for "Bad Move".

Since demographics are also expected to generate a large number of non-predictive features, we apply feature selection to them as described in Section 3.2.2.

5 Enforcing Constraints

We mentioned earlier that an average SodaHead question contains 208 comments. This implies that there are only about 31−125 comments[5] in the average training set for one of our ME classifiers. It would be difficult to train a good classifier from a training set this small even if we had feature sets tailored to work well on each of the 4,803 questions. While we have already attempted to exploit user information (in the form of demographic features) to help improve our system's performance, this approach still treats the task as 4,803 separate classification problems. It does not allow for the possibility that classification on one question may be improved by exploiting information gleaned from votes on other questions.

One way we might exploit such information is by first noticing that, for any pair of questions, there may be multiple users who commented on both. This overlap between questions allows us to calculate how predictive a user's vote on one question is of how she will vote on the other. For example, on the question "Who Would You Rather Have Dinner With?", we found that users who voted for "Mitt Romney" were much more likely to choose "No, I'm still voting for him" on the question "Does Mitt Romney's 'Entitled' Remarks Change Your Opinion of Him?". Similarly, users who voted to have dinner with "Barack Obama" were much more likely to vote "Yes, I'm not voting for him anymore" on the "entitled" question. A system that somehow takes into account this information might correctly classify a difficult comment on the "entitled" question if it notices that the comment was written by a user who commented on both questions and it knows how the user voted on the "dinner" question. We call the kind of constraint described here a **QuestionPair** constraint.

We might also exploit information from other questions by noticing that there are users who share similar attitudes on a wide variety of topics in our dataset. We can gauge how often a pair of users agree with each other by comparing their votes on every question on which they have both voted where their comments appear in the training set. So for example, if we see that two users have agreed on questions about George H.W. Bush, Bill Clinton, and George W. Bush, we can guess that they will also agree on a question about Barack Obama. Similarly, if they disagreed on all those questions, they are likely to disagree on the last question. A system that takes into account this kind of information could correctly classify an otherwise difficult comment if it knows how another user voted on this question and also knows how often the two users agree on other questions. We call the kind of constraint described here a **VoterPair** constraint.

In order to enforce both kinds of constraints, we introduce a variation of the label propagation algorithm (Zhu and Ghahramani, 2002). In our version of the label propagation algorithm, each comment in our dataset is represented by a node in a graph. Each node is associated with a probability distribution indicating the likelihood that the

[5] At the low and high end of the learning curve respectively.

comment belongs to each of its question's possible answers. Thus, when we initialize the graph, each training set node's probability distribution is set to reflect its comment's actual label (with a probability of 1 for the comment's actual label and 0 for each other answer), and each development or test set node's probability distribution is set to the value predicted by another classifier such as B_2 or $B_2 + Dem$ since the algorithm is not permitted to see the comment's actual label. Lines 7−12 in Figure 1 describe the graph's initialization.

Now that we have set up the graph's nodes, we need to explain how our graph's edges work. As we discussed earlier in this section, the edges in our graph will represent two kinds of soft constraints. Each edge allows one of a node's neighbors to cast a vote (in the form of a probability distribution over possible answers) for what it thinks the node's answer should be. Let us call the comment node whose label we are trying to predict the **target** node and the comment node which casts the vote the **source** node.

Our graph contains a QuestionPair edge between any source and target comments written by the same user. Since a user cannot comment more than once on any question, the source and target comments will occur in two different questions. In order to determine how the source node votes over a QuestionPair edge, we need to calculate some probabilities. In particular, we need to determine the probability that a user will vote for possible answer k in the target question Q_I given that she voted for answer l in the source question Q_J:

$$P(Q_{I_k}|Q_{J_l}) = \frac{C(Q_{I_k},Q_{J_l})+\gamma}{\sum_{m\in A(Q_I)}(C(Q_{I_m},Q_{J_l})+\gamma)}$$

where $C(Q_{I_n}, Q_{J_l})$ is the number of users who voted for answer n in Q_I and answer l in Q_J, and $A(Q_I)$ is the set of possible answers on Q_I. We set γ, the smoothing factor, to 10 since this value worked well in earlier experiments. The source node S casts its vote on target node T for the probability distribution given by:

$$QP_{S,T}(Q_{I_k}) = \sum_{m\in A(Q_J)} P_S(Q_{J_m})P(Q_{I_k}|Q_{J_m})$$

where $P_S(Q_{J_m})$ is the probability currently associated with answer m in S's question (Q_J).

The graph contains a VoterPair edge between any source and target nodes on the same question if the users who posted these comments have both voted on at least one other question together and their comments on the other question(s) occurred in the training set. To determine how the source node votes over a VoterPair edge, we need to calculate the probability that the source and target users will agree on a generic issue:

$$P_{agr}(U_S, U_T) = \frac{C_{agr}(U_S,U_T)+1}{C_{agr}(U_S,U_T)+C_{dis}(U_S,U_T)+2}$$

where $C_{agr}(U_S, U_T)$ is the number of questions on which users U_S and U_T voted for the same answer and both their comments occurred in the training set, $C_{dis}(U_S, U_T)$ is the number of questions on which U_S and U_T voted for different answers where both their comments occurred in the training set, and the $+1$ and $+2$ are used for smoothing. The probability distribution that the source node S votes for on target node T is then given by:

$$VP_{S,T}(Q_{I_k}) = P_S(Q_{I_k})P_{agr}(U_S, U_T) + \sum_{\substack{m\in A(Q_I),\\ m\neq k}} (P_S(Q_{I_m}))\frac{1-P_{agr}(U_S,U_T)}{|A(Q_I)|-1}$$

where $P_S(Q_{I_n})$ is the probability currently associated with answer n in the source node's question (Q_I), and $|A(Q_I)|$ is the number of possible answers on Q_I. We divide the second term, which deals with disagreement, by $|A(Q_I)| - 1$ because, even if we know that the target and source users disagreed on the answer to a particular question and that the source user did not vote for answer k, there is only a $\frac{1}{|A(Q_I)|-1}$ chance that the target user voted for answer k since there are $|A(Q_I)|-1$ non-k answers to choose from.

Now that we have described how edges are added to the graph and how source comment nodes vote over the edges, we are ready to begin iterating over the label propagation algorithm (line 13 in Figure 1). For each iteration of the algorithm, we update each development or test set node's answer probability distribution by assigning it a weighted sum of (1) the initial probability distribution assigned to the node, (2) the sum of the QuestionPair edges' votes, and (3) the sum of the VoterPair edges' votes (line 16 in Figure 1). Upon completion of the algorithm, if our soft constraints work as expected, the new labeling of comment nodes should be more accurate than their initial labeling.

We tune the parameters W_I, W_V, W_Q, and $iterations$ jointly by an exhaustive search of the parameter space to maximize classification accuracy on the development set. Each of the weight parameters is allowed to take one of the values 0, 1, or 2, and the iteration parameter is allowed take one of the values 0, 1, 2, 3, 4, 5.

18: Remove all edges targeting node C
19: **end for**
20: **end for**

Figure 1: Our label propagation algorithm.

One may be surprised to notice how we add edges to the graph in the algorithm only to delete them three lines later (lines 15 and 18 in Figure 1). Though edges can be added at any point in the algorithm, one benefit of using the label propagation algorithm is that it is simple enough that it is not necessary store all the edges in memory at once. The only time we need to store an edge is when its target is being voted on. This means that the label propagation algorithm can handle large datasets like ours with huge numbers of nodes and edges without being prohibitively space-expensive.

6 Evaluation

6.1 Experimental Setup

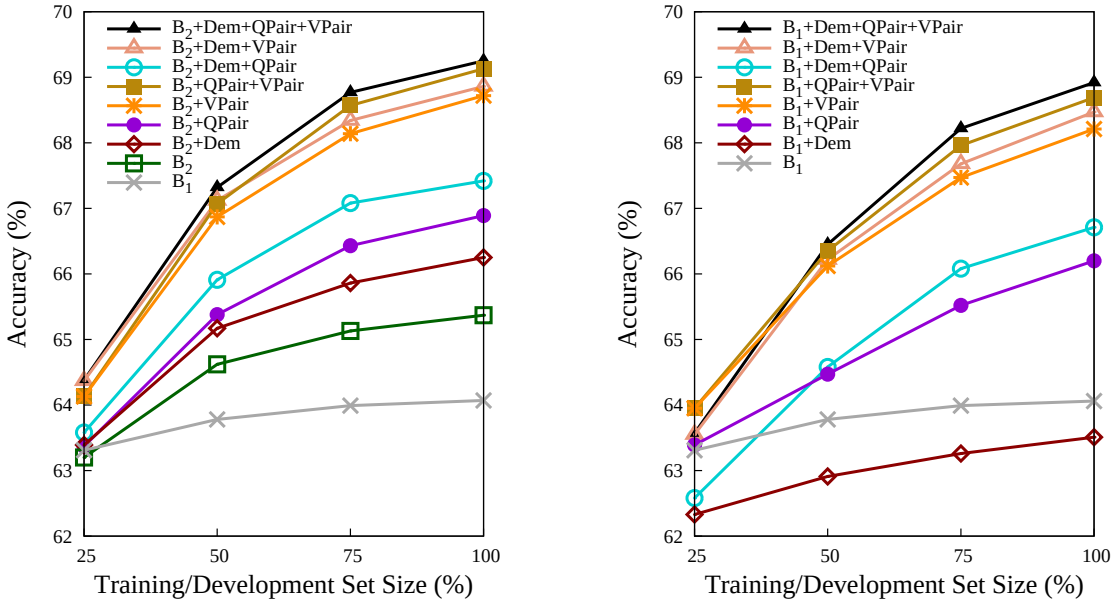
We mentioned in Section 3 that we split our dataset of 997,379 comments into a test set comprising about 20% of the dataset's comments and a training and development set comprising some fraction of the remaining 80% of the comments. We actually split the data up like this five different times so that each comment appears in an experiment's test set exactly once. In this way, through the use of five fold cross-validation, we can report our results on the entire dataset.

6.2 Results and Discussion

Figure 2a shows the accuracy of the predictions made by various systems. First, let us compare our first and second baselines. Recall that the first baseline (B_1) predicts that all test comments will have the same label as the majority of training comments, and the second baseline's (B_2) predictions are the output of ME classifiers trained with a generic feature set. As we can see from the graph, at very small training set sizes, the standard set of features supplied to B_2 does little more than confuse the ME learner, as it performs slightly but not significantly worse[6] than the first baseline when the training/development set comprises only 25% of the available data. This is understandable, as 25% of an average question's available data is only 42 comments, an extremely small number of examples to learn from for most NLP tasks. Clearly a better approach than the one provided by the second baseline is needed. Though the average training set sizes at the 50%, 75%, and 100% levels are still relatively small, B_2 significantly outperforms B_1 at all these levels.

The small improvement sizes yielded by B_2 may be attributable to some of the inherent difficulties of the problem, particularly that (1) it is composed of so many (4,803) separate subproblems that it is impractical for us to tailor a unique feature set for each one, (2) the average question is associated with a very small number of comments (about 208), making it difficult to train a reasonably good classifier for any question, and (3) many of the comments contain insufficient information for inferring the underlying votes. Perhaps some of our proposed extensions to B_2 can help address

[6] All significance tests are paired t-tests, with $p < 0.05$. Because we calculate a large number of significance results, the p values we report are obtained using Holm-Bonferroni multiple testing correction (Holm, 1979).



(a) Vote prediction.

(b) Arbitrary User Vote Prediction.

Figure 2: Five-fold cross-validation vote prediction learning curves.

some of these problems.

The first improvement we proposed involved exploiting demographic features provided by users to help with our prediction tasks. When we combine Dem and B_2's feature sets, the resulting system ($B_2 + Dem$) performs better than any of the systems discussed thus far at all four training/development set size levels, yielding significant improvements over B_2 at all four levels. This demonstrates that our demographic features are a useful complement to a standard approach like the one used by B_2.

The second improvement we proposed involved using a variation of the label propagation algorithm to enforce QuestionPair constraints. QuestionPair constraints, recall, allowed us to exploit the observed voting patterns of users who voted in the training set on any particular pair of questions. These constraints were expected to improve our predictions for any user who voted on both questions when at least one of their votes appeared in the test set. System $B_2 + QPair$ corresponds to following the algorithm in Figure 1, using system B_2's ME classifiers to initialize a label propagation graph, and then setting the VoterPair edge weight (W_V) to 0, thus allowing only QuestionPair constraints. When we compare this system to B_2, we see that the performance boost QuestionPair constraints give us over the baseline is consistently greater than the boost given by adding demographic features to it ($B_2 + Dem$) across all training/development set sizes. The improvement over B_2 is even significant at the 75% and 100% training/development set sizes.

The last improvement we proposed involved adding VoterPair constraints to the label propagation graph. Recall that VoterPair constraints allowed us to exploit how frequently we observed two users agreeing with each other to predict whether they will agree on any question they both voted on. System $B_2 + VPair$ corresponds to following the label propagation algorithm using B_2's ME classifiers to initialize the graph, then setting the QuestionPair edge weight (W_Q) to 0, thus allowing only VoterPair constraints. The addition of VoterPair constraints yields the largest significant improvements over B_2 at all four levels, indicating that, in the absence of our other proposed improvements, VoterPair edge constraints are the most important addition we can make to our baseline.

While we have now shown that each of our proposed extensions yields significant improvements over B_2, this does not necessarily mean that each one is useful in the presence of the others. For example, it might be the case that QuestionPair constraints and Demographic features correct the same kinds of classification errors, and therefore it may be sufficient to use either one or the other to obtain good results, but using both is unnecessary. To test how useful they are in each other's pres-

ence, we perform the following experiment. First, we run the algorithm using all three improvements ($B_2 + Dem + QPair + VPair$ in Figure 2a). We then run the same experiment three more times, each time removing one of the three extensions. By measuring how much performance decreases when we remove each of the three improvements, we can determine whether each improvement provides unique useful information, or whether the information it provides is already being provided by one of the other improvements.

To see what happens when we remove demographic features from the full system, we need to compare $B_2 + Dem + QPair + VPair$ and $B_2 + QPair + VPair$ in Figure 2a. While the decrease in performance after removing demographic features was modest, the difference is nevertheless significant at all four training/development set sizes, suggesting that demographic features do provide unique information to the system.

By comparing line $B_2 + Dem + QPair + VPair$ to line $B_2 + Dem + VPair$, we can determine the impact of QuestionPair constraints. Removing QuestionPair constraints also had a modest impact on the full system's performance, decreasing accuracy at all four training/development set sizes, significantly so at the 50%, 75%, and 100% levels. Interestingly, the impact of QuestionPair constraints appears to grow with the training set, while the demographic features appear to have a greater impact when the training set is small. We can see this by noting that the two lines cross at around 55%. This suggests that QuestionPair constraints are especially useful in problems where it is cheap to obtain a lot of training data, but in problems where the data has to be manually annotated, demographic features are more useful.

Finally, we can compare line $B_2 + Dem + QPair + VPair$ to line $B_2 + Dem + QPair$ to see what happens when we remove VoterPair constraints from our system. This comparison illustrates that VoterPair constraints are by far the most important improvement we removed from the full system, as removing them yielded large significant decreases at all four levels.

Though thus far we have only used it to analyze the the contributions of different individual improvements, the full system $B_2 + Dem + QPair + VPair$ is interesting in itself. Of all the systems we have constructed, it performs the best, yielding improvements of up to 5.18% and 3.88% when compared to B_1 and B_2 respectively. Its improvements over both baselines are statistically significant at all four training/development set sizes.

6.3 Arbitrary User Vote Prediction

One interesting question that we have not yet addressed is, is it possible to predict how a user would vote on a question she has not yet seen? This problem is interesting because an average question receives votes from only 0.2% of the users in our dataset, and thus a system for predicting an arbitrary user's vote would be able to predict the votes of the other 99.8% of users. A solution to this prediction problem would have practical applications in areas such as directed advertising (e.g., if we could predict how a user would vote on the magazine question in Table 1, we would have a better idea of what kinds of reading devices/services would interest her).

We can mimic this problem with our dataset by treating the comment text associated with test votes as unseen since we cannot expect an arbitrary user to have commented on any particular question we are interested in[7]. It does, however, make sense for us to expect our arbitrary user to have provided some personal demographic information, and thus a system for making these types of predictions could reasonably make use of demographic features. Similarly, in this situation we would expect to have knowledge of all users' training set voting histories. Thus, it would also be reasonable for our system to exploit the QuestionPair and VoterPair constraints described in Section 5. Thus, to test how well our system performs on this task, we repeat all experiments from the previous section while replacing B_2 (which uses a ME classifier trained on comment-based features) with B_1 (the most frequent baseline, which uses a ME classifier trained using only a bias feature). The results of these experiments are shown in Figure 2b.

If we compare the results from B_1 to $B_1 + Dem$ (which compliments B_1's bias feature with the demographic feature set), we notice that $B_1 + Dem$ is significantly worse than B_1 at all training set sizes. This confirms our suspicion from the pre-

[7] Although we are trying to mimic the situation in which we predict how an arbitrary user would vote on an arbitrary question, we caution that the vote data we train and evaluate on was not obtained from a set of arbitrary SodaHead users. It consists only of votes from users who chose which questions they wanted to answer. For this reason, the data we train and evaluate on for any question might not be a representative sample of SodaHead users as a whole.

vious section that demographic features by themselves serve only to confuse the learner, though we will see in a moment that they are a helpful supplement to more sophisticated systems.

We can evaluate QuestionPair constraints in this setting by comparing the results from B_1 to $B_1 + QPair$. $B_1 + QPair$ consistently outperforms B_1 at all four training set sizes, significantly so at the 75% and 100% levels, and thus QuestionPair constraints are also a useful addition to our system.

VoterPair constraints can be evaluated in this setting by comparing B_1 to $B_1 + VPair$. $B_1 + VPair$ significantly outperforms B_1 at all four training set sizes, and from the graph it appears to be our most beneficial improvement.

To evaluate whether demographic features are useful in the presence of the other improvements, we compare the full system, $B_1 + Dem + QPair + VPair$, to its corresponding version without demographic features, $B_1 + QPair + VPair$. Though $B_1 + QPair + VPair$ significantly outperforms the full system at the 25% training set size, the full system significantly outperforms $B_1 + QPair + VPair$ at the 75% and 100% levels, indicating that in this setting, demographic features are useful in the presence of a large training set.

We can evaluate the utility of QuestionPair constraints in this setting by comparing the full system to $B_1 + Dem + VPair$. When we remove QuestionPair constraints, accuracy is consistently lowered at all four training set sizes, significantly so at 50%, 75%, and 100%. This tells us that QuestionPair constraints are useful in this setting.

We can evaluate how useful VoterPair constraints are by checking how much $B_1 + Dem + VPair + QPair$'s performance drops when we remove VoterPair constraints from it, yielding $B_1 + Dem + QPair$. Performance drops considerably and significantly at all four training set sizes after removing VoterPair constraints, suggesting that in this setting, VoterPair constraints are still the most important of our proposed improvements.

Finally, while we have already established that all our proposed improvements can improve performance under both settings (comments visible and comments invisible), it may be worthwhile to compare the two sets of experiments to determine whether the comment features used in systems with B_2 are useful.

A casual inspection of the two figures shows that, broadly, each system that uses comment-based features in Figure 2a tends to slightly outperform the most comparable system in Figure 2b. At the low end of the curves, the two systems often differ by about 1.0% in absolute accuracy, though at the high end, the difference tends to be much smaller, with the full system with comment features outperforming the full system without comment features by only 0.3%. Since in this setting it is reasonable to assume a large training set, this last result is the one we are most interested in, and it suggests that our full system's performance does not suffer much due to the absence of comment features.

One final observation we can make is that, when comments are not visible, demographic features appear to actively harm the performance of systems trained on a small amount of data, though at larger training set sizes they are mostly helpful. We can tell this by comparing systems with demographic features to systems without them in Figure 2b (e.g., by comparing $B_1 + Dem + QPair$ to $B_1 + QPair$ or $B_1 + Dem + VPair$ to $B_1 + VPair$) at the 25% training set size. This is not the case in the setting where comments are visible, as we see that demographic features always appear helpful in Figure 2a. This reinforces the notion that demographic features provide useful information in general, but that they are by themselves too sparsely available to do more than confuse the learner. They need to be supplemented by other information sources in order for the learner to draw correct conclusions.

7 Conclusion

We examined the task of vote prediction on comments from the SodaHead website. To address this task, we exploited not only information extracted from the comments but also extra-textual information, including demographic information and two types of inter-comment constraints, QuestionPair constraints and VoterPair constraints. Our experiments involving 997,379 comments showed that each of these extensions significantly improved a baseline that exploited only textual information, with VoterPair constraints being the most effective and demographic information being the least effective. When used in combination, they obtained up to a 3.88% improvement in absolute accuracy over the baseline. To stimulate research on this task, we make our dataset publicly available.

Abstract

In this paper we first exploit cash-tags ("$" followed by stocks' ticker symbols) in Twitter to build a stock network, where nodes are stocks connected by edges when two stocks co-occur frequently in tweets. We then employ a labeled topic model to jointly model both the tweets and the network structure to assign each node and each edge a topic respectively. This Semantic Stock Network (SSN) summarizes discussion topics about stocks and stock relations. We further show that social sentiment about stock (node) topics and stock relationship (edge) topics are predictive of each stock's market. For prediction, we propose to regress the topic-sentiment time-series and the stock's price time series. Experimental results demonstrate that topic sentiments from close neighbors are able to help improve the prediction of a stock markedly.

1 Introduction

Existing research has shown the usefulness of public sentiment in social media across a wide range of applications. Several works showed social media as a promising tool for stock market prediction (Bollen et al., 2011; Ruiz et al., 2012; Si et al., 2013). However, the semantic relationships between stocks have not yet been explored. In this paper, we show that the latent semantic relations among stocks and the associated social sentiment can yield a better prediction model.

On Twitter, cash-tags (e.g., $aapl for Apple Inc.) are used in a tweet to indicate that the tweet talks about the stocks or some other related information about the companies. For example, one tweet containing cash-tags: $aapl and $goog (Google Inc.), is *"$AAPL is loosing customers. everybody is buying android phones! $GOOG"*. Such joint mentions directly reflect some kind of latent relationship between the involved stocks, which motivates us to exploit such information for the stock prediction.

We propose a notion of Semantic Stock Network (SSN) and use it to summarize the latent semantics of stocks from social discussions. To our knowledge, this is the first work that uses cash-tags in Twitter for mining stock semantic relations. Our stock network is constructed based on the co-occurrences of cash-tags in tweets. With the SSN, we employ a labeled topic model to jointly model both the tweets and the network structure to assign each node and each edge a topic respectively. Then, a lexicon-based sentiment analysis method is used to compute a sentiment score for each node and each edge topic. To predict each stock's performance (i.e., the up/down movement of the stock's closing price), we use the sentiment time-series over the SSN and the price time series in a vector autoregression (VAR) framework.

We will show that the neighbor relationships in SSN give very useful insights into the dynamics of the stock market. Our experimental results demonstrate that topic sentiments from close neighbors of a stock can help improve the prediction of the stock market markedly.

2 Related work

2.1 Social Media & Economic Indices

Many algorithms have been proposed to produce meaningful insights from massive social media data. Related works include detecting and summarizing events (Weng and Lee, 2011; Weng et al., 2011; Baldwin et al., 2012; Gao et al., 2012) and analyzing sentiments about them (Pang and Lee, 2008; Liu, 2012), etc. Some recent literature also used Twitter as a sentiment source for stock market prediction (Bollen et al., 2011; Si et al., 2013). This paper extends beyond the correlation between social media and stock market, but fur-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1139–1145,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ther exploits the social relations between stocks from the social media context.

Topic modeling has been widely used in social media. Various extensions of the traditional LDA model (Blei et al., 2003) has been proposed for modeling social media data (Wang et al., 2011, Jo and Oh, 2011; Liu et al., 2007; Mei et al., 2007; Diao et al., 2012). Ramage et al. (2009; 2011) presented a partially supervised learning model called Labeled LDA to utilize supervision signal in topic modeling. Ma et al. (2013) predicted the topic popularity based on hash-tags on Twitter in a classification framework.

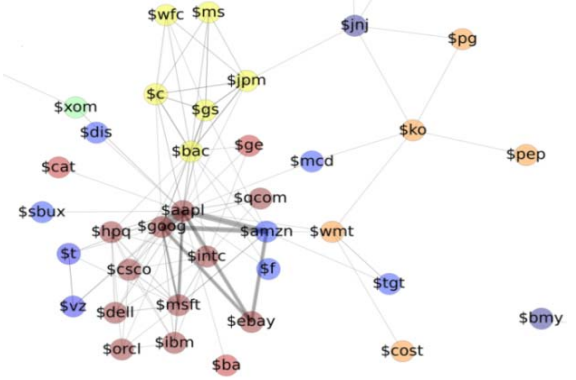

Figure 1. An example stock network.

2.2 Financial Networks for Stock

Financial network models study the correlations of stocks in a graph-based view (Tse et al., 2010; Mantegna, 1999; Vandewalle et al., 2001; Onnela et al., 2003; Bonanno et al., 2001). The usual approach is to measure the pairwise correlation of stocks' historical price series and then connect the stocks based on correlation strengths to build a correlation stock network (CSN).

However, our approach leverages social media posts on stock tickers. The rationale behind is that micro-blogging activities have been shown to be highly correlated with the stock market (Ruiz et al., 2012; Mao et al., 2012). It is more informative, granular to incorporate latest developments of the market as reflected in social media instead of relying on stocks' historical price.

3 Semantic Stock Network (SSN)

3.1 Construction of SSN

We collected five months (Nov. 2 2012 - Apr. 3 2013) of English tweets for a set of stocks in the Standard & Poor's 100 list via Twitter's REST API, using cash-tags as query keywords. For preprocessing, we removed tweets mentioning more than five continuous stock tickers as such tweets usually do not convey much meaning for our task. Finally, we obtained 629,977 tweets in total. Table 1 shows the top five most frequent stocks jointly mentioned with Apple Inc. in our dataset. Formally, we define the stock network as an undirected graph $G = \{V, E\}$. The node set V comprises of stocks, $e_{u,v} \in E$ stands for the edge between stock nodes u and v and the edge weight is the number of co-occurrences. On exploring the co-occurrence statistics in pilot studies, we set a minimum weight threshold of 400 to filter most non-informative edges. Figure 1 demonstrates a segment of the stock network constructed from our dataset.

$goog	$amzn	$ebay	$msft	$intc
43263	23266	14437	11891	2486

Table 1. co-occurrence statistics with $aapl.

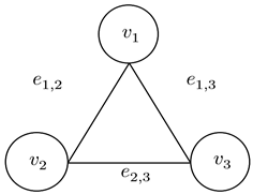

Figure 2. Tweet label design.

3.2 Semantic Topics over the Network

Figure 2 illustrates our annotation for each tweet. For a tweet, d with three cash-tags: $\{v_1, v_2, v_3\}$, we annotate d with the label set, $L_d = \{v_1, v_2, v_3, e_{1,2}, e_{1,3}, e_{2,3}\}$. ($e_{1,2}$ is "aapl_goog" if $v_1$is "aapl" and v_2 is "goog"). Then, the topic assignments of words in d are constrained to topics indexed by its label set, L_d. Given the annotations as labels, we use the Labeled LDA model (Ramage et al., 2009) to jointly learn the topics over nodes and edges. Labeled-LDA assumes that the set of topics are the distinct labels in a labeled set of documents, and each label corresponds to a unique topic. Similar to LDA (Blei et al., 2003), Labeled-LDA models each document as an admixture of latent topics and generates each word from a chosen topic. Moreover, Labeled-LDA incorporates supervision by simply constraining the model to use only those topics that correspond to a document's observed label set (Ramage et al., 2009). For model inference, we use collapsed Gibbs sampling (Bishop, 2006) and the symmetric Dirichlet Priors are set to: $\eta = 0.01, \alpha = 0.01$ as suggested in (Ramage et al., 2010). The Gibbs Sampler is given as:

$$p(z_i = k|z_{-i}) \sim \frac{N(d_i,k)_{-1} + \alpha}{N(d_i,*)_{-1} + |L_{d_i}|*\alpha} * \frac{N(k,w_i)_{-1} + \eta}{N(k,*)_{-1} + |V|*\eta} \quad (1)$$

where $N(d_i, k)$ is the number of words in d_i assigned to topic k, while $N(d_i,*)$ is the marginalized sum. $|L_{d_i}|$ is the size of label subset of d_i.

$N(k,w)$ is the term frequency of word w in topic k. $|V|$ is the vocabulary size. The subscript $_{-1}$ is used to exclude the count assignment of the current word w_i. The posterior on the document's topic distribution $\{\theta_{d,k}\}$ and topic's word distribution $\{\beta_{k,w}\}$ can be estimated as follows:

$$\theta_{d,k} = \frac{N(d_i,k)+\alpha}{N(d_i,*)+|L_{d_i}|*\alpha} \quad (2)$$

$$\beta_{k,w} = \frac{N(k,w_i)+\eta}{N(k,*)+|V|*\eta} \quad (3)$$

Later, parameters $\{\beta_{k,w}\}$ will be used to compute the sentiment score for topics.

3.3 Leveraging Sentiment over SSN for Stock Prediction

We define a lexicon based sentiment score in the form of opinion polarity for each node-indexed and edge-indexed topic as follows:

$$S(k) = \sum_{w=1}^{|V|} \beta_{k,w}\, l(w),\ S(k) \in [-1,1] \quad (4)$$

where $l(w)$ denotes the opinion polarity of word w. $\beta_{k,w}$ is the word probability of w in topic k (Eq.3). Based on an opinion lexicon O, $l(w)$ = +1 if $w \in O_{pos}$, $l(w)$ = -1 if $w \in O_{neg}$ and $l(w)$ = 0 otherwise. We use the opinion English lexicon contributed by Hu and Liu (2004).

Considering the inherent dynamics of both the stock markets and social sentiment, we organize the tweets into daily based sub-sets according to their timestamps to construct one SSN_t ($t \in [1,T]$) for each day. Then, we apply a Labeled LDA for each SSN_t and compute the sentiment scores for each SSN_t's nodes and edges. This yields a sentiment time series for the node, v, $\{S(v)_1, S(v)_2, \ldots, S(v)_T\}$ and for the edge, $e_{u,v}$, $\{S(e_{u,v})_1, S(e_{u,v})_2, \ldots, S(e_{u,v})_T\}$. We introduce a vector autoregression model (VAR) (Shumway and Stoffer, 2011) by regressing sentiment time series together with the stock price time series to predict the up/down movement of the stock's daily closing price.

As usual in time series analysis, the regression parameters are learned during a training phase and then are used for forecasting under sliding windows, i.e., to train in period $[t, t+w]$ and to predict on time $t+w+1$. Here the window size w refers to the number of days in series used in model training. A VAR model for two variables $\{x_t\}$ and $\{y_t\}$ can be written as:

$$y_t = \sum_{i=1}^{lag} (\vartheta_i^x x_{t-i} + \vartheta_i^y y_{t-i}) + \varepsilon_t \quad (5)$$

where $\{\varepsilon\}$ are white noises, $\{\vartheta\}$ are model parameters, and lag notes the time steps of historical information to use. In our experiment, $\{y_t\}$ is the target stock's price time series, $\{x_t\}$ is the covariate sentiment/price time series, and we will try $lag \in \{2,3\}$. We use the "dse" library in R language to fit our VAR model based on least square regression.

4 Experiments

4.1 Tweets in Relation to the Stock Market

Micro-blogging activities are well correlated with the stock market. Figure 3 shows us how the Twitter activities response to a report announcement of $aapl (Jan. 23 2013). The report was made public soon after the market closed at 4:00pm, while the tweets volume rose about two hours earlier and reached the peak at the time of announcement, then it arrived the second peak at the time near the market's next opening (9:30am). By further accumulating all days' tweet volume in our dataset as hourly based statistics, we plot the volume distribution in Figure 4. Again, we note that trading activities are well reflected by tweet activities. The volume starts to rise drastically two or three hours before the market opens, and then reaches a peak at 9:00pm. It drops during the lunch time and reaches the second peak around 2:00pm (after lunch). Above observations clearly show that market dynamics are discussed in tweets and the content in tweets' discussion very well reflects the fine-grained aspects of stock market trading, opening and closing.

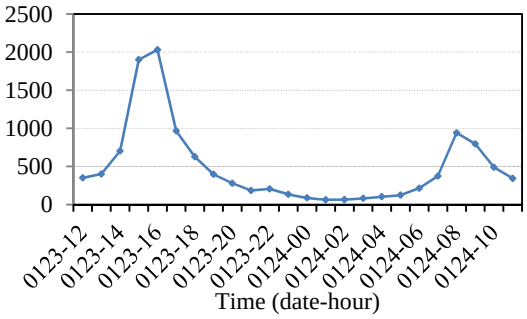

Figure 3. Tweet activity around $aapl's earnings report date on Jan. 23 2013.

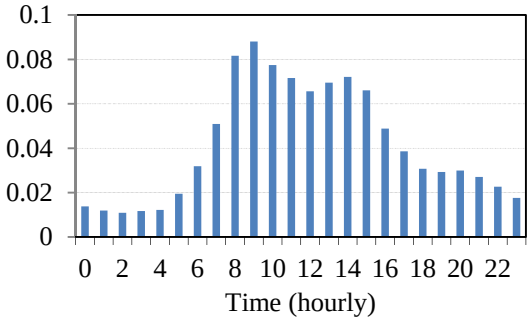

Figure 4. Tweet volume distribution in our data over hours averaged across each day.

4.2 Stock Prediction

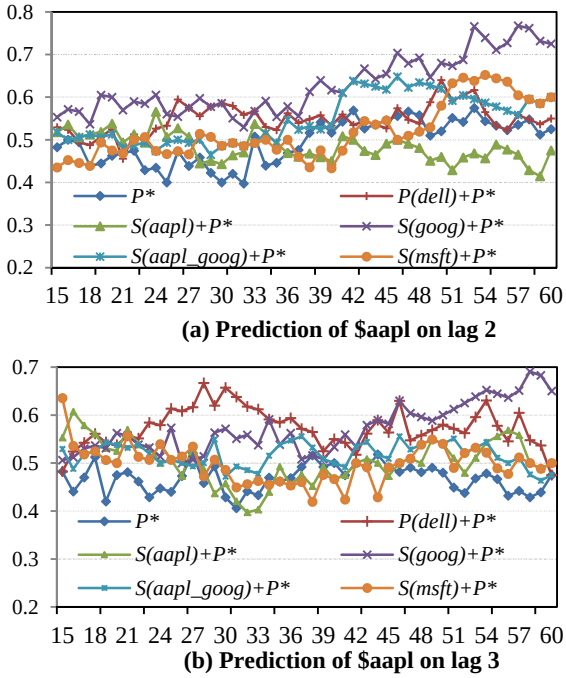
This section demonstrates the effectiveness of our SSN based approach for stock prediction. We leverage the sentiment time-series on two kinds of topics from SSN: 1). Node topic from the target stock itself, 2). Neighbor node/edge topics. We note that the price correlation stock network (CSN) (e.g., Bonanno et al., 2001; Mantegna, 1999) also defines neighbor relationships based on the Pearson's correlation coefficient (Tse et al., 2010) between pair of past price series (We get the stock dataset from Yahoo! Finance, between Nov. 2 2012 and Apr. 3 2013).

We build a two variables VAR model to predict the movement of a stock's daily closing price. One variable is the price time series of the target stock ($\{y_t\}$ in Eq.5); another is the covariate sentiment/price time series ($\{x_t\}$ in Eq.5). We setup two baselines according to the sources of the covariate time series as follows:

1. Covariate price time series from CSN, we try the price time series from the target stock's closest neighbor which takes the maximum historical price correlation in CSN.
2. With no covariate time series, we try the target stock's price only based on the univariate autoregression (AR) model.

To summarize, we try different covariate sentiment ($S(.)$) or price ($P(.)$) time series from SSN or CSN together with the target stock's price time series (P^*) to predict the movement of one day ahead price (P^{**}). The accuracy is computed based on the correctness of the predicted directions as follows, i.e., if the prediction P^{**} takes the same direction as the actual price value, we increment $\#(posPred)$ by 1, $\#(totalTest)$ is the total number of test.

$$Accuracy = \frac{\#(posPred)}{\#(totalTest)} \quad (6)$$



(a) Prediction of $aapl on lag 2

(b) Prediction of $aapl on lag 3

Figure 5. Prediction on $aapl. (x-axis is the training window size, y-axis is the prediction accuracy) with different covariate sources.

	Source	Lag = 2	Lag = 3
P^* only	self	0.49(0.57)	0.47(0.52)
CSN: $P(.)+P^*$	dell	0.55(0.64)	0.57(0.67)
SSN: $S(.)+P^*$	aapl	0.48(0.56)	0.50(0.61)
	goog	**0.62(0.78)**	**0.57(0.69)**
	aapl_goog	0.55(0.65)	0.52(0.56)
	msft	0.52(0.65)	0.54(0.61)

Table 2. Performance comparison of the average and best (in parentheses) prediction accuracies over all training window sizes for prediction on $aapl.

Figure 5 details the prediction of $aapl on different training window sizes of [15, 60] and lags. $\{S(aapl), S(goog), S(msft), S(aapl\_goog)\}$ are from SSN, $P(dell)$ is from CSN ($dell (Dell Inc.) takes the maximum price correlation score of 0.92 with $aapl), and $P^* = P(aapl)$ is the univariate AR model, using the target stock's price time series only. Table 2 further summarizes the performance comparison of different approaches reporting the average (and best) prediction accuracies over all time windows and different lag settings. Comparing to the univariate AR model (P^* only), we see that the sentiment based time-series improve performances significantly. Among SSN sentiment based approaches, the $S(goog)$ helps improve the performance mostly and gets the best accuracy of 0.78 on lag 2 and training window size of 53. On average, $S(goog)$ achieves a net gain over $S(aapl)$ in the range of 29% with lag 2 (0.62 = 1.29 x 0.48) and 14% with lag 3 (0.57 = 1.14 x 0.50). Also, $S(aapl\_goog)$ performs better than $S(aapl)$. The result indicates that $aapl's stock performance is highly influenced by its competitor. $P(dell)$ also performs well, but we will see relationships from CSN may not be so reliable.

We further summarize some other prediction cases in Table 3 to show how different covariate sentiment sources ($S(.)$) and price sources ($P(.)$) from their closest neighbor nodes help predict their stocks, which gives consistent conclusions. We compute the t-test for SSN based prediction accuracies against that of CSN or price only based approaches among all testing

window sizes ([15, 60]), and find that SSN based approaches are significantly (p-value < 0.001) better than others.

We note that tweet volumes of most S&P100 stocks are too small for effective model building, as tweets discuss only popular stocks, other stocks are not included due to their deficient tweet volume.

We make the following observations:

1. CSN may find some correlated stock pairs like $ebay and $amzn, $wmt and $tgt, but sometimes, it also produces pairs without real-world relationships like $tgt and $vz, $qcom and $pfe, etc. In contrast, SSN is built on large statistics of human recognition in social media, which is likely to be more reliable as shown.

2. Sentiment based approaches $\{S(\cdot)\}$ consistently perform better than all price based ones $\{P^*,\ P(\cdot)\}$. For $S(\cdot)$ based predictions, sentiment discovered from the target stock's closest neighbors in SSN performs best in general. This empirical finding dovetails with qualitative results in the financial analysis community (Mizik & Jacobson, 2003; Porter, 2008), where companies' market performances are more likely to be influenced by their competitors. But for Google, its stock market is not so much influenced by other companies (it gets the best prediction accuracy on $S(goog)$, i.e., the internal factor). It can be explained by Google Inc.'s relatively stable revenue structure, which is well supported by its leading position in the search engine market.

3. The business of offline companies like Target Corp. ($tgt) and Wal-Mart Stores Inc. ($wmt) are highly affected by online companies like $amzn. Although competition exists between $tag and $wmt, their performances seem to be affected more by a third-party like $amzn (In Table 3, $S(amzn)$ predicts the best for both). Not surprisingly, these offline companies have already been trying to establish their own online stores and markets.

5 Conclusion

This paper proposed to build a stock network from co-occurrences of ticker symbols in tweets. The properties of SSN reveal some close relationships between involved stocks, which provide good information for predicting stocks based on social sentiment. Our experiments show that SSN is more robust than CSN in capturing the neighbor relationships, and topic sentiments from close neighbors of a stock significantly improve the prediction of the stock market.

Abstract

Demographic lexica have potential for widespread use in social science, economic, and business applications. We derive predictive lexica (words and weights) for age and gender using regression and classification models from word usage in Facebook, blog, and Twitter data with associated demographic labels. The lexica, made publicly available,[1] achieved state-of-the-art accuracy in language based age and gender prediction over Facebook and Twitter, and were evaluated for generalization across social media genres as well as in limited message situations.

1 Introduction

Use of social media has enabled the study of psychological and social questions at an unprecedented scale (Lazer et al., 2009). This allows more data-driven discovery alongside the typical hypothesis-testing social science process (Schwartz et al., 2013b). Social media may track disease rates (Paul and Dredze, 2011; Google, 2014), psychological well-being (Dodds et al., 2011; De Choudhury et al., 2013; Schwartz et al., 2013a), and a host of other behavioral, psychological and medical phenomena (Kosinski et al., 2013).

Unlike traditional hypothesis-driven social science, such large-scale social media studies rarely take into account—or have access to—age and gender information, which can have a major impact on many questions. For example, females live almost five years longer than males (cdc, 2014; Marengoni et al., 2011). Men and women, on average, differ markedly in their interests and work preferences (Su et al., 2009). With age, personalities gradually change, typically becoming less open to experiences but more agreeable and conscientious (McCrae et al., 1999). Additionally, social media language varies by age (Kern et al., 2014; Pennebaker and Stone, 2003) and gender (Huffaker and Calvert, 2005). Twitter may have a male bias (Mislove et al., 2011), while social media in general skew towards being young and female (pew, 2014).

Accessible tools to predict demographic variables can substantially enhance social media's utility for social science, economic, and business applications. For example, one can post-stratify population-level results to reflect a representative sample, understand variation across age and gender groups, or produce personalized marketing, services, and sentiment recommendations; a movie may be generally disliked, except by people in a certain age group, whereas a product might be used primarily by one gender.

This paper describes the creation of age and gender predictive lexica from a dataset of Facebook users who agreed to share their status updates and reported their age and gender. The lexica, in the form of words with associated weights, are derived from a penalized linear regression (for continuous valued age) and support vector classification (for binary-valued gender). In this modality, the lexica are simply a transparent and portable means for distributing predictive models based on words. We test generalization and adapt the lexica to blogs and Twitter, plus consider situations when limited messages are available. In addition to use in the computational linguistics community, we believe the lexicon format will make it easier for social scientists to leverage data-driven models where manually created lexica currently dominate[2] (Dodds et al., 2011; Tausczik and Pennebaker, 2010).

2 Related Work

Online behavior is representative of many aspects of a user's demographics (Pennacchiotti and Popescu, 2011; Rao et al., 2010). Many studies have used linguistic cues (such as ngrams) to determine if someone belongs to a certain age group, be it on Twitter or another social media platform (Al Zamal et al., 2012; Argamon et al., 2009; Nguyen et al., 2013; Rangel and Rosso, 2013). Gender prediction has been studied across blogs (Burger and Henderson, 2006; Goswami et al., 2009), Yahoo! search queries (Jones et al., 2007), and Twitter (Burger et al., 2011; Nguyen et al., 2013; Liu and Ruths, 2013; Rao et al., 2010). Because Twitter does not make gender or age available, such work infers gender and age by leveraging profile information, such as gender-discriminating names or crawling for links to publicly available data (e.g. Burger et al.,

[1]download at http://www.wwbp.org/data.html

[2]The LIWC lexicon, derived manually based on psychological theory, (Pennebaker et al., 2001) had 1136 citations in 2013 alone.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1146–1151,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

2011).

While many studies have examined prediction of age or gender, none (to our knowledge) have released a model to the public, much less in the form of a lexicon. Additionally, most works in age prediction classify users into bins rather than predicting a continuous real-valued age as we do (exceptions: Nguyen et al., 2013; Jones et al., 2007). People have also used online media to infer other demographic-like attributes such as native language (Argamon et al., 2009), origin (Rao et al., 2010), and location (Jones et al., 2007). An approach similar to the one presented here could be used to create lexica for any of these outcomes.

While lexica are not often used for demographics, data-driven lexicon creation over social media has been well studied for sentiment, in which univariate techniques (e.g. *point-wise mutual information*) dominate[3]. For example, Taboada et al. (2011) expanded an initial lexicon by adding on co-occurring words. More recently, Mohammad's sentiment lexicon (Mohammad et al., 2013) was found to be the most informative feature for the top system in the SemEval-2013 social media sentiment analysis task (Wilson et al., 2013). Approaches like point-wise mutual information take a univariate view on words–i.e. the weight given to one feature (word) is not affected by other features. Since language is highly collinear, we take a multivariate lexicon development approach, which takes covariance into account (e.g. someone who mentions 'hair' often is more likely to mention 'brushing', 'style', and 'cut'; weighting these words in isolation might "double-count" some information).

3 Method

Primary data. Our primary dataset consists of Facebook messages from users of the MyPersonality application (Kosinski and Stillwell, 2012). Messages were posted between January 2009 and October 2011. We restrict our analysis to those Facebook users meeting certain criteria: they must indicate English as a primary language, have written at least 1,000 words in their status updates, be younger than 65 years old (data beyond this age becomes very sparse), and indicate their gender and age. This resulted in a dataset of N = 75,394 users, who wrote over 300 million words collectively. We split our sample into training and test sets. Our primary *test set* consists of a 1,000 randomly selected Facebook users, while the *training set* that we used for creating the lexica was a subset (N = 72,874) of the remaining users.

Additional data To evaluate our predictive lexica in differing situations, we utilize three additional datasets: stratified Facebook data, blogs, and tweets. The stratified Facebook data (exclusively used for testing) consists of equal proportions of 1,520 males and females across 12 4-year age bins starting at 13 and ending at 60.[4] This roughly matchs the size of the main *test set*.

Seeking out-of-domain data, we downloaded age and gender annotated blogs from 2004 (Schler et al., 2006) (also used in Goswami et al., 2009) and gender labeled tweets (Volkova et al., 2013). Limiting the sample to users who wrote at least 1000 words, the total number of bloggers is 15,006, of which 50.6% are female and only 15% are over 27 (reflecting the younger population standard in social media). From this we use a randomly selected 1,000 bloggers as a blogger test set and the remaining 14,006 bloggers for training. Similarly for the Twitter dataset, we use 11,000 random gender-only annotated users, in which 51.9% are female. We again randomly select 1,000 users as a test set for gender prediction and use the remaining 10,000 for training.

3.1 Lexicon Creation

We present a method of weighted lexicon creation by using the coefficients from linear multivariate regression and classification models. Before delving into the creation process, consider that a weighted lexicon is often applied as the sum of all weighted word relative frequencies over a document:

$$usage_{lex} = \sum_{word \in lex} w_{lex}(word) * \frac{freq(word, doc)}{freq(*, doc)}$$

where $w_{lex}(word)$ is the lexicon (lex) weight for the $word$, $freq(word, doc)$ is frequency of the word in the document (or for a given user), and $freq(*, doc)$ is the total word count for that document (or user).

Further consider how one applies linear multivariate models in which the goal is to optimize feature coefficients that best fit the continuous outcome (regression) or separate two classes (classification):

$$y = (\sum_{f \in features} w_f * x_f) + w_0$$

where x_f is the value for a feature (f), w_f is the feature coefficient, and w_0 is the intercept (a constant fit to shift the data such that it passes through the origin). In the case of regression, y is the outcome value (e.g. age) while in classification y is used to separate classes (e.g. $>= 0$ is female, < 0 is male). If all features are word relative frequencies ($\frac{freq(word,doc)}{freq(*,doc)}$) then many multivariate modeling techniques can simply be seen as learning a weighted lexicon plus an intercept[5].

[3]Note that the point-wise information-derived sentiment lexica are often used as features in a supervised model, essentially dimensionally reducing a large set of words into positive and negative sentiment, while our lexica represent the predictive model itself.

[4]65 females and 65 males in each of the first 11 bins: [13,16], [17,20], ..., [53, 56]; the last bin ([57, 60]) contained 45 males and 45 females. The [61.64] bin was excluded as it was much smaller.

T_{lex}							.816	.820	.763	.889
FB+BG+T_{lex}							.919	.910	.820	.900

Table 1: Prediction accuracies for age (Pearson correlation coefficient(r); mean absolute error (mae) in years) and gender (accuracy %). Baseline for age is mean age of training sample; for gender, it is the most frequent class (female). Lexica tested include those derived from Facebook (FB_{lex}), blogs (BG_{lex}), and Twitter (T_{lex}). We evaluate over a random Facebook sample (randFB), a stratified Facebook sample (stratFB), a random blogger sample (randBG), and a random twitter sample (randT). All results were a significant ($p < 0.001$) improvement over the baseline.

In practice, we learn our 1gram coefficients (i.e. lexicon weights) from ridge regression (Hoerl and Kennard, 1970) for age (continuous variable) and from support vector classification (Fan et al., 2008) for gender (binary variable). Ridge regression uses an L2 ($\alpha||\beta||^2$) penalization to avoid overfitting (Hoerl and Kennard, 1970). Although some words no doubt have a non-linear relationship with age (e.g., 'fiance' peaks in the 20s), we still find high accuracy from a linear model (see Table 1) and it allows for a distribution of the model in the accessible form of a lexicon. For gender prediction, we use an SVM with a linear kernel with L1 penalization ($\alpha||\beta||_1$) (Tibshirani, 1996). Because the L1 penalization zeros-out many coefficients, it has the added advantage of effectively reducing the size of the lexica. Using the training data, we test a variety algorithms including the lasso, elastic net regression, and L2 penalized SVMs in order to decide which learning algorithms to use.

To extract the words (1grams) to use as features and which make up lexica, we use the Happier Fun Tokenizer,[6] which handles social media content and markup such as emoticons or hashtags. For our main user-level models, word usage is aggregated as the relative frequency ($\frac{freq(word,user)}{freq(*,user)}$). Due to the sparse and large vocabulary of social media data, we limit the 1grams to those used by at least 1% of users.

4 Evaluation

We evaluate our predictive lexica across held-out user data. First, we see how well lexica derived from Facebook users predict a random set of additional users. Then, we explore generalization of the models in various other settings: on a stratified Facebook test sample, blogs, and Twitter. Finally, we compare lexica fit to a restricted number of messages per user.

Results of our evaluation over Facebook users are shown in Table 1 (randFB columns). Accuracies for age are reported as Pearson correlation coefficients (r) and mean absolute errors (mae), measured in years. For gender, we use an accuracy % (number-correct over test-size). As baselines, we use the mean for age (23.0 years old) and the most frequent class (female) for gender. We see that for both age and gender, accuracies are substantially higher than the baseline. These accuracies were just below with no significant difference previous state-of-the-art results (Schwartz et al., 2013; r = 0.84 for age and 91.9% accuracy for gender). [7]

Because of the nature of our datasets (the Facebook data is private) and task (*user-level* predictions), comparable previous studies are nearly nonexistent. Nonetheless, the Twitter data was a random subset of users based on the (Burger et al., 2011) dataset excluding non-English tweets, making it somewhat comparable. In this case, the lexica outperformed previous results for gender prediction of Twitter users, which ranged from 75.5% to 87% (Burger et al., 2011; Ciot et al., 2013; Liu and Ruths, 2013; Al Zamal et al., 2012). However, the lexica were unable to match the 92.0% accuracy Burger et al. (2011) achieved when using profile information in addition to text. No other similar studies — to the best of our knowledge — have been conducted.

Application in other settings. While Facebook is the ideal setting to apply our lexica, we hope that they generalize to other situations. To evaluate their utility in other settings, we first tested them over a gender and age stratified Facebook sample. Our random sample, like all of Facebook, is biased toward the young; this stratified test sample contains equal numbers of males and females, ages 13 to 60. Next, we use the lexica to predict data from other domains: blogs (Schler et al., 2006) and Twitter (Volkova et al., 2013). In this case, our goal was to account for the content and stylistic variation that may be specific to Facebook.

[6] downloaded from http://www.wwbp.org/data.html

[7] Adding 2 and 3-grams increases the performance of our model (r = 0.85, 92.7%), just above our previous results (Schwartz et al., 2013b). However, with the accessibility of single word lexica in mind, this current work focuses on features based entirely on 1grams.

# Msgs:	**all**	**100**	**20**	**5**	**1**
age	**.831**	.820	.688	.454	.156
gender	**.919**	.901	.796	.635	.554

Table 2: Prediction accuracies for age (Pearson correlation) and gender (accuracy %) when reducing the number of messages from each user.

Results over these additional datasets are shown in Table 1 (stratFB, randBG, and randT columns). The performance decreases as expected since these datasets have differing distributions, but it is still substantially above mean and most frequent class baselines on the stratified dataset. Over blogs and Twitter, both age and gender prediction accuracies drop to a greater degree (when only using the Facebook-trained models), suggesting stylistic or content differences between the domains. However, when using lexica created with data from across multiple domains, the results in Facebook, blogs, and Twitter remain in line with results from models created specifically over their respective domains. In light of this result, we release the FB+BG age & FB+BG+T gender models as lexica (available at www.wwbp.org/data.html).

Limiting messages per user. As previously noted, some applications of demographic estimation require predictions over more limited messages. We explore the accuracy of user-level age and gender predictions as the number of messages per user decreases in Table 2. For these tests we used the FB+BG age & FB+BG+T gender lexica. Confirming findings by Van Durme (2012), the fewer posts one has for each user, the less accurate the gender and age predictions. Still, given the average user posted 205 messages, it seems that not all messages from a user are necessary to make a decent inference on their age and gender. Future work may explore models developed specifically for these limited situations.

5 Conclusion

We created publicly available lexica (words and weights) using regression and classification models over language usage in social media. Evaluation of the lexica over Facebook yielded accuracies in line with state-of-the-art age ($r = 0.831$) and gender (91.9% accuracy) prediction. By deriving the lexica from Facebook, blogs, and Twitter, we found the predictive power generalized across all three domains with little sacrifice to any one domain, suggesting the lexica may be used in additional social media domains. We also found the lexica maintain reasonable accuracy when writing samples were somewhat small (e.g. 20 messages) but other approaches may be best when dealing with more limited data.

Given that manual lexica are already extensively employed in social sciences such as psychology, economics, and business, using lexical representations of data-driven models allows the utility of our models to extend beyond the borders of the field of NLP.

Abstract

Dependency parsing is a core task in NLP, and it is widely used by many applications such as information extraction, question answering, and machine translation. In the era of social media, a big challenge is that parsers trained on traditional newswire corpora typically suffer from the domain mismatch issue, and thus perform poorly on social media data. We present a new GFL/FUDG-annotated Chinese treebank with more than 18K tokens from Sina Weibo (the Chinese equivalent of Twitter). We formulate the dependency parsing problem as many small and parallelizable arc prediction tasks: for each task, we use a programmable probabilistic first-order logic to infer the dependency arc of a token in the sentence. In experiments, we show that the proposed model outperforms an off-the-shelf Stanford Chinese parser, as well as a strong MaltParser baseline that is trained on the same in-domain data.

1 Introduction

Weibo, in particular Sina Weibo[1], has attracted more than 30% of Internet users (Yang et al., 2012), making it one of the most popular social media services in the world. While Weibo posts are abundantly available, NLP techniques for analyzing Weibo posts have not been well-studied in the past.

Syntactic analysis of Weibo is made difficult for three reasons: first, in the last few decades, Computational Linguistics researchers have primarily focused on building resources and tools using standard English newswire corpora[2], and thus, there are fewer resources in other languages in general. Second, microblog posts are typically short, noisy (Gimpel et al., 2011), and can be considered as a "dialect", which is very different from news data. Due to the differences in genre, part-of-speech taggers and parsers trained on newswire corpora typically fail on social media texts. Third, most existing parsers use language-independent standard features (McDonald et al., 2005), and these features may not be optimal for Chinese (Martins, 2012). To most of the application developers, the parser is more like a blackbox, which is not directly programmable. Therefore, it is non-trivial to adapt these generic parsers to language-specific social media text.

In this paper, we present a new probabilistic dependency parsing approach for Weibo, with the following contributions:

- We present a freely available Chinese Weibo dependency treebank[3], manually annotated with more than 18,000 tokens;
- We introduce a novel probabilistic logic programming approach for dependency arc prediction, making the parser directly programmable for theory engineering;
- We show that the proposed approach outperforms an off-the-shelf dependency parser, as well as a strong baseline trained on the same in-domain data.

In the next section, we describe existing work on dependency parsing for Chinese. In Section 3, we present the new Chinese Weibo Treebank to the research community. In Section 4, we introduce the proposed efficient probabilistic programming approach for parsing Weibo. We show the experimental results in Section 5, and conclude in Section 6.

2 Related Work

Chinese dependency parsing has attracted many interests in the last fifteen years. Bikel and Chiang (2000; 2002) are among the first to use Penn Chinese Tree Bank for dependency parsing, where they adapted Xia's head rules (Xia, 1999). An important milestone for Chinese dependency parsing is that, a few years later, the CoNLL shared task launched a track for multilingual dependency parsing, which also included Chinese (Buchholz and Marsi, 2006; Nilsson et al., 2007). These shared tasks soon popularized Chinese dependency parsing by making datasets available, and there has been growing amount of literature since then (Zhang and Clark, 2008; Nivre et al., 2007; Sagae and Tsujii, 2007; Che et al., 2010; Carreras, 2007; Duan et al., 2007).

Besides the CoNLL shared tasks, there are also many interesting studies on Chinese dependency parsing. For example, researchers have studied case (Yu et al., 2008) and morphological (Li and Zhou, 2012) structures for learning a Chinese dependency parser. Another direction is to perform joint learning and inference for POS tagging and dependency parsing (Li et al., 2011; Hatori et al., 2011; Li et al., 2011; Ma et al., 2012). In recent years, there has been growing interests in dependency arc prediction in Chinese (Che et al., 2014), and researchers have also investigated character-level Chinese dependency parsing (Zhang et al., 2014). However, even though the above methods all have merits, the results are reported only on standard newswire based Chinese Treebank (e.g. from People's Daily (Liu et al., 2006)), and it is unclear how they would perform on Weibo data.

To the best of our knowledge, together with the recent study on parsing tweets (Kong et al., 2014), we are among the first to study the problem of dependency parsing for social media text.

3 The Chinese Weibo Treebank

We use the publicly available μtopia dataset (Ling et al., 2013) for dependency annotation. An interesting aspect of this Weibo dataset is that, besides the Chinese posts, it also includes a copy of the English translations. This allows us to observe some interesting phenomena that mark the differences of the two languages. For example:

- Function words are more frequently used in English than in Chinese. When examining this English version of the Weibo corpus for the total counts of the word "the", there are 2,084 occurrences in 2,003 sentences. Whereas in Chinese, there are only 52 occurrences of the word "the" out of the 2,003 sentences.

- The other interesting thing is the position of the head. In English, the head of the tree occurs more frequent on the left-to-middle of the sentence, while the distribution of the head is more complicated in Chinese. This is also verified from the parallel Weibo data.

- Another well-known issue in Chinese is that Chinese is a pro-drop topical language. This is extremely prominent in the short text, which clearly creates a problem for parsing. For example, in the Chinese Weibo data, we have observed the sentence in Figure 1.

想吃 鸡蛋 就 得 忍受 鸡叫

(If you) Want to eat chicken eggs,
(you) have to bear the chicken sound

Figure 1: An example of pro-drop phenomenon from the Weibo data.

To facilitate the annotation process, we first preprocess the Weibo posts using the Stanford NLP pipeline, including a Chinese Word Segmenter (Tseng et al., 2005) and a Chinese Part-of-Speech tagger (Toutanova and Manning, 2000). Two native speakers of Chinese with strong linguistic backgrounds have annotated the dependency relations from 1,000 posts of the μtopia dataset, using the FUDG (Schneider et al., 2013) and GFL annotation tool (Mordowanec et al., 2014). The annotators communicate regularly during the annotation process, and a coding manual that relies majorly on the Stanford Dependencies (Chang et al., 2009) is designed. The annotation process has two stages: in the first stage, we rely on the word segmentation produced by the segmenter, and produce a draft version of the treebank; in the second stage, the annotators actively discuss the difficult cases to reach agreements, manually correct the mis-segmented word tokens, and revise the annotations of the tricky cases. The final inter-annotator agreement rate on a randomly-selected subset of 373 tokens in this

treebank is 82.31%.

Fragmentary Unlabeled Dependency Grammar (FUDG) is a newly proposed flexible framework that offers a relative easy way to annotate the syntactic structure of text. Beyond the traditional tree view of dependency syntax in which the tokens of a sentence form nodes in a tree, FUDG also allows the annotation of additional lexical items such as multiword expressions. It provides special devices for coordination and coreference; and facilitates underspecified (partial) annotations where producing a complete parse would be difficult. Graph Fragment Language (GFL) is an implementation of unlabeled dependency annotations in the FUDG framework, which fully supports Chinese, English and other languages. The training set of our Chinese Weibo Treebank[4] includes 14,774 tokens, while the development and test sets include 1,846 and 1,857 tokens respectively.

4 A Programmable Parser with Personalized PageRank Inference

A key problem in multilingual dependency parsing is that generic feature templates may not work well for every language. For example, Martins (2012) shows that for Chinese dependency parsing, when adding the generic grandparents and siblings features, the performance was worse than using the standard bilexical, unilexical, and part-of-speech features. Unfortunately, for many parsers such as Stanford Chinese Parser (Levy and Manning, 2003) and MaltParser (Nivre et al., 2007), it is very difficult for programmers to specify the feature templates and inference rules for dependency arc prediction.

In this work, we present a Chinese dependency parsing method for Weibo, based on efficient probabilistic first-order logic programming (Wang et al., 2013). The advantage of probabilistic programming for parsing is that, software engineers can simply conduct theory engineering, and optimize the performance of the parser for a specific genre of the target language. Recently, probabilistic programming approaches (Goodman et al., 2012; Wang et al., 2013; Lloyd et al., 2014) have demonstrated its efficiency and effectiveness in many areas such as information extraction (Wang et al., 2014), entity linking, and text classification (Wang et al., 2013).

[4]The corpus is freely available for download at the URL specified in Section 1.

Algorithm 1 A Dependency Arc Inference Algorithm for Parsing Weibo

Given:
(1) a sentence with tokens T_i, where i is the index, and L is the length;
(2) a database D of token relations from the corpus;
(3) first-order logic inference rule set R.

for $i = 1 \rightarrow L$ tokens **do**
  $\mathbb{S} \leftarrow ConstructSearchSpace(T_i, R, D)$;
  $\vec{P}_i \leftarrow InferParentUsingProPPR(T_i, \mathbb{S})$;
end for

Greedy Global Inference
for $i = 1 \rightarrow L$ tokens **do**
  $Y_i = \arg\max \vec{P}_i$;
end for

4.1 Problem Formulation

We formulate the dependency parsing problem as many small dependency arc prediction problems. For each token, we form the parent inference problem of a token T_i as solving a query $edge(T_i, ?)$ using stochastic theorem proving on a search graph. Our approach relies on a database D of inter-token relations. To construct the database, we automatically extract the token relations from the text data. For example, to denote the adjacency of two tokens T_1 and T_2, we store the entry $adjacent(T_1, T_2)$ in D. One can also store the part-of-speech tag of a token in the form $haspos(T_1, DT)$. There is no limitations on the arity and the types of the predicates in the database.

Given the database of token relations, one then needs to construct the first-order logic inference theory R for predicting dependency arcs. For example, to construct simple bilexical and bi-POS inference rules to model the dependency of an adjacent head and a modifier, one can write first-order clauses such as:

```
edge(V1,V2) :-
  adjacent(V1,V2),hasword(V1,W1),
  hasword(V2,W2),keyword(W1,W2) #adjWord.

edge(V1,V2) :-
  adjacent(V1,V2),haspos(V1,W1),
  haspos(V2,W2),keypos(W1,W2) #adjPos.

keyword(W1,W2) :- # kw(W1,W2).
keypos(W1,W2) :- # kp(W1,W2).
```

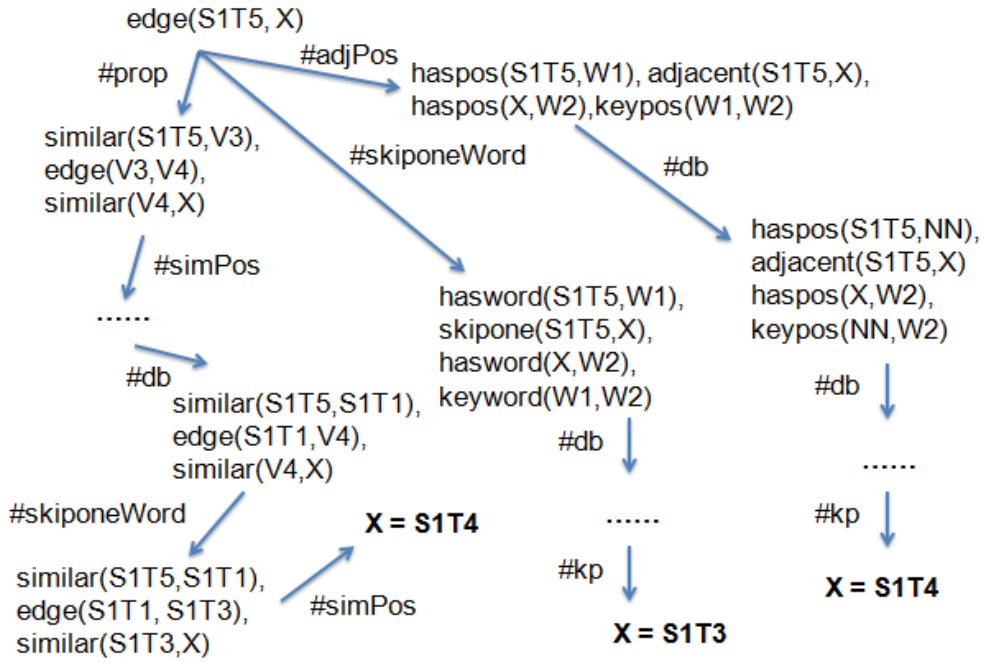

Figure 2: After mapping the database D to theory R, here is an example of search space for dependency arc inference. The query is $edge(S_1T_5, X)$, and there exists one correct and multiple incorrect solutions (highlighted in **bold**).

Here, we associate a feature vector ϕ_c with each clause, which is annotated using the # symbol after each clause in the theory set. Note that the last two (*keyword* and *keypos*) clauses are feature templates that allow us to learn the specific bi-POS tags and bilexical words from the data. In order for one to solve the query $edge(T_i, ?)$, we first need to map the entities from D to R to construct the search space. The details for constructing and searching in the graph can be found in previous studies on probabilistic first-order logic (Wang et al., 2013) and stochastic logic programs (Cussens, 2001). An example search space is illustrated in Figure 2. Note that now the edges in the search graph correspond to the feature vector ϕ_c in R.

The overall dependency arc inference algorithm can be found in Algorithm 1. For each of the parent inference subtask, we use ProPPR (Wang et al., 2013) to perform efficient personalized PageRank inference. Note that to ensure the validity of the dependency tree, we break the loops in the final parse graph into a parse tree using the maximum personalized PageRank score criteria. When multiple roots are predicted, we also select the most likely root by comparing the personalized PageRank solution scores.

To learn the more plausible theories, one needs to upweight weights for relevant features, so that they have higher transition probabilities on the corresponding edges. To do this, we use stochastic gradient descent to learn from training queries, where the correct and incorrect solutions are known. The details of the learning algorithm are described in the last part of this section.

4.2 Personalized PageRank Inference

For the inference of the parent of each token, we utilize ProPPR (Wang et al., 2013). ProPPR allows a fast approximate proof procedure, in which only a small subset of the full proof graph is generated. In particular, if α upper-bounds the reset probability, and d upperbounds the degree of nodes in the graph, then one can efficiently find a subgraph with $O(\frac{1}{\alpha\epsilon})$ nodes which approximates the weight for every node within an error of $d\epsilon$ (Wang et al., 2013), using a variant of the PageRank-Nibble algorithm of Andersen *et al* (2008).

4.3 Parameter Estimation

Our parameter learning algorithm is implemented using a parallel stochastic gradient descent variant to optimize the log loss using the supervised personalized PageRank algorithm (Backstrom and

Method	Dev.	Test
Stanford Parser (Xinhua)	0.507	0.489
Stanford Parser (Chinese)	0.597	0.581
MaltParser (Full)	**0.669**	0.654
Our methods — ProPPR		
ReLU (Bi-POS)	0.506	0.517
ReLU (Bilexical)	0.635	0.616
ReLU (Full)	0.668	0.666
Truncated $tanh$ (Bi-POS)	0.601	0.594
Truncated $tanh$ (Bilexical)	0.650	0.634
Truncated $tanh$ (Full)	0.667	**0.675***

Table 1: Comparing our Weibo parser to other baselines (UAS). The off-the-shelf Stanford parser uses its attached Xinhua and Chinese factored models, which are trained on external Chinese treebank of newswire data. MaltParser was trained on the same in-domain data as our proposed approach. * indicates $p < .001$ comparing to the MaltParser.

Leskovec, 2011). The idea is that, given the training queries, we perform a random walk with restart process, and upweight the edges that are more likely to end up with a known correct parent. We learn the transition probability from two nodes (u, v) in the search graph using: $\Pr_{\mathbf{w}}(v|u) = \frac{1}{Z} f(\mathbf{w}, \Phi^c_{\text{restart}})$, where we use two popular non-linear parameter learning functions from the deep learning community:

- Rectified Linear Unit (ReLU) (Nair and Hinton, 2010): $max(0, x)$;
- The Hyperbolic Function (Glorot and Bengio, 2010): $tanh(x)$.

as the f in this study. ReLU is a desirable non-linear function, because it does not have the vanishing gradient problem, and produces sparse weights. For the weights learned from $tanh(x)$, we truncate the negative weights on the edges, since the default weight on the feature edges is $\mathbf{w} = 1.0$ (existence), and $\mathbf{w} = 0.0$ means that the edge does not exist in the inference stage.

5 Experiments

In this experiment, we compare the proposed parser with two well-known baselines. First, we compare with an off-the-shelf Stanford Chinese Parser (Levy and Manning, 2003). Second, we compare with the MaltParser (Nivre et al., 2007) that is trained on the same in-domain Weibo dataset. The train, development, and test splits are described in Section 3. We tune the regularization hyperparameters of the models on the dev. set, and report Unlabeled Attachment Score (UAS) results for both the dev. set and the hold-out test set. We experiment with the bilexical and bi-POS first-order logic theory separately, as well as a combined full model with directional and distance features.

The results are shown in Table 1. We see that both of the two attached pre-trained models from the Stanford parser do not perform very well on this Weibo dataset, probably because of the mismatched training and test data. MaltParser is widely considered as one of the most popular dependency parsers, not only because of its speed, but also the acclaimed accuracy. We see that when using the full model, the UAS results between our methods and MaltParser are very similar on the development set, but both of our approaches outperform the Maltparser in the holdout test set. The truncated $tanh$ variant of ProPPR obtains the best UAS score of 0.675.

6 Conclusion

In this paper, we present a novel Chinese dependency treebank, annotated using Weibo data. We introduce a probabilistic programming dependency arc prediction approach, where theory engineering is made easy. In experiments, we show that our methods outperform an off-the-shelf Stanford Chinese Parser, as well a strong MaltParser that is trained on the same in-domain data. The Chinese Weibo Treebank is made freely available to the research community. In the future, we plan to apply the proposed approaches to dependency and semantic parsing of other languages.

Exploiting Community Emotion for Microblog Event Detection

Abstract

Microblog has become a major platform for information about real-world events. Automatically discovering real-world events from microblog has attracted the attention of many researchers. However, most of existing work ignore the importance of emotion information for event detection. We argue that people's emotional reactions immediately reflect the occurring of real-world events and should be important for event detection. In this study, we focus on the problem of community-related event detection by community emotions. To address the problem, we propose a novel framework which include the following three key components: *microblog emotion classification*, *community emotion aggregation* and *community emotion burst detection*. We evaluate our approach on real microblog data sets. Experimental results demonstrate the effectiveness of the proposed framework.

1 Introduction

Microblog has become a popular and convenient platform for people to share information about social events in real time. When an external event occurs, it will be quickly propagated between microblog users. During propagation process of an event, sufficient amount of users will express their emotions. Taking Sina Weibo[1] as an example, more than 12 percent of users use emoticons[2] when reposting an event-related microblog message.

The emotion information can not only help us better understand a given event, but also be utilized to discover new events. Figure 1 shows

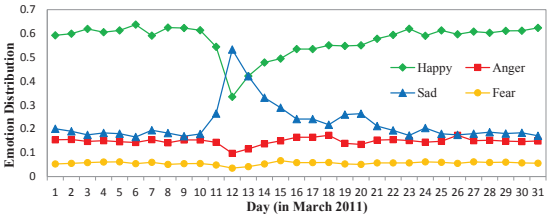

Figure 1: The global emotion dynamics

the emotional distribution dynamics of the overall microblog messages in March 2011. The sudden change of the public emotion distribution on March 12 indicates a public event: *3.11 Earthquake in Japan*. We can see that emotional changes immediately reflect the occurring of real-world events, thus it is reasonable to use them to perform event detection.

Most existing research on microblog event detection (Weng and Lee, 2011; Sakaki et al., 2010; Becker et al., 2010) only account for the factual information (e.g., burstness of topic keywords). They usually ignore the importance of emotion information for event detection. Although there have recently been a few papers (Zhao et al., 2012a; Nguyen et al., 2013; Akcora et al., 2010) in this direction, they have a number of disadvantages. Firstly, they can not detect community-related events. Since they all aggregate emotion at global level, they can only discover national attention events, such as public holidays ("Christmas" and "Spring Festival") or natural disasters. In many applications, discovering events related to a certain group of users or a certain topic is more meaningful. Consider the following questions: "*what happened in the football community last week?*" and "*what are the most significant events in the lawyer community last month?*" Secondly, they assign equal weight to each microblog message or user when aggregating them to a global emotion score. Such approaches may lead to incorrect results when a user posts emotion spam

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

in the community. Thirdly, there is a lack of quantitative evaluation using real-world events in existing work. For example, there is only case study in (Zhao et al., 2012a) and (Akcora et al., 2010).

In this study, we focus on a new task of detecting community-related events via community emotion. Our intuition is inspired from the social psychology theory of *group emotion*. In social psychology, *group emotion* refers to the moods, emotions and dispositional affects of a group of people [3]. It can arise as a result of group-relevant events (Smith et al., 2007). For example, people will feel happy when their favorite football team wins a game and feel sad when their team loses a game. Thus we can use the community emotion as signals to detect community-related events. To achieve good performance of this new task, the following two factors must be considered: 1) *how to measure the community emotion based on microblog message or user emotion* and 2) *how to perform event detection based on the sequence of community emotion*.

To measure community emotion, we argue that in a given community, different users have different emotional authorities. The emotion of highly influential people in the community may be more important in determining the community emotion (Barsäde and Gibson, 1998). We propose to use the user's emotion authority computed by the social network of the community to weight the user when aggregating community emotion. Since spam user is unlikely to have high emotion authority in the community, our method can reduce the effect of emotion spam. Based on the community emotion, we present an emotion burst detection algorithm for the community emotion distribution sequence. We identify two emotional states of the community: "emotion stable" state and "emotion burst" state. We use the Dirichlet distribution to model the generation process of the community emotion distribution. An efficient emotion burst detection algorithm is presented to detect community-related events.

We evaluate our approach on large-scale microblog data sets by using real-world event list for each community. Experimental results demonstrate that the community emotion is an effective signal for community-related event detection. In comparison with several baseline methods, our emotion burst detection algorithm also improves the event detection performance in terms of precision, recall and F-measure.

2 Related Work

In this section, we review the related work on sentiment analysis and event detection in microblog, respectively.

Sentiment Analysis in Microblog: Sentiment analysis (Pang and Lee, 2008; Liu, 2012) is mainly about analyzing people's opinions, sentiments and emotions towards a given event, topic, product, etc. Microblog platforms like Twitter and Weibo, provide people a convenient way to post their emotional reactions towards social events in almost real time. This leads to increasing number of interests on sentiment analysis in microblog data (Davidov et al., 2010; Liu et al., 2012; Go et al., 2009; Agarwal et al., 2011; Pak and Paroubek, 2010; Jiang et al., 2011; Speriosu et al., 2011; Bermingham and Smeaton, 2010). The training data for microblog sentiment analysis are usually obtained in an automatic manner by utilizing emoticons, hashtags and smileys. Davidov et al. (2010) propose an approach to automatically obtain labeled training examples by exploiting hashtags and smileys. Liu et al. (2012) proposed an emoticon smoothed method to integrate both manually labeled data and noisy labeled data for Twitter sentiment classification.

Different from existing microblog sentiment analysis work, which aims at discovering sentiments and emotions for an event or topic given in advance, we are interested in utilizing the emotion information in microblog messages for real-world event detection. Our work use sentiment analysis as a tool to perform microblog emotion classification. Then we propose an event detection algorithm based on the sequence of community level emotion distribution.

Event Detection in Microblog: Event detection from microblog data has attracted increasing attention recently. We divide existing work into the following two categories: *non-emotion-based* methods and *emotion-based* methods. *Non-emotion-based* methods try to exploit keyword or activity patterns to discover events (Weng and Lee, 2011; Sakaki et al., 2010; Becker et al., 2010; Mathioudakis and Koudas, 2010). Mathioudakis and Koudas (2010) first identify "bursty" keywords and then discover events by grouping bursty keywords together. Zhao et al. (2012b) focuses on

identifying event-related burst from social media based on multiple activities. They propose a unified optimization model to integrate multiple correlated activity streams based on the state machine in (Kleinberg, 2003).

Emotion-based methods try to exploit the emotional reactions to discover events (Zhao et al., 2012a; Akcora et al., 2010). Akcora et al. (2010) model public emotion as an emotion vector computed by counting emotion words and then use a rule-based method to identify public breakpoints. Zhao et al. (2012a) use a simple top-k method to detect abnormal events based on sequence of sentiment variance.

Our method is also an emotion-based method. However, our approach is different from existing emotion-based methods in the following aspects. Firstly, while existing work aggregates emotion for all users, we focus on emotion for a certain community to discover community-related events. Secondly, existing methods assume that the emotions of different users are of equal importance. We distinguish user's emotional authority based on the community structure of users.

3 Preliminary Definitions

In this section, we first give some basic concepts before formally defining our problem.

Topical Community: A group of connected users that are interested in a specific topic. A topical community can be denoted as $C = \{V, E, M\}$, where V is the set of community users, E is the set of relationships of between users. $M = \{M_1, M_2, ..., M_T\}$ is the microblog message collection in the community, which is segmented according to time. M_t is the microblog message collection in time interval t.

Emotion Distribution: An emotion distribution e_t is a real-value N-dimension vector sampled from the emotion space, satisfying the constraint $\sum_{i=1}^{N} e_{ti} = 1$. It indicates the emotional state of a microblog message, a user or a community at time t. At a given time interval t, a user emotion distribution $e_t(u)$ is computed by an aggregation function over the emotion distribution of the microblog messages posted by u in time interval t. Community emotion distribution $e_t(c)$ is computed by an aggregation function over the emotion distribution of the community users in c at time interval t.

Community Emotion Burst: Given an emotion distribution sequence e_t for community c, an emotion burst is defined as period $[t_s, t_e]$ in which some event relevant to c takes places. During the time period, the emotion distribution of c is :1) significantly different from its average emotion distribution, or 2) extremely uneven distributed.

Given the above definitions, our object is then to detect community-related events from the emotion distribution sequence of the community.

4 The Proposed Framework

In this section, we describe our microblog event detection framework. The framework aims to detect community-related events based on the community emotion. The overview of our framework is shown in Figure 2. In particular, we define the following four main components:

1) **Microblog emotion classification:** We train emotion classification model by automatically acquiring training data using the emoticons.

2) **Community emotion aggregation:** We assume that in a given community, different users have different weights when aggregating community emotion. Thus we propose a novel weighting approach based on the user's authority.

3) **Community emotion burst detection:** Given the community emotion, we propose an emotion burst detection algorithm to detect community emotion bursts.

4) **Event extraction:** The function of this component is to extract event keywords for each community emotion burst. We count the document frequency (DF) of each term contained in the microblog messages in the burst period. Then the top-5 DF terms are used to describe the event occurring during the burst period, although there exist alternative techniques (Ritter et al., 2012; Li et al., 2010).

Since the last component is not the main focus of this work, we only introduce the first three components in detail in the following subsections.

4.1 Microblog Emotion Classification

We build an emotion classifier using the multinomial Naïve Bayes classifier for each community to classify microblog messages into different emotion classes. Here we are interested in the setting where the microblog messages arrive as stream, thus it is not appropriate to use a constant set of manually labeled messages. To avoid manual annotation cost, we adopt a distant supervision approach (Go et al., 2009; Davidov et al., 2010; Hu

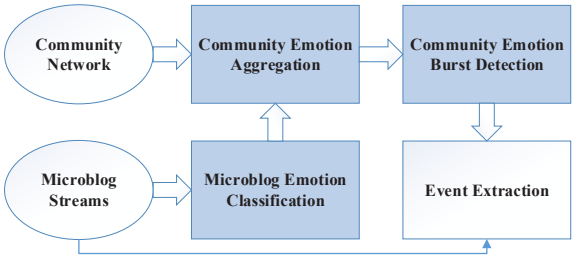

Figure 2: Overview of our community-related event detection framework

Table 1: List of emoticons

Happy(26)	good	laugh	love	smile	cute
Anger *(19)*	anger	hate	curse	despise	crazy
Sad(13)	sad	disappoint	cry	unhappy	unwell
Fear(11)	fear	surprise	shame	doubt	fright

et al., 2013) to acquire labeled microblog messages automatically by using the emoticons. We first select a set of emoticons which are most frequently used to express emotion in microblog. Then we manually map each emoticon into four emotion classes (26 for *happy*, 19 for *anger*, 13 for *sad* and 11 for *fear*). We only show the top five emoticons for each emotion type in Table 1. The labeled emoticons can then be used to acquire training data to train an emotion classifier for a community in any time period.

We combine the features which have been proven effective by previous work, such as punctuation and emotion lexicons. Specifically, we use the following features : 1) Words appearing in the microblog message serve as word features, 2) Number of "!" characters and "?" in the microblog message, and 3) Each term in a general emotion lexicon serves as an emotion lexicon feature.

The emotion distribution $e(m)$ of a microblog message m is represented by a N-dimension distribution vector. For example, if a microblog message m is classified as *happy*, then its emotion distribution $e(m)$ is $[1, 0, 0, 0]$. The emotion distribution of $e(u)$ of user u at time t is average emotion distribution of the microblog messages posted by him during time t.

$$e_t(u) = \frac{1}{N_{ut}} \sum_{m=1}^{N_{ut}} e(m) \quad (1)$$

where N_{ut} is the number of microblog messages posted by user u at time t.

4.2 Community-level Emotion Aggregation

A common strategy to measure community emotion is to compute the average emotion of the community users. It is based on the assumption that the emotion of different community users are with equal importance. This is implemented by employing an *average* aggregation function on the individual emotion distribution $e_t(u)$:

$$e_t(c) = \frac{1}{N_c} \sum_{u \in c} e_t(u) \quad (2)$$

where N_c is the number of users in community c.

Intuitively, the emotion of user with higher authority in community should be more important in determining community emotion. Thus we estimate community emotion by taking into account user's emotional authority, which is based on the assumption that different users in a community have different emotional authorities.

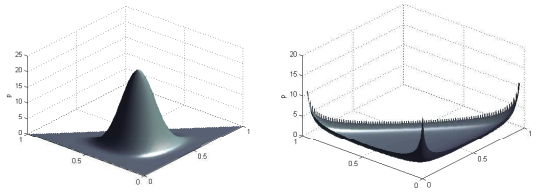
We employ HITS algorithm(Kleinberg, 1999) to compute the user authority $auth(u)$ based on the user network $\{V, E\}$ of the community. Then $auth(u)$ is used to represent the emotional authority of user u. This authority-based community emotion aggregation approach can also reduce the effect of spam users, since they usually have low authorities in the community network. For simplicity and computation efficiency, we assume that $auth(u)$ is time independent, which means that we only need to run the HITS algorithm once for each community. Given the user emotion distributions and the user emotional authorities, the emotion distribution for a community c in time interval t can be measured as:

$$e_t(c) = \frac{1}{A_{ct}} \sum_{u \in c} auth(u) e_t(u) \quad (3)$$

where $A_{ct} = \sum_{u \in c_t} auth(u)$ is the normalization term.

4.3 Community Emotion Burst Detection

We formulate our problem into the binary state model framework (Kleinberg, 2003). For a given community c, there are T time intervals in total, with community emotion distribution sequence $e = (e_1, e_2, ..., e_T)$ and state sequence $q = (q_1, q_2, ..., q_T)$. Each q_t can be one of the following two states: $q_t = 0$ ("emotion stable" state) and $q_t = 1$ ("emotion burst" state). Our objective



(a) "emotion stable" state (b) "emotion burst" state

Figure 3: Emotion probability density for "emotion stable" state and "emotion burst" state

is to find an optimal state sequence q^* given the emotion distribution sequence e.

Since each e_t is a distribution rather than positive integer, the emotion generation process can no longer be modeled by a Poisson distribution. We choose to model the emotion generation process by the Dirichlet distribution. This process is analogous to the document-level topic generation in the LDA topic model (Blei et al., 2003).

If community c is in an "emotion stable" state in time interval t, its emotion distribution e_t should be close to the average emotion distribution e_a. The density function is defined as $f(e_t, e_a, s_t = 0) = Dirichlet(\alpha_0 e_a)$, where $s_t = 0$ indicates that the community is in an "emotion stable" state and α_0 is a positive parameter. To ensure that e_t closer to e_a will get higher probability, α_0 should satisfy the constraint $\alpha_0 \cdot \min e_a > 1$. An example of the probability density function of $f(e_t, e_a, s_t = 0)$ in a three dimension emotion space is shown in Figure 3(a).

If community c is in an "emotion burst" state in time interval t, the emotion distribution of c is : 1) significantly different from its average emotion distribution, or 2) extremely uneven distributed. For example, assume $e_a = [0.25, 0.25, 0.25, 0.25]$, if community is in burst in time interval t, its emotion distribution is more likely to be $[0.1, 0.4, 0.1, 0.4]$ (significantly different from e_a) or $[0.1, 0.7, 0.1, 0.1]$ (extremely *anger*). The density function is then defined as $f(e_t, e_a, s_t = 1) = Dirichlet(\alpha_1 e_a)$. $s_t = 1$ indicates that the community is in an "emotion burst" state and α_1 should satisfy the constraint: $\alpha_1 \cdot \max e_a < 1$. An example of the probability density function of $f(e_t, e_a, s_t = 1)$ in a three dimension emotion space is shown in Figure 3(b).

Based on above discussion, the cost function for an emotion state sequence q can be defined as:

$$cost(q|e) = \sum_{t=1}^{T} -\ln(f_t(e_t, e_a, q_t)) + b\ln(\frac{1-\pi}{\pi}) \quad (4)$$

where π is the probability the community will change the emotion state in two consecutive time intervals t and $t+1$. b denotes the number of emotion state changes in the whole time intervals $[1, T]$.

Equation 4 is exactly the objective function we need to optimize. This optimization problem can be efficiently solved by using a dynamic programming procedure, as summarized in Algorithm 1. Algorithm 1 mainly consists of two phases: a forward phase (line 5 - line 10) which calculates the minimal cost for emotion distribution subsequence and a backward phase to construct the optimal emotion state sequence (line 11 - line 14).

For convenience, we use $f_t(s)$ to denote $f_t(e_t, e_a, s)$. $\pi_{s's} = \pi$ if $s' \neq s$, otherwise $\pi_{s's} = (1-\pi)$. $c_t(s)$ denotes the minimal cost of generating the emotion distribution sub-sequence $\{e_1, ..., e_t\}$ with $q_t = s$. $q'_t(s)$ stores the state of time interval $t-1$ for the most likely state subsequence so far with $q_t = s$.

Algorithm 1 Emotion Burst Extraction

Input: The emotion distribution sequence $e = (e_1, e_2, ..., e_T)$, the state transition cost π and the parameters α_0 and α_1

1: **for** each $s \in \{0, 1\}$ **do**
2: Initialize $c_1(s) = -\ln f_1(s)$
3: Initialize $q'_1(s) = 0$
4: **end for**
5: **for** each $t = 2, \cdots, T$ **do**
6: **for** each $s \in \{0, 1\}$ **do**
7: $c_t(s) = \min_{s'}(c_{t-1}(s') - \ln f_t(s) - \ln \pi_{s's})$
8: $q'_t(s) = \arg\min_s(c_{t-1}(s') - \ln \pi_{s's})$
9: **end for**
10: **end for**
11: $q^*(T) = \arg\min_s c_T(s)$
12: **for** each $t = T-1, \cdots, 2$ **do**
13: $q^*(t) = q'_{t+1}(q^*(t+1))$
14: **end for**

Output: The optimal emotion state sequence q^*

Table 2: Basic statistics of data sets

Community	#User	#Link	#Microblog	#Event
legal cases	4937	97639	269871	31
football	9928	105483	416631	75
economy	2657	65403	179584	46
singer	3759	79458	478265	53

5 Experimental Setup

5.1 Data Set

We use a large microblog data set crawled from Sina Weibo, which is the most popular microblog service in China. This data set contains 212,859,466 Chinese microblog messages posted by 916,126 users in a period of about 8 months (1/12/2010∼ 20/7/2011). We also crawled the *following* network, which resulted in 15,681,296 *following* relationships for the 916,126 users.

We choose four communities: "legal cases", "football", "economy" and "singer". To obtain the members for each topical community, we manually selected several keywords and input them as queries to the user search page[4]. After filtering out the users whose microblog messages are not collected in our corpora, we extract the sub-network of the users from the whole *following* network.

We use a simple but efficient method to extract microblog messages for each topical community: 1) If a microblog message is posted by the community members and also contains keywords of the community, it belongs to the community; 2) If a microblog message is posted by community member u and it is *reposting*, *commenting on* or *replying to* another microblog posted by community member v, then it belongs to the community. The basic statistics of our data sets are shown in Table 2.

5.2 Ground Truth Generation

Algorithm 1 generates a list of emotion bursts for each community. Since our goal is to identify community-related events, we need to evaluate how well the generated emotion bursts correspond to the ground truth real-world events. To generate the ground truth for evaluation, we utilize the news website Sina News[5]. Two PhD students are invited to manually generate a list of real events for each community by referring to the annual topic summary page[6] of Sina News. The annotation agreement is higher than 90%. Each event is also associated with its occurred date. The number of events for each community is shown in the last column of Table 2. For each community, the event list is then used to evaluate the performance of different event detection models.

5.3 Evaluation Metric

We use precision, recall and F-measure as evaluation metric. For each community, we compare the event list $\mathcal{E}^c$ and the generated burst list $\mathcal{B}^c$ to compute the above metric. Specifically, the precision, recall and F-measure for a community c are defined as follows:

$$P = \frac{\sum_{j=1}^{|\mathcal{E}^c|}\sum_{k=1}^{|\mathcal{B}^c|} I(\mathcal{E}_j^c \in \mathcal{B}_k^c)}{|\mathcal{B}^c|} \quad (5)$$

$$R = \frac{\sum_{j=1}^{|\mathcal{E}^c|}\sum_{k=1}^{|\mathcal{B}^c|} I(\mathcal{E}_j^c \in \mathcal{B}_k^c)}{|\mathcal{E}^c|} \quad (6)$$

$$F = \frac{2 \times P \times R}{P + R} \quad (7)$$

where $\mathcal{E}_j^c$ is the occurring time of the j-th event in community c, $\mathcal{B}_k^c$ is the k-th identified burst for community c. $I(.)$ is the indicator function (which equals 1 if its argument is true and 0 otherwise).

The final precision, recall and F-measure are averaged over different communities.

5.4 Compared Methods

We now introduce four methods used for comparison as follows:

EmoPeakFind: The method proposed in (Akcora et al., 2010), which aims at discovering breakpoints from public emotion. They use the following simple rule to find breakpoints from emotion sequences:

$$Sim(e_{t-1}, e_t) < Sim(e_{t-2}, e_{t-1}) \quad (8)$$

$$Sim(e_{t-1}, e_t) < Sim(e_t, e_{t+1}) \quad (9)$$

where Sim is a similarity function. We use the cosine similarity function in our evaluation.

TopKEmoVar: The method used in (Zhao et al., 2012a). They first derive a sequence of relative variation V^n for each single emotion sequence e^n. Then they define a sequence of emotion variation as $(\sum_{n=1}^{4} |V_t^n|)$. This sequence is sorted in descending order and the top-k t is selected as burst

[5]http://news.sina.com.cn

[6]http://news.sina.com.cn/zt/

Table 3: Event detection performance of different methods

Method	Precision	Recall	F-measure
EmoPeakFind	0.313	0.625	0.417
TopKEmoVari	0.423	0.423	0.423
KLB	0.575	0.702	0.632
MBurst	0.534	0.497	0.515
Our Method	**0.654**	**0.715**	**0.683**

state points, where k is set to be the size of the event list for each community.

KLB: The method proposed in (Kleinberg, 2003). Note that *KLB* can only deal with a single sequence $e^n = (e_1^n, ..., e_t^n, ...e_T^n)$ for emotion type n. We first apply *KLB* to find the optimal state sequences for each emotion type. Then we perform an OR function to merge the N state sequences to a global emotion state sequence.

MBurst: The method proposed in (Zhao et al., 2012b) for multi-stream burst detection. *MBurst* is evaluated on three activity streams in (Zhao et al., 2012b). Here we apply *MBurst* to the N emotion streams. Then we perform an OR function to merge the N state sequences to a global emotion state sequence.

6 Experimental Results

6.1 Performance Comparison Results

In this experiment, we compare our method with different baseline methods as introduced in Section 5.4. We use Equation (3) to aggregate community emotion for all the compared methods. The parameter α_0 and α_1 are empirically set to be $\frac{5}{\min_n e_a^n}$ and $\frac{0.5}{\max_n e_a^n}$, respectively. The experimental results are shown in Table 3.

Table 3 shows that *EmoPeakFind* and *TopKEmoVari* are less effective than other methods. The simple rule used in *EmoPeakFind* produced many noisy bursts, leading to low precision. *TopKEmoVari* only considers the relative variation of two consecutive time intervals. The choose of k is also nontrivial since it is hard to know the number of events before the events are identified. Note that *EmoPeakFind* and *TopKEmoVari* are both rule-based methods, while *KLB*, *MBurst* and *Our Method* are state machine based methods. This demonstrates that for community-related emotion burst detection, it is more appropriate to use a state machine based model.

It looks surprising that *MBurst* performs worse than *KLB*, since *MBurst* is specifically designed for multiple streams. However, *MBurst* is based on the assumption that the states of multiple streams in the same time interval tend to be the same (i.e., there is positive correlation between two different streams). This assumption no longer holds in the context of different emotion streams. For example, if a negative event occurs in the community, while sad emotion is likely to be in a burst state, $happy$ emotion is not likely to be in a burst state.

We can see from Table 3 that our method outperforms the four baselines. The main reason is that our burst detection method is based on the sequence of community emotion distribution. Modeling community emotion as a distribution is more suitable than modeling several different emotion types.

We further show some example events detected by our model in Table 4. Since the event keywords are manually translated from Chinese, one keyword may include more than one English words. We can see that community emotion can help to detect emotionally significant events for different communities. For example, the "legal cases" community is in a strong *anger* emotional state on December 25, 2010, which indicates an important event "Qian Yunhui's case".

Table 5: Performance of different weighting schemes in terms of F-measure

Community	Weighting schema	
	equal	*HITS-based*
legal cases	0.517	0.590
football	0.674	0.765
economy	0.642	0.712
singer	0.589	0.665
avg	0.605	0.683

6.2 Effect of Emotion Aggregation Functions

In this experiment, we show the importance of correctly aggregation community level emotion for community-related event detection. We compare the two aggregation approaches introduced in section 4.2. The first approach assigns equal weight to each community users, while the second approach assigns weights to users based on their authorities in the community.

The performance in terms of F-measure is shown in Table 5. It is obvious that, for all commu-

Table 4: Examples of events and the corresponding community emotions for two communities. The four emotion types (*happy*, *anger*, *sad* and *fear*) are mapped to green, red, blue and yellow color, respectively.

Community	Date	Emotion	Event keywords
legal cases	25/12/2010		Qian Yunhui, village head, Yueqing, run over, Zhejiang
	22/4/2011		Yao Jiaxin, death penalty, first instance, Xi'an, intentional killing
	9/5/2011		Xia Junfeng, final judgment, death penalty, pedlar, Shenyang
football	2/12/2010		Qatar, 2022, world cup bid, win, FIFA
	14/2/2011		Ronaldo, retire, legend, football, Brazil
	29/5/2011		Barcelona, 2011, Champions League final, win, UEFA

nities, HITS-based weighting approach performs better than equal weighting approach. Thus we can conclude that user authority is important when aggregating community emotion.

We further perform an empirically analysis of the events that successfully identified by HITS-based approach but failed by equal weighting approach. By manually analyzing the microblog messages of the corresponding time intervals, we found that most of the errors of equal weighting approach were caused by emotion spam. Users of low authority post many microblog messages with extreme emotion to claim the attention of the community. Since there is no significant community-related events at that time interval, we do not observe emotional changes of the high authority uses. In the equal weighting method, the existence of emotion spam lead to wrong result of community emotion. Since the weights of users who post emotion spam are small in the HITS-based approach, they have little effect on the community emotion. This is the main reason why HITS-based weighting method is more effective than equal weighting method.

6.3 Parameter Sensitivity

In this experiment, we test the sensitivity of our model by different choices of the parameters α_0 and α_1. $\alpha_0 \min_n e_a^n$ is set to be $[2, 3, 4, 5, 6, 7, 8]$ and $\alpha_1 \max_n e_a^n$ is set to be $[0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8]$. The event detection results of different parameter settings are shown in Figure 4.

It can be seen from Figure 4 that: 1) The performance is relatively good in a particular range of the parameters. When $\frac{2}{\min_n e_a^n} \leq \alpha_0 \leq \frac{7}{\min_n e_a^n}$ and $\frac{0.3}{\max_n e_a^n} \leq \alpha_1 \leq \frac{0.7}{\max_n e_a^n}$, the F-measure is consistently larger than 0.55. 2) In general, the performance is more sensitive to α_1 than to α_0. Note that α_1 controls the generation process of the emotion distribution when the community is in the "emotion burst" state, thus it is relatively more important to tune α_1 than α_0. The experimental results demonstrates that when $\frac{0.3}{\max_n e_a^n} \leq \alpha_1 \leq \frac{0.7}{\max_n e_a^n}$, the performance can be relatively good.

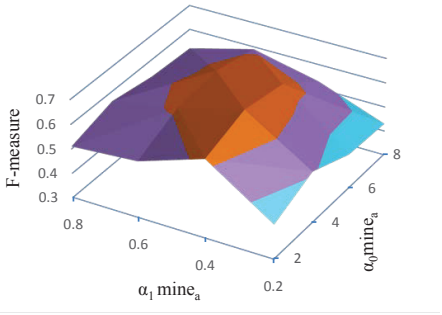

Figure 4: F-measure of our method for event detection in different parameter settings

7 Conclusion

Microblog has become a popular and convenient platform for people to share information about social events in real time. In this paper, we focus on the problem of community-related event detection by community emotions. We propose a novel method to compute community-level emotion by considering the user authority in the community network. Then we present an effective emotion burst detection algorithm for the community emotion distribution sequence.

We evaluate our approach on real microblog data sets. Experimental results demonstrate that it is important to take into account the user authority when aggregating community emotion for

community-related event detection. Our emotion burst detection algorithm also achieves better performance than several baseline methods.

Detecting Disagreement in Conversations using Pseudo-Monologic Rhetorical Structure

Kelsey Allen **Giuseppe Carenini** **Raymond T. Ng**
Department of Computer Science, University of British Columbia
Vancouver, BC, V6T 1Z4, Canada
{kelseyra, carenini, rng}@cs.ubc.ca

Abstract

Casual online forums such as Reddit, Slashdot and Digg, are continuing to increase in popularity as a means of communication. Detecting disagreement in this domain is a considerable challenge. Many topics are unique to the conversation on the forum, and the appearance of disagreement may be much more subtle than on political blogs or social media sites such as twitter. In this analysis we present a crowd-sourced annotated corpus for topic level disagreement detection in Slashdot, showing that disagreement detection in this domain is difficult even for humans. We then proceed to show that a new set of features determined from the rhetorical structure of the conversation significantly improves the performance on disagreement detection over a baseline consisting of unigram/bigram features, discourse markers, structural features and meta-post features.

1 Introduction

How does disagreement arise in conversation? Being able to detect agreement and disagreement has a range of applications. For an online educator, dissent over a newly introduced topic may alert the teacher to fundamental misconceptions about the material. For a business, understanding disputes over features of a product may be helpful in future design iterations. By better understanding how debate arises and propagates in a conversation, we may also gain insight into how authors' opinions on a topic can be influenced over time.

The long term goal of our research is to lay the foundations for understanding argumentative structure in conversations, which could be applied to NLP tasks such as summarization, information retrieval, and text visualization. Argumentative structure theory has been thoroughly studied in both psychology and rhetoric, with negation and discourse markers, as well as hedging and dispreferred responses, being known to be indicative of argument (Horn, 1989; Brown and Levinson, 1987). As a starting point, in this paper we focus on the detection of disagreement in casual conversations between users. This requires a generalized approach that can accurately identify disagreement in topics ranging from something as mundane as whether GPS stands for galactic positioning system or global positioning system, to more ideological debates about distrust in science.

Motivated by the widespread consensus in both computational and theoretical linguistics on the utility of discourse markers for signalling pragmatic functions such as disagreement and personal opinions (Webber and Prasad, 2008; Abbott et al., 2011; J. E. Fox-Tree, 2010), we introduce a new set of features based on the Discourse Tree (DT) of a conversational text. Discourse Trees were formalized by Mann and Thompson (1988) as part of their Rhetorical Structure Theory (RST) to represent the structure of discourse. Although this theory is for monologic discourse, we propose to treat conversational dialogue as a collection of linked monologues, and subsequently build a *relation graph* describing both rhetorical connections within user posts, as well as between different users. Features obtained from this graph offer significant improvements on disagreement detection over a baseline consisting of meta-post features, lexical features, discourse markers and conversational features. Not only do these features improve disagreement detection, but the discovered importance of relations known to be theoretically relevant to disagreement detection, such as COMPARISON (Horn, 1989), suggest that this approach may be capturing the essential aspects of the conversational argumentative structure.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1169–1180,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

As a second contribution of this work, we provide a new dataset consisting of 95 topics annotated for disagreement. Unlike the publicly available *ARGUE* corpus based on the online debate forum 4forums.com (Abbott et al., 2011), our corpus is based on Slashdot, which is a general purpose forum not targeted to debates. Therefore, we expect that detecting disagreement may be a more difficult task in our new corpus, as certain topics (like discussing GPS systems) may be targeted towards objective information sharing without any participants expressing opinions or stances. Because of this, our corpus represents an excellent testbed to examine methods for more subtle disagreement detection, as well as the major differences between news-style and argument-style dialogue.

2 Related Work

In the past decade, there have been a number of computational approaches developed for the task of disagreement and controversy detection, particularly in synchronous conversations such as meetings (Somasundaran et al., 2007; Raaijmakers et al., 2008) and in monologic corpora such as news collections (Awadallah et al., 2012) and reviews (Popescu et al., 2005; Mukherjee and Liu, 2012).

In the domain of synchronous conversations, prosodic features such as duration, speech rate and pause have been used for spoken dialogue (Wang et al., 2011; Galley et al., 2004). Galley et al. (2004) found that local features, such as lexical and structural features, as well as global contextual features, were particularly useful for identifying agreement/disagreement in the ICSI meeting corpus. Germesin and Wilson (2009) also showed accuracies of 98% in detecting agreement in the AMI corpus using lexical, subjectivity and dialogue act features. However, they note that their system could not classify disagreement accurately due to the small number of training examples in this category. Somasundaran et al. additionally show that dialogue act features complement lexical features in the AMI meeting corpus (Somasundaran et al., 2007). These observations are taken into account with our feature choices, and we use contextual, discourse and lexical features in our analysis.

In the monologic domain, Conrad et al. (2012) recently found rhetorical relations to be useful for argument labelling and detection in articles on the topic of healthcare. Additionally, discourse markers and sentiment features have been found to assist with disagreement detection in collections of news documents on a particular topic, as well as reviews (Choi et al., 2010; Awadallah et al., 2012; Popescu et al., 2005).

In the asynchronous domain, there has been recent work in disagreement detection, especially as it pertains to stance identification. Content based features, including sentiment, duration, and discourse markers have been used for this task (Yin et al., 2012; Somasundaran and Wiebe, 2009; Somasundaran and Wiebe, 2010). The structure of a conversation has also been used, although these approaches have focused on simple rules for disagreement identification (Murakami and Raymond, 2010), or have assumed that adjacent posts always disagree (Agrawal et al., 2003). More recent work has focused on identifying users' attitudes towards each other (Hassan et al., 2010), influential users and posts (Nguyen et al., 2014), as well as identifying subgroups of users who share viewpoints (Abu-Jbara et al., 2010). In Slashdot, the h-index of a discussion has been used to rank articles according to controversiality, although no quantitative evaluation of this approach has been given, and, unlike in our analysis, they did not consider any other features (Gomez et al., 2008). Content based features such as polarity and cosine similarity have also been used to study influence, controversy and opinion changes on microblogging sites such as Twitter (Lin et al., 2013; Popescu and Pennacchiotti, 2010).

The simplified task of detecting disagreement between just two users (either a question/response pair (Abbott et al., 2011) or two adjacent paragraphs (Misra and Walker, 2013)) has also been recently approached on the *ARGUE* corpus. Abbott et al. (2011) use discourse markers, generalized dependency features, punctuation and structural features, while Misra and Walker (2013) focus on n-grams indicative of denial, hedging and agreement, as well as cue words and punctuation. Most similar to our work is that by Mishne and Glance (2006). They performed a general analysis of weblog comments, using punctuation, quotes, lexicon counts, subjectivity, polarity and referrals to detect disputative and non-disputative comments. Referrals and questions, as well as polarity measures in the first section of the post, were found to be most useful. However, their analysis did not

Type	Num	P/A	S/P	W/P	Num Authors	W/S	TBP	TT	TP	Length
Disagreement - C	19.00	1.02	3.21	65.86	15.84	20.47	4.60	50.90	16.21	49.11
Disagreement - NC	27.00	1.00	3.08	59.80	14.07	19.33	3.89	42.29	14.11	42.26
No disagreement - NC	28.00	1.03	2.85	57.25	10.29	19.94	6.83	50.12	10.50	28.00
No disagreement - C	21.00	1.00	3.69	69.66	6.29	20.22	6.14	18.22	6.29	19.81

Table 1: Characteristics of the four categories determined from the crowd-sourced annotation. All values except for the number of topics in the category are given as the average score per topic across all topics in that category. **Key: C and NC:** Confident ($score \geq 0.75$) and Not confident ($score < 0.75$), **Num:** Number of topics in category, **P/A:** Posts per author, **S/P:** Sentences per post, **W/P:** Words per post, **Num Authors:** Number of authors, **W/S:** Words per sentence, **TBP:** Time between posts (minutes), **TT:** Total time in minutes, **TP:** Total posts, and **Length:** Length of topic in sentences

take into account many features that have been subsequently shown to be relevant, such as discourse markers and conversational structure, and was hampered by a severe imbalance in the test set (with very few disputative comments).

Our method takes advantage of insights from many of these previous studies, focusing on discussion thread structure as well as text based features to form our basic feature set. It is unlike Mishne and Glance's work in that we incorporate several new features, have a balanced testing and training set, and only use comments from one type of online blog. Furthermore, it is a very different task from those so far performed on the *ARGUE* corpus, as we consider topics discussed by more than two users. We aim to compare our features to those found to be previously useful in these related tasks, and expect similar feature sets to be useful for the task of disagreement detection in this new corpus.

3 Corpus

The corpus stems from the online forum Slashdot.[1] Slashdot is a casual internet forum, including sections for users to ask questions, post articles, and review books and games. For the task of disagreement detection, we focus our analysis on the section of the site where users can post articles, and then comment either on the article or respond to other users' posts. This results in a tree-like dialogue structure for which the posted article is the root, and branches correspond to threads of comments. Each comment has a timestamp at the minute resolution as well as author information (although it is possible to post on the forum anonymously). Additionally, other users can give different posts scores (in the range -1 to 5) as well as categorizing posts under "funny", "interesting", "informative", "insightful", "flamebait", "off topic", or "troll". This user moderation, as well as the formalized reply-to structure between comments, makes Slashdot attractive over other internet forums as it allows for high-quality and structured conversations.

In a previous study, Joty et al. (2013) selected 20 articles and their associated comments to be annotated for topic segmentation boundaries and labels by an expert Slashdot contributor. They define a topic as a subset of the utterances in a conversation, while a topic label describes what the given topic is about (e.g., Physics in videogames). Of the 98 annotated topics from their dataset, we filtered out those with only one contributing user, for a total of 95 topics. Next, we developed a Human Intelligence Task (HIT) using the crowdsourcing platform Crowdflower.[2] The objective of this task was to both develop a corpus for testing our disagreement detection system, as well as to investigate how easily human annotators can detect disagreement in casual online forums. For training, users were shown 3 sample topics, labelling them as containing disagreement or not. In each round, annotators were shown 5 topics, with a set of radio buttons for participants to choose "Yes", "No", or "Not sure" in response to asking whether or not the users in the conversation disagree on the topic. In order to limit the number of spam responses, users were shown test questions, which consisted of topics where there was obvious disagreement, as well as topics where there was obviously no disagreement (either agreement, or more news-style information sharing). We required that users correctly identify 4 of these test topics before they were allowed to continue with the task. Users were also shown test questions throughout the task, which, if answered incorrectly, would reduce the amount of money they received for the task, and ultimately disqualify them.

For each topic, five different judgements were obtained. We consider the trust of each partici-

(a) Discourse tree **(b)** Relation graph

Figure 1: Discourse tree (left) with extracted relation graph (right) for a sample conversation involving three users with three different posts P1, P2 and P3. N1, N2 and N3 are the corresponding nodes in the relation graph.

pant as the fraction of test questions which they answered correctly. Then, each topic is assigned a score according to a weighted average of the responses, with the weight being the trust of each participant:

$$score = A \sum_{users} (\frac{test_{correct}}{test_{total}})_{user_i} \times (0, 0.5, 1) \quad (1)$$

where 0, 0.5 and 1 represent the answers "No", "Not sure" and "Yes" to the question of disagreement existence, and A is a normalization factor. If the score is less than 0.5, its confidence would be $1 - score$ towards "No disagreement", whereas greater than 0.5 would be a confidence of $score$ towards "Disagreement". The average confidence score across all topics was 0.73. Our corpus consists of 49 topics without disagreement and 46 topics with disagreement. Interestingly, 22 topics had confidence scores below 55%, which suggests that subtle disagreement detection is a subjective and difficult task. Further statistics for the developed corpus are given in Table 1.

4 Features for Disagreement Detection

The features we use in our experiments combine information from conversational structure, rhetorical relations, sentiment features, n-gram models, Slashdot meta-features, structural features, and lexicon features.

4.1 Rhetorical Relation Graphs

Discourse markers have been found to aid in argument and disagreement detection, and for tasks such as stance identification (Abbott et al., 2011; Misra and Walker, 2013; Somasundaran and Wiebe, 2009). We aim to improve over discourse markers by capturing the underlying discourse structure of the conversation in terms of discourse relations.

In Rhetorical Structure Theory, Discourse trees are a hierarchical representation of document structure for monologues (Mann and Thompson, 1988). At the lowest level, Elementary Discourse Units (EDUs) are connected by discourse relations (such as ELABORATION and COMPARISON), which in turn form larger discourse units that are also linked by these relations. Computational systems (discourse parsers) have been recently developed to automatically generate a discourse tree for a given monologue (Joty et al., 2013). Although theoretically the rhetorical relations expected in dialogues are different from those in monologues (Stent and Allen, 2000), no sophisticated computational tools exist yet for detecting these relations reliably. The core idea of this work is that some useful (although noisy) information about the discourse structure of a conversation can be obtained by applying state-of-the-art document level discourse parsing to parts of the conversation.

More specifically, posts on a particular topic are concatenated according to their temporal order. This pseudo-monologic document is then fed to a publicly available document level discourse parser (Joty et al., 2013). A discourse tree such as that seen in Figure 1a is output by the parser. Then, we extract the novel *relation graph* (Figure 1b) from the discourse tree. In this graph, each node (N1, N2, N3) corresponds to a post (P1, P2, P3) and links aim to capture the argumentative structure. There are three cases when a link is added between two nodes in the relation graph. Firstly, links existing between two posts directly, such as the COMPARISON relation between P2 and P3, are added between the corresponding nodes in the re-

lation graph (N2 and N3). Secondly, links existing between fractions of posts in the discourse tree are added to the relation graph (e.g. if (S2,P2) was connected to (S1,P3) directly, N2 and N3 would have an additional link with that label). Finally, when posts are connected through internal nodes (such as P1 and I1 in Figure 1a), a labelled link is added for each post in the internal node to the relation graph (N1->N2 and N1->N3 in Figure 1b).

This relation graph allows for the extraction of many features that may reflect argumentative structure, such as the *number of connections*, the frequency of each rhetorical relation in the graph per post (*diff per post*), and the frequency as a percentage of all rhetorical relations (*diff percentage*). For example, COMPARISON relations are known to indicate disagreement (Horn, 1989), so we expect higher frequencies of this relation if the conversation contains argument. Features from the discourse tree such as the *average depth* of each rhetorical relation are also added to reflect the cohesiveness of conversation. Moreover, features combining the graph and tree representations, such as the ratio of the frequency of a rhetorical relation occurring between different posts to the average depth ($\frac{\text{CONTRAST between different posts}}{\text{Average depth of CONTRAST}}$), called *avg ratio* are implemented. These reflect the hypothesis that relations connecting larger chunks of text (or whole posts) may be more important than those connecting sentences or only partial posts.

Finally, the sub-trees corresponding to individual posts are used to extract the average frequency of rhetorical relations within a post (*same per post*) and the average frequency of a rhetorical relation with respect to other rhetorical relations in the post (*same percentage*). A measure of how often a rhetorical relation connects different users compared to how often it connects discourse units in the same post (*same to diff*), is also added. These capture the intuition that certain rhetorical relations such as CAUSE, EVIDENCE and EXPLANATION are expected to appear more within a post if users are trying to support their perspective in an argument. In total, there are 18 (rhetorical relations)×7 (*avg ratio, avg depth, same per post, same percentage, diff percentage, diff per post, same to diff*) + 1 (number of connections) = 127 features.

4.2 Discourse Markers

Motivated by previous work, we include a frequency count of 17 discourse markers which were found to be the most common across the *ARGUE* corpus (Abbott et al., 2011). Furthermore, we hypothesize that individual discourse markers might have low frequency counts in the text. Therefore, we also include an aggregated count of all 17 discourse markers in each fifth of the posts in a topic (e.g. the count of all 17 discourse markers in the first fifth of every post in the topic). Altogether, there are 5 aggregated discourse marker features in addition to the 17 frequency count features.

4.3 Sentiment Features

Sentiment polarity features have been shown to be useful in argument detection (Mishne and Glance, 2006). For this work, we use four sentiment scoring categories: the *variance*, *average score*, *number of negative sentences*, and *controversiality score* (Carenini and Cheung, 2008) of sentences in a post. These are determined using SoCAL (Taboada et al., 2011), which gives each sentence a polarity score and has been shown to work well on user-generated content.

Overall, we have two main classes of sentiment features. The first type splits all the posts in a topic into 4 sections corresponding to the sentences in each quarter of the post. The sentiment scores described above are then applied to each section of the posts (e.g. one feature is the number of negative sentences in the first quarter of each post). As a separate feature, we also include the scores on just the first sentence, as Mishne and Glance (2006) previously found this to be beneficial. This gives a total of 4×5 = 20 features. We refer to this set as "sentiment".

Motivated by the rhetorical features, our second main class of sentiment features aims to identify "more important" posts for argument detection by applying the four categories of sentiment scores to only those posts connected by each of our 18 rhetorical relations. This is done for both posts with an inner rhetorical connection (identified by the sub-tree for that post), as well as for posts connected by a rhetorical relation in the relation graph. This results in a total of (4 sentiment categories)×(2 (different + same post connections))×(18 rhetorical relations) = 144 features. This set is referred to as "RhetSent".

4.4 Fragment Quotation Graphs

As previously noted in (Murakami and Raymond, 2010; Gomez et al., 2008), the structure of discussion threads can aid in disagreement detection. In online, threaded conversations, the standard approach to extracting conversational structure is through reply-to relations usually present in online forums. However, if users strongly disagree on a topic (or sub-topic), they may choose to quote a specific paragraph (defined as a fragment) of a previous post in their reply. Being able to determine which specific fragments are linked by relations may then be useful for more targeted content-based features, helping to reduce noise. In order to address this, we use the Fragment Quotation Graph (FQG), an approach previously developed by Carenini et al. (2007) for dialogue act modelling and topic segmentation (Joty et al., 2011; Joty et al., 2013).

For our analysis, the FQG is found over the entire Slashdot article. We then select the subgraph corresponding to those fragments in the target topic. From the fragment quotation sub-graph, we are then able to extract features for disagreement detection such as the *number of connections*, *total number of fragments*, and the *average path length* between nodes which we hypothesize to be useful. We additionally extract the *h-index* (Gomez et al., 2008) and *average branching ratio per fragment* of the topic from the simpler reply-to conversational structure. In total, there are 8 FQG features.

4.5 N-gram models

As noted previously (Somasundaran and Wiebe, 2010; Thomas et al., 2006), it is often difficult to outperform a unigram/bigram model in the task of disagreement and argument detection. In this analysis, because of the very small number of samples, we do not consider dependency or part-of-speech features, but do make a comparison with a filtered unigram/bigram model. In the filtering, we remove stop words and any words that occur in fewer than three topics. This helps to prevent topic specific words from being selected, and limits the number of possible matches slightly. Additionally, we use a lexicon of bias-words (Recasens et al., 2013) to extract a bias-word frequency score over all posts in the topic as a separate feature.

4.6 Structural Features

Length features have been well documented in the literature to provide useful information about whether or not arguments exist, especially in online conversations that may be more informative than subjective (Biyani et al., 2014; Yin et al., 2012). In this work, length features include the *length of the post in sentences*, the *average number of words per sentence*, the *average number of sentences per post*, the *number of contributing authors*, the *rate of posting*, and the *total amount of time* of the conversation. This results in a total of 9 features.

4.7 Punctuation

Like many other features already described, frequency counts of '?','!',"","", and '.' are found for each fifth of the post (the first fifth, second fifth, etc.). These counts are then aggregated across all posts for a total of $5 \times 5 = 25$ features.

4.8 Referrals

Referrals have been found to help with the detection of disagreement (Mishne and Glance, 2006), especially with respect to other authors. Since there are no direct referrals to previous authors in this corpus, references to variations of "you", "they", "us", "I", and "he/she" in each fifth of the post are included instead, for a total of $5 \times 5 = 25$ features.

4.9 Meta-Post Features

Slashdot allows users to rank others' posts with the equivalent of a "like" button, changing the "score" of the post (to a maximum of 5). They are also encouraged to tag posts as either "Interesting", "Informative", "Insightful", "Flamebait", "Troll", "Off-topic" or "Funny". Frequency counts of these tags as a percentage of the total number of comments are included as features, as well as the overall fraction of posts which were tagged with any category. The *average score* across the topic, as well as the *number of comments with a score of 4 or 5*, are also added. These are expected to be informative features, since controversial topics may encourage more up and down-voting on specific posts, and generally more user involvement. This results in 9 meta-post features.

Feature Set	Random Forest					SVM

Table 2: Basic: Meta-post, all structural, bias words, discourse markers, referrals, punctuation **RhetAll:** Structural and sentiment based rhetorical features **All:** Basic, all rhetorical, sentiment and FQG features. The N-gram models include unigrams and bi-grams. All feature sets in the bottom part of the table include rhetorical reatures.

5 Experiments

Experiments were all performed using the Weka machine learning toolkit. Two different types of experiments were conducted - one using all annotated topics in a binary classification of containing disagreement or not, and one using only those topics with confidence scores greater than 0.75 (corresponding to the more certain cases). All results were obtained by performing 10 fold cross-validation on a balanced test set. Additionally, in-fold cross-validation was performed to determine the optimal number of features to use for each feature set. Since this is done in-fold, a paired t-test is still a valid comparison of different feature sets to determine significant differences in F-score and accuracy.

5.1 Classifiers

Two classifiers were used for this task: Random Forest and SVM. Random Forest was selected because of its ability to avoid over-fitting data despite large numbers of features for relatively few samples. For all runs, 100 trees were generated in the Random Forest, with the number of features to use being determined by in-fold optimization on the F-score. For the SVM classifier, we use the normalized poly-vector kernel with a maximum exponent of 2 (the lowest possible), and a C parameter of 1.0 (Weka's default value). This was chosen to avoid over-fitting our data. We additionally use a supervised in-fold feature selection algorithm, Chi-Squared, to limit over-fitting in the SVM. The number of features to be used is also optimized using in-fold cross-validation on the F-score. Both the SVM classifier and the Random Forest classifier were tested on the same training/testing fold pairs, with a total of 10 iterations.

6 Results

The results of the experiments are shown in Tables 2 and 3. In order to compare to previous analyses, unigram and bigram features are shown, as well as a combination of the basic features with the n-grams. When performing the experiments, we noticed that the n-gram features were hurting the performance of the classifiers when included with most of our other feature sets (or not changing results significantly), and therefore those results are not shown here. As seen in the table,

Feature Set	Random Forest					SVM				
	P	R	F1	A	ROC-AUC	P	R	F1	A	ROC-AUC
N-grams	0.70	0.70	0.70	0.71	0.77	0.63	0.70	0.66	0.63	0.66

All	0.73	0.69	0.71	0.70	0.76	0.71	0.70	0.70	0.69	0.74

Table 3: Precision, recall, F1, accuracy and ROC-AUC scores for the simpler task of identifying the cases deemed "high confidence" in the crowd-sourcing task.

the best performing feature sets are those that include rhetorical features under the SVM+χ^2 classifier. In fact, these feature sets perform significantly better than a unigram/bigram baseline according to a paired t-test between the best classifiers for each set ($p < 0.0001$). The inclusion of rhetorical structure also significantly outperforms the "basic" and "basic+N-grams" feature baselines (which includes discourse markers, referrals, punctuation, bias word counts and structural features) with respect to both the F-score and accuracy ($p < 0.02$ for all feature sets with rhetorical features). Overall, the feature sets "Basic+RhetAll" and "All" under the SVM+χ^2 classifier perform best. This performance is also better than previously reported results for the *ARGUE* Corpus (Abbott et al., 2011), even though the basic and unigram/bigram features perform similarly to that reported in previous analyses.

As an additional check, we also conduct experiments on the "high confidence" data (those topics with a confidence score greater than 0.75). These results are shown in Table 3. Clearly the basic features perform better on this subset of the samples, although the addition of rhetorical structure still provides significant improvement ($p < 0.001$). Overall, this suggests that the rhetorical, sentiment and FQG features help more when the disagreement is more subtle.

Structural	*Length of topic in sentences, total number of authors, quotes in first sentence, quotes in second sentence, questions in first sentence, questions in second sentence, referrals to you and they in first half of post*
Meta	*Number of comments with labels, number of comments labelled 'Flamebait', number of comments with scores of 4 or 5*
FQG	*Number of connections, Number of fragments, Maximum number of links from one node*
RhetStruct	COMPARISON *(same to diff, diff per post, diff percentage, avg ratio, same per post, same percentage),* EXPLANATION *(avg ratio, diff per post),* JOINT *(diff percentage),* ELABORATION *(average depth)*
Discourse Markers	*Aggregated first sentence, Aggregated middle, 'and', 'oh', 'but' frequency counts*
N-grams	*'don't ?', 'plus', 'private', 'anti', 'hey', 'present', 'making', 'developers'*
RhetSent	ELABORATION *(variance in same post),* ATTRIBUTION *(variance in same post),* CONTRAST *(range in same post)*
Sentiment	*Range of sentiment scores in first sentence of all posts, range of sentiment scores over all posts*

Table 4: Features found to be commonly selected over different iterations of the classifiers

7 Analysis and Discussion

In order to examine the quality of our features, we report on the rhetorical features selected, and show that these are reasonable and in many cases, theoretically motivated. Furthermore, we check whether the commonly selected features in each of our feature categories are similar to those found to be useful over the *ARGUE* corpus, as well as within other argument detection tasks in online forums.

The rhetorical features that are consistently selected are very well motivated in the context of argument detection. From the rhetorical structural features, we find COMPARISON relation features to be most commonly selected across all rhetorical feature sets. Other highly ranked features include the proportion of JOINT relations linking different authors, EXPLANATION relations between different authors, and the average depth of ELABORATION relations.

The COMPARISON relations are expected to indicate disagreement as motivated by theoretical considerations (Horn, 1989). The importance of other rhetorical relation features can also be explained by examining conversations in which they appear. In particular, EXPLANATION relations often link authors who share viewpoints in a debate, especially when one author is trying to support the claim of another. The JOINT relations are also very well motivated. In the extreme case, conversations with a very high number of JOINT relations between different users are usually news based. The high proportion of these relations indicates that many users have added information to the conversation about a specific item, such as adding new suggested videogame features to an ongoing list. Fewer JOINT relations seem to indicate disagreement, especially when found in conjunction with COMPARISON relations between different users. This appears to generally indicate that users are taking sides in a debate, and commenting specifically on evidence which supports their viewpoint.

The average depth of ELABORATION relations reveals how deep the perceived connections are between users in a conversation over time. Deeper ELABORATION connections seem to indicate that the conversation is more cohesive. Alone, this does not signify disagreement/agreement but does seem to signify argument-style over news-style dialogues. This is particularly helpful for differentiating between articles with many COMPARISON relations, as COMPARISON may be present in both news-style dialogues (e.g. comparing citation styles) as well as argument style dialogues (e.g. arguing over which of two operating systems is superior).

For the combined sentiment and rhetorical relations, range and variance in ELABORATION, CONTRAST and ATTRIBUTION within the same post are found to be the most informative features. Additionally, neither ATTRIBUTION nor CONTRAST are useful features when only their structural information is considered. In the case of ATTRIBUTION, we hypothesize that the added sentiment score within the post differentiates between a neutral attribution (which would not signify disagreement) and a negative or positive attribution (which may signify disagreement). For CONTRAST, the added sentiment helps to distinguish between responses such as "*We will be trying the Microsoft software. We won't, however, be able to test the Apple equivalent.*" and "*We will be trying the Microsoft software. We won't, however, be trying the inferior Apple equivalent.*" where the second example more likely signals, or even provokes, disagreement.

Outside of the rhetorical features, the discourse markers which are found to be the most useful in our experiments agree with those found in the *ARGUE* corpus (Abbott et al., 2011). Namely, 'oh', 'but', 'because' and 'and' are discovered to be the most informative features. We also find the aggregated discourse marker frequency count in the first part of each post to be useful.

Previous analysis on Slashdot as a social network (Gomez et al., 2008) suggests that the h-index of the conversation is relevant for detecting controversy in a posted article. We include the h-index as part of the Fragment Quotation Graph feature set, but surprisingly do not find this to be a useful feature. This may be due to our corpus involving relatively shallow conversational trees - the maximum h-index across all topics is three.

Comparing to Mishne and Glance's work, we also find quotations, questions and sentiment range near the beginning of a post to be very informative features. These are often selected across all feature sets which include the "basic" set.

The topics most often misclassified across all feature sets are those with relatively few sentences. In these cases, the rhetorical structure is not very well defined, and there is much less content available for detecting quotes, punctuation and referrals. Additionally, the feature sets which only use rhetorical and sentiment features consistently misclassify the same set of conversations (those that have lower quality discourse trees with few connections). When combined with the "basic" feature set, these errors are mitigated, and the topics which the "basic" features miss are picked up by the rhetorical features. This leads to the best overall accuracy and F-score.

7.1 Discourse Parser

A major source of error in detecting disagreement arises because of inaccuracies in our discourse parser. In particular, document-level discourse parsing is a challenging task, with relatively few parsers available at the time of this analysis (Joty et al., 2013; Hernault et al., 2010). We chose to use the discourse parser developed by Joty et al. which both identifies elementary discourse units in a text, and then builds a document-level discourse tree using Conditional Random Fields. Because their approach uses an optimal parsing algorithm as opposed to a greedy parsing algorithm, they are able to achieve much higher accuracies in relation and structure identification than other available parsers. Here, results from their parser on the standard RST-DT dataset are presented since there is no currently available dialogic corpora to compare to.

	RST-DT			Instructional
Metrics	Joty	HILDA	Human	Joty
Span	83.84	74.68	88.70	81.88
Nuclearity	68.90	58.99	77.72	63.13
Relation	55.87	44.32	65.75	43.60

Table 5: Joty et al. document-level parser accuracy of the parser used in this paper. The parser was originally tested on two corpora: RST-DT and Instructional. HILDA was the state-of-the-art parser at that time. Span and Nuclearity metrics assess the quality of the structure of the resulting tree, while the Relation metric assesses the quality of the relation labels.

Figure 2: Confusion matrix for relation labels on RST-DT. The X-axis represents predicted relations, while the Y-axis corresponds to true values. The relations are Topic-Change (T-C), Topic-Comment (T-CM), Textual Organization (T-O), Manner-Means (M-M), Comparison (CMP), Evaluation (EV), Summary (SU), Condition (CND), Enablement (EN), Cause (CA), Temporal (TE), Explanation (EX), Background (BA), Contrast (CO), Joint (JO), Same-Unit (S-U), Attribution (AT) and Elaboration (EL).

for the discourse parser in Figure 2, some of the chosen rhetorical features make even more sense. In particular, the confusion of ELABORATION and EXPLANATION may account for the perceived importance of ELABORATION relations in the analysis. Likewise, CAUSE (which may be present when users attribute positive or negative qualities to an entity, signalling disagreement) is often confused with JOINT and ELABORATION which were often picked as important features by our classifiers.

8 Conclusions and Future Work

In this paper, we have described a new set of features for detecting disagreement in online blog forums. By treating a written conversation as a series of linked monologues, we can apply a document level discourse parser to extract a discourse tree for the conversation. We then aggregate this information in a *relation graph*, which allows us to capture post-level rhetorical relations between users. Combining this approach with sentiment features shows significantly improved performance in both accuracy and F-score over a baseline consisting of structural and lexical features as well as referral counts, punctuation, and discourse markers. In building our new crowd-sourced corpus from Slashdot, we have also shown the challenges of detecting subtle disagreement in a dataset that contains a significant number of news-style discussions.

In future work, we will improve sentiment features by considering methods to detect opinion-topic pairs in conversation, similar to Somasundaran and Wiebe (2009). Additionally, we will incorporate generalized dependency and POS features (Abbott et al., 2011), which were not used in this analysis due to the very small number of training samples in our dataset. The fragment quotation graph features did not perform as well as we expected, and in future work we would like to investigate this further. Furthermore, we will also explore how to create a discourse tree from the thread structure of a conversation (instead of from its temporal structure), and verify whether this improves the accuracy of the relation graphs, especially when the temporal structure is not representative of the reply-to relationships.

Finally, we plan to apply our novel feature set to other corpora (e.g., *ARGUE*) in order to study the utility of these features across genres and with respect to the accuracy of the discourse parser. This may provide insights into where discourse parsers can be most effectively used, as well as how to modify parsers to better capture rhetorical relations between participants in conversation.

+/-EffectWordNet: Sense-level Lexicon Acquisition for Opinion Inference

Yoonjung Choi and **Janyce Wiebe**
Department of Computer Science
University of Pittsburgh
yjchoi, wiebe@cs.pitt.edu

Abstract

Recently, work in NLP was initiated on a type of opinion inference that arises when opinions are expressed toward events which have positive or negative effects on entities (*+/-effect events*). This paper addresses methods for creating a lexicon of such events, to support such work on opinion inference. Due to significant sense ambiguity, our goal is to develop a sense-level rather than word-level lexicon. To maximize the effectiveness of different types of information, we combine a graph-based method using WordNet[1] relations and a standard classifier using gloss information. A hybrid between the two gives the best results. Further, we provide evidence that the model is an effective way to guide manual annotation to find +/-effect senses that are not in the seed set.

1 Introduction

Opinion mining (or sentiment analysis) identifies positive or negative opinions in many kinds of texts such as reviews, blogs, and news articles. It has been exploited in many application areas such as review mining, election analysis, and information extraction. While most previous research focusses on explicit opinion expressions, recent work addresses a type of opinion inference that arises when opinions are expressed toward events which have positive or negative effects on entities (Deng et al., 2013; Deng and Wiebe, 2014). We call such events *+/-effect* events.[2] Deng and Wiebe (2014) show how sentiments toward one entity may be propagated to other entities via opinion inference rules. They give the following example:

> (1) *The bill would curb skyrocketing health care costs.*

The writer expresses an explicit **negative** sentiment (by *skyrocketing*) toward the **object** (*health care costs*). The event, *curb*, has a **negative effect** on *costs*, since they are reduced. We can reason that the writer is **positive** toward the **event** because it has a negative effect on *costs*, toward which the writer is negative. From there, we can reason that the writer is **positive** toward *the bill*, since it is the agent of the positive event. Deng and Wiebe (2014) show that such inferences may be exploited to significantly improve explicit sentiment analysis systems.

However, to achieve its results, the system developed by Deng and Wiebe (2014) requires that all instances of +/-effect events in the corpus be manually provided as input. For the system to be fully automatic, it needs to be able to recognize +/-effect events automatically. This paper addresses methods for creating lexicons of such events, to support such work on opinion inference. We have discovered that there is significant sense ambiguity, meaning that words often have mixtures of senses among the classes *+effect*, *-effect*, and *Null*. Thus, we develop a sense-level rather than word-level lexicon.

One of our goals is to investigate whether the +/-effect property tends to be shared among semantically-related senses, and another is to use a method that applies to all word senses, not just to the senses of words in a given word-level lexicon. Thus, we build a graph-based model in which each node is a WordNet sense, and edges represent semantic WordNet relations between senses. In addition, we hypothesized that glosses also contain useful information. Thus, we develop

[1] WordNet 3.0, http://wordnet.princeton.edu/

[2] While the term *goodFor/badFor* is used in previous papers (Deng et al., 2013; Deng and Wiebe, 2014; Deng et al., 2014), we have since decided that +/-effect is a better term.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1181–1191,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

a supervised gloss classifier and define a hybrid model which gives the best overall performance. Finally, because all WordNet verb senses are incorporated into the model, we investigate the ability of the method to identify unlabeled senses that are likely to be +/-effect senses. We find that by iteratively labeling the top-weighted unlabeled senses and rerunning the model, it may be used as an effective method for guiding annotation efforts.

2 Background

There are many varieties of +/-effect events, including *creation/destruction* (changes in states involving existence), *gain/loss* (changes in states involving possession), and *benefit/injury* (Anand and Reschke, 2010; Deng et al., 2013). The *creation*, *gain*, and *benefit* classes are +effect events. For example, *baking a cake* has a positive effect on the cake because it is created;[3] *increasing the tax rate* has a positive effect on the tax rate; and *comforting the child* has a positive effect on the child. The antonymous classes of each are -effect events: *destroying the building* has a negative effect on the building; *demand decreasing* has a negative effect on demand; and *killing Bill* has a negative effect on Bill.[4]

While sentiment (Esuli and Sebastiani, 2006; Wilson et al., 2005; Su and Markert, 2009) and connotation lexicons (Feng et al., 2011; Kang et al., 2014) are related, sentiment, connotation, and +/-effects are not the same; a single event may have different sentiment and +/-effect polarities, for example. Consider the following example:

> **perpetrate**:
> S: (v) perpetrate, commit, pull (perform an act, usually with a negative connotation) "perpetrate a crime"; "pull a bank robbery"

This sense of *perpetuate* has a **negative** connotation, and is an objective term in `SentiWordNet`. However, it has a **positive effect** on the object, *a crime*, since performing a crime brings it into existence.

As we mentioned, the +/-effect ambiguity cannot be avoided in a word-level lexicon. In the +/-effect corpus of Deng et al. (2013),[5] +/-effect events and their agents and objects are annotated at the word level. In that corpus, 1,411 +/-effect instances are annotated; 196 different +effect words and 286 different -effect words appear in these instances. Among them, 10 words appear in both +effect and -effect instances, accounting for 9.07% of all annotated instances. They show that +/-effect events (and the inferences that motivate this work) appear frequently in sentences with explicit sentiment. Further, **all** instances of +/-effect words that are **not** identified as +/-effect events are false hits from the perspective of a recognition system.

The following is an example of a word with senses of different classes:

> **purge**:
> S: (v) purge (oust politically) "Deng Xiao Ping was purged several times throughout his lifetime" **-effect**
> S: (v) purge (clear of a charge) **+effect**
> S: (v) purify, purge, sanctify (make pure or free from sin or guilt) "he left the monastery purified" **+effect**
> S: (v) purge (rid of impurities) "purge the water"; "purge your mind" **+effect**

This is part of the WordNet output for the word *purge*. In the first sense, the polarity is -effect since it has a negative effect on the object, *Deng Xizo Ping*. However, the other cases have positive effect on the object. Moreover, although a word may not have both +effect and -effect senses, it may have mixtures of ((+effect or -effect) and Null). A purely word-based approach is blind to these cases.

3 Related Work

Lexicons are widely used in sentiment analysis and opinion mining. Several works such as Hatzivassiloglou and McKeown (1997), Turney and Littman (2003), Kim and Hovy (2004), Strapparava and Valitutti (2004), and Peng and Park (2011) have tackled automatic lexicon expansion or acquistion. However, in most such work, the lexicons are word-level rather than sense-level.

[3] Deng et al. (2013) point out that +/-effect objects are not equivalent to benefactive/malefactive semantic roles. An example they give is *She baked a cake for me*: *a cake* is the object of the +effect event *baked* as just noted, while *me* is the filler of its benefactive semantic role (Ziga and Kittil, 2010).

[4] Their annotation manual, which gives additional cases, is available with the annotated data at http://mpqa.cs.pitt.edu/.

[5] Called the *goodFor/badFor* corpus in that paper.

For the related (but different) tasks of developing subjectivity, sentiment and connotation lexicons, some do take a sense-level approach. Esuli and Sebastiani (2006) construct `SentiWordNet`. They assume that terms with the same polarity tend to have similar glosses. So, they first expand a manually selected seed set of senses using WordNet lexical relations such as *also-see* and *direct antonymy* and train two classifiers, one for positive and another for negative. As features, a vectorial representation of glosses is adopted. These classifiers were applied to all WordNet senses to measure positive, negative, and objective scores. In extending their work (Esuli and Sebastiani, 2007), the PageRank algorithm is applied to rank senses in terms of how strongly they are positive or negative. In the graph, each sense is one node, and two nodes are connected when they contain the same words in their WordNet glosses. Moreover, a random-walk step is adopted to refine the scores in their recent work (Baccianella et al., 2010). In contrast, our approach uses WordNet relations and graph propagation in addition to gloss classification.

Gyamfi et al. (2009) construct a classifier to label the subjectivity of word senses. The hierarchical structure and domain information in WordNet are exploited to define features in terms of similarity (using the LCS metric in Resnik (1995)) of target senses and a seed set of senses. Also, the similarity of glosses in WordNet is considered. Even though they investigated the hierarchical structure by LCS values, WordNet relations are not exploited directly.

Su and Markert (2009) adopt a semi-supervised mincut method to recognize the subjectivity of word senses. To construct a graph, each node corresponds to one WordNet sense and is connected to two classification nodes (one for subjectivity and another for objectivity) via a weighted edge that is assigned by a classifier. For this classifier, WordNet glosses, relations, and monosemous features are considered. Also, several WordNet relations (e.g., *antonymy*, *similiar-to*, *direct hypernym*, etc.) are used to connect two nodes. Although they make use of both WordNet glosses and relations, and gloss information is utilized for a classifier, this classifier is generated only for weighting edges between sense nodes and classification nodes, not for classifying all senses.

Kang et al. (2014) present a unified model that assigns connotation polarities to both words and senses. They formulate the induction process as collective inference over pairwise-Markov Random Fields, and apply loopy belief propagation for inference. Their approach relies on selectional preferences of *connotative predicates*; the polarity of a connotation predicate suggests the polarity of its arguments. We have not discovered an analogous type of predicate for the problem we address.

Goyal et al. (2010) generate a lexicon of patient polarity verbs (PPVs) that impart positive or negative states on their patients. They harvest PPVs from a Web corpus by co-occurance with Kind and Evil agents and by bootstrapping over conjunctions of verbs. Riloff et al. (2013) learn positive sentiment phrases and negative situation phrases from a corpus of tweets with hashtag "sarcasm". However, both of these methods are word-level rather than sense-level.

Ours is the first NLP research into developing a sense-level lexicon for events that have negative or positive effects on entities.

4 +/-Effect Word-Level Seed Lexicon and Sense Annotations

To create the corpus used in this work, we developed a word-level seed lexicon, and then manually annotated all the senses of the words in that lexicon.

FrameNet[6] is based on a theory of meaning called Frame Semantics. In FrameNet, a Lexical Unit (LU) is a pairing of a word with a meaning, i.e., it corresponds to a sense in WordNet. Each LU of a polysemous word belongs to a different semantic frame, which is a description of a type of event, relation, or entity and, where appropriate, its participants. For instance, in the **Creating** frame, the definition is that a **Cause** leads to the formation of a **Created_entity**. It has a positive effect on the object, **Created_entity**. This frame contains about 10 LUs such as *assemble*, *create*, *yield*, and so on. FrameNet consists of about 1,000 semantic frames and about 10,000 LUs.

FrameNet is a useful resource to select +/-effect words since each semantic frame covers multiple LUs. We believe that using FrameNet to find +/-effect words is easier than finding +/-effect words without any information since words may

[6]FrameNet, https://framenet.icsi.berkeley.edu/fndrupal/

be filtered by semantic frames. To select +/-effect words, an annotator (who is not a co-author) first identified promising frames as +/-effect and extracted all LUs from them. Then, he went through them and picked out the LUs which he judged to be +effect or -effect. In total, 736 +effect LUs and 601 -effect LUs were selected from 463 semantic frames.

While Deng et al. (2013) and Deng and Wiebe (2014) specifically focus on events affecting objects (i.e., themes), we do not want to limit the lexicon to only that case. Sometimes, events have positive or negative effects on agents or other entities as well. Thus, in this paper, we consider a sense to be +effect (-effect) if it has +effect (-effect) on an entity, which may be the agent, the theme, or some other entity.

In a previous paper (Choi et al., 2014), we conducted a study of the sense-level +/-effect property. For the evaluation, two annotators (who are co-authors of that paper) independently annotated senses of selected words, where some are from pure +effect (-effect) words (i.e., all senses of the words are classified into the same class) and some are from mixed words (i.e., the words have both +effect and -effect senses). In the agreement study, we calculated percent agreement and κ (Artstein and Poesio, 2008), and achieved 0.84 percent agreement and 0.75 κ value.

For a seed set and an evaluation set in this paper, we need annotated sense-level +/-effect data. Mappings between FrameNet and WordNet are not perfect. Thus, we opted to manually annotate the senses of the words in the word-level lexicon. We first extracted all words from 736 +effect LUs and 601 -effect LUs; this extracts 606 +effect words and 537 -effect words (the number of words is smaller than the number of LUs because one word can have more than one LU). Among them, 14 words (e.g., *crush, order,* etc.) are in both the +effect word set and the -effect word set. That is, these words have both +effect and -effect meanings. Recall that this annotator was focusing on frames, not on words - he did not look at all the senses of all the words. As we will see just below, when all the senses of all the words are annotated, a much higher percentage of the words have both +effect and -effect senses. We will also see that many of the senses are revealed to be Null, showing that +effect vs. Null and -effect vs. Null ambiguities are quite prevalent.

A different annotator (a co-author) then went through all senses of all the words from the previous step and manually annotated each sense as to whether it is +effect, -effect, or Null. Note that this annotator participated in an agreement study with positive results in Choi et al. (2014).

For the experiments in this paper, we divided this annotated data into two equal-sized sets. One is a fixed test set that is used to evaluate both the graph model and the gloss classifier. The other set is used as a seed set by the graph model, and as a training set by the gloss classifer. Table 1 shows the distribution of the data. In total, there are 258 +effect senses, 487 -effect senses, and 880 Null senses. To avoid too large a bias toward the Null class,[7] we randomly chose half (i.e., the Null set contains 440 senses). Half of each set is used as seed and training data, and the other half is used for evaluation.

	+effect	**-effect**	**Null**
# annotated data	258	487	880
# Seed/TrainSet	129	243	220
# TestSet	129	244	220

Table 1: Distribution of annotated data.

5 Graph-based Semi-Supervised Learning for WordNet Relations

WordNet (Miller et al., 1990) is organized by semantic relations such as *hypernymy*, *troponymy*, *grouping*, and so on. These semantic relations can be used to build a network. Since the most frequently encoded relation is the super-subordinate relation, most verb senses are arranged into hierarchies; verb senses towards the bottom of the graph express increasingly specific manner. Thus, by following this hierarchical information, we hypothesized that +/-effect polarity tends to propagate. We use a graph-based semi-supervised learning (GSSL) method to carry out the label propagation.

5.1 Graph Formulation

We formulate a graph for semi-supervised learning as follows. Let $G = \{X, E, W\}$ be the undirected graph in which X is the set of nodes, E is the set

[7] As mentioned in the introduction, we want our method to be able to identify unlabeled senses that are likely to be +/-effect senses (see Section 8); we resize the Null class to support this goal.

of edges, and W represents the edge weights (i.e., the weight of edge E_{ij} is W_{ij}). The weight matrix is a non-negative matrix.

Each data point in X = $\{x_1, ... ,x_n\}$ is one sense. The labeled data of X is represented as X_L = $\{x_1, ... ,x_l\}$ and the unlabeled data is represented as X_U = $\{x_{l+1}, ... ,x_n\}$). The labeled data X_L is associated with labels Y_L = $\{y_1, ... ,y_l\}$, where $y_i \in \{1, ..., c\}$ (c is the number of classes). As is typical in such settings, $l \ll n$: n is 13,767, i.e., the number of verb senses in WordNet. Seed/TrainSet in Table 1 is the labeled data.

To connect two nodes, WordNet relations are utilized. We first connect nodes by the hierarchical relations. Since *hypernym* relations represent more general senses and *troponym* relations represent more specific verb senses, we hypothesized that hypernyms or troponyms of a verb sense tends to have its same polarity. *Verb groups* relations that represent verb senses having a similar meaning are also promising. Even though verb-group coverage is not large, its relations are reliable since they are manually grouped. The *entailment* relation is defined as the verb Y is entailed by X if you must be doing Y by doing X. Since pairs connected by this relation are co-extensive, we can assume that both are the same type of event. The *synonym* relation is not used because it is already defined in senses (i.e., each node in the graph is a synset), and the *antonym* relation is also not applied since the weight matrix should be non-negative. The weight value of all edges is 1.0.

5.2 Label Propagation

Given a constructed graph, the label inference (or prediction) task is to propagate the seed labels to the unlabeled nodes. One of the classic GSSL label propagation methods is the local and global consistency (LGC) method suggested by Zhou et al. (2004). The LGC method is a graph transduction algorithm which is sufficiently smooth with respect to the intrinsic structure revealed by known labeled and unlabeled data. The cost function typically involves a tradeoff between the smoothness of the predicted labels over the entire graph and the accuracy of the predicted labels in fitting the given labeled nodes X_L. LGC fits in a univariate regularization framework, where the output matrix is treated as the only variable in optimization, and the optimal solutions can be easily obtained by solving a linear system. Thus, we adopt the LGC method in this paper. Although there are some robust GSSL methods for handling noisy labels, we do not need to handle noisy labels because our input is the annotated data.

Let F be a $n \times c$ matrix to save the output values of label propagation. So, we can label each instance x_i as a label $y_i = \text{argmax}_{j \le c} F_{ij}$ after the label propagation. The initial discrete label matrix Y, which is also $n \times c$, is defined as $Y_{ij} = 1$ if x_i is labeled as $y_i = j$ in Y_L, and $Y_{ij} = 0$ otherwise. The vertex degree matrix $D = \text{diag}([D_{11}, ..., Dnn])$ is defined by $D_{ii} = \sum_{j=1}^{n} W_{ij}$.

LGC defines the cost function Q which integrates two penalty components, global smoothness and local fitting (μ is the regularization parameter):

$$Q = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} W_{ij} \| \frac{F_i}{\sqrt{D_{ii}}} - \frac{F_j}{\sqrt{D_{jj}}} \|^2 + \mu \sum_{i=1}^{n} \|F_i - Y_i\|^2$$

The first part of the cost function is the *smoothness constraint*: a good classifying function should not change too much between nearby points. That is, if x_i and x_j are connected with an edge, the difference between them should be small. The second is the *fitting constraint*: a good classifying function should not change too much from the initial label assignment. The final label prediction matrix F can be obtained by minimizing the cost function Q.

5.3 Experimental Results

Note that, in the rest of this paper, all tables except the last one give results on the same fixed test set (TestSet in Table 1).

We can apply the graph model in two ways.

- **UniGraph**: All three classes (+effect, -effect, and Null) are represented in one graph.
- **BiGraph**: Two separate graphs are first constructed and then combined. One graph is for classifying +effect and Other (i.e., -effect or Null). This graph is called *+eGraph*. The other graph, called *-eGraph*, is for classifying -effect and Other (i.e., +effect or Null).

		UniGraph	BiGraph	BiGraph*
baseline-accuracy		0.411		
accuracy		**0.630**	**0.623**	**0.658**
+effect	P	0.621	0.610	0.642
	R	0.655	0.647	0.680
	F	0.637	0.628	**0.660**
-effect	P	0.644	0.662	0.779
	R	0.720	0.677	0.612
	F	0.680	0.670	**0.686**
Null	P	0.615	0.583	0.583
	R	0.516	0.550	0.695
	F	0.561	0.561	**0.634**

Table 2: Results of UniGraph, BiGraph, and BiGraph*.

These are combined into one model as follows. Nodes that are labeled as +effect by +eGraph and Other by -eGraph are regarded as +effect, and nodes that are labeled as -effect by -eGraph and Other by +eGraph are regarded as -effect. If nodes are labeled as +effect by +eGraph and -effect by -eGraph, they are deemed to be Null. Nodes that are labeled Other by both graphs are also considered as Null.

We had two motivations for experimenting with the BiGraph model: (1) SVM, the supervised learning method used for gloss classification, tends to have better performance on binary classification tasks, and (2) the two graphs of the combined model can "negotiate" with each other via constraints.

In Table 2, we calculate precision (P), recall (R), and f-measure (F) for all three classes. The baseline shown in the top row is the accuracy of a majority class classifier. The first two columns of Table 2 show the results of UniGraph and BiGraph when they are built using the *hypernym*, *troponym*, and *verb group* relations. UniGraph outperforms BiGraph in this experiment.

To improve the results by performing something possible with BiGraph (but not UniGraph), constraints are added when determining the class. As we explained, the label of instance x_i is determined by F_i in the graph. When the label of x_i is decided to be j, we can say that its confidence value is F_{ij}. There are two constraints as follows.

		H+T	+V	+E
+effect	P	0.653	0.642	0.651
	R	0.660	0.680	0.683
	F	0.656	0.660	**0.667**
-effect	P	0.784	0.779	0.786
	R	0.547	0.612	0.604
	F	0.644	**0.686**	0.683
Null	P	0.557	0.583	0.564
	R	0.735	0.695	0.691
	F	**0.634**	**0.634**	0.621

Table 3: Effect of each relation

- If a sense is labeled as +effect (-effect), but the confidence value is less than a threshold, we count it as Null.
- If a sense is labeled as both +effect and -effect by BiGraph, we choose the label with the higher confidence value only if the higher one is larger than a threshold and the lower one is less than a threshold.

The thresholds are determined on Seed/TrainSet by running BiGraph several times with different thresholds, and choosing the one that gives the best performance **on Seed/TrainSet**. (The chosen value is 0.025 for +effect and 0.03 for -effect).

As can be seen in Table 2, BiGraph with constraints (called *BiGraph**) outperforms not only BiGraph without any constraints but also UniGraph. Especially, for BiGraph*, the recall of the Null class is considerably increased, showing that constraints not only help overall, but are particularly important for detecting Null cases.

Table 3 gives ablation results, showing the contribution of each WordNet relation in BiGraph*. With only hierarchical information (i.e., *hypernym* (H) and *troponym* (T) relations), it already shows good performance for all classes. However, they cannot cover some senses. Among the 13,767 verb senses in WordNet, 1,707 (12.4%) cannot be labeled because there are not sufficient hierarchical links to propagate polarity information. When adding the *verb group* (+V) relation, it shows improvement in both +effect and -effect. Especially, the recall for +effect and -effect is significantly increased. In addition, the coverage of the 13,767 verb senses increases to 95.1%. For *entailment* (+E), whereas adding it shows a slight improvement in +effect (and increases coverage by 1.1 percentage points), the

performance is decreased a little bit in the -effect and Null classes. Since the average f-measure for all classes is the highest with *hypernym* (H), *troponym* (T), and *verb group* (V) relations (not *entailment*), we only consider these three relations when constructing the graph.

6 Supervised Learning applied to WordNet Glosses

In WordNet, each sense contains a gloss consisting of a definition and optional example sentences. Since a gloss consists of several words and there are no direct links between glosses, we believe that a word vector representation is appropriate to utilize gloss information as in Esuli and Sebastiani (2006). For that, we adopt an SVM classifier.

6.1 Features

Two different feature types are used.

Word Features (WF): The bag-of-words model is applied. We do not ignore stop words for several reasons. Since most definitions and examples are not long, each gloss contains a small number of words. Also, among them, the total vocabulary of WordNet glosses is not large. Moreover, some prepositions such as *against* are sometimes useful to determine the polarity (+effect or -effect).

Sentiment Features (SF): Some glosses of +effect (-effect) senses contain positive (negative) words. For instance, the definition of {*hurt#4, injure#4*} is "cause damage or affect negatively." It contains a negative word, *negatively*. Since a given event may positively (negatively) affect entities, some definitions or examples already contain positive (negative) words to express this. Thus, as features, we check how many positive (negative) words a given gloss contains. To detect sentiment words, the subjectivity lexicon provided by Wilson et al. (2005)[8] is utilized.

6.2 Gloss Classifier

We have three classes, +effect, -effect, and Null. Since SVM shows better performance on binary classification tasks, we generate two binary classifiers, one (*+eClassifier*) to determine whether a given sense is +effect or Other, and another (*-eClassifier*) to classify whether a given sense is -effect or Other. Then, they are combined as in BiGraph.

[8] Available at http://mpqa.cs.pitt.edu/

6.3 Experimental Results

Seed/TrainSet in Table 1 is used to train the two classifiers, and TestSet is utilized for the evaluation. So, the training set for +eClassifier consists of 129 +effect instances and 463 Other instances, and the training set for -eClassifier contains 243 -effect instances and 349 Other instances. As a baseline, we adopt a majority class classifier.

Table 4 shows the results on TestSet. Performance is better for the -effect than for the +effect class, perhaps because the -effect class has more instances.

When sentiment features (SF) are added, all metric values increase, providing evidence that sentiment features are helpful to determine +/-effect classes.

		WF	WF+SF
baseline accuracy		0.411	
accuracy		**0.509**	**0.539**
+effect	P	0.541	0.588
	R	0.354	0.393
	F	0.428	**0.472**
-effect	P	0.616	0.672
	R	0.500	0.511
	F	0.552	**0.580**
Null	P	0.432	0.451
	R	0.612	0.657
	F	0.507	**0.535**

Table 4: Results of the gloss classifier.

7 Hybrid Method

To use more combined knowledge, the gloss classifier and BiGraph* can be combined. That is, for WordNet gloss information, the gloss classifier is utilized, and for WordNet relations, BiGraph* is used. With the Hybrid method, we can see not only the effect of propagation by WordNet relations but also the usefulness of gloss information and sentiment features. Also, while BiGraph* cannot cover all senses in WordNet, the Hybrid method can.

The outputs of the gloss classifier and BiGraph* are combined as follows. The label of the gloss classifier is one of +effect, -effect, Null, or Both (when a given sense is classified as both +effect by +eClassifier and -effect by -eClassifier). Possible labels of BiGraph* are +effect, -effect, Null, Both, or None (when a given sense is not

labeled by BiGraph*). There are five rules:

- If both labels are +effect (-effect), it is +effect (-effect).
- If one of them is Both and the other is +effect (-effect), it is +effect (-effect).
- If the label of BiGraph* is None, believe the label of the gloss classifier
- If both labels are Both, it is Null
- Otherwise, it is Null

The results for Hybrid are given in the first row of the lower half of Table 5; the results for BiGraph* are in the first row of the upper half, for comparison. Generally, the Hybrid method shows better performance than the gloss classifier and BiGraph*. In the Hybrid method, since more +/-effect senses are detected than by BiGraph*, while precision is decreased, recall is increased by more. However, by the same token, the overall performance for the Null class is decreased. Actually, that is expected since the Null class is determined by the Other class in the gloss classifier and BiGraph*. Through this experiment, we see that the Hybrid method is better for classifying +/-effect senses.

7.1 Model Comparison

To provide evidence for our assumption that different models are needed for different information to maximize effectiveness, we compare the hybrid method with the supervised learning and the graph-based learning (GSSL) methods, each utilizing both WordNet relations and gloss information.

Supervised Learning (*onlySL*): The gloss classifier is trained with word features and sentiment features for WordNet Gloss. To exploit WordNet relations in supervised learning, especially the hierarchical information, we use least common subsumer (LCS) values as in Gyamfi et al. (2009), which, recall, performs supervised learning of subjective/objective senses. The values are calculated as follows. For a target sense t and a seed set S, the maximum LCS value between a target sense and a member of the seed set is found as:

$$Score(t, S) = max_{s \in S} LCS(t, s)$$

With this LCS feature and the features described in Section 6, we run SVM on the same training and test data. For LCS values, the similarity using the information content proposed by Resnik (1995) is measured. WordNet Similarity[9] package provides pre-computed pairwise similarity values for that.

Table 6 shows results of onlySL. Compared to Table 4, while +effect and Null classes show a slight improvement, the performance is degraded for -effect. This means that the added feature is rather harmful to -effect. Even though the hierarchical feature is very helpful to expand +/-effect, it is not helpful for onlySL since SVM cannot capture propagation according to the hierarchy.

Graph-based Learning (*onlyGraph*): In Section 5, the graph is constructed by using WordNet relations. To apply WordNet gloss information in onlyGraph, we calculate a cosine similarity between glosses. If the similarity value is higher than a threshold, two nodes are connected with this similarity value. The threshold is determined by training and testing on Seed/TrainSet (the chosen value is 0.3).

Comparing Tables 2 and 6, BiGraph* generally outperforms onlyGraph (the exception is precision of +effect). By gloss similarity, many nodes are connected to each other. However, since uncertain connections can cause incorrect propagation in the graph, this negatively affects the performance.

Through this experiment, we see that since each type of information has a different character, we need different models to maximize the effectiveness of each type. Thus, the hybrid method with different models can have better performance.

		Hybrid	**onlySL**	**onlyGraph**
+effect	P	0.610	0.584	0.701
	R	0.735	0.400	0.364
	F	**0.667**	0.475	0.480
-effect	P	0.717	0.778	0.651
	R	0.669	0.316	0.562
	F	**0.692**	0.449	0.603

Table 5: Results of an iterative approach.

8 Guided Annotation

Recall that Seed/TrainSet and TestSet, the data used so far, are all the senses of the words in a word-level +/-effect lexicon. This section presents evidence that our method can guide annotation efforts to find other words that have +/-effect senses. A bonus is that the method pinpoints particular +/-effect senses of those words.

All unlabeled data are senses of words that are not included in the original lexicon. Since presumably the majority of verbs do not have any +/-effect senses, a sense randomly selected from WordNet is very likely to be Null. We explore an iterative approach to guided annotation, using BiGraph* and Hybrid as the method for assigning labels.

The system is initially created as described above using Seed/TrainSet as the initial seed set. Each iteration has four steps: 1) rank all unlabeled data (i.e., the data other than TestSet and the current seed set) based on the F_{ij} confidence values (see Section 5.3); 2) choose the top 5% and manually annotate them (the same annotator as above did this); 3) add them to the seed set; 4) rerun the system using the expanded seed set. We performed four iterations in this paper.

The upper and lower parts of Table 5 show the intial results and the results after each iteration for BiGraph* and Hybrid. Recall that these are results on the fixed set, TestSet. Overall for both models, f-measure increases for both the +effect and -effect classes as more seeds are added, mainly due to improvements in recall. The evaluation on the fixed set is also useful in the annotation process because it trades off +/-effect vs. Null annotations. If the new manual annotations were biased, in that they incorrectly label Null senses as +/-effect, then the f-measure results would instead degrade on the fixed TestSet, since the system is created each time using the increased seed set.

We now consider the accuracy of the system on the newly labeled annotated data in Step 2. Note that our method is similar to Active Learning (Tong and Koller, 2001), in that both automatically identify which unlabeled instances the human should annotate next. However, in active learning, the goal is to find instances that are difficult for a supervised learning system. In our case, the goal is to find needles in the haystack of WordNet senses. In Step 3, we add the newly labeled senses to the seed set, enabling the model to find unlabeled senses close to the new seeds when the system is rerun for the next iteration.

We assess the system's accuracy on the newly labeled data by comparing the system's labels with the human's new labels. Accuracy for +effect and -effect is calculated such as:

$$Accuracy_{+effect} = \frac{\text{\# annotated +effect}}{\text{\# top 5\% +effect data}}$$

$$Accuracy_{-effect} = \frac{\text{\# annotated -effect}}{\text{\# top 5\% -effect data}}$$

That is, the accuracy means that out of the top 5% of the +effect (-effect) data as scored by the system, what percentage are correct as judged by a human annotator. Table 7 shows the accuracy for each iteration in the top part and the number of senses labeled in the bottom part. As can be seen, the accuracies range between 60% and 78%; these

values are much higher than what would be expected if labeling senses of words randomly chosen from WordNet.[10] The annotator spent, on average, approximately an hour to label 100 senses. For finding new words with +/-effect usages, it would be much more cost-effective if a significant percentage of the data chosen for annotation are senses of words that in fact have +/-effect senses.

	1st	2nd	3rd	4th
+effect	65.63%	62.50%	63.79%	59.83%
-effect	73.55%	73.97%	77.78%	70.30%
+effect	128	122	116	117
-effect	155	146	153	145
total	283	268	269	262

Table 7: Accuracy and frequency of the top 5% for each iteration

9 Conclusion and Future Work

In this paper, we investigated methods for creating a sense-level +/-effect lexicon. To maximize the effectiveness of each type of information, we combined a graph-based method using WordNet relations and a standard classifier using gloss information. A hybrid between the two gives the best results. Further, we provide evidence that the model is an effective way to guide manual annotation to find +/-effect words that are not in the seed word-level lexicon. This is important, as the likelihood that a random WordNet sense (and thus word) is +effect or -effect is not large.

So as not to limit the inferences that may be drawn, our annotations include events that are +effect or -effect either the agent or object. In future work, we plan to exploit corpus-based methods using patterns as in Goyal et al. (2010) combined with semantic role labeling to refine the lexicon to distinguish which is the affected entity. Further, to actually exploit the acquired lexicon to process corpus data, an appropriate coarse-grained sense disambiguation process must be added, as Akkaya et al. (2009) and Akkaya et al. (2011) did for subjective/objective classification.

We hope the general methodology will be effective for other semantic properties. In opinion mining and sentiment analysis this is particularly needed, because different meanings of *positive* and *negative* are appropriate for different applications. This is a way to create lexicons that are customized with respect to one's own definitions.

It would be promising to combine our method with other methods to enable it to find +effect and -effect senses that are outside the coverage of WordNet. However, a WordNet-based lexicon gives a substantial base to build from.

[10]For reference, in 5th iteration, the +effect accuracy is 60.18% and the -effect accuracy is 69.93%, and in 6th iteration, the +effect accuracy is 59.81% and the -effect accuracy is 69.12%.

Abstract

Aspect-based opinion mining has attracted lots of attention today. In this paper, we address the problem of product aspect rating prediction, where we would like to extract the product aspects, and predict aspect ratings simultaneously. Topic models have been widely adapted to jointly model aspects and sentiments, but existing models may not do the prediction task well due to their weakness in sentiment extraction. The sentiment topics usually do not have clear correspondence to commonly used ratings, and the model may fail to extract certain kinds of sentiments due to skewed data. To tackle this problem, we propose a sentiment-aligned topic model(SATM), where we incorporate two types of external knowledge: product-level overall rating distribution and word-level sentiment lexicon. Experiments on real dataset demonstrate that SATM is effective on product aspect rating prediction, and it achieves better performance compared to the existing approaches.

1 Introduction

Online reviews have become an important source of information for consumers. People tend to read reviews to help them compare products, and make informed decisions. As the volume of product reviews continues to grow, it is often impossible to read all of them, which calls for efficient methods for opinion mining. Nowadays, for each product, many websites aggregate the overall rating of reviews, and display its distribution. However, this cannot provide detailed information. For example, two products may have similar overall rating distributions, while people talk about different unsatisfactory aspects. This problem has inspired a new line of research on aspect-level opinion mining(Hu and Liu, 2004).

An aspect refers to a rateable feature, such as staff and location in hotel reviews, or size and battery for digital camera reviews. In this paper, we deal with the problem of *product aspect rating prediction*. The input is a collection of products, and each product is associated with a set of reviews. The goal is to extract the corpus-level aspects, and predict the aspect ratings for each product. This kind of fine-grained sentiment analysis will help users efficiently digest the reviews, and gain more insight into the product quality.

The product aspect rating prediction problem usually involves two subtasks: aspect extraction and sentiment identification(Titov and McDonald, 2008b). Given some text, we would like to know what aspects it talks about, and what kind of sentiments are expressed. For example, given a sentence "the room is filthy", we would like to know that it talks about the aspect "room". Also, "filthy" is a sentiment word, and it expresses strongly negative sentiment towards the aspect "room".

Topic models(Blei et al., 2003; Hofmann, 1999) have been popular in aspect-based opinion mining(Liu, 2012). Existing works have used topic models to extract only aspects(Titov and McDonald, 2008a; Brody and Elhadad, 2010; Chen et al., 2013), or jointly model aspects and sentiments (Mei et al., 2007; Lin and He, 2009; Li et al., 2010; Jo and Oh, 2011; Moghaddam and Ester, 2011; Lakkaraju et al., 2011; Sauper et al., 2011; Mukherjee and Liu, 2012; Lazaridou et al., 2013; Moghaddam and Ester, 2013; Kim et al., 2013). In the joint modelling approaches, a sentiment topic is usually modelled as a sentiment label-word distribution, analogous to the topic-word distribution in standard topic models. However, the difference is that the sentiment topics need to be ordered. If the model is to be applied for aspect rating prediction, the sentiment topics should have clear cor-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1192–1202,

respondence to the ratings. Suppose there are 5 sentiment topics with sentiment labels from 1 to 5. The sentiment topic with label i is expected to correspond to the rating i on the 1-5 rating scale. For example, the sentiment topic with label 5 should have high probability over positive sentiment words, so it expresses highly positive sentiment, which matches our natural interpretation for the rating 5. In this case, sentiment labels and ratings are *aligned*. However, in a standard topic model, the learned sentiment topics may not have clear correspondence with different ratings. Also, if the positive reviews are dominant in the data, the topic model may fail to capture the negative sentiments with any sentiment topic, so no sentiment labels are matched with low ratings. If the sentiment labels are not correctly aligned to the ratings, we cannot use these sentiment labels to predict aspect ratings. Consequently, the aspect rating prediction accuracy is compromised, and the method is less practical. We call this the *sentiment label alignment* problem. To tackle this problem, models in the literature usually use some seed words for each sentiment topic to define Dirichlet priors with asymmetric concentration parameter vectors (Sauper et al., 2011; Kim et al., 2013), or use seed words to initialize word assignment to sentiment topic(Lin and He, 2009), or both(Li et al., 2010; Jo and Oh, 2011). However, these seed words are usually arbitrarily selected, and how to define asymmetric priors is not clear, especially when we would like to capture more than two (positive and negative) kinds of sentiments.

In this paper, we propose a sentiment-aligned topic model(SATM) for product aspect rating prediction, which focuses the sentiment label alignment problem. We use two kinds of external knowledge: the product overall rating distribution, and a sentiment lexicon. For each product, the overall rating distribution is available on most online review websites. It provides the big picture of the product-level sentiments. In SATM, for each product and each aspect, we define a multinomial distribution over sentiment labels, with prior parameterized by the overall rating distribution. Sentiment lexicon is constructed by linguistic experts, and every word in the lexicon is associated with a sentiment polarity score(Taboada et al., 2011). We treat the polarity score as an extra word feature in a semi-supervised framework. By incorporating both product-level and word-level knowledge into the model, the sentiment labels can be aligned with ratings, and the extracted sentiment topics can capture different kinds of sentiments, ranging from highly positive to highly negative. Experiments on a TripAdvisor dataset demonstrate that our method can effectively deal with the sentiment label alignment problem, and outperforms state-of-the-art methods in terms of product aspect rating prediction accuracy.

2 Related work

Several methods have been proposed for product aspect rating prediction, and many of them are based on topic models.

In (Lu et al., 2009), the authors studied the problem of generating an aspect rating summary for short comments. The text was first preprocessed into phrases of the format <headterm, sentiment word>, and the headterms are clustered by Structured PLSA to find K major aspects. Then, phrase ratings are predicted by either Local Prediction or Global Prediction, and they are aggregated to get aspect ratings. The method in (Brody and Elhadad, 2010) also first uses topic models to find aspects. Then, for each aspect, it extracts all the relevant adjectives, and builds a conjunction graph. A label propagation algorithm(Zhu and Ghahramani, 2002) is used on the graph to learn the sentiment polarity score of adjective words. Although this approach is not proposed for aspect rating prediction, it can be used for this task if the polarity scores of adjective words are aggregated for each aspect. All the methods above perform aspect extraction and sentiment identification separately, while our approach takes a joint modelling approach so that different subtasks can potentially reinforce with each other. To demonstrate this, we use these methods as baselines in our experiments.

Wang et al. worked on the *Latent Aspect Rating Analysis* problem(Wang et al., 2010; Wang et al., 2011), the task of inferring aspect ratings for each review and the relative weights reviewers have placed on each aspect. In (Wang et al., 2010), aspect keywords are provided as user input, and a two-stage method, called Latent Rating Regression(LRR), is proposed. The first stage uses a bootstrapping algorithm to obtain more related words for each aspect, and segments the document content. In the second stage, the overall rating is "generated" as weighted combination of the latent aspect ratings, and LRR is used to infer both the

weights and aspect ratings. Their follow-up work (Wang et al., 2011) does not need keyword specification from users, and replaces the bootstrapping method with a topic model. However, both methods implicitly require that each review talks about all aspects, which is not always true due to the data sparsity in online reviews.

In (Moghaddam and Ester, 2011), ILDA was proposed for product aspect rating prediction. Later, it was extended to FLDA (Moghaddam and Ester, 2013) to address the cold start problem, when there are few reviews associated with a product. Similar to (Lu et al., 2009), in ILDA and FLDA, a preprocessing step parses the text into phrases of the format <headterm, sentiment word>, and a review is modelled as a bag of phrases. We also adopt this assumption in our model. The method in (Sauper et al., 2011; Sauper and Barzilay, 2013) does not use phrases, but instead uses "snippets", and an snippet is a short sentence or phrase. However, the sentiment label alignment problem is not well addressed in these models, which limits their practicality. ILDA and FLDA did not deal with this problem. The model in (Sauper et al., 2011; Sauper and Barzilay, 2013) follows the most common approach of using seed words to define asymmetric priors. It supports only two kinds of sentiment topics: positive and negative, while how to define asymmetric priors for more sentiment topics becomes unclear. More importantly, the prior approach may not work well in practice(see Experiment Section). Lakkaraju et al. try to tackle the sentiment label alignment problem by assuming that the overall rating is generated as response variable(Lakkaraju et al., 2011), with the sentiment topic proportions as features. However, how the sentiment labels are related to ratings is still unknown until learned, and we may not get the desired alignment. Lazaridou et al. attempt to connect sentiment labels with ratings by Kronecker symbol, but this method only applies to three sentiment polarities: -1(negative), 0(neutral), $+1$(positive), and it does not explore the word-level lexicon, which is also an important source of knowledge.

Another line of research on product aspect rating prediction or summarization does not use topic models, but relies mainly on word frequency and grammatical relations(Hu and Liu, 2004; Popescu and Etzioni, 2005; Blair-goldensohn et al., 2008), or specialized review selection(Long et al., 2014). In this case, the extracted aspect words need to be clustered manually. For example, *picture* and *photo* may refer to the same aspect in digital camera reviews. By comparison, topic modelling approaches extract aspect words and cluster them simultaneously.

Our method incorporates the product overall rating distributions and sentiment lexicons into the model, so it is also related to topic models which use observed features or domain knowledge(Mimno and McCallum, 2008; Andrzejewski et al., 2009; Andrzejewski et al., 2011). Mimno et al. introduces two general frameworks to integrate observed features into the generative process: downstream and upstream topic models(Mimno and McCallum, 2008). In the context of aspect-based opinion mining, MaxEnt-LDA(Zhao et al., 2010) integrates a discriminative maximum entropy component to help separate aspect words and sentiment words. The SAS model (Mukherjee and Liu, 2012) uses seed words to provide guidance for aspect discovery, and MC-LDA (Chen et al., 2013) uses must-links and cannot-links to extract coherent aspects. However, MaxEnt-LDA, SAS and MC-LDA cannot be used for aspect rating prediction, since they fail to identify the sentiment polarity of sentiment words.

3 Method

3.1 Preliminaries

We first introduce several key concepts used in our model.

Products: Let $P = \{P_1, P_2, \dots\}$ be a set of products. Each product P_i is associated with a set of reviews $D_i = \{d_1, d_2, \dots d_{N_i}\}$, and also an overall rating distribution Y_i. Y_i is a multinomial distribution on R ratings. It is available on most online review websites, and usually $R = 5$.

Aspects: An aspect is a rateable feature of a product, and each aspect is modelled as a distribution over aspect words. The number of aspects is predefined as K.

Sentiment topics: A sentiment topic is modelled as a distribution over sentiment words, and each sentiment topic is associated with a sentiment label. To make it consistent with commonly used rating scale, we assume there are R sentiment labels, corresponding to the R ratings. The challenge is that sentiment labels with higher values are expected to be associated with sentiment topics which express more positive sentiments, so that

we can match sentiment labels with ratings.

Phrases: An opinion phrase $f =< h, m >$ is a pair of aspect word h and sentiment word m, such as $< room, filthy >$(Lu et al., 2009; Moghaddam and Ester, 2011). For each product P_i, we first parse the related reviews D_i into phrases F_i, and each product can be modelled as a bag of phrases.

Sentiment lexicons : A sentiment lexicon L is a list of sentiment words, and each word $m \in L$ is associated with a sentiment polarity score s_m. s_m can take T values. Note that the lexicon L usually only covers a small subset of sentiment words in the whole vocabulary.

Sentiment association: The sentiment label takes R values, and there are T different values for the polarity score in the sentiment lexicon. However, the relation between sentiment labels and polarity scores are unknown. If we have training instances where a sentiment word m is associated with both a sentiment label r_m and polarity score s_m, we can build a classifier, where the explanatory variable for the classifier is a sentiment label, and outcome is the polarity score. In this case, $H(s_m|r_m)$ can be interpreted as the probability of observing a polarity score s_m, given its sentiment label r_m. We refer to this probability H as sentiment association. This is a key component in our model. It naturally bridges the gap between sentiment labels and polarity scores, and captures the uncertainty in their relations. Note that H can be trained independent of the topic model part. For each training instance, suppose the sentiment word is $m \in L$, we need to know its sentiment label r_m and polarity score s_m. s_m can be retrieved directly from the sentiment lexicon, and r_m can be either manually or automatically annotated. For example, suppose the word m appears in review d, we can assign the overall rating of d as its sentiment label. In this case, each word $m \in L$ can be associated with multiple training instances that have the same value for s_m but different sentiment labels r_m. We adopt this approach to automatically annotate sentiment labels, and details are described in the Experiments section.

3.2 Problem definition

The product aspect rating prediction problem can be defined as follows. The input is a set of products P. Each product P_i has a bag of phrases F_i, and an overall rating distribution Y_i over R ratings. The output is the K corpus-level aspects, and for each product, we predict its ratings on the K aspects, also in the $[1, R]$ rating scale. We assume products in P are in the same category so they share the same aspects.

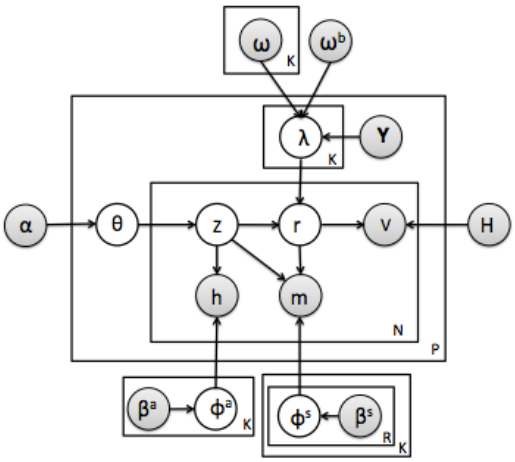

Figure 1: Graphical model of SATM

3.3 The SATM model

We introduce the Sentiment-aligned Topic Model(SATM) in this section, and its graphical representation is shown in Figure 1. Note that the sentiment association H is observed, because it is trained independently of the topic model part.

At the word level, each observed phrase $< h, m >$ is associated with two latent variables: aspect z and sentiment label r. Aspect z models what aspect this phrase talks about, and r determines the sentiment of m. If m is in the sentiment lexicon, we assume r is also responsible for generating a word feature v_m, based on the sentiment association H, which is equal to its polarity score s_m in the lexicon. In this case, the observed data becomes $(< h, m >, v_m)$, and the latent sentiment label r is responsible for generating both word m, and word feature v_m. For example, for the phrase <room, filthy>, we observe a word feature $v = -5$, since the sentiment polarity score for the word "filthy" is -5. Given H, sentiment labels 1 or 2 are more likely to generate a word feature -5. Also, people tend to use "filthy" to express low ratings, like 1 or 2, so the sentiment labels and ratings can be aligned.

At the product level, for each product p and each aspect k, we define a multinomial distribution $\lambda_{p,k}$ over R sentiment labels. Since Y_p already gives us the big picture about the overall senti-

ment expressed on this product, we assume $\lambda_{p,k}$ is drawn from a dirichlet distribution $Dir(\boldsymbol{\pi_{p,k}})$ with asymmetric concentration parameters, where $\boldsymbol{\pi_{p,k}} = f(\boldsymbol{Y_p}, \boldsymbol{\omega_k}, \omega^b)$. We can use a linear parametrization, and set

$$f(\boldsymbol{Y_p}, \boldsymbol{\omega_k}, \omega^b) = \omega_k^1 \boldsymbol{Y_p} + \omega_k^0 + \omega^b \quad (1)$$

ω_k^1 captures the influence of the product overall rating distribution, and can favour certain sentiment labels in the prior. ω_k^0 and ω^b are the aspect-specific and corpus-level bias, respectively. Through this linear parametrization, we build a direct matching between sentiment label i and rating i. For example, for a product p, if its overall rating distribution Y_p has high probability over rating 4, for aspect k, we assume its product-aspect-sentiment label distribution also has high probability on sentiment label 4 in the prior. The actual aspect rating is affected by both the text which talks about aspect k, and also the prior.

To sum up, we assume the generative process as follows:

- For each aspect $k = 1, 2, \ldots K$,
  - draw an aspect-word distribution $\phi_k^a \sim Dir(\boldsymbol{\beta}^a)$
  - For each sentiment label $r = 1, 2, \ldots R$, draw an aspect-sentiment label-word distribution $\phi_{k,r}^s \sim Dir(\boldsymbol{\beta}^s)$
- For each product $p \in P$,
  - draw a product-aspect distribution $\theta_p \sim Dir(\boldsymbol{\alpha})$
  - for each aspect k, draw a product-aspect-sentiment label distribution $\lambda_{p,k} \sim Dir(\boldsymbol{\pi_{p,k}})$ where $\boldsymbol{\pi_{p,k}} = f(\boldsymbol{Y_p}, \boldsymbol{\omega_k}, \omega^b)$
- For each phrase $f =< h, m >$ of product p,
  1. Draw an aspect z from θ_p
  2. Draw a sentiment label r from $\lambda_{p,z}$
  3. Draw an aspect word h from ϕ_z^a
  4. Draw a sentiment word m from $\phi_{z,r}^s$. If $m \in L$, generate a word feature v_m based on H.

By integrating out $\boldsymbol{\theta}$, $\boldsymbol{\phi}$ and $\boldsymbol{\lambda}$, the joint probability can be defined as:

$$P(\boldsymbol{z}, \boldsymbol{r}, \boldsymbol{h}, \boldsymbol{m}, \boldsymbol{v} | \boldsymbol{\alpha}, \boldsymbol{\beta^a}, \boldsymbol{\beta^s}, \boldsymbol{\pi}, H) = P(\boldsymbol{z}|\boldsymbol{\alpha}) P(\boldsymbol{r}|\boldsymbol{z}, \boldsymbol{\pi}) P(\boldsymbol{h}|\boldsymbol{z}, \boldsymbol{\beta^a}) P(\boldsymbol{m}|\boldsymbol{z}, \boldsymbol{r}, \boldsymbol{\beta^s}) P(\boldsymbol{v}|\boldsymbol{r}, H) \quad (2)$$

3.4 Inference

We use Gibbs Sampling(Griffiths and Steyvers, 2004) to estimate the posterior distribution given the observed data.

We jointly sample the aspect z and sentiment label r for the ith phrase $< h, m >$ of product p, given the assignments of other phrases:

$$P(z_i = k, r_i = l | \boldsymbol{z}_{-i}, \boldsymbol{r}_{-i}, \boldsymbol{h}, \boldsymbol{m}, \boldsymbol{v}) \propto (n_{p,k} + \alpha) \frac{n_{k,h}^a + \beta^a}{\sum_{h'} (n_{k,h'}^a + \beta^a)} \frac{n_{p,k,l} + \pi_{p,k,l}}{\sum_{l'} (n_{p,k,l'} + \pi_{p,k,l'})} \frac{n_{k,l,m}^s + \beta^s}{\sum_{m'} (n_{k,l,m'}^s + \beta^s)} g(m, l) \quad (3)$$

where $g(m, l) = H(v_m | l)$ if $m \in L$. In this case, when we sample the sentiment label r for this phrase, the probability of generating word feature v_m from r is also considered. For example, the word "excellent" has a word feature value $v_m = 5$. Based on H, the probability of generating a word feature 5 is higher for sentiment labels with larger values. If $m \notin L$, there is no $g(m, l)$ term, since no word feature is associated with this phrase. In Equation 3, $n_{p,k}$ is the number of times aspect k is assigned to phrases of product p, and $n_{k,h}^a$ is the number of times aspect word h is assigned to aspect k. $n_{p,k,l}$ is the number of times sentiment label l is assigned to aspect k for product p, and $n_{k,l,m}^s$ is the number of times sentiment word m is assigned to aspect k and sentiment label l. All these counts exclude assignments for the current phrase $< h, m >$.

Based on the samples, we can estimate $\lambda_{p,k,r}$ as:

$$\lambda_{p,k,r} = \frac{n_{p,k,r} + \pi_{p,k,r}}{\sum_{r'} (n_{p,k,r'} + \pi_{p,k,r'})} \quad (4)$$

Since sentiment labels and atings are aligned, the aspect rating t_{pk} of product p on aspect k can be simply calculated as the expectation of $\boldsymbol{\lambda_{p,k}}$:

$$t_{pk} = \sum_r \lambda_{p,k,r} \cdot r \quad (5)$$

4 Experiments

In this section, we describe the experiments and analyze the results.

4.1 Dataset

We use the TripAdvisor dataset[1](Wang et al., 2010) for evaluation, since in this dataset, reviews are not only associated with overall ratings, but also with ground truth aspect ratings on 7 aspects: *value, room, location, cleanliness, check in/front desk, service, business service*. All the ratings in the dataset are in the range from 1 star to 5 stars. We first remove reviews with any missing aspect ratings or very short reviews(less than three sentences). Then we adopt the dependency parser technique to identify opinion phrases, and collect phrases with adjective sentiment words. The dependency parser can deal with conjunctions, negations and bigram aspect words, and it results in the best performance according to (Moghaddam and Ester, 2012). Some sample phrases are shown in Table 1. All words are converted into lower case, and we remove phrases containing words that appear no more than 10 times or stop words. Since we are only interested in product-level aspect rating prediction, for each product, we aggregate all the review overall ratings to get the overall rating distribution. The statistics of the dataset is shown in Table 2. The average rating is the rating averaged over all reviews and all products. As we can see, positive reviews are dominant in the data, which raises the challenge of discovering negative sentiment topics.

Sentences	Phrases
The room, facing the courtyard, was large and comfortable.	<room, large>, <room, comfortable>
The room was not really clean.	<room, no_clean>
Internet access was available.	<Internet access, available>

Table 1: Sample extracted phrases

#Products	#Reviews	Avg rating	#Phrases
1850	61306	4.03	740982

Table 2: Statistics of the dataset

4.2 Metrics

We use three evaluation metrics for comparison.

RMSE: Root-mean-square error is used to measure the difference between the predicted aspect ratings and ground truth aspect ratings. It is defined as:

$$RMSE = \sqrt{\frac{\sum_p \sum_k (t_{pk} - \hat{t}_{pk})^2}{|P| \times K}} \quad (6)$$

where t_{pk} is the predicted aspect rating for product p on aspect k, and $\hat{t}_{pk}$ is the ground truth.

Precision@N: For each aspect k, we rank the hotels based on their predicted aspect ratings, and get the top N results. A hotel is considered *relevant* if its ground truth aspect rating is in the top 10% of the ground truth aspect ratings of all hotels. Precision@N is defined as the percentage of the top N results that are relevant:

$$Precision@N = \frac{|\{\text{relevant hotels}\} \cap \{\text{top N ranked hotels}\}|}{N} \quad (7)$$

We use $N = 10$, and the result is averaged over K aspects.

$\boldsymbol{\rho_{hotel}}$: Pearson correlation across hotels(Wang et al., 2010) is defined as:

$$\boldsymbol{\rho_{hotel}} = \frac{\sum_k \rho(\boldsymbol{t_k}, \hat{\boldsymbol{t}}_{\boldsymbol{k}})}{K} \quad (8)$$

where $\boldsymbol{t_k}$ is the predicted aspect rating vector for all hotels on aspect k, and $\hat{\boldsymbol{t}}_{\boldsymbol{k}}$ is the corresponding ground truth vector. $\rho(\boldsymbol{t_k}, \hat{\boldsymbol{t}}_{\boldsymbol{k}})$ is the Pearson correlation between these two vectors. It measures how the predicted ratings of aspect k can preserve the order in the ground truth(Wang et al., 2010). If we can predict an aspect-specific ranking similar to the ground truth, we can use the predicted aspect ratings to answer questions like "Is hotel a better than hotel b on aspect k?"

4.3 Baselines

The first three baselines are **Local Prediction**, **Global Prediction** and **Graph Propagation**. They all separate aspect extraction and sentiment identification. For each phrase $f =< h, m >$ from review d of product p, we first find the aspect assignment of this phrase. Then, we use three methods to get the phrase rating. Local Prediction(Lu et al., 2009) simply uses the overall rating of d as its phrase rating. Global Prediction(Lu et al., 2009) trains a multi-class classifier to classify the sentiment word m into a rating category $r \in 1, 2 \ldots R$,

[1] http://sifaka.cs.uiuc.edu/~wang296/Data/index.html

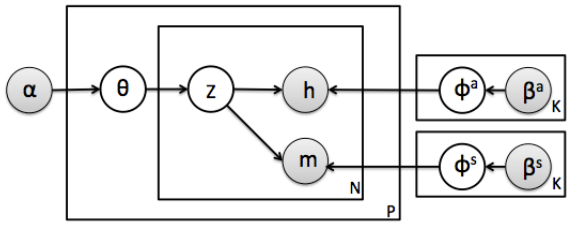

Figure 2: Method for aspect extraction in Local Prediction, Global Prediction and Graph Propagation

then assigns r as the phrase rating. Graph Propagation(Brody and Elhadad, 2010) builds a conjunction graph for sentiment words, and uses a Label Propagation algorithm on the graph to learn the sentiment polarity score for each sentiment word. The score of m is set as phrase rating. Finally, we aggregate all the phrases of each aspect to predict the aspect ratings. To apply these methods in our experiments, in the aspect extraction step, we adapt our model to extract only aspects, as shown in Figure 2. In this simplified model, no sentiment labels is involved, and the latent aspect explains both the aspect word and sentiment word.

ILDA(Moghaddam and Ester, 2011) was proposed for aspect rating prediction, but it fails to deal with the sentiment label alignment problem, so it cannot be directly used for this task. We adopt the common approach of providing seed words to set priors for each sentiment topic.

LRR(Wang et al., 2010) was proposed to predict aspect ratings for each review, but it can also be used to predict product aspect ratings by aggregating all the reviews of a product into a single "h-review"(Wang et al., 2011). First, we can run a topic model to learn aspects, and annotate each sentence with an aspect. Then LRR is applied on the annotated sentences to predict aspect ratings. This approach provided the best result, according to (Wang et al., 2011). In the first step we use the sentence-LDA(Jo and Oh, 2011) to annotate sentences, which is slightly different from the original method, but still provides a good analogy.

We also test two simplified version of the SATM model. First, we remove the part which involves sentiment lexicons, so we only use the product overall rating distribution. We call this method **SATM-O**. Second, we use only sentiment lexicons, ignoring the influence of overall rating distribution. We call it **SATM-L**. These two baselines can help us identify how the sentiment lexicon and overall rating distribution can improve the results, if used separately.

Our last baseline simply uses the overall rating of a hotel as its aspect ratings. For each hotel, its overall rating is defined as the average overall rating of its reviews. This method is referred to as **Overall**.

4.4 Experimental Setup

For all topic modelling based approaches, the number of aspects is set to 7. Since we can evaluate aspect rating prediction only on the predefined aspects, we need to ensure the discovered aspects match the predefined aspects. To do this, we adopt the common approach of providing a few seed words for each aspect as priors, as in (Wang et al., 2010). The seed words are listed in Table 3. There may be better methods to use seed words for aspect discovery (Jagarlamudi et al., 2012; Mukherjee and Liu, 2012), and it would be interesting to combine their methods with ours. However, this is beyond the scope of this paper, and we list it as future work.

Aspects	Seed words
Value	value, price, worth
Room	room, rooms
Location	location
Cleanliness	room, dirty, smelled, clean
Check in/front desk	staff
Service	service, breakfast, food
Business service	internet, wifi

Table 3: Seed words for aspect discovery

We use 5 sentiment labels in SATM, SATM-L and SATM-O, as this is the number of distinct ratings. The lexicon L used in our experiment is part of (Taboada et al., 2011) where words are associated with polarity scores in the range $[-5,-1] \cup [1,5]$. We observe that words with polarity score 1 and -1 express too weak sentiments, so we discard them in our experiment. To get training instances for sentiment association H, we treat each appearance of word $m \in L$ in the data as one training instance. The polarity score s_m is directly retrieved from L, and the sentiment label r_m is the overall rating of review d where m appears. This approach avoids the need for manual annotation of sentiment labels, and the annotation result captures the characteristics of the dataset. How-

ever, all training instances in a review will have the same sentiment label, which means that we assume all sentiment words in a review express the same sentiment, no matter what aspects they talk about. This is not true, thus will introduce noise to the training. To reduce noise, for words with positive polarity score, we ignore their appearance in reviews with rating 1 and 2, since we assume positive sentiment words rarely express negative sentiments, even if they appear in negative reviews. Therefore, $H(s_m|r_m) = 0$ for $r_m = 1, 2$ and s_m in the range $[2, 5]$. A similar method is used to deal with words with negative polarity score.

For Global Prediction, in (Lu et al., 2009), the prior for the multi-class classifier is uniform, while in our experiment, for product p, we used product overall rating distribution on r as the prior for rating category r, which achieves better results than uniform prior.

The Graph Propagation method requires a small set of sentiment words as seeds, from which the algorithm can learn sentiment score for other words. The method in (Brody and Elhadad, 2010) constructs these seed words based on morphology in an unsupervised way, and can only support two kinds of sentiment: positive and negative. In our experiment, since the sentiment lexicon is available, the sentiment seed words are from the lexicon, and we update the polarity score for those not in the lexicon.

For ILDA, since we need to provide seed words as priors for sentiment topics, we have two options, and we use both for experiment. First, we can employ the common approach of using two sentiment labels(R=2, positive and negative). Then, words with positive polarity scores in lexicon L are used as priors for the positive sentiment topic, and similarly words with negative polarity scores for negative sentiment topic. An alternative approach is to use 5 sentiment labels(R=5). It provides finer grained sentiment extraction, but raises the question of how to choose seed words for each sentiment topic. To do this, we use the full sentiment lexicon in (Taboada et al., 2011), where sentiment words have polarity score in the range of $[-5, -1] \cup [1, 5]$. We divide the lexicon, and use words with polarity score 4 and 5 as prior for the sentiment topic with label 5. Then, words with polarity score 2 and 3 are used for the sentiment topic with label 4, and so on.

For all topic modelling based approaches, we set the number of iterations for Gibbs Sampling to 3000, and take samples from the markov chain every 50 iterations after a burn-in period of 1000 iterations. In SATM and SATM-O, for all aspects k, we need to choose the parameters $\boldsymbol{\omega_k}$ and also w^b. We use a small portion of dataset with ground truth to choose the best value, and we set $\omega_k^1 = 20$, $w_k^0 = 0.01, w^b = 0$. Automatically learning these parameters are feasible. One possible option is to use stochastic EM sampling scheme, as in (Mimno and McCallum, 2008). For the LRR implementation[2], we use the default parameters included in the package, and train the model with seed words provided by the author(Wang et al., 2010).

4.5 Results

The experimental results are listed in Table 4. For RMSE, the smaller the better, while for the other two measures, the larger the better. Graph Propagation, ILDA and SATM-L do not use the overall ratings(except for training sentiment association H), so we group them together. Similarly we group Local Prediction, Global Prediction, SATM-O and SATM. The Overall method is a special baseline that does not do any aspect based prediction. For the LRR method, after the first step of sentence annotation, we notice that sentence-LDA fails to annotate the "h-review" of some hotel with all 7 aspects, mainly because these hotels are associated with less reviews. In this case, the LRR model will fail in the second step, so we do not include LRR in Table 4. Instead, we compared our method with LRR on a subset of products that comment on all aspects based on the sentence annotation. There are 1533 hotels in this subset, and the result is shown in Table 5. Note that our experimental results for LRR are far worse than those reported in the original paper(Wang et al., 2011). We believe this maybe due to different parameter settings, or due to the choice of different reviews.

We observe that SATM achieves the best RMSE value, i.e., it produces the most accurate aspect rating prediction. The Overall method does better in ranking all the hotels(ρ_{hotel}), but SATM is better at ranking top hotels($P@10$). When we compare the results of SATM with SATM-L and SATM-O, we find that the good performance of SATM is mainly due to the use of the overall rating distribution. On one hand, this is reasonable, since in-

Table 5: Experimental comparison with LRR

tuitively aspect ratings usually do not diverge too far from the overall rating, especially for hotels with higher overall ratings. As we can see from the result of Overall, the overall rating has good correlation with aspect ratings, and using overall rating only is already a strong predictor for aspect ratings. Also, in most cases, methods using overall ratings(Overall and the four methods in the middle of Table 4) are better than others(first four methods). On the other hand, we should not rely only on the overall rating distribution. By incorporating the sentiment lexicon, for RMSE, SATM achieves 10% improvement over SATM-O and 7% improvement than Overall. Also, the overall rating may not always be a good aspect rating predictor, depending on the dataset.

To take a closer look at cases where the overall rating is not a good aspect rating predictor, we evaluate the RMSE on different subsets of hotels. We divide the hotels into different overall rating ranges: [1.2), [2,3), [3,4) and [4,5]. The results are shown in Table 7. Going from the [4,5] group to [1,2) group, the overall rating becomes less and less reliable to predict aspect ratings, and the gain of SATM increases compared to SATM-O and Overall. For a hotel with higher overall rating(good hotel), its aspect ratings are closer to the overall rating. This matches our intuition that good hotels are expected to be good on most aspects, if not on all aspects. For a hotel with average and lower overall rating, the average difference between aspect ratings and overall rating is larger. In this case, the overall rating can not tell us the whole story, which calls for aspect based prediction. Our method achieves the best RMSE gain on this group of hotels.

Methods	[1,2)	[2,3)	[3,4)	[4-5]
Local Prediction	0.789	0.772	0.621	0.456

4.6 Qualitative analysis

To provide a qualitative analysis, we can list the top words for the aspect-sentiment label-word distributions. In Table 6, we list them for the aspect "room", with 5 different sentiment labels. We observe that, as the sentiment label value increases, the sentiment topics express more and more positive sentiments. This means the sentiment labels and ratings are indeed aligned, so that we can use these sentiment labels to predict ratings.

5 Conclusion and future work

In this paper, we proposed a sentiment aligned topic model(SATM) for product aspect rating prediction. By incorporating the overall rating distribution and a sentiment lexicon, our SATM model can align sentiment labels with ratings. Experiments on a TripAdvisor dataset demonstrate the effectiveness of SATM on aspect rating prediction.

In SATM, for each product and each aspect, the multinomial distribution over sentiment labels has

prior parameterized by product overall rating distribution. We assume linear dependency, but it will be interesting to explore other dependencies. Another direction is to learn the parameters $\boldsymbol{\omega_k}$ automatically, so that $\boldsymbol{\omega_k}$ can be different for different k, capturing the influence of the overall rating on different aspects.

Finally, we assume each phrase is associated with one latent aspect. However, aspects may be correlated. For example, the phrase <room, filthy> gives us information about the aspect *room* and also the aspect $cleanliness$. To deal with this problem, we can relax the assumption that one phrase talks about one aspect, or we can model correlation among aspects.

Abstract

We present a weakly supervised approach for learning hashtags, hashtag patterns, and phrases associated with five emotions: AFFECTION, ANGER/RAGE, FEAR/ANXIETY, JOY, and SADNESS/DISAPPOINTMENT. Starting with seed hashtags to label an initial set of tweets, we train emotion classifiers and use them to learn new emotion hashtags and hashtag patterns. This process then repeats in a bootstrapping framework. Emotion phrases are also extracted from the learned hashtags and used to create phrase-based emotion classifiers. We show that the learned set of emotion indicators yields a substantial improvement in F-scores, ranging from +%5 to +%18 over baseline classifiers.

1 Introduction

Identifying emotions in social media text can be beneficial for many applications, for example to help companies understand how people feel about their products, to assist governments in recognizing growing anger or fear associated with an event, or to help media outlets understand people's emotional response toward controversial issues or international affairs. On the Twitter micro-blogging platform, people often use hashtags to express an emotional state (e.g., *#happyasalways*, *#angryattheworld*). While some hashtags consist of a single word (e.g., *#angry*), many hashtags include multiple words and creative spellings (e.g., *#cantwait4tmrw, #Youredabest*), which can not be easily recognized using sentiment or emotion lexicons.

Our research learns three types of emotion indicators for tweets: hashtags, hashtag patterns, and phrases for one of five emotions: AFFECTION, ANGER/RAGE, FEAR/ANXIETY, JOY, or SADNESS/DISAPPOINTMENT. We present a bootstrapping framework for learning emotion hashtags and extend the framework to also learn more general hashtag patterns. We then harvest emotion phrases from the hashtags and hashtag patterns for contextual emotion classification.

First, we make the observation that emotion hashtags often share a common prefix. For example, *#angryattheworld* and *#angryatlife* both have the prefix *"angry at"*, which suggests the emotion ANGER. Consequently, we generalize beyond specific hashtags to create *hashtag patterns* that will match all hashtags with the same prefix, such as the pattern *#angryat** which will match both *#angryattheworld* and *#angryatlife*.

A key challenge is that a seemingly strong emotion word or phrase can have a different meaning depending upon the following words. For example, *#angry** may seem like an obvious pattern to identify ANGER tweets. But *#angrybirds* is a popular hashtag that refers to a game, not the writer's emotion. Similarly, "love you" usually expresses AFFECTION when it is followed by a person (e.g., *#loveyoumom*). But it may express JOY in other contexts (e.g., *#loveyoulife*). We use probability estimates to determine which hashtag patterns are reliable indicators for an emotion.

Our second observation is that hashtags can also be used to harvest emotion phrases. For example, if we learn that the hashtag *#lovelife* is associated with JOY, then we can extract the phrase "love life" from the hashtag and use it to recognize emotion in the body of tweets. However, unlike hashtags, which are self-contained, the words surrounding a phrase in a tweet must also be considered. For example, negation can toggle polarity (*"don't love life"* may suggest SADNESS, not JOY) and the aspectual context may indicate that no emotion is being expressed (e.g., *"I would love life if ..."*). Consequently, we train classifiers to determine if a tweet contains an emotion based on both an emotion phrase and its context.

2 Related Work

In addition to sentiment analysis, which has been widely studied (e.g., (Barbosa and Feng, 2010; Brody and Diakopoulos, 2011; Kouloumpis et al., 2011; Mitchell et al., 2013)), recognizing emotions in social media text has also become a popular research topic in recent years. Researchers have studied feature sets and linguistic styles (Roberts et al., 2012), emotion influencing behaviors (Kim et al., 2012), sentence contexts (Yang et al., 2007b), hierarchical emotion classification (Ghazi et al., 2010; Esmin et al., 2012) and emotion lexicon creation (Yang et al., 2007a; Mohammad, 2012a; Staiano and Guerini, 2014). Researchers have also started to utilize the hashtags of tweets, but primarily to collect labeled data (e.g., for sarcasm (Davi-

dov et al., 2010; Riloff et al., 2013) and for sentiment/emotion data (Wang et al., 2012; Mohammad et al., 2013; Choudhury et al., 2012; Purver and Battersby, 2012; Mohammad, 2012a)).

Wang et al. (2011) investigated several graph based algorithms to collectively classify hashtag sentiments, but their work is focused on positive versus negative polarity classification. Our research extends the preliminary work on bootstrapped learning of emotion hashtags (Qadir and Riloff, 2013) to additionally learn patterns corresponding to hashtag prefix expressions and to extract emotion phrases from the hashtags, which are used to train phrase-based emotion classifiers.

3 Learning Emotion Hashtags, Hashtag Patterns and Phrases

For our research, we collapsed Parrot's emotion taxonomy (Parrott, 2001)[1] into 5 emotion classes that frequently occur in tweets and minimally overlap with each other: AFFECTION, ANGER/RAGE, FEAR/ANXIETY, JOY, and SADNESS/DISAPPOINTMENT. We also used a NONE OF THE ABOVE class for tweets that do not express any emotion or express an emotion different from our five classes. For each of these categories, we identified 5 common hashtags that are strongly associated with the emotion and used them as seeds. Table 1 shows the seed hashtags.

Compared to the Ekman emotion classes (Ekman, 1992), one of the emotion taxonomies frequently used in NLP research (Strapparava and Mihalcea, 2007; Mohammad, 2012b), JOY, ANGER, SADNESS and FEAR are comparable to 4 of our 5 emotion classes. We do not study Ekman's SURPRISE and DISGUST classes, but include AFFECTION.

3.1 Learning Hashtags

Figure 1 presents the framework of the bootstrapping algorithm for hashtag learning. The process begins by collecting tweets that contain the seed hashtags and labeling them with the corresponding emotion. For this purpose, we collected 323,000 tweets in total that contain at least one of our seed hashtags. We also exploit a large pool of *unlabeled tweets* to use during bootstrapping, consisting of 2.3 million tweets with at least one hashtag per tweet (because we want to learn hashtags), collected using Twitter's streaming API. We did not include retweets or tweets with URLs, to reduce duplication and focus on tweets with original content. The *unlabeled tweets* dataset had 1.29 average hashtags-per-tweet and 3.95 average tweets-per-hashtag. We preprocessed the tweets with CMU's tokenizer (Owoputi et al., 2013) and normalized with respect to case.

Emotion Classes	Seed Hashtags
AFFECTION	*#loveyou*, *#sweetheart*, *#bff* *#romantic*, *#soulmate*
ANGER & RAGE	*#angry*, *#mad*, *#hateyou* *#pissedoff*, *#furious*
FEAR & ANXIETY	*#afraid*, *#petrified*, *#scared* *#anxious*, *#worried*
JOY	*#happy*, *#excited*, *#yay* *#blessed*, *#thrilled*
SADNESS & DISAPPOINTMENT	*#sad*, *#depressed* *#disappointed*, *#unhappy* *#foreveralone*

Table 1: Emotion Classes and Seed Hashtags

The labeled tweets are then used to train a set of emotion classifiers. We trained one logistic regression classifier for each emotion class using the LIBLINEAR package (Fan et al., 2008). We chose logistic regression because it produces probabilities with its predictions, which are used to assign scores to hashtags. As features, we used unigrams and bigrams with frequency $>$ 1. We removed the seed hashtags from the tweets so the classifiers could not use them as features.

For each emotion class $e \in E$, the tweets containing a seed hashtag for e were used as positive training instances. The negative training instances consisted of the tweets containing seed hashtags for the competing emotions as well as 100,000 randomly selected tweets

[1]There were other emotions in Parrott's taxonomy such as SURPRISE, NEGLECT, etc. that we did not use for this research.

Affection	Anger & Rage	Fear & Anxiety	Joy	Sadness & Disappointment

Table 2: Examples of Learned Hashtags

from our unlabeled tweets. Although some of the unlabeled tweets may correspond to emotion e, we expect that most will have no emotion or an emotion different from e, giving us a slightly noisy but large, diverse set of negative instances.

We then apply each emotion classifier to the unlabeled tweets. For each emotion e, we collect the tweets classified as e and extract the hashtags from those tweets to create a candidate pool H_e of hashtags for emotion e. To limit the number of candidates, we discard hashtags that occur < 10 times, have just one character, or have > 20 characters. Next, we score each candidate hashtag h by computing the average probability assigned by the logistic regression classifier for emotion e over all of the tweets containing hashtag h. For each emotion class, we select the 10 hashtags with the highest scores. From the *unlabeled tweets*, we then add all tweets with one of the learned hashtags to the training instances, and the bootstrapping process continues. Table 2 shows examples of the learned hashtags.

3.2 Learning Hashtag Patterns

We learn hashtag patterns in a similar but separate bootstrapping process. We first expand each hashtag into a sequence of words using an N-gram based word segmentation algorithm[2] supplied with corpus statistics from our tweet collection. For example, *#angryatlife* expands[3] to the phrase *"angry at life"*. We use a Prefix Tree (Trie) data structure to represent all possible prefixes of the expanded hashtag phrases, but the prefixes consist of words instead of characters.

Next, we traverse the tries and consider all possible prefix paths as candidate hashtag patterns. We only consider prefixes that have occurred with at least one following word. For example, *#angryashell*, *#angryasalways*, *#angrybird*, *#angryatlife*, *#angryatyou* would produce patterns: *#angry**, *#angryas**, *#angryat** as shown in Figure 2.

We score each pattern by applying the classifier for emotion e (trained in the same way as hashtag learning) to all tweets having hashtags that match the pattern. We compute the average probability produced by the classifier, and for each emotion class, we select the 10 hashtag patterns with the highest scores. From the *unlabeled tweets*, we then add all tweets with hashtags that match one of the learned hashtag patterns to the training instances, and the bootstrapping process continues. Table 3 shows examples of learned hashtag patterns and matched hashtags.

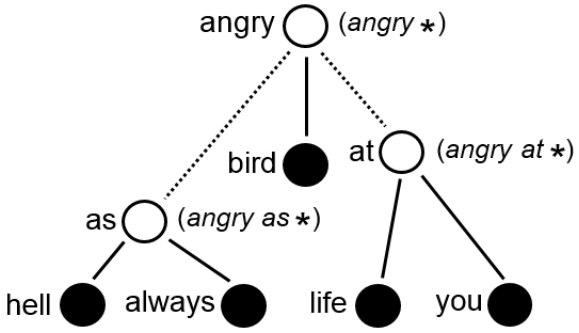

Figure 2: Trie of example hashtags with prefix *angry*. Dotted lines lead to non-terminal nodes where patterns are extracted.

3.3 Creating Phrase-based Classifiers

The third type of emotion indicator that we acquire are emotion phrases. At the end of the bootstrapping process, we apply the word segmentation algorithm to all of the learned hashtags and hashtag patterns to expand them into phrases (e.g., *#lovemylife* → *"love my life"*). Each phrase is assumed to express the same emotion as the original hashtag. However, as we will see in Section 4, just the presence of a phrase yields low precision, and surrounding context must also be taken into account.

Consequently, we train a logistic regression classifier for each emotion e, which classifies a tweet with respect to emotion e based on the presence of a learned phrase for e as well as a context window of size 6 around the phrase (set of 3 words on its left and set of 3

[2]http://norvig.com/ngrams/

[3]On a random sample of 100 hashtags, we found expansion accuracy to be 76% (+8% partially correct expansions).

Emotion	Hashtag Pattern	Examples of Matching Hashtags
AFFECTION	#bestie*	#bestiefolyfe, #bestienight, #bestielove
	#missedyou*	#missedyoutoomuch, #missedyouguys, #missedyoubabies
ANGER & RAGE	#godie*	#godieoldman, #godieyou, #godieinahole
	#pissedoff*	#pissedofffather, #pissedoffnow, #pissedoffmood
FEAR & ANXIETY	#tooscared*	#tooscaredtogoalone, #tooscaredformama, #tooscaredtomove
	#nightmares*	#nightmaresfordays, #nightmaresforlife, #nightmarestonight
JOY	#feelinggood*	#feelinggoodnow, #feelinggoodforme, #feelinggoodabout
	#goodmood*	#goodmooditsgameday, #goodmoodmode, #goodmoodnight
SADNESS & DISAPPOINTMENT	#bummed*	#bummedout, #bummedaf, #bummednow
	#singlelife*	#singlelifeblows, #singlelifeforme, #singlelifesucks

Table 3: Examples of Learned Hashtag Patterns and Matching Hashtags

words on its right). Tweets containing a learned phrase for e and a seed hashtag for e are the positive training instances. Tweets containing a learned phrase for e and a seed hashtag for a different emotion are used as the negative training instances. For example, when *"love my life"* is learned as an emotion phrase for JOY, the tweet, *"how can I love my life when everybody leaves me! #sad"* will have one feature each for the left words *"how"*, *"can"*, and *"I"*, one feature each for the right words *"when"*, *"everybody"* and *"leaves"*, and one feature for the phrase *"love my life"*. The tweet will then be considered a negative instance for JOY because *"#sad"* indicates a different emotion.

4 Experimental Results

To evaluate our learned emotion indicators, we manually selected 25 topic keywords/phrases[4] that we considered to be strongly associated with emotions, but not necessarily with any specific emotions of our study. We then searched in Twitter using Twitter Search API for any of these topic phrases and their corresponding hashtags. These 25 topic phrases are: *Prom, Exam, Graduation, Marriage, Divorce, Husband, Wife, Boyfriend, Girlfriend, Job, Hire, Laid Off, Retirement, Win, Lose, Accident, Failure, Success, Spider, Loud Noise, Chest Pain, Storm, Home Alone, No Sleep* and *Interview*. Since the purpose is to evaluate the quality and coverage of the emotion hashtags that we learn, we filtered out any tweet that did not have at least one hashtag.

Two annotators were given annotation guidelines and were instructed to label each tweet with up to two emotions. The instructions specified that the emotion must be felt by the writer. The annotators annotated 500 tweets with an inter-annotator agreement level of 0.79 Kappa (κ) (Carletta, 1996). The annotation disagreements in these 500 tweets were then adjudicated, and each annotator labeled an additional 2,500 tweets. Altogether this gave us an emotion annotated dataset of 5,500 tweets. We randomly separated out 1,000 tweets from this collection as a tuning set, and used the remaining 4,500 tweets as evaluation data. The distribution of emotions in the evaluation data was 6% for AFFECTION, 9% for ANGER/RAGE, 13% for FEAR/ANXIETY, 22% for JOY, and 12% for SADNESS/DISAPPOINTMENT. 42% of the tweets had none of the 5 emotions and 4% of the tweets had more than one emotions in the same tweet.

We created two baseline systems to assess the difficulty of the emotion classification task. First, we created SVM classifiers for each emotion using N-gram features and performed 10-fold cross-validation on the test data. We used LIBSVM (Chang and Lin, 2011) and set the $cost$ and $gamma$ parameters based on the tuning data. Second, we acquired the NRC Emotional Tweets Lexicon (Mohammad, 2012a), which contains emotion unigrams and bigrams for 8 emotions, 4 that are comparable to ours: ANGER, FEAR, JOY and SADNESS. We created a hashtag from each term in the lexicon by appending a # symbol on the front and removing whitespace. For each term, we chose the emotion with the highest score in the lexicon.

Table 4 shows our experimental results. The baseline classifiers (SVM_1 uses unigrams, SVM_{1+2} uses unigrams and bigrams) have low recall but 63-78% precision. The hashtags created from the NRC Lexicon have low precision. This could be due to possible entries (e.g., *"candy"* or *"idea"*), which without context are not much indicative of any specific emotion.

The second section of Table 4 shows the results when we label a tweet based on the presence of a hashtag or hashtag pattern. First, we use just the 5 seed hashtags to assess their coverage (as expected, high precision but low recall). Next, we add the hashtags learned during bootstrapping. For most emotions, the hashtags achieve performance similar to the supervised SVMs. The following row shows results for our learned hashtag patterns. Recall improves by +14% for AFFECTION, which illustrates the benefit of more general hashtag patterns, and at least maintains similar level of precision for other emotions. When the hashtags and hashtag patterns are combined (HTs+HPs), we see the best of both worlds with improved recall as high as +17% in AFFECTION and +10% in FEAR/ANXIETY

Table 4: Emotion Classification Results (P = Precision, R = Recall, F = F-score)

compared to All HTs, as well as improved F-scores across the board.

The third section of Table 4 presents the results for the emotion phrases. The first row (Emotion Phrases) shows that labeling a tweet based solely on the presence of a phrase is not very accurate. Next, we applied the trained models of the phrase-based classifiers (described in Section 3.3) to each tweet of the evaluation data. This provided us with probability of an emotion for each of the 5 emotions. The phrase-based classifiers (PC) yield higher precision, albeit with low recall. Finally, we use these probabilities as 5 additional features to SVM_1. The corresponding SVM_1+PC row shows a consistent 1-2 point F score gain over the original SVM_1 baseline.

The last section of Table 4 shows the best results with a hybrid system, which labels a tweet with emotion e if EITHER the enhanced SVM labels it as e OR the tweet contains a hashtag or hashtag pattern associated with e. This combined approach achieves substantially higher performance than any individual method across all 5 emotion classes, with improved F-scores ranging from +%5 to +%18 over the baseline classifiers, demonstrating that the different types of emotion indicators are complementary.

5 Conclusions

We have shown that three types of emotion indicators can be learned from tweets with weakly supervised bootstrapping: hashtags, hashtag patterns, and phrases. Our findings suggest that emotion hashtags are strong indicators for recognizing writer's emotion in tweets, and can be further generalized into hashtag patterns by learning prefix expressions corresponding to an emotion. Phrases learned from the hashtags and patterns are not always reliable by themselves, but training additional classifiers with the emotion phrases and their surrounding context provides added benefits to emotion classification in tweets. Our results showed that combining the learned emotion indicators with an N-gram classifier in a hybrid approach substantially improves performance across 5 emotion classes.

Fine-Grained Contextual Predictions for Hard Sentiment Words

Sebastian Ebert and **Hinrich Schütze**
Center for Information and Language Processing
University of Munich, Germany
ebert@cis.lmu.de, inquiries@cislmu.org

Abstract

We put forward the hypothesis that high-accuracy sentiment analysis is only possible if word senses with different polarity are accurately recognized. We provide evidence for this hypothesis in a case study for the adjective "hard" and propose contextually enhanced sentiment lexicons that contain the information necessary for sentiment-relevant sense disambiguation. An experimental evaluation demonstrates that senses with different polarity can be distinguished well using a combination of standard and novel features.

1 Introduction

This paper deals with fine-grained sentiment analysis. We aim to make three contributions. First, based on a detailed linguistic analysis of contexts of the word "hard" (Section 3), we give evidence that highly accurate sentiment analysis is only possible if senses with different polarity are accurately recognized.

Second, based on this analysis, we propose to return to a lexicon-based approach to sentiment analysis that supports identifying sense distinctions relevant to sentiment. Currently available sentiment lexicons give the polarity for each word or each sense, but this is of limited utility if senses cannot be automatically identified in context. We extend the lexicon-based approach by introducing the concept of a *contextually enhanced sentiment lexicon* (CESL). The lexicon entry of a word w in CESL has three components: (i) the senses of w; (ii) a sentiment annotation of each sense; (iii) a data structure that, given a context in which w occurs, allows to identify the sense of w used in that context.

As we will see in Section 3, the CESL sense inventory – (i) above – should be optimized for sentiment analysis: closely related senses with the same sentiment should be merged whereas subtle semantic distinctions that give rise to different polarities should be distinguished.

The data structure in (iii) is a statistical classification model in the simplest case. We will give one other example for (iii) below: it can also be a set of centroids of context vector representations, with a mapping of these centroids to the senses.

If sentiment-relevant sense disambiguation is the first step in sentiment analysis, then powerful contextual features are necessary to support making fine-grained distinctions. Our third contribution is that we experiment with deep learning as a source of such features. We look at two types of deep learning features: word embeddings and neural network language model predictions (Section 4). We show that deep learning features significantly improve the accuracy of context-dependent polarity classification (Section 5).

2 Related work

Initial work on sentiment analysis was either based on sentiment lexicons that listed words as positive or negative sentiment indicators (e.g., Turney (2002), Yu and Hatzivassiloglou (2003)), on statistical classification approaches that represent documents as ngrams (e.g., Pang et al. (2002)) or on a combination of both (e.g., Riloff et al. (2003), Whitelaw et al. (2005)). The underlying assumption of lexicon-based sentiment analysis is that a word always has the same sentiment. This is clearly wrong because words can have senses with different polarity, e.g., "hard wood" (neutral) vs. "hard memory" (negative).

Ngram approaches are also limited because ngram representations are not a good basis for relevant generalizations. For example, the neutral adverbial sense 'intense' of "hard" ("laugh hard", "try hard") vs. the negative adjectival mean-

Table 1: Sense inventory of "hard".

ing 'difficult' ("hard life", "hard memory") cannot be easily distinguished based on an ngram representation. Moreover, although ngram approaches could learn the polarity of these phrases they do not generalize to new phrases.

More recent compositional approaches to sentiment analysis can outperform lexicon and ngram-based methods (e.g., Socher et al. (2011), Socher et al. (2013)). However, these approaches conflate two different types of contextual effects: differences in sense or lexical meaning ("hard memory" vs. "hard wood") on the one hand and meaning composition like negation on the other hand. From the point of view of linguistic theory, these are different types of contextual effects that should not be conflated. Recognizing that "hard" occurs in the scope of negation is of no use if the basic polarity of the contextually evoked sense of "hard" (e.g., negative in "no hard memories" vs. neutral in "no hard wood") is not recognized.

Wilson et al. (2009) present an approach to classify contextual polarity building on a two-step process. First, they classify if a sentiment word is polar in a phrase and if so, second, they classify its polarity. Our approach can be seen as an extension of this approach; the main difference is that we will show in our analysis of "hard" that the polarity of phrases depends on the senses of the words that are used. This is evidence that high-accuracy polarity classification depends on sense disambiguation.

There has been previous work on assigning polarity values to senses of words taken from WordNet (e.g., Baccianella et al. (2010), Wiebe and Mihalcea (2006)). However, these approaches are not able to disambiguate the sense of a word given its context.

Previous work on representation learning for sentiment analysis includes (Maas and Ng, 2010) and (Maas et al., 2011). Their models learn word embeddings that capture semantic similarities and word sentiment at the same time. Their approach focuses on sentiment of entire sentences or documents and does not consider each sentiment word instance at a local level.

We present experiments with one supervised and one semisupervised approach to word sense disambiguation (WSD) in this paper. Other WSD approaches, e.g., thesaurus-based WSD (Yarowsky, 1992), could also be used for CESL.

3 Linguistic analysis of sentiment contexts of "hard"

We took a random sample of 5000 contexts of "hard" in the Amazon Product Review Data (Jindal and Liu, 2008). We use 200 as a test set and set aside 200 for future use. We analyzed the remaining 4600 contexts using a tool we designed for this study, which provides functionality for selecting and sorting contexts, including a keyword in context display. If a reliable pattern has been identified (e.g., the phrase "die hard"), then all contexts matching the pattern can be labeled automatically.

Our goal is to identify the different uses of "hard" that are relevant for sentiment. The basis for our inventory is the Cobuild (Sinclair, 1987)

lexicon entry for "hard". We use Cobuild because it was compiled based on an empirical analysis of corpus data and is therefore more likely to satisfy the requirements of NLP applications than a traditional dictionary.

Cobuild lists 16 senses. One of these senses (3) is split into two to distinguish the adverbial ("to accelerate hard") and adjectival ("hard acceleration") uses of "hard" in the meaning 'intense'. We conflated five senses (2, 4, 9, 10, 11) referring to different types of difficulty: "hard question" (2), "hard work" (4), "hard life" (11) and two variants of "hard on": "hard on someone" (9), "hard on something" (10); and four different senses (3a, 5, 6, 7) referring to different types of intensity: "to work hard" (3a), "to look hard" (5), "to kick hard" (6), "to laugh hard" (7). Furthermore, we identified a number of noncompositional meanings or phrases (lists NEGATIVE-P and NEUTRAL-P in the supplementary material[1]) in addition to the four listed by Cobuild (13, 14, 15, 16). In addition, new senses for "hard" are introduced for opposites of senses of "soft": the opposite of 'quiet/gentle voice/sound' (7: MUSIC; e.g., "hard beat", "not too hard of a song") and the opposite of 'smooth surface/texture' (8: CONTRAST; e.g., "hard line", "hard edge").

Table 1 lists the 10 different uses that are the result of our analysis. For each use, we give the corresponding Cobuild sense numbers, syntactic information, meaning, an example, typical patterns, polarity, and number of occurrences in training and test sets.

7 uses are neutral and 3 are negative. As "hard's" polarity in most sentiment lexicons is negative, but only 3 out of 7 senses are negative, "hard" provides evidence for our hypothesis that senses need to be disambiguated to allow for fine-grained and accurate polarity recognition.

We hired two PhD students to label each of the 200 contexts in the test set with one of the 10 labels in Table 1 ($\kappa = .78$). Disagreement was resolved by a third person.

We have published the labeled data set of 4600+200 contexts as supplementary material.

4 Deep learning features

We use two types of deep learning features to be able to make the fine-grained distinctions necessary for sense disambiguation. First, we use word embeddings similar to other recent work (see below). Second, we use a deep learning language model (LM) to predict the distribution of words for the position at which the word of interest occurs. For example, an LM will predict that words like "granite" and "concrete" are likely in the context "a * countertop" and that words like "serious" and "difficult" are likely in the context "a * problem". This is then the basis for distinguishing contexts in which "hard" is neutral (in the meaning 'firm, solid') from contexts in which it is a sentiment indicator (in the meaning 'difficult'). We will use the term *predicted context distribution* or PCD to refer to the distribution predicted by the LM.

We use the vectorized log-bilinear language model (vLBL) (Mnih and Kavukcuoglu, 2013) because it has three appealing features. (i) It learns state of the art word embeddings (Mnih and Kavukcuoglu, 2013). (ii) The model is a language model and can be used to calculate PCDs. (iii) As a linear model, vLBL can be trained much faster than other models (e.g., Bengio et al. (2003)).

The vLBL trains one set of word embeddings for the input space (R) and one for the target space (Q). We denote the input representation of word w as $\boldsymbol{r}_w$ and the target representation as $\boldsymbol{q}_w$. For a given context $c = w_1, \ldots, w_n$ the model predicts a target representation $\hat{\boldsymbol{q}}$ by linearly combining the context word representations with position dependent weights:

$$\hat{\boldsymbol{q}}(c) = \sum_{i=1}^{n} \boldsymbol{d}_i \odot \boldsymbol{r}_{w_i}$$

where $\boldsymbol{d}_i \in D$ is the weight vector associated with position i in the context and $\odot$ is pointwise multiplication. Given the model parameters $\theta = \{R, Q, D, \boldsymbol{b}\}$ the similarity between $\hat{\boldsymbol{q}}$ and the correct target word embedding is computed by the similarity function

$$s_\theta(w, c) = \hat{\boldsymbol{q}}(c)^T \boldsymbol{q}_w + b_w$$

where b_w is a bias term.

We train the model with stochastic gradient descent on mini-batches of size 100, following the noise-contrastive estimation training procedure of Mnih and Kavukcuoglu (2013). We use AdaGrad (Duchi et al., 2011) with the initial learning rate set to $\eta = 0.5$. The embeddings size is set to 100.

Table 2: Classification results; bl: baseline

During training we do not need to normalize the similarity explicitly, because the normalization is implicitly learned by the model. However, normalization is still necessary for prediction. The normalized PCD for a context c of word w is computed using the softmax function:

$$P_\theta^c(w) = \frac{\exp(s_\theta(w, c))}{\sum_{w'} \exp(s_\theta(w', c))}$$

We use a window size of $ws = 7$ for training the model. We found that the model did not capture enough contextual phenomena for $ws = 3$ and that results for $ws = 11$ did not have better quality than $ws = 7$, but had a negative impact on the training time. Using a vocabulary of the 100,000 most frequent words, we train the vLBL model for 4 epochs on 1.3 billion 7-grams randomly selected from the English Wikipedia.

5 Experiments

The lexicon entry of "hard" in CESL consists of (i) the senses, (ii) the polarity annotations (neutral or negative) and (iii) the sense disambiguation data structure. Components (i) and (ii) are shown in Table 1. In this section, we evaluate two different options for (iii) on the task of sentiment classification.

	1	2	3	4	5	6	7	8

4	‡	‡	·					
5	‡			‡				
6	‡			‡				
7	‡	‡	*		‡	‡		
8	‡	*	*	‡		*	‡	

Table 3: Significant differences of lines 1–8 in Table 2; ‡: p=0.01, *: p=0.05, ·: p=0.1

The first approach is to use a statistical classification model as the sense disambiguation structure. We use liblinear (Fan et al., 2008) with standard parameters for classification based on three different feature types: ngrams, embeddings (embed) and PCDs. Ngram features are all n-grams for $n \in \{1, 2, 3\}$. As embedding features we use (i) the mean of the input space (R) embeddings and (ii) the mean of the target space (Q) embeddings of the words in the context (see Blacoe and Lapata (2012) for justification of using simple mean). As PCD features we use the PCD predicted by vLBL for the sentiment word of interest, in our case "hard".

We split the set of 4600 contexts introduced in Section 3 into a training set of 4000 and a development set of 600.

Table 2 (lines 1–8) shows the classification results on the development set for all feature type combinations. Significant differences between results – computed using the approximate randomization test (Padó, 2006) – are given in Table 3. The majority baseline (bl), which assigns a negative label to all examples, reaches $F_1 = .76$. The classifier is significantly better than the baseline for all feature combinations with F_1 ranging from .89 to .94. We obtain the best classification result (.94) when all three feature types are combined (significantly better than all other feature combinations except for 5).

Manually labeling all occurrences of a word is expensive. As an alternative we investigate *clustering of the contexts of the word of interest*. Therefore, we represent each of the 4000 contexts of "hard" in the training set as its PCD[2], use

[2]To transform vectors into a format that is more appropriate for the underlying Gaussian model of kmeans, we take the square root of each probability in the PCD vectors.

kmeans clustering with $k = 100$ and then label each cluster. This decreases the cost of labeling by an order of magnitude since only 100 clusters have to be labeled instead of 4000 training set contexts.

Table 2 (lines 9–15) shows results for this semisupervised approach to classification, using the same classifier and the same feature types, but the cluster-based labels instead of manual labels.

For most feature combinations, F_1 drops compared to fully supervised classification. The best performing model for supervised classification (ngram+PCD+embed) loses 5%.

This is not a large drop considering the savings in manual labeling effort. All results are significantly better than the baseline. There are no significant differences between the different feature sets (lines 9–15) with the exception of embed, which is significantly worse than the other 6 sets.

The centroids of the 100 clusters can serve as an alternative sense disambiguation structure for the lexicon entry of "hard" in CESL.[3] Each sense s is associated with the centroids of the clusters whose majority sense is s.

As final experiment (lines 16–18 in Table 2), we evaluate performance for the baseline and for PCD+ngram+embed – the best feature set – on the test set. On the test set, baseline performance is .80 (.04 higher than .76 on line 1, Table 2); F_1 of PCD+ngram+embed is .92 (.02 less than development set) for supervised classification and is .88 (.01 less) for semisupervised classification (comparing to lines 8 and 15 in Table 2). Both results (.92 and .88) are significantly higher than the baseline (.80).

6 Conclusion

The sentiment of a sentence or document is the output of a causal chain that involves complex linguistic processes like contextual modification and negation. Our hypothesis in this paper was that for high-accuracy sentiment analysis, we need to model the root causes of this causal chain: the meanings of individual words. This is in contrast to other work in sentiment analysis that conflates different linguistic phenomena (word sense ambiguity, contextual effects, negation) and attempts to address all of them with a single model.

For sense disambiguation, the first step in the causal chain of generating sentiment, we proposed CESL, a contextually enhanced sentiment lexicon that for each word w holds the inventory of senses of w, polarity annotations of these senses and a data structure for assigning contexts of w to the senses. We introduced new features for sentiment analysis to be able to perform the fine-grained modeling of context needed for CESL. In a case study for the word "hard", we showed that high accuracy in sentiment disambiguation can be achieved using our approach. In future work, we would like to show that our findings generalize from the case of "hard" to the entire sentiment lexicon.

Abstracts

Identifying parallel web pages from bilingual web sites is a crucial step of bilingual resource construction for cross-lingual information processing. In this paper, we propose a link-based approach to distinguish parallel web pages from bilingual web sites. Compared with the existing methods, which only employ the internal translation similarity (such as content-based similarity and page structural similarity), we hypothesize that the external translation similarity is an effective feature to identify parallel web pages. Within a bilingual web site, web pages are interconnected by hyperlinks. The basic idea of our method is that the translation similarity of two pages can be inferred from their neighbor pages, which can be adopted as an important source of external similarity. Thus, the translation similarity of page pairs will influence each other. An iterative algorithm is developed to estimate the external translation similarity and the final translation similarity. Both internal and external similarity measures are combined in the iterative algorithm. Experiments on six bilingual websites demonstrate that our method is effective and obtains significant improvement (6.2% F-Score) over the baseline which only utilizes internal translation similarity.

1 Introduction

Parallel corpora have played an important role in multilingual Natural Language Processing, especially in Machine Translation (MT) and Cross-lingual Information Retrieval(CLIR). However, it's time-consuming to build parallel corpora manually. Some existing parallel corpora are subject to subscription or license fee and thus not freely available, while others are domain-specific. Therefore, a lot of previous research has focused on automatically mining parallel corpora from the web.

In the past decade, there have been extensive studies on parallel resource extraction from the web (e.g., Chen and Nie, 2000; Resnik 2003; Jiang et al., 2009) and many effective Web mining systems have been developed such as STRAND, PTMiner, BITS and WPDE. For most of these mining systems, there is a typical parallel resource mining strategy which involves three steps: (1) locate the bilingual websites (2) identify parallel web pages from these bilingual websites and (3) extract bilingual resources from the parallel web pages.

In this paper, we focus on the step (2) which is regarded as the core of the mining system (Chunyu, 2007). Estimating the translation similarity of two pages is the most basic and key problem in this step. Previous approaches have tried to tackle this problem by using the information within the pages. For example, in the STRAND and PTMiner system, a structural filtering process that relies on the analysis of the underlying HTML structure of pages is used to determine a set of pair-specific structural values, and then the values are used to decide whether the pages are translations of one another. The BITS system filters out bad pairs by using a large bilingual dictionary to compute a content-based similarity score and comparing the score with a threshold. The WPDE system combines URL similarity, structure similarity with content-based similarity to discover and verify candidate parallel page pairs. Some other features or rules such as page size ratio, predefined hypertexts which link to different language versions of a web page are also used in most of these systems. Here, all of the mining systems are simply using the information within the page in the process of find-

ing parallel web pages. In this paper, we attempt to explore other information to identify parallel web pages.

On the Internet, most web pages are linked by hyperlinks. We argue that the translation similarity of two pages depends on not only their internal information but also their neighbors. The neighbors of a web page are a set of pages, which link to the page. We find that the similarity of neighbors can provide more reliable evidence in estimating the translation similarity of two pages.

The main issues are discussed in this paper as follows:

- *Can the neighbors of candidate page pairs really contribute to estimating the translation similarity?*
- *How to estimate the translation similarity of candidate page pairs by using their neighbors?*

Our method has the following advantages:

High performance

The external and internal information is combined to verify parallel page pairs in our method, while in previous mining systems, only internal information was used. Experimental results show that compared with existing parallel page pair identification technologies, our method obtains both higher precision and recall (6.2% and 6.3% improvement than the baseline, respectively). In addition, the external information used in our method is a more effective feature than internal features alone such as structural similarity and content-based similarity.

Language independent

In principle, our method is language independent and can be easily ported to new language pairs, except for the language-specific bilingual lexicons. Our method takes full advantage of the link information that is language-independent. For the bilingual lexicons in our experiments, compared to previous methods, our method does not need a big bilingual lexicon, which is good news to less-resource language pairs.

Unsupervised and fewer parameters

In previous work, some parameters need to be optimized. Due to the diversity of web page styles, it is not trivial to obtain the best parameters. Some previous researches(Resnik, 2003; Zhang et al., 2006) attempt to optimize parameters by employing machine learning method. In contrast, in our method, only two parameters need to be estimated. One parameter remains stable for different style websites. Another parameter can be easily adjusted to achieve the best performance. Therefore, our method can be used in other websites with different styles, without much effort to optimize these parameters.

2 Related Work

A large amount of literature has been published on parallel resource mining from the web. According to the existing form of the parallel resource on the Internet, related work can be categorized as follows:

Mining from bilingual websites

Most existing web mining systems aimed at mining bilingual resource from the bilingual websites, such as PTMiner (Nie et al., 1999), STRAND (Resnik and Smith, 2003), BITS (Ma and Liberman, 1999), PTI (Chen et al., 2004). PTMiner uses search engines to pinpoint the candidate sites that are likely to contain parallel pages, and then uses the collected URLs as seeds to further crawl each web site for more URLs. Web page pairs are extracted based on manually defined URL pattern matching, and further filtered according to several criteria. STRAND uses a search engine to search for multilingual websites and generated candidate page pairs based on manually created substitution rules. Then, it filters some candidate pairs by analyzing the HTML pages. PTI crawls the web to fetch (potentially parallel) candidate multilingual web documents by using a web spider. To determine the parallelism between potential document pairs, a filename comparison module is used to check filename resemblance, and a content analysis module is used to measure the semantic similarity. BITS was the first to obtain bilingual websites by employing a language identification module, and then for each bilingual website, it extracts parallel pages based on their content.

Mining from bilingual web pages

Parallel/bilingual resources may exist not only in two parallel monolingual web pages, but also in single bilingual web pages. Jiang et al. (2009) used an adaptive pattern-based method to mine interesting bilingual data based on the observation that bilingual data usually appears collectively following similar patterns. They found that bilingual web pages are a promising source of up-to-date bilingual terms/sentences which cover many domains and application scenarios. In addition, Feng et al. (2010) proposed a new method

to automatically acquire bilingual web pages from the result pages of a search engine.

Mining from comparable corpus

Several attempts have been made to extract parallel resources from comparable corpora. Zhao et al. (2002) proposed a robust, adaptive approach for mining parallel sentences from a bilingual comparable news collection. In their method, sentence length models and lexicon-based models were combined under a maximum likelihood criterion. Smith et al. (2010) found that Wikipedia contains a lot of comparable documents, and adopted a ranking model to select parallel sentence pairs from comparable documents. Bharadwaj et al. (2011) used a SVM classifier with some new features to identify parallel sentences from Wikipedia.

3 Iterative Link-based Parallel Web Pages Mining

As mentioned, the basic idea of our method is that the similarity of two pages can be inferred from their neighbors. This idea is illustrated in Figure 1.

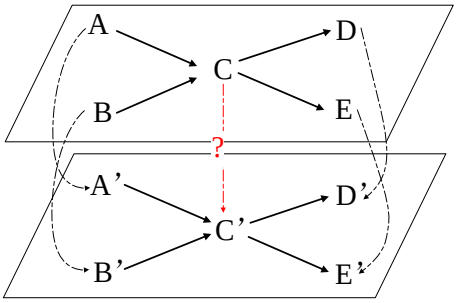

Figure 1 Illustration of the link-based method

In Figure 1, *A*, *B*, *C*, *D* and *E* are some pages in the same language; while *A'*, *B'*, *C'*, *D'* and *E'* are some pages in another language. The solid black arrows indicate the links between these pages. For example, page *A* points to *C*, page *B'* points to *C'* and so on. Then the page set {*A*, *B*, *D*, *E*} is called the neighbors of page *C*. Similarly, the page set {*A'*, *B'*, *D'*, *E'*} contains the neighbors of page *C'*. If the page pairs : <*A*, *A'*>, <*B*, *B'*>, <*D*, *D'*> and <*E*, *E'*> have high translation similarities, then it can be inferred that page *C* and *C'* have a high probability to be a pair of parallel pages. Every page has its own neighbors. For each web page, our method views link-in and link-out hyperlinks as the same. Thus, the linked pages will influence each other in estimating the translation similarity. For example, the similarities of two pairs <*A*, *A'*> and <*C*, *C'*> will influence each other. It is an iterative process. We will elaborate the process in the following sections.

Since our goal is to find parallel pages in a specific website, the key task is to evaluate the translation similarity of two pages (which are in different languages) as accurately as possible. The final similarity of two pages should depend both on their internal similarity and external similarity. The internal similarity means the similarity estimated by using the information in the page itself, such as the structure similarity and the content-based similarity of the two pages. On the other hand, the external similarity of two pages is the similarity depending on their neighbors. The final translation similarity is called the **Enhanced Translation Similarity** (*ETS*). The *ETS* of two pages can be calculated as follows:

$$ETS(e,c) = \alpha \cdot S_{ext}(e,c) + (1-\alpha) \cdot S_{in}(e,c), \alpha \in [0,1] \quad (1)$$

Where, $S_{in}(e,c)$ is the internal translation similarity of two pages: e and c; $S_{ext}(e,c)$ represents the external translation similarity of pages e and c. $ETS(e,c)$ indicates the final similarity of two pages, which combines the internal with external translation similarity.

In this paper, we conduct the experiments on English-Chinese parallel page pair mining. However, our method is language-independent. Thus, it can be applied to other language pairs by only replacing a bilingual lexicon. The symbol e and c always indicate an English page and a Chinese page respectively in this paper. In the following sections, we will describe how to calculate the $S_{in}(e,c)$ and $S_{ext}(e,c)$ step by step.

3.1 Preprocessing

The input of our method is a bilingual website. This paper aims to find English/Chinese parallel pages. So a 3-gram language model is used to identify (or classify) the language of a certain document. The performance of the language identification module achieves 99.5% accuracy through in-house testing. As a result, a set of English pages and a set of Chinese pages are obtained. In order to get the neighbors of a page, for each bilingual website, two networks are constructed based on the hyperlinks, one for English pages and another for Chinese pages.

3.2 The Internal Translation Similarity

Following Resnik and Smith (2003), three features are used to evaluate the internal translation similarity of two pages:

The size ratio of two pages

The length ratio of two documents is the simplest criterion for determining whether two documents are parallel or not. Parallel documents tend to be similar in length. And it is reasonable to assume that for text *E* in one language and text *F* in another language, length(*E*) ≈ *C*•length(*F*), where *C* is a constant that depends on the language pair. Here, the content length of a web page is regarded as its length.

The structure similarity of two pages

The HTML tags describe and control a web page's structure. Therefore, the structure similarity of two pages can be calculated by their HTML tags. Here, the HTML tags of each page are extracted (except the visual tags such as "B", "FONT".) as a linear sequence. Then the structure similarity of two pages is computed by comparing their linearized sequences. In this paper, the LCS algorithm (Dan, 1997) is adopted to find the longest common sequences of the two HTML tag sequences. The ratio of LCS length and the average length of two HTML tag sequences are used as the structure similarity of the two pages.

The content-based translation similarity of two pages

The basic idea is that if two documents are parallel, they will contain word pairs that are mutual translations (Ma, 1999). So the percentage of translation word pairs in the two pages can be considered as the content-based similarity. The translation words of two documents can be extracted by using a bilingual lexicon. Here, for each word in English document, we will try to find a corresponding word in Chinese document.

Finally, the internal translation similarity of two pages is calculated as follows:

$$S_{in}(e,c) = \beta \cdot S_{cb}(e,c) + (1-\beta) \cdot S_{struct}(e,c), \beta \in [0,1] \quad (2)$$

Where, $S_{cb}(e,c)$ and $S_{struct}(e,c)$ are the content-based and structural similarity of page e and c respectively. In addition, the size ratio of two pages is used to filter invalid page pairs.

3.3 The External and Enhanced Translation Similarity

As described above, the external translation similarity of two pages depends on their neighbors:

$$S_{ext}(e,c) = Sim\big(PG(e), PG(c)\big) \quad (3)$$

Where, *PG(x)*, a set of pages, is the neighbors of page *x*. Obviously, the similarity of two sets relies on the similarity of the elements in the two sets. Here, the elements are namely web pages. So, $S_{ext}(e,c)$ equals to $Sim\big(PG(e), PG(c)\big)$, and $Sim\big(PG(e), PG(c)\big)$ depends on $ETS\big(e_i, c_j\big)$ (e_i, c_j belongs to $PG(e)$, $PG(c)$, respectively) and $ETS(e,c)$. According to Equation (1), $ETS(e,c)$ depends on $S_{in}(e,c)$ and $S_{ext}(e,c)$. Therefore, it is a process of iteration. $ETS(e,c)$ will converge after a certain number of iterations. Thus, $ETS^i(e,c)$ is defined as the enhanced similarity of page *e* and *c* after the *i*-th iteration, and the same is for $S^i_{ext}(e,c)$ and $Sim^i\big(PG(e), PG(c)\big)$. $Sim^i\big(PG(e), PG(c)\big)$ is computed by the following algorithm:

Algorithm 1: Estimating the external translation similarity

Input: $PG(e), PG(c)$
Output: $S^i_{ext}(e,c)$

Procedure:

$sum \leftarrow 0$
$e\_set \leftarrow PG(e)$
$c\_set \leftarrow PG(c)$
While e_set and c_set are both not empty:
  $< x, y >$
  $\leftarrow arg\,max_{x \in e\_set,\ y \in c\_set}\ (ETS^{i-1}(x,y))$
  $sum \leftarrow sum +$ $\mathrm{ETS}^{i-1}(x,y)$
  Remove x from e_set
  Remove y from c_set
$S^i_{ext}(e,c) = Sim^i\big(p(e), p(c)\big)$
$= 2 \cdot sum \,/\, (|PG(e)| + |PG(c)|)$

Algorithm 2 Estimating the enhanced translation similarity

Input: P_e, P_c, (*the English and Chinese page set*)
Output: ETS(e, c), $e \in P_e, c \in P_c$
Initialization: Set *ETS*(*e*, *c*) random value or small value

Procedure:

LOOP:
  For each e in P_e :
    For each c in P_c:
      $ETS^i(e,c) = \alpha \cdot S^i_{ext}(e,c) + (1-\alpha) \cdot S_{in}(e,c)$
  Parameters normalization
UNTIL $ETS(e,c)$ is stable

Algorithm 1 tries to find the real parallel pairs from $PG(e)$ and $PG(c)$. The similarity of $PG(e)$ and $PG(c)$ is calculated based on the similarity

values of these pairs. Finally, $ETS(e,c)$ is calculated by the following algorithm 2.

In Algorithm 2, the input P_e and P_c are English and Chinese page sets in a certain bilingual website. We use algorithm 2 to estimate the enhanced translation similarity.

3.4 Find the Parallel Page Pairs

At last, the enhanced translation similarity of every pair is obtained, and the parallel page pairs can be extracted in terms of these similarities:

Algorithm 3 Finding parallel page pairs

Input: P_e, P_c
$ETS(x,y),\ \ x \in P_e, y \in P_c$
MAX_P (or MIN_SIM)

Output: Parallel Page Pairs List : PPL

Procedure:

LOOP:
$< x,y > = \ arg\,max_{x \in P_e, y \in P_c}\,(ETS(x,y))$
Add $< x,y >$ to PPL
Remove x from P_e
Remove y from P_c
UNTIL size of PPL > MAX_P (or $ETS(x,y)$ < MIN_SIM)

This algorithm is similar to Algorithm 1 in each bilingual website. The input MAX_P is an integer threshold which means that only top MAX_P page pairs will be extracted in a certain website. It needs to be noted that MAX_P is always less than $|P_e|$ and $|P_c|$. While the input MIN_SIM is another kind of threshold that is used for extracting page pairs with high translation similarity.

4 Experiments and Analysis

4.1 Experimental setup

Our experiments focus on six bilingual websites. Most of them are selected from HK government websites. All the web pages were retrieved by using a web site download tool: HTTrack[1]. We notice that a small amount of pages doesn't always contain valuable contents. So, we put a threshold (100 bytes in our experiment) on the web pages' content to filter meaningless pages. In order to evaluate our method, the bilingual page pairs of each website are annotated by a human annotator. Finally, we got 23109 pages and 11684 bilingual page pairs in total for testing. The basic information of these websites is listed in Table 1.

It's time-consuming to annotate whether two pages is parallel or not. Note that if a website contains *N* English pages and *M* Chinese pages, an annotator has to label *N*M* page pairs. To the best of our knowledge, there is no large scale and public parallel page pair dataset with human annotation. So we try to build a reliable and large-scale dataset.

In our experiments, *URL* similarity is used to reduce the workload for annotation. For a certain website, firstly, we obtain its *URL* pattern between English and Chinese pages manually. For example, in the website "www.gov.hk", the *URL* pairs like:

http://www.gov.hk/en/about/govdirectory/ (English)

http://www.gov.hk/sc/about/govdirectory/ (Chinese)

The *URL* pairs always point to a pair of parallel pages. So <"/en/","/sc/"> is considered as a *URL* pattern that was used to find parallel pages. For the other *URLs* that can't match the pattern, we have to label them by hand. The column "No pattern pairs" in Table 1 shows that the number of parallel page pairs which mismatch any patterns.

Table 1 Number of pages and bilingual page pairs of each websites

Site ID	En/Ch pages	Total pairs	No pattern pairs	URL
S1	1101/1098	1092	20	www.gov.hk
S2	501/497	487	7	www.customs.gov.hk
S3	995/775	768	12	www.sbc.edu.sg
S4	4085/3838	3648	4	www.swd.gov.hk
S5	660/637	637	0	www.landsd.gov.hk
S6	4733/4626	4615	8	www.td.gov.hk
total	12075/11471	11684	51	

Each website listed in Table 1 has a *URL* pattern for most parallel web pages. Some previous researches used the *URL* similarity or patterns to find parallel page pairs. However, due to the diversity of web page styles and website maintenance mechanisms, bilingual websites adopt varied naming schemes for parallel documents (Shi, et al, 2006). The effect of *URL* pattern-based mining always depends on the style of website. In order to build a large dataset, the *URL* pattern is not used in our method. Our method is able to handle bilingual websites without *URL* pattern rules.

In addition, an English-Chinese dictionary with 64K words pairs is used in our experiments. Algorithm 3 needs a threshold MAX_P or

[1] http://www.httrack.com/

MIN_SIM. It is very hard to tune the MIN_SIM because it varies a lot in different websites and language pairs. However, Table 1 shows that the number of parallel pages is smaller than that of English and Chinese pages. Here, for each website, the MAX_P is set to the number of Chinese pages (which is always smaller than that of English pages). In this way, the precision will never reach 100%, but it is more practical in a real application. As a result, in some experiments, we only report the F-score, and the precision and recall can be calculated as follows:

$$Precision = \frac{F_{score} \cdot (N_{Pairs} + MAX\_P)}{2 \cdot MAX\_P} \quad (4)$$

$$Recall = \frac{F_{score} \cdot (N_{Pairs} + MAX\_P)}{2 \cdot N_{Pairs}} \quad (5)$$

Where, N_{Pairs} for each website is listed in the "Total pairs" column of Table 1.

4.2 Results and Analysis

Performance of the Baseline

Let's start by presenting the performance of a baseline method as follows. The baseline only employs the internal translation similarity for parallel web pages mining. Algorithm 3 is also used to get the page pairs in baseline system. Here, the input $ETS(x, y)$ is replaced by $S_{in}(x, y)$. The parameter β in Equation 2 is a discount factor. For different β values, the performance of baseline system on six websites is shown in Figure 2. In the Figure 2, it shows that when β is set to 0.6, the baseline system achieves the best performance. The precision, recall and F-score are 85.84%, 87.55% and 86.69% respectively. So in the following experiments, we always set β to 0.6.

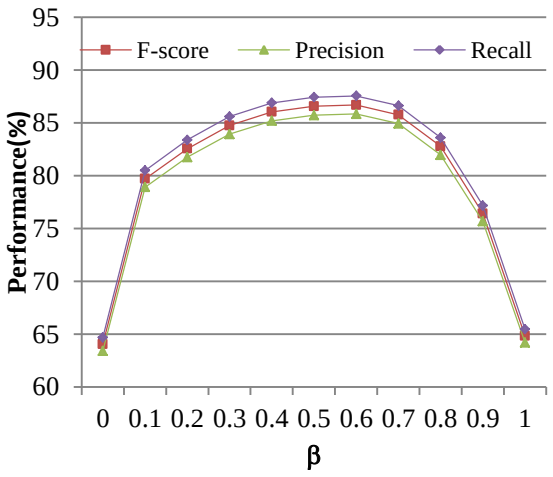

Figure 2 Performances of baseline system with different β value

Performance of Our Method

As described in Section 3, our method combines the internal with external translation similarity in estimating the final translation similarity (i.e., ETS) of two pages. So, the discount factor α in Equation (1) is important in our method. Besides, as shown in Algorithm 2, the iterative algorithm is used to calculate the similarity. Then, one question is that how many iterations are required in our algorithm. Figure 3 shows the performance of our method on each website. Its horizontal axis represents the number of iterations and the vertical axis represents the F-score. And for each website, the F-scores with different α (range from 0.2 to 0.8) are also reported in this figure. From Figure 3, it is very easy to find that the best iteration number is 3. For almost all the websites, the performance of our method achieves the maximal values and converges after the third iteration. In addition, Figure 3 also indicates that our method is robust for different websites. In the following experiments, the iteration number is set to 3.

Next, let's turn to the discount factor α. Figure 4 reports the experimental results on the whole dataset. Here, the horizontal axis represents the discount factor α and the vertical axis represents the F-score. $\alpha = 0$ means that only the internal similarity is used in the algorithm, so the F-score equals to that in Figure 2 when $\beta = 0.6$. On the contrary, $\alpha = 1$ means that only the external similarity is used in the method, and the F-score is 80.20%. The performance is lower than the baseline system when only the external link information is used, but it is much better than the performance of the content-based method and structure-based method whose F-scores are 64.82% and 64.0% respectively. Besides, it is shown from Figure 4, the performance is improved significantly when the internal and external similarity measures are combined together. Furthermore, it is somewhat surprising that the discount factor α is not important as we previously expected. In fact, if we discard the cases that α equals to 0 or 1, the difference between the maximum and minimum F-score will be 0.76% which is very small. This finding indicates that the internal and external similarity can easily be combined and we don't need to make many efforts to tune this parameter when our method is applied to other websites. The reason of this phenomenon is that, no matter how much weight (i.e., 1- α) was assigned to the internal similarity, the internal similarity always provides a relatively good initial

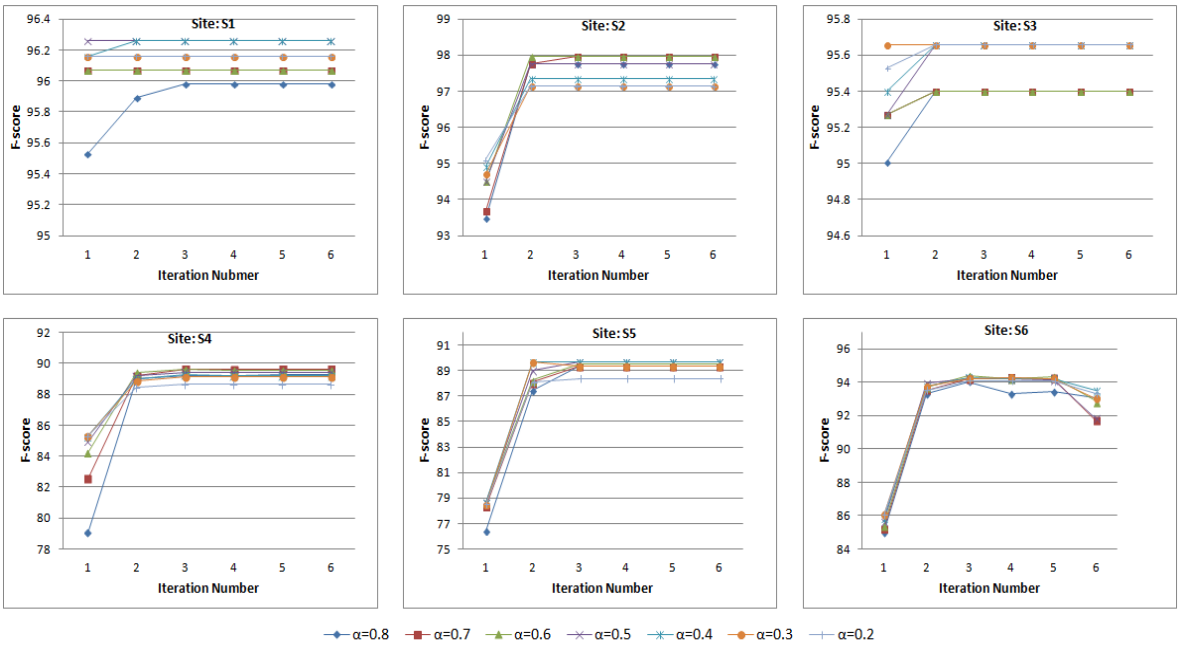

Figure 3 Experiment results of our method on each website

iterative direction. In the following experiments, the parameter α is set to 0.6.

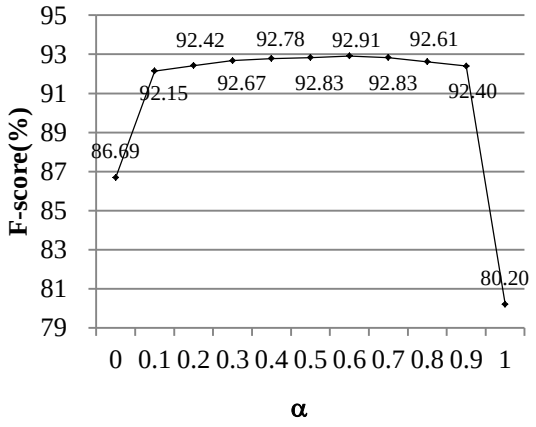

Figure 4 The F-scores of our method with different the value of α

The weight of pages

The weight of the neighbor pages should also be considered. For example, in the most websites, it is very common that most of the web pages contain a hyperlink which points to the homepage of the website. While in most of the English/Chinese websites, almost every English page will link to the English homepage and each Chinese page will point to Chinese homepage. The English and Chinese homepages are probably parallel, but they will be helpless to find parallel web pages, because they are neighbors of almost every page in the site. On the contrary, sometimes the parallel homepages have negative effects on finding parallel pages They will increase the translation similarity of two pages which are not indeed mutual translations. So it is necessary to amend the Algorithm 1.

The weight of each page is calculated according to its popularity:

$$w(p) = log\frac{N+c}{Freq(p)+c} \quad (6)$$

where $w(p)$ indicates the weight of page p, N is the number of all pages, $Freq(p)$ is the number of pages pointing to page p and c is a constant for smoothing.

In this paper, the weights of pages are used in two ways:

Weight 1: The 9th line of Algorithm 1 is amended by the page weight as follows:

$sum \leftarrow sum + ETS^{i-1}(x,y) \cdot (w(x)+w(y))/2$

Weight 2: The pages with low weight are removed from the input of Algorithm 1.

The experiment results are shown in Table 2.

Table 2 The effect of page weight

Type	No Weight	Weight 1	Weight 2
F-score (%)	92.91	92.78	92.75

Surprisingly, no big differences are found after the introduction of the page weight. The side effect of popular pages is not so large in our method. In the neighbor pages of a certain page, the popular pages are the minority. Besides, the iterative process makes our method more stable and robust.

The impact of the size of bilingual lexicon

The baseline system mainly combines the content-based similarity with structure similarity.

And two kinds of similarity measures are also used in our method. As Ma and Liberman (1999) pointed out, not all translators create translated pages that look like the original page which means that the structure similarity does not always work well. Compared to the structure similarity, the content-based is more reliable and has wider applicability. Furthermore, the bilingual lexicon is the only information that relates to the language pairs, and other features (such as structure and link information) are all language independent. So, it's important to investigate the effect of lexicon size in our method. We test the performance of our method with different size of the bilingual dictionary. The experiment results are shown in Figure 5. In this figure, the horizontal axis represents the bilingual lexicon size and the vertical axis represents the F-score. With the decline of the lexicon size, the performances of both the baseline method and our method are decreased. However, we can find that the descent rate of our method is smaller than that of the baseline. It indicates that our method does not need a big bilingual lexicon which is good news for the low-resource language pairs.

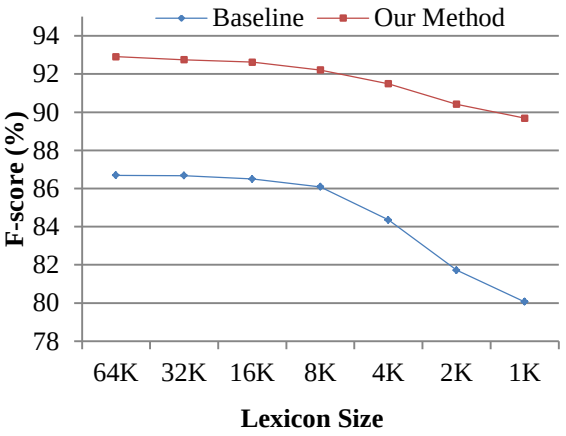

Figure 5 The impact of the size of bilingual lexicon

Error analysis

Errors occur when the two pages are similar in terms of structure, content and their neighbors. For example, Figure 6 illustrates a typical web page structure. There are 5 parts in the web page: U, L, M, R and B. Part M always contains the main content of this page. While part U, L, R and B always contain some hyperlinks such as "home" in part U and "About us" in part B. Links in L and R sometimes relate to the content of the page. For such a kind of non-parallel page pairs, let's assume that the two pages have the same structure (as shown in Figure 6). In addition, their content part M is very short and contains the same or related topics. As a result, the links in other 4 parts are likely to be similar. In this case, our method is likely to regard the two pages as parallel.

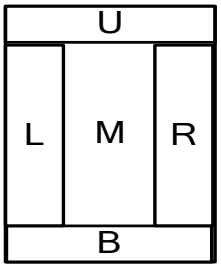

Figure 6 A typical web page structure

There are about 920 errors when our system obtains its best performance. By carefully investigating the error page pairs, we find that more than 90% errors fall into the category discussed above. The websites used in our experiments mainly come from Hong Kong government websites. Some government departments regularly publish quarterly or monthly work reports on one issue through their websites. These reports look very similar except the publish date and some data in them. The other 10% errors happen because of the particularity of the web pages, e.g. very short pages, broken pages and so on.

5 Conclusions and Future Work

Parallel corpora are valuable resources for a lot of NLP research problems and applications, such as MT and CLIR. This paper introduces an efficient and effective solution to bilingual language processing. We first explore how to extract parallel page pairs in bilingual websites with link information between web pages. Firstly, we hypothesize that the translation similarity of pages should be based on both internal and external translation similarity. Secondly, a novel iterative method is proposed to verify parallel page pairs. Experimental results show that our method is much more effective than the baseline system with 6.2% improvement on F-Score. Furthermore, our method has some significant contributions. For example, compared to previous work, our method does not depend on bilingual lexicons, and the parameters in our method have little effect on the final performance. These features improve the applicability of our method.

In the future work, we will study some method on extracting parallel resource from existing parallel page pairs, which are challenging tasks due to the diversity of page structures and styles. Besides, we will evaluate the effectiveness of our mined data on MT or other applications.

Abstract

Analyses of computer aided translation typically focus on either frontend interfaces and human effort, or backend translation and machine learnability of corrections. However, this distinction is artificial in practice since the frontend and backend must work in concert. We present the first holistic, quantitative evaluation of these issues by contrasting two assistive modes: post-editing and interactive machine translation (MT). We describe a new translator interface, extensive modifications to a phrase-based MT system, and a novel objective function for re-tuning to human corrections. Evaluation with professional bilingual translators shows that post-edit is faster than interactive at the cost of translation quality for French-English and English-German. However, re-tuning the MT system to interactive output leads to larger, statistically significant reductions in HTER versus re-tuning to post-edit. Analysis shows that tuning directly to HTER results in fine-grained corrections to subsequent machine output.

1 Introduction

The goal of machine translation has always been to reduce human effort, whether by partial assistance or by outright replacement. However, preoccupation with the latter—fully automatic translation—at the exclusion of the former has been a feature of the research community since its first nascent steps in the 1950s. Pessimistic about progress during that decade and future prospects, Bar-Hillel (1960, p.3) argued that more attention should be paid to a "machine-post-editor partnership," whose decisive problem is "the region of optimality in the continuum of possible divisions of labor." Today, with human-quality, fully automatic machine translation (MT) elusive still, that decades-old recommendation remains current.

This paper is the first to look at both sides of the partnership in a single user study. We compare two common flavors of machine-assisted translation: post-editing and interactive MT. We analyze professional, bilingual translators working in both modes, looking first at user productivity. Does the additional machine assistance available in the interactive mode affect translation time and/or quality?

Then we turn to the machine side of the partnership. The user study results in corrections to the baseline MT output. Do these corrections help the MT system, and can it learn from them quickly enough to help the user? We perform a re-tuning experiment in which we directly optimize human Translation Edit Rate (HTER), which correlates highly with human judgments of fluency and adequacy (Snover et al., 2006). It is also an intuitive measure of human effort, making fine distinctions between 0 (no editing) and 1 (complete rewrite).

We designed a new user interface (UI) for the experiment. The interface places demands on the MT backend—not the other way around. The most significant new MT system features are *prefix decoding*, for translation completion based on a user prefix; and *dynamic phrase table augmentation*, to handle target out-of-vocabulary (OOV) words. Discriminative re-tuning is accomplished with a novel cross-entropy objective function.

We report three main findings: (1) post-editing is faster than interactive MT, corroborating Koehn (2009a); (2) interactive MT yields higher quality translation when baseline MT quality is high; and (3) re-tuning to interactive feedback leads to larger held-out HTER gains relative to post-edit. Together these results show that a human-centered approach to computer aided translation (CAT) may involve tradeoffs between human effort and machine learnability. For example, if speed is the top priority, then a design geared toward post-editing

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1225–1236,

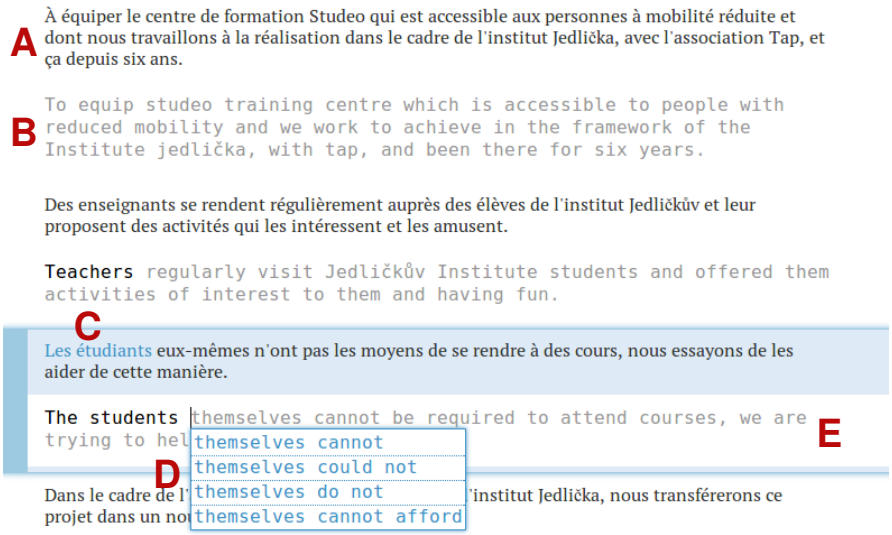

Figure 1: Main translation interface. The user sees the full document context, with French source inputs (A) interleaved with suggested English translations (B). The sentence in focus is indicated by the blue rectangle, which can be moved via two hot keys. Source coverage (C) of the user prefix—shaded in blue—updates as the user works, as do autocomplete suggestions (D) and a full completion (E).

is appropriate. However, if reductions in HTER ultimately correspond to lower human effort, then investing slightly more time in the interactive mode, which results in more learnable output, may be optimal. Mixed UI designs may offer a compromise. Code and data from our experiments are available at: `http://nlp.stanford.edu/software/phrasal/`

A holistic comparison with human subjects necessarily involves many moving parts. Section 2 briefly describes the interface, focusing on NLP components. Section 3 describes changes to the backend MT system. Section 4 explains the user study, and reports human translation time and quality results. Section 5 describes the MT re-tuning experiment. Analysis (section 6) and related work (section 7) round out the paper.

2 New Translator User Interface

Figure 1 shows the translator interface, which is designed for expert, bilingual translators. Previous studies have shown that expert translators work and type quickly (Carl, 2010), so the interface is designed to be very responsive, and to be primarily operated by the keyboard. Most aids can be accessed via either typing or four hot keys. The current design focuses on the point of text entry and does not include conventional translator workbench features such as workflow management, spell checking, and text formatting tools.

In the trivial post-edit mode, the interactive aids are disabled and a 1-best translation pre-populates the text entry box.

We have described the HCI-specific motivations for and contributions of this new interface in Green et al. (2014c). This section focuses on interface elements built on NLP components.

2.1 UI Overview and Walkthrough

We categorized interactions into three groups: **source comprehension**: word lookups, *source coverage highlighting*; **target gisting**: 1-best translation, *real-time target completion*; **target generation**: real-time autocomplete, *target reordering*, insert complete translation. The interaction designs are novel; those in *italic* have, to our knowledge, never appeared in a translation workbench.

Source word lookup When the user hovers over a source word, a menu of up to four ranked translation suggestions appears (Figure 2). The menu is populated by a phrase-table query of the word plus one token of left context. This query usually returns in under 50ms. The width of the horizontal bars indicates confidence, with the most confident suggestion 'regularly' placed at the bottom, nearest to the cursor. The user can insert a translation suggestion by clicking.

Source coverage highlighting The source coverage feature (Figure 1C) helps the user quickly find untranslated words in the source. The interaction is

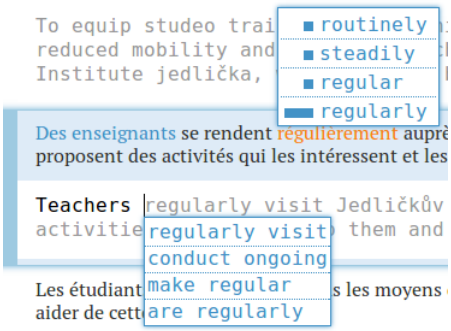

Figure 2: Source word lookup and target autocomplete menus. The menus show different suggestions. The word lookup menu (top) is not dependent on the target context *Teachers*, whereas the autocomplete dropdown (bottom) is.

based on the word alignments between source and target generated by the MT system. We found that the raw alignments are too noisy to show users, so the UI filters them with phrase-level heuristics.

1-best translation The most common use of MT output is *gisting* (Koehn, 2010, p.21). The gray text below each black source input shows the best MT system output (Figure 1B).

Real-time target completion When the user extends the black prefix, the gray text will update to the most probable completion (Figure 1E). This update comes from decoding under the full translation model. All previous systems performed inference in a word lattice.

Real-time autocomplete The autocomplete dropdown at the point of text entry is the main translation aid (Figures 1D and 2). Each real-time update actually contains a distinct 10-best list for the full source input. The UI builds up a trie from these 10-best lists. Up to four distinct suggestions are then shown at the point of translation. The suggestion length is based on a syntactic parse of the fixed source input. As an offline, pre-processing step, we parse each source input with Stanford CoreNLP (Manning et al., 2014). The UI combines those parses with word alignments from the full translation suggestions to project syntactic constituents to each item on the n-best list. Syntactic projection is a very old idea that underlies many MT systems (see: Hwa et al. (2002)). Here we make novel use of it for suggestion prediction filtering.[1] Presently, we project noun phrases, verb phrases (minus the verbal arguments), and prepositional phrases. Crucially, these units are natural to humans, unlike statistical target phrases.

Target Reordering Carl (2010) showed that expert translators tend to adopt *local planning*: they read a few words ahead and then translate in a roughly online fashion. However, word order differences between languages will necessarily require longer range planning and movement. To that end, the UI supports keyboard-based reordering. Suppose that the user wants to move a span in gray text to the insertion position for editing. Typing the prefix of this string will update the autocomplete dropdown with matching strings from the gray text. Consequently, sometimes the autocomplete dropdown will contain suggestions from several positions in the full suggested translation.

Insert complete translation The user can insert the full completion via a hot key. Notice that if the user presses this hot key immediately, all gray text becomes black, and the interface effectively switches to post-edit mode. This feature greatly accelerates translation when the MT is mostly correct, and the user only wants to make a few changes.

2.2 User Activity Logging

A web application serves the Javascript-based interface, relays translation requests to the MT system, and logs user records to a database. Each user record is a tuple of the form $(f, \hat{e}, h, u)$, where f is the source sequence, $\hat{e}$ is the latest 1-best machine translation of f, h is the correction of $\hat{e}$, and u is the log of interaction events during the translation session. Our evaluation corpora also include independently generated references e for each f.

3 Interactive MT Backend

Now we describe modifications to Phrasal (Green et al., 2014b), the phrase-based MT system that supports the interface. Phrasal follows the log-linear approach to phrase-based translation (Och and Ney, 2004) in which the decision rule has the familiar linear form

$$\hat{e} = \arg\max_{e} w^{\top} \phi(e, f) \quad (1)$$

[1]The classic TransType system included a probabilistic prediction length component (Foster et al., 2002), but we find that the simpler projection technique works well in practice.

where $w \in \mathbb{R}^d$ is the model weight vector and $\phi(\cdot) \in \mathbb{R}^d$ is a feature map.

3.1 Decoding

The default Phrasal search algorithm is cube pruning (Huang and Chiang, 2007). In the post-edit condition, search is executed as usual for each source input, and the 1-best output is inserted into the target textbox. However, in interactive mode, the full search algorithm is executed *each time* the user modifies the partial translation. Machine suggestions $\hat{e}$ must match user prefix h. Define indicator function $\text{pref}(\hat{e}, h)$ to return true if $\hat{e}$ begins with h, and false otherwise. Eq. 1 becomes:

$$\hat{e} = \underset{e \text{ s.t. } \text{pref}(e,h)}{\arg\max} \; w^\top \phi(e, f) \qquad (2)$$

Cube pruning can be straightforwardly modified to satisfy this constraint by simple string matching of candidate translations. Also, the pop limit must be suspended until at least one legal candidate appears on each beam, or the priority queue of candidates is exhausted. We call this technique *prefix decoding*.[2]

There is another problem. Human translators are likely to insert unknown target words, including new vocabulary, misspellings, and typographical errors. They might also reorder source text so as to violate the phrase-based distortion limit. To solve these problems, we perform *dynamic phrase table augmentation*, adding new synthetic rules specific to each search. Rules allowing any source word to align with any unseen or ungeneratable (due to the distortion limit) target word are created.[3] These synthetic rules are given rule scores lower than any other rules in the set of queried rules for that source input f. Then candidates are allowed to compete on the beam. Candidates with spurious alignments will likely be pruned in favor of those that only turn to synthetic rules as a last resort.

3.2 Tuning

We choose BLEU (Papineni et al., 2002) for baseline tuning to independent references, and HTER for re-tuning to human corrections. Our rationale is as follows: Cer et al. (2010) showed that BLEU-tuned systems score well across automatic metrics and also correlate with human judgment better than systems tuned to other metrics. Conversely, systems tuned to edit-distance-based metrics like TER tend to produce short translations that are heavily penalized by other metrics.

When human corrections become available, we switch to HTER, which correlates with human judgment and is an interpretable measure of editing effort. Whereas TER is computed as $\text{TER}(e, \hat{e})$, HTER is $\text{HTER}(h, \hat{e})$. HBLEU is an alternative, but since BLEU is invariant to some permutations (Callison-Burch et al., 2006), it is less interpretable. We find that it also does not work as well in practice.

We previously proposed a fast, online tuning algorithm (Green et al., 2013b) based on AdaGrad (Duchi et al., 2011). The default loss function is expected error (EE) (Och, 2003; Cherry and Foster, 2012). Expected BLEU is an example of EE, which we found to be unstable when switching metrics. This may result from direct incorporation of the error metric into the gradient computation.

To solve this problem, we propose a *cross-entropy loss* which, to our knowledge, is new in MT. Let $\hat{E} = \{\hat{e}_i\}_{i=1}^n$ be an n-best list ranked by a gold metric $G(e, \hat{e}) \geq 0$. Assume we have a preference of a higher G (e.g., BLEU or $1-$HTER). Define the model distribution over $\hat{E}$ as $q(\hat{e}|f) \propto \exp[w^\top \phi(\hat{e}, f)]$ normalized so that $\sum_{\hat{e} \in \hat{E}} q(\hat{e}|f) = 1$; q indicates how much the model prefers each translation. Similarly, define $p(\hat{e}|f)$ based on any function of the gold metric so that $\sum_{\hat{e} \in \hat{E}} p(\hat{e}|f) = 1$; p indicates how much the metric prefers each translation. We choose a DCG-style[4] parameterization that skews the p distribution toward higher-ranked items on the n-best list: $p(\hat{e}_i|f) \propto G(e, \hat{e}_i)/\log(1+i)$ for the ith ranked item. The cross-entropy (CE) loss function is:

$$\ell_{\text{CE}}(w; E) = \mathbb{E}_{p(\hat{e}|f)}[-\log(q(\hat{e}|f)] \qquad (3)$$

It turns out that if p is simply the posterior distribution of the metric, then this loss is related to the log of the standard EE loss:[5]

$$\ell_{\text{EE}}(w; E) = -\log[\mathbb{E}_{p(\hat{e}|f)}[q(\hat{e}|f)]] \qquad (4)$$

We can show that $\ell_{\text{CE}} \geq \ell_{\text{EE}}$ by applying Jensen's inequality to the function $-\log(\cdot)$. So minimizing ℓ_{CE} also minimizes a convex upper bound of the log expected error. This convexity given the n-

[2] Och et al. (2003) describe a similar algorithm for word graphs.

[3] Ortiz-Martínez et al. (2009) describe a related technique in which *all* source and target words can align, with scores set by smoothing.

[4] Discounted cumulative gain (DCG) is widely used in information retrieval learning-to-rank settings. n-best MT learning is standardly formulated as a ranking task.

[5] For expected error, $p(\hat{e}_i) = G(e, \hat{e}_i)$ is not usually normalized. Normalizing p adds a negligible constant.

best list does not mean that the overall MT tuning loss is convex, since the n-best list contents and order depend on the parameters w. However, all regret bounds and other guarantees of online convex optimization would now apply in the CE case since $\ell_{\text{CE},t}(w_{t-1}; E_t)$ is convex for each t. This is attractive compared to expected error, which is non-convex even given the n-best list. We empirically observed that CE converges faster and is less sensitive to hyperparameters than EE.

Faster decoding trick We found that online tuning also permits a trick that speeds up decoding during deployment. Whereas the Phrasal default beam size is 1,200, we were able to reduce the beam size to 800 and run the tuner longer to achieve the same level of translation quality. For example, at the default beam size for French-English, the algorithm converges after 12 iterations, whereas at the lower beam size it achieves that level after 20 iterations. In our experience, batch tuning algorithms seem to be more sensitive to the beam size.

3.3 Feature Templates

The baseline system contains 19 dense feature templates: the nine Moses (Koehn et al., 2007) baseline features, the eight-feature hierarchical lexicalized re-ordering model of Galley and Manning (2008), the (log) count of each rule in the bitext, and an indicator for unique rules. We found that sparse features, while improving translation quality, came at the cost of slower decoding due to feature extraction and inner products with a higher dimensional feature map ϕ. During prototyping, we observed that users found the system to be sluggish unless it responded in approximately 300ms or less. This budget restricted us to dense features.

When re-tuning to corrections, we extract features from the user logs u and add them to the baseline dense model. For each tuning input f, the MT system produces candidate derivations $d = (f, \hat{e}, a)$, where a is a word alignment. The user log u also contains the *last MT derivation*[6] accepted by the user $d_u = (f, \hat{e}_u, a_u)$. We extract features by comparing d and d_u. The heuristic we take is *intersection*: $\phi(d) \leftarrow \phi(d) \cap \phi(d_u)$.

Lexicalized and class-based alignments Consider the alignment in Figure 3. We find that user derivations often contain many unigram rules,

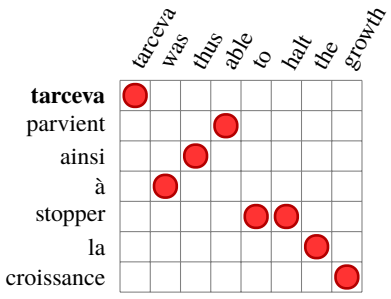

Figure 3: User translation word alignment obtained via prefix decoding and dynamic phrase table augmentation.

which are less powerful than larger phrases, but nonetheless provide high-precision lexical choice information. We fire indicators for both unigram links and multiword cliques. We also fire class-based versions of this feature.

Source OOV blanket Source OOVs are usually more frequent when adapting to a new domain. In the case of European languages—our experimental setting—many of the words simply transfer to the target, so the issue is where to position them. In Figure 3, the proper noun *tarceva* is unknown, so the decoder OOV model generates an identity translation rule. We add features in which the source word is concatenated with the left, right, and left/right contexts in the target, e.g., {`<s>-tarceva, tarceva-was, <s>-tarceva-was`}. We also add versions with target words mapped to classes.

3.4 Differences from Previous Work

Our backend innovations support the UI and enable feature-based learning from human corrections. In contrast, most previous work on incremental MT learning has focused on extracting new translation rules, language model updating, and modifying translation model probabilities (see: Denkowski et al. (2014a)). We regard these features as additive to our own work: certainly extracting new, unseen rules should help translation in a new domain. Moreover, to our knowledge, all previous work on updating the weight vector w has considered *simulated post-editing*, in which the independent references e are substituted for corrections h. Here we extract features from and re-tune to actual corrections to the baseline MT output.

[6]Extracting features from intermediate user editing actions is an interesting direction for future work.

4 Translation User Study

We conducted a human translation experiment with a 2 (translation conditions) $\times$ n (source sentences) mixed design, where n depended on the language pair. Translation conditions (post-edit and interactive) and source sentences were the independent variables (factors). Experimental subjects saw all factor levels, but not all combinations, since one exposure to a sentence would influence another.

Subjects completed the experiment remotely on their own hardware. They received personalized login credentials for the translation interface, which administered the experiment. Subjects first completed a demographic questionnaire about prior experience with CAT and language proficiency. Next, they completed a training module that included a 4-minute tutorial video and a practice "sandbox" for developing proficiency with the UI. Then subjects completed the translation experiment. Finally, they completed an exit questionnaire.

Unlike the experiment of Koehn (2009a), subjects were under time pressure. An idle timer prevented subjects from pausing for more than three minutes while the translator interface was open. This constraint eliminates a source of confound in the timing analysis.

We randomized the order of translation conditions and the assignment of sentences to conditions. At most five sentences appeared per screen, and those sentences appeared in the source document order. Subjects could move among sentences within a screen, but could not revise previous screens. Subjects received untimed breaks both between translation conditions and after about every five screens within a translation condition.

4.1 Linguistic Materials

We chose two language pairs: French-English (Fr-En) and English-German (En-De). Anecdotally, French-English is an easy language pair for MT, whereas English-German is very hard due to reordering and complex German morphology.

We chose three text genres: software, medical, and informal news. The software text came from the graphical interfaces of Autodesk AutoCAD and Adobe Photoshop. The medical text was a drug review from the European Medicines Agency. These two data sets came from TAUS[7] and included independent reference translations. The informal news text came from the WMT 2013 shared task test set (Bojar et al., 2013). The evaluation corpus was constructed from equal proportions of the three genres.

The Fr-En dataset contained 3,003 source tokens (150 segments); the En-De dataset contained 3,002 (173 segments). As a rule of thumb, a human translator averages about 2,700 source tokens per day (Ray, 2013, p.36), so the experiment was designed to replicate a slightly demanding work day.

4.2 Selection of Subjects

For each language pair, we recruited 16 professional, freelance translators on Proz, which is the largest online translation community.[8] We posted ads for both language pairs at a fixed rate of $0.085 per source word, an average rate in the industry. In addition, we paid $10 to each translator for completing the training module. All subjects had significant prior experience with a CAT workbench.

4.3 Results

We analyze the translation conditions in terms of two response variables: time and quality. We excluded one Fr-En subject and two En-De subjects from the models. One subject misunderstood the instructions of the experiment and proceeded without clarification; another skipped the training module entirely. The third subject had a technical problem that prevented logging. Finally, we also filtered segment-level sessions for which the log of translation time was greater than 2.5 standard deviations from the mean.

4.3.1 Translation Time

We analyze time with a linear mixed effects model (LMEM) estimated with the `lme4` (Bates, 2007) R package. When experimental factors are sampled from larger populations—e.g., humans, sentences, words—LMEMs are more robust to type II errors (see: Baayen et al. (2008)). The log-transformed time is the response variable and translation condition is the main independent variable. The maximal random effects structure (Barr et al., 2013) contains intercepts for subject, sentence id, and text genre, each with random slopes for translation condition.

We found significant main effects for translation condition (Fr-En, $p < 0.05$; En-De, $p < 0.01$). The orientation of the coefficients indicates that interactive is slower for both language pairs. For Fr-En, the LMEM predicts a mean time (intercept) of 46.0 sec/sentence in post-edit vs. 54.6 sec/sentence

	Fr-En		En-De	
	TER	**HTER**	**TER**	**HTER**
post-edit	47.32	23.51	56.16	37.15
interactive	47.05	24.14	55.89	39.55

Table 1: Automatic assessment of translation quality. Here we change the definitions of TER and HTER slightly. TER is the human translations compared to the independent references. HTER is the baseline MT compared to the human corrections.

in interactive, or 18.7% slower. For En-De, the mean is 51.8 sec/sentence vs. 63.3 sec/sentence in interactive, or 22.1% slower.

We found other predictive covariates that reveal more about translator behavior. When subjects did not edit the MT suggestion, they were significantly faster. When token edit distance from MT or source input length increased, they were slower. Subjects were usually faster as the experiment progressed, a result that may indicate increased proficiency with practice. Note that all subjects reported professional familiarity with post-edit, whereas the interactive mode was entirely new to them. In the exit survey many translators suggested that with more practice, they could have been as fast in the interactive mode.[9]

4.3.2 Translation Quality

We evaluated translation quality with both automatic and manual measures. Table 1 shows that in the interactive mode, TER is lower and HTER is higher: subjects created translations closer to the references (lower TER), but performed more editing (higher HTER). This result suggests better translations in the interactive mode.

To confirm that intuition, we elicited judgments from professional human raters. The setup followed the manual quality evaluation of the WMT 2014 shared task (Bojar et al., 2014). We hired six raters—three for each language pair—who were paid between $15–20 per hour. The raters logged into Appraise (Federmann, 2010) and for each source segment, ranked five randomly selected translations. From these 5-way rankings we extracted pairwise judgments $\pi = \{<, =\}$, where $u_1 < u_2$ indicates that subject u_1 provided a better translation than subject u_2 for a given source input (Table 2).

[9]See (Green et al., 2014c) for significance levels of the other covariates along with analysis of subject learning rates, subject behavior, and qualitative feedback.

	Fr-En		En-De	
#pairwise	14,211		15,001	
#ties (=)	5,528		2,964	
IAA	0.419	(0.357)	0.407	(0.427)
EW (inter.)	0.512		0.491	

Table 2: Pairwise judgments for the manual quality assessment. Inter-annotator agreement (*IAA*) κ scores are measured with the official WMT14 script. For comparison, the WMT14 IAA scores are given in parentheses. *EW (inter.)* is expected wins of interactive according to Eq. (6).

	Fr-En		En-De	
	sign	p	sign	p
ui (interactive)	$+$	$\bullet$	$-$	
log edit distance	$-$	$\bullet\bullet\bullet$	$+$	$\bullet\bullet\bullet$
gender (female)	$-$		$+$	$\bullet$
log session order	$-$		$+$	$\bullet$

Table 3: LMEM manual translation quality results for each fixed effect with contrast conditions for binary predictors in (). The signs of the coefficients can be interpreted as in ordinary regression. *edit distance* is token-level edit distance from baseline MT. *session order* is the order in which the subject translated the sentence during the experiment. Statistical significance was computed with a likelihood ratio test: $\bullet\bullet\bullet\ p < 0.001$; $\bullet\ p < 0.05$.

In WMT the objective is to rank individual systems; here we need only compare interface conditions. However, we should control for translator variability. Therefore, we build a binomial LMEM for quality. The model is motivated by the simple and intuitive *expected wins* (EW) measure used at WMT. Let S be the set of pairwise judgments and $\text{wins}(u_1, u_2) = |\{(u_1, u_2, \pi) \in S \mid \pi = <\}|$. The standard EW measure is:

$$e(u_1) = \frac{1}{|S|} \sum_{u_1 \neq u_2} \frac{\text{wins}(u_1, u_2)}{\text{wins}(u_1, u_2) + \text{wins}(u_2, u_1)} \quad (5)$$

Sakaguchi et al. (2014) showed that, despite its simplicity, Eq. (5) is nearly as effective as model-based methods given sufficient high-quality judgments. Since we care only about the two translation conditions, we reinterpret the u_i as interface conditions, i.e., $u_1 =$ int and $u_2 =$ pe. We can then disregard

the normalizing term to obtain:

$$e(u_1) = \frac{\text{wins}(u_1, u_2)}{\text{wins}(u_1, u_2) + \text{wins}(u_2, u_1)} \quad (6)$$

which is the expected value of a Bernoulli distribution (so $e(u_2) = 1 - e(u_1)$). The intercept-term of the binomial LMEM will be approximately this value subject to other fixed and random effects.

To estimate the model, we convert each pairwise judgment $u_1 < u_2$ to two examples where the response is 1 for u_1 and 0 for u_2. We add the fixed effects shown in Table 3, where the numeric effects are centered and scaled by their standard deviations. The maximal random effects structure contains intercepts for sentence id nested within subject along with random slopes for interface condition.

Table 3 shows the p-values and coefficient orientations. The models yield probabilities that can be interpreted like Eq. (6) but with all fixed predictors set to 0. For Fr-En, the value for post-edit is 0.472 vs. 0.527 for interactive. For En-De, post-edit is 0.474 vs. 0.467 for interactive. The difference is statistically significant for Fr-En, but not for En-De.

When MT quality was anecdotally high (Fr-En), high token-level edit distance from the initial suggestion decreased quality. When MT was poor (En-De), significant editing improved quality. Female En-De translators were better than males, possibly due to imbalance in the subject pool (12 females vs. 4 males). En-De translators seemed to improve with practice (positive coefficient for *session order*).

The Fr-En results are the first showing an interactive UI that improves over post-edit.

5 MT Re-tuning Experiment

The human translators corrected the output of the BLEU-tuned, baseline MT system. No updating of the MT system occurred during the experiment to eliminate a confound in the time and quality analyses. Now we investigate re-tuning the MT system to the corrections by simply re-starting the online learning algorithm from the baseline weight vector w, this time scoring with HTER instead of BLEU.

Conventional incremental MT learning experiments typically resemble domain adaptation: small-scale baselines are trained and tuned on mostly out-of-domain data, and then re-tuned incrementally on in-domain data. In contrast, we start with large-scale systems. This is more consistent with a professional translation environment where translators receive suggestions from state-of-the-art systems like Google Translate.

	Bilingual		**Monolingual**
	#Segments	***#Tokens***	***#Tokens***
En-De	4.54M	224M	1.7B
Fr-En	14.8M	842M	2.24B

Table 4: Gross statistics of MT training corpora.

	En-De	**Fr-En**
baseline-tune	9,469	8,931
baseline-dev	9,012	9,030
int-tune	680	589
int-test	457	368
pe-tune	764	709
pe-test	492	447

Table 5: Tuning, development, and test corpora (#segments). **tune** and **dev** were used for baseline system preparation. Re-tuning was performed on **int-tune** and **pe-tune**, respectively. We report held-out results on the two test data sets. All sets are supplied with independent references.

5.1 Datasets

Table 4 shows the monolingual and parallel training corpora. Most of the data come from the constrained track of the WMT 2013 shared task (Bojar et al., 2013). We also added 61k parallel segments of TAUS data to the En-De bitext, and 26k TAUS segments to the Fr-En bitext. We aligned the parallel data with the Berkeley Aligner (Liang et al., 2006) and symmetrized the alignments with the grow-diag heuristic. For each target language we used lmplz (Heafield et al., 2013) to estimate unfiltered, 5-gram Kneser-Ney LMs from the concatenation of the target side of the bitext and the monolingual data. For the class-based features, we estimated 512-class source and target mappings with the algorithm of Green et al. (2014a).

The upper part of Table 5 shows the baseline tuning and development sets, which also contained 1/3 TAUS medical text, 1/3 TAUS software text, and 1/3 WMT newswire text (see section 4).

The lower part of Table 5 shows the organization of the human corrections for re-tuning and testing. Recall that for each unique source input, eight human translators produced a correction in each condition. First, we filtered all corrections for which a log u was not recorded (due to technical problems). Second, we de-duplicated the corrections so that each h was unique. Finally, we split the unique (f, h) tuples according to a natural division in the

System	tune	BLEU↑	TER↓	HTER
baseline	bleu	23.12	60.29	44.05

re-tune+feat	hter	21.73	*59.71*	**42.35**

(a) En-De int-test results.

System	tune	BLEU↑	TER↓	HTER
baseline	bleu	39.33	45.29	28.28
re-tune	hter	39.99	45.73	26.96
re-tune+feat	hter	*40.30*	45.28	**26.40**

(b) Fr-En int-test results.

Table 6: Main re-tuning results for interactive data. **baseline** is the BLEU-tuned system used in the translation user study. **re-tune** is the baseline feature set re-tuned to HTER on int-tune. **re-tune+feat** adds the human feature templates described in section 3.3. **bold** indicates statistical significance relative to the baseline at $p < 0.001$; *italic* at $p < 0.05$ by the permutation test of Riezler and Maxwell (2005).

data. There were five source segments per document, and each document was rendered as a single screen during the translation experiment. *Segment order was not randomized*, so we could split the data as follows: assign the first three segments of each screen to tune, and the last two to test. This is a clean split with no overlap.

This tune/test split has two attractive properties. First, if we can quickly re-tune on the first few sentences on a screen and provide better translations for the last few, then presumably the user experience improves. Second, source inputs f are repeated—eight translators translated each input in each condition. This means that a reduction in HTER means better average suggestions for multiple human translators. Contrast this experimental design with tuning to the corrections of a single human translator. There the system might overfit to one human style, and may not generalize to other human translators.

5.2 Results

Table 6 contains the main results for re-tuning to interactive MT corrections. For both language pairs, we observe large statistically significant reductions in HTER. However, the results for BLEU and TER—which are computed with respect to the independent references—are mixed. The lower En-De BLEU score is explained by a higher brevity penalty for the re-tuned output (0.918 vs. 0.862). However, the re-tuned 4-gram and 3-gram precisions are significantly higher. The unchanged Fr-En TER value can be explained by the observation that no human translators produced TER scores higher than the baseline MT. This odd result has also been observed for BLEU (Culy and Riehemann, 2003), although here we do observe a slight BLEU improvement.

System	HTER↓ int	System	HTER↓ pe
baseline	44.05	baseline	41.05
re-tune (int)	43.99	re-tune (pe)	**40.34**
re-tune+feat	**42.35**	–	–
Δ	−1.80		−0.71

Table 7: En-De test results for re-tuning to post-edit (pe) vs. interactive (int). Features cannot be extracted from the post-edit data, so the re-tune+feat system cannot be learned. The Fr-En results are similar but are omitted due to space.

The additional features (854 for Fr-En; 847 for En-De) help significantly and do not slow down decoding. We used the same L_1 regularization strength as the baseline, but feature growth could be further constrained by increasing this parameter. Tuning is very fast at about six minutes *for the whole dataset*, so tuning during a live user session is already practical.

Table 7 compares re-tuning to interactive vs. post-edit corrections. Recall that the int-test and pe-test datasets are different and contain different references. The post-edit baseline is lower because humans performed less editing in the baseline condition (see Table 1). Features account for the greatest reduction in HTER. Of course, the features are based mostly on word alignments, which could be obtained for the post-edit data by running an online word alignment tool (see: Farajian et al. (2014)). However, the interactive logs contain much richer user state information that we could not exploit due to data sparsity. We also hypothesize that the final interactive corrections might be more useful since suggestions prime translators (Green et al., 2013a), and the MT system was able to refine its suggestions.

6 Re-tuning Analysis

Tables 6 and 7 raise two natural questions: what accounts for the reduction in HTER, and why are the TER/BLEU results mixed? Comparison of the BLEU-tuned baseline to the HTER re-tuned systems gives some insight. For both questions, fine-

grained corrections appear to make the difference.

Consider this French test example (with gloss):

(1) une ligne de chimiothérapie antérieure
one line of chemotherapy previous

The independent reference for *une ligne de chimiothérapie* is 'previous chemotherapy treatment', and the baseline produces 'previous chemotherapy line.' The source sentence appears seven times with the following user translations: 'one line or more of chemotherapy', 'one prior line of chemotherapy', 'one previous line of chemotherapy' (2), 'one line of chemotherapy before' (2), 'one protocol of chemotherapy'. The re-tuned, feature-based system produces 'one line of chemotherapy before', matching two of the humans exactly, and six of the humans in terms of idiomatic medical jargon ('line of chemotherapy' vs. 'chemotherapy treatment'). However, the baseline output would have received better BLEU and TER scores.

Sometimes re-tuning improves the translations with respect to both the reference and the human corrections. This English phrase appears in the En-De test set:

(2) depending on the file
abhängig von der datei

The baseline produces exactly the gloss shown in Ex. (2). The human translators produced: 'je nach datei' (6), 'das dokument', and 'abhängig von der datei'. The re-tuned system rendered the phrase 'je nach dokument', which is closer to both the independent reference 'je nach datei' and the human corrections. This change improves TER, BLEU, and HTER.

7 Related Work

The process study most similar to ours is that of Koehn (2009a), who compared scratch, post-edit, and simple interactive modes. However, he used undergraduate, non-professional subjects, and did not consider re-tuning. Our experimental design with professional bilingual translators follows our previous work Green et al. (2013a) comparing scratch translation to post-edit.

Many research translation UIs have been proposed including TransType (Langlais et al., 2000), Caitra (Koehn, 2009b), Thot (Ortiz-Martínez and Casacuberta, 2014), TransCenter (Denkowski et al., 2014b), and CasmaCat (Alabau et al., 2013). However, to our knowledge, none of these interfaces were explicitly designed according to mixed-initiative principles from the HCI literature.

Incremental MT learning has been investigated several times, usually starting from no data (Barrachina et al., 2009; Ortiz-Martínez et al., 2010), via simulated post-editing (Martínez-Gómez et al., 2012; Denkowski et al., 2014a), or via re-ranking (Wäschle et al., 2013). No previous experiments combined large-scale baselines, full re-tuning of the model weights, and HTER optimization.

HTER tuning can be simulated by re-parameterizing an existing metric. Snover et al. (2009) tuned TERp to correlate with HTER, while Denkowski and Lavie (2010) did the same for METEOR. Zaidan and Callison-Burch (2010) showed how to solicit MT corrections for HTER from Amazon Mechanical Turk.

Our learning approach is related to coactive learning (Shivaswamy and Joachims, 2012). Their basic preference perceptron updates toward a correction, whereas we use the correction for metric scoring and feature extraction.

8 Conclusion

We presented a new CAT interface that supports post-edit and interactive modes. Evaluation with professional, bilingual translators showed post-edit to be faster, but prior subject familiarity with post-edit may have mattered. For French-English, the interactive mode enabled higher quality translation. Re-tuning the MT system to interactive corrections also yielded large HTER gains. Technical contributions that make re-tuning possible are a cross-entropy objective, prefix decoding, and dynamic phrase table augmentation. Larger quantities of corrections should yield further gains, but our current experiments already establish the feasibility of Bar-Hillel's virtuous "machine-post-editor partnership" which benefits both humans and machines.

Abstract

The combinatorial space of translation derivations in phrase-based statistical machine translation is given by the intersection between a translation lattice and a target language model. We replace this intractable intersection by a tractable relaxation which incorporates a low-order upperbound on the language model. Exact optimisation is achieved through a coarse-to-fine strategy with connections to adaptive rejection sampling. We perform exact optimisation with unpruned language models of order 3 to 5 and show search-error curves for beam search and cube pruning on standard test sets. This is the first work to tractably tackle exact optimisation with language models of orders higher than 3.

1 Introduction

In Statistical Machine Translation (SMT), the task of producing a translation for an input string $\mathbf{x} = \langle x_1, x_2, \ldots, x_I \rangle$ is typically associated with finding the best derivation $\mathbf{d}^*$ compatible with the input under a linear model. In this view, a derivation is a structured output that represents a sequence of steps that covers the input producing a translation. Equation 1 illustrates this *decoding* process.

$$\mathbf{d}^* = \underset{\mathbf{d} \in \mathcal{D}(\mathbf{x})}{\operatorname{argmax}} f(\mathbf{d}) \tag{1}$$

The set $\mathcal{D}(\mathbf{x})$ is the space of all derivations compatible with $\mathbf{x}$ and supported by a model of translational equivalences (Lopez, 2008). The function $f(\mathbf{d}) = \Lambda \cdot \mathbf{H}(\mathbf{d})$ is a linear parameterisation of the model (Och, 2003). It assigns a real-valued score (or weight) to every derivation $\mathbf{d} \in \mathcal{D}(\mathbf{x})$, where $\Lambda \in \mathbb{R}^m$ assigns a relative importance to different aspects of the derivation independently captured by m feature functions $\mathbf{H}(\mathbf{d}) = \langle H_1(\mathbf{d}), \ldots, H_m(\mathbf{d}) \rangle \in \mathbb{R}^m$.

The fully parameterised model can be seen as a discrete weighted set such that feature functions factorise over the steps in a derivation. That is, $H_k(\mathbf{d}) = \sum_{e \in \mathbf{d}} h_k(e)$, where h_k is a (local) feature function that assesses steps independently and $\mathbf{d} = \langle e_1, e_2, \ldots, e_l \rangle$ is a sequence of l steps. Under this assumption, each step is assigned the weight $w(e) = \Lambda \cdot \langle h_1(e), h_2(e), \ldots, h_m(e) \rangle$. The set $\mathcal{D}$ is typically finite, however, it contains a very large number of structures — exponential (or even factorial, see §2) with the size of $\mathbf{x}$ — making exhaustive enumeration prohibitively slow. Only in very restricted cases combinatorial optimisation techniques are directly applicable (Tillmann et al., 1997; Och et al., 2001), thus it is common to resort to heuristic techniques in order to find an approximation to $\mathbf{d}^*$ (Koehn et al., 2003; Chiang, 2007).

Evaluation exercises indicate that approximate search algorithms work well in practice (Bojar et al., 2013). The most popular algorithms provide solutions with unbounded error, thus precisely quantifying their performance requires the development of a tractable exact decoder. To date, most attempts were limited to short sentences and/or somewhat toy models trained with artificially small datasets (Germann et al., 2001; Iglesias et al., 2009; Aziz et al., 2013). Other work has employed less common approximations to the model reducing its search space complexity (Kumar et al., 2006; Chang and Collins, 2011; Rush and Collins, 2011). These do not answer whether or not current decoding algorithms perform well at real translation tasks with state-of-the-art models.

We propose an exact decoder for phrase-based SMT based on a coarse-to-fine search strategy (Dymetman et al., 2012). In a nutshell, we relax the decoding problem with respect to the Language Model (LM) component. This coarse view is incrementally refined based on evidence col-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1237–1249,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

lected via maximisation. A refinement increases the complexity of the model only slightly, hence dynamic programming remains feasible throughout the search until convergence. We test our decoding strategy with realistic models using standard data sets. We also contribute with optimum derivations which can be used to assess future improvements to approximate decoders. In the remaining sections we present the general model (§2), survey contributions to exact optimisation (§3), formalise our novel approach (§4), present experiments (§5) and conclude (§6).

2 Phrase-based SMT

In phrase-based SMT (Koehn et al., 2003), the building blocks of translation are pairs of phrases (or *biphrases*). A translation derivation $\mathbf{d}$ is an ordered sequence of *non-overlapping* biphrases which covers the input text in arbitrary order generating the output from left to right.[1]

$$f(\mathbf{d}) = \psi(\mathbf{y}) + \sum_{i=1}^{l} \phi(e_i) + \sum_{i=1}^{l-1} \delta(e_i, e_{i-1}) \quad (2)$$

Equation 2 illustrates a standard phrase-based model (Koehn et al., 2003): ψ is a weighted target n-gram LM component, where $\mathbf{y}$ is the yield of $\mathbf{d}$; ϕ is a linear combination of features that decompose over phrase pairs directly (e.g. backward and forward translation probabilities, lexical smoothing, and word and phrase penalties); and δ is an unlexicalised penalty on the number of skipped input words between two adjacent biphrases. The weighted logic program in Figure 1 specifies the fully parameterised weighted set of solutions, which we denote $\langle \mathcal{D}(\mathbf{x}), f(\mathbf{d}) \rangle$.[2]

A weighted logic program starts from its axioms and follows exhaustively deducing new items by combination of existing ones and no deduction happens twice. In Figure 1, a *nonteminal* item summarises partial derivation (or *hypotheses*). It is denoted by $[C, r, \gamma]$ (also known as *carry*), where: C is a coverage vector, necessary to impose the non-overlapping constraint; r is the rightmost position most recently covered, necessary for the computation of δ; and γ is the last $n-1$ words

$$\begin{array}{ll}
\textsc{Item} & \left[\{0,1\}^I, [0, I+1], \Delta^{n-1}\right] \\
\textsc{Goal} & \left[1^I, I+1, \textsc{eos}\right] \\
\textsc{Axiom} & \\
& \dfrac{\langle \textsc{bos} \rightarrow \textsc{bos} \rangle}{[0^I, 0, \textsc{bos}] : \psi(\textsc{bos})} \\
\textsc{Expand} & \\
& \dfrac{\left[C, r, y_{j-n+1}^{j-1}\right] \quad \left\langle x_i^{i'} \xrightarrow{\phi_r} y_j^{j'} \right\rangle}{\left[C', i', y_{j'-n+2}^{j'}\right] : w} \quad \bigoplus_{k=i}^{i'} c_k = \bar{0} \\
& \text{where} \quad c'_k = c_k \text{ if } k < i \text{ or } k > i' \text{ else } \bar{1} \\
& \qquad\quad w = \phi_r \otimes \delta(r, i) \otimes \psi(y_j^{j'} | y_{j-n+1}^{j-1}) \\
\textsc{Accept} & \\
& \dfrac{\left[1^I, r, \gamma\right]}{[1^I, I+1, \textsc{eos}] : \delta(r, I+1) \otimes \psi(\textsc{eos}|\gamma)} \quad r \leq I
\end{array}$$

Figure 1: Specification for the weighted set of translation derivations in phrase-based SMT with unconstrained reordering.

in the yield, necessary for the LM component. The program expands partial derivations by concatenation with a translation rule $\left\langle x_i^{i'} \xrightarrow{\phi_r} y_j^{j'} \right\rangle$, that is, an instantiated biphrase which covers the span $x_i^{i'}$ and yields $y_j^{j'}$ with weight ϕ_r. The side condition imposes the non-overlapping constraint (c_k is the kth bit in C). The antecedents are used to compute the weight of the deduction, and the carry is updated in the consequent (item below the horizontal line). Finally, the rule ACCEPT incorporates the end-of-sentence boundary to complete items.[3]

It is perhaps illustrative to understand the set of weighted translation derivations as the intersection between two components. One that is only locally parameterised and contains all translation derivations (a translation *lattice* or *forest*), and one that re-ranks the first as a function of the interactions between translation steps. The model of translational equivalences parameterised only with ϕ is an instance of the former. An n-gram LM component is an instance of the latter.

2.1 Hypergraphs

A *backward-hypergraph*, or simply *hypergraph*, is a generalisation of a graph where edges have multiple origins and one destination (Gallo et al., 1993). They can represent both finite-state and context-free weighted sets and they have been widely used in SMT (Huang and Chiang, 2007). A hypergraph is defined by a set of nodes (or ver-

[1] Preventing phrases from overlapping requires an exponential number of constraints (the powerset of $\mathbf{x}$) rendering the problem NP-complete (Knight, 1999).

[2] Weighted logics have been extensively used to describe weighted sets (Lopez, 2009), operations over weighted sets (Chiang, 2007; Dyer and Resnik, 2010), and a variety of dynamic programming algorithms (Cohen et al., 2008).

[3] Figure 1 can be seen as a specification for a weighted acyclic finite-state automaton whose states are indexed by $[l, C, r]$ and transitions are labelled with biphrases. However, for generality of representation, we opt for using acyclic hypergraphs instead of automata (see §2.1).

tices) V and a weighted set of edges $\langle E, w \rangle$. An edge e connects a sequence of nodes in its tail $\mathrm{t}[e] \in V^*$ under a head node $\mathrm{h}[e] \in V$ and has weight $w(e)$. A node v is a *terminal node* if it has no incoming edges, otherwise it is a *nonterminal node*. The node that has no outgoing edges, is called *root*, with no loss of generality we can assume hypergraphs to have a single root node.

Hypergraphs can be seen as instantiated logic programs. In this view, an item is a template for the creation of nodes, and a weighted deduction rule is a template for edges. The tail of an edge is the sequence of nodes associated with the antecedents, and the head is the node associated with the consequent. Even though the space of weighted derivations in phrase-based SMT is finite-state, using a hypergraph as opposed to a finite-state automaton makes it natural to encode multi-word phrases using tails. We opt for representing the target side of the biphrase as a sequence of terminals nodes, each of which represents a target word.

3 Related Work

3.1 Beam filling algorithms

Beam search (Koehn et al., 2003) and cube pruning (Chiang, 2007) are examples of state-of-the-art approximate search algorithms. They approximate the intersection between the translation forest and the language model by expanding a limited beam of hypotheses from each nonterminal node. Hypotheses are organised in priority queues according to common traits and a fast-to-compute heuristic view of *outside weights* (cheapest way to complete a hypothesis) puts them to compete at a fairer level. Beam search exhausts a node's possible expansions, scores them, and discards all but the k highest-scoring ones. This process is wasteful in that k is typically much smaller than the number of possible expansions. Cube pruning employs a priority queue at beam filling and computes k high-scoring expansions directly in near best-first order. The parameter k is known as *beam size* and it controls the time-accuracy trade-off of the algorithm.

Heafield et al. (2013a) move away from using the language model as a black-box and build a more involved beam filling algorithm. Even though they target approximate search, some of their ideas have interesting connections to ours (see §4). They group hypotheses that share partial language model state (Li and Khudanpur, 2008) reasoning over multiple hypotheses at once. They fill a beam in best-first order by iteratively visiting groups using a priority queue: if the top group contains a single hypothesis, the hypothesis is added to the beam, otherwise the group is partitioned and the parts are pushed back to the queue. More recently, Heafield et al. (2014) applied their beam filling algorithm to phrase-based decoding.

3.2 Exact optimisation

Exact optimisation for monotone translation has been done using A* search (Tillmann et al., 1997) and finite-state operations (Kumar et al., 2006). Och et al. (2001) design near-admissible heuristics for A* and decode very short sentences (6-14 words) for a word-based model (Brown et al., 1993) with a maximum distortion strategy ($d = 3$).

Zaslavskiy et al. (2009) frame phrase-based decoding as an instance of a generalised Travelling Salesman Problem (TSP) and rely on robust solvers to perform decoding. In this view, a *salesman graph* encodes the translation options, with each node representing a biphrase. Non-overlapping constraints are imposed by the TSP solver, rather than encoded directly in the salesman graph. They decode only short sentences (17 words on average) using a 2-gram LM due to salesman graphs growing too large.[4]

Chang and Collins (2011) relax phrase-based models w.r.t. the non-overlapping constraints, which are replaced by soft penalties through Lagrangian multipliers, and intersect the LM component exhaustively. They do employ a maximum distortion limit ($d = 4$), thus the problem they tackle is no longer NP-complete. Rush and Collins (2011) relax a hierarchical phrase-based model (Chiang, 2005)[5] w.r.t. the LM component. The translation forest and the language model trade their weights (through Lagrangian multipliers) so as to ensure agreement on what each component believes to be the maximum. In both approaches, when the dual converges to a compliant solution, the solution is guaranteed to be optimal. Other-

[4] Exact decoding had been similarly addressed with Integer Linear Programming (ILP) in the context of word-based models for very short sentences using a 2-gram LM (Germann et al., 2001). Riedel and Clarke (2009) revisit that formulation and employ a cutting-plane algorithm (Dantzig et al., 1954) reaching 30 words.

[5] In hierarchical translation, reordering is governed by a synchronous context-free grammar and the underlying problem is no longer NP-complete. Exact decoding remains infeasible because the intersection between the translation forest and the target LM is prohibitively slow.

wise, a subset of the constraints is explicitly added and the dual optimisation is repeated. They handle sentences above average length, however, resorting to compact rulesets (10 translation options per input segment) and using only 3-gram LMs.

In the context of hierarchical models, Aziz et al. (2013) work with unpruned forests using upperbounds. Their approach is the closest to ours. They also employ a coarse-to-fine strategy with the OS* framework (Dymetman et al., 2012), and investigate unbiased sampling in addition to optimisation. However, they start from a coarser upperbound with unigram probabilities, and their refinement strategies are based on exhaustive intersections with small n-gram matching automata. These refinements make forests grow unmanageable too quickly. Because of that, they only deal with very short sentences (up to 10 words) and even then decoding is very slow. We design better upperbounds and a more efficient refinement strategy. Moreover, we decode long sentences using language models of order 3 to 5.[6]

4 Approach

4.1 Exact optimisation with OS*

Dymetman et al. (2012) introduced OS*, a unified view of optimisation and sampling which can be seen as a cross between adaptive rejection sampling (Robert and Casella, 2004) and A* optimisation (Hart et al., 1968). In this framework, a complex goal distribution is upperbounded by a simpler proposal distribution for which optimisation (and sampling) is feasible. This proposal is incrementally refined to be closer to the goal until the maximum is found (or until the sampling performance exceeds a certain level).

Figure 2 illustrates exact optimisation with OS*. Suppose f is a complex target goal distribution, such that we cannot optimise f, but we can assess $f(\mathbf{d})$ for a given $\mathbf{d}$. Let $g^{(0)}$ be an upperbound to f, i.e., $g^{(0)}(\mathbf{d}) \geq f(\mathbf{d})$ for all $\mathbf{d} \in \mathcal{D}(\mathbf{x})$. Moreover, suppose that $g^{(0)}$ is simple enough to be optimised efficiently. The algorithm proceeds by solving $\mathbf{d}_0 = \text{argmax}_{\mathbf{d}}\, g^{(0)}(\mathbf{d})$ and computing the quantity $r_0 = f(\mathbf{d}_0)/g^{(0)}(\mathbf{d}_0)$. If r_0 were sufficiently close to 1, then $g^{(0)}(\mathbf{d}_0)$ would be sufficiently close to $f(\mathbf{d}_0)$ and we would have found the optimum. However, in the illustration $g^{(0)}(\mathbf{d}_0) \gg f(\mathbf{d}_0)$, thus $r_0 \ll 1$. At this point the algorithm has concrete evidence to motivate a refinement of $g^{(0)}$ that can lower its maximum, bringing it closer to $f^* = \max_{\mathbf{d}} f(\mathbf{d})$ at the cost of some small increase in complexity. The refined proposal must remain an upperbound to f. To continue with the illustration, suppose $g^{(1)}$ is obtained. The process is repeated until eventually $g^{(t)}(\mathbf{d}_t) = f(\mathbf{d}_t)$, where $\mathbf{d}_t = \text{argmax}_{\mathbf{d}}\, g^{(t)}(\mathbf{d})$, for some finite t. At which point $\mathbf{d}_t$ is the optimum derivation $\mathbf{d}^*$ from f and the sequence of upperbounds provides a proof of optimality.[7]

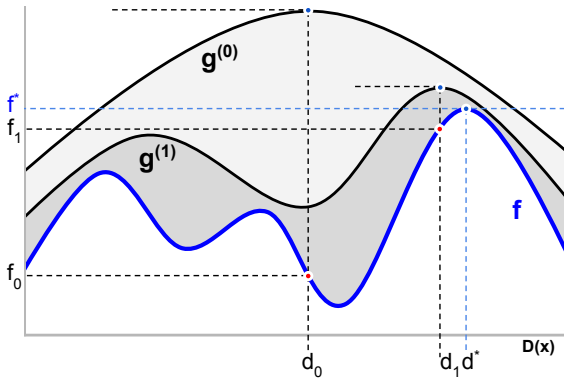

Figure 2: Sequence of incrementally refined upperbound proposals.

4.2 Model

We work with phrase-based models in a standard parameterisation (Equation 2). However, to avoid having to deal with NP-completeness, we constrain reordering to happen only within a limited window given by a notion of *distortion limit*. We require that the last source word covered by any biphrase must be within d words from the leftmost uncovered source position (Lopez, 2009). This is a widely used strategy and it is in use in the Moses toolkit (Koehn et al., 2007).[8]

Nevertheless, the problem of finding the best

[6]The intuition that a full intersection is wasteful is also present in (Petrov et al., 2008) in the context of approximate search. They start from a coarse distribution based on automatic word clustering which is refined in multiple passes. At each pass, hypotheses are pruned a posteriori on the basis of their marginal probabilities, and word clusters are further split. We work with upperbounds, rather than word clusters, with unpruned distributions, and perform exact optimisation.

[7]If $\mathbf{d}$ is a maximum from g and $g(\mathbf{d}) = f(\mathbf{d})$, then it is easy to show by contradiction that $\mathbf{d}$ is the actual maximum from f: if there existed $\mathbf{d}'$ such that $f(\mathbf{d}') > f(\mathbf{d})$, then it follows that $g(\mathbf{d}') \geq f(\mathbf{d}') > f(\mathbf{d}) = g(\mathbf{d})$, and hence $\mathbf{d}$ would not be a maximum for g.

[8]A distortion limit characterises a form of pruning that acts directly in the generative capacity of the model leading to induction errors (Auli et al., 2009). Limiting reordering like that lowers complexity to a polynomial function of I and an exponential function of the distortion limit.

derivation under the model remains impracticable due to nonlocal parameterisation (namely, the n-gram LM component). The weighted set $\langle \mathcal{D}(\mathbf{x}), f(\mathbf{d}) \rangle$, which represents the objective, is a complex hypergraph which we cannot afford to construct. We propose to construct instead a simpler hypergraph for which optimisation by dynamic programming is feasible. This *proxy* represents the weighted set $\langle \mathcal{D}(\mathbf{x}), g^{(0)}(\mathbf{d}) \rangle$, where $g^{(0)}(\mathbf{d}) \geq f(\mathbf{d})$ for every $\mathbf{d} \in \mathcal{D}(\mathbf{x})$. Note that this proposal contains **exactly** the same translation options as in the original decoding problem. The simplification happens only with respect to the parameterisation. Instead of intersecting the complete n-gram LM distribution explicitly, we implicitly intersect a simpler upperbound view of it, where by *simpler* we mean *lower-order*.

$$g^{(0)}(\mathbf{d}) = \sum_{i=1}^{l} \omega(\mathrm{y}[e_i]) + \sum_{i=1}^{l} \phi(e_i) + \sum_{i=1}^{l-1} \delta(e_i, e_{i-1}) \quad (3)$$

Equation 3 shows the model we use as a proxy to perform exact optimisation over f. In comparison to Equation 2, the term $\sum_{i=1}^{l} \omega(\mathrm{y}[e_i])$ replaces $\psi(\mathbf{y}) = \lambda_\psi p_{\text{LM}}(\mathbf{y})$. While ψ weights the yield $\mathbf{y}$ taking into account all n-grams (including those crossing the boundaries of phrases), ω weights edges in isolation. Particularly, $\omega(\mathrm{y}[e_i]) = \lambda_\psi q_{\text{LM}}(\mathrm{y}[e_i])$, where $\mathrm{y}[e_i]$ returns the sequence of target words (a target phrase) associated with the edge, and $q_{\text{LM}}(\cdot)$ is an upperbound on the true LM probability $p_{\text{LM}}(\cdot)$ (see §4.3). It is obvious from Equation 3 that our proxy model is much simpler than the original — the only form of nonlocal parameterisation left is the distortion penalty, which is simple enough to represent exactly.

The program in Figure 3 illustrates the construction of $\langle \mathcal{D}(\mathbf{x}), g^{(0)}(\mathbf{d}) \rangle$. A nonterminal item $[l, C, r]$ stores: the leftmost uncovered position l and a truncated coverage vector C (together they track d input positions); and the rightmost position r most recently translated (necessary for the computation of the distortion penalty). Observe how nonterminal items **do not** store the LM state.[9] The rule ADJACENT expands derivations by concatenation with a biphrase $\left\langle x_i^{i'} \rightarrow y_j^{j'} \right\rangle$ starting at the leftmost uncovered position $i = l$. That causes the coverage window to move ahead to the next leftmost uncovered position: $l' = l + \alpha_1(C) + 1$,

[9] Drawing a parallel to (Heafield et al., 2013a), a nonterminal node in our hypergraph groups derivations while exposing only an empty LM state.

ITEM $\left[[1, I+1], \{0,1\}^{d-1}, [0, I+1]\right]$

Figure 3: Specification of the initial proposal hypergraph. This program allows the same reorderings as (Lopez, 2009) (see logic WLd), however, it does not store LM state information and it uses the upperbound LM distribution $\omega(\cdot)$.

where $\alpha_1(C)$ returns the number of leading 1s in C, and $C' \ll \alpha_1(C) + 1$ represents a left-shift. The rule NON-ADJACENT handles the remaining cases $i > l$ provided that the expansion skips at most d input words $|r - i + 1| \leq d$. In the consequent, the window C is simply updated to record the translation of the input span $i..i'$. In the non-adjacent case, a *gap constraint* imposes that the resulting item will require skipping no more than d positions before the leftmost uncovered word is translated $|i' - l + 1| \leq d$.[10] Finally, note that deductions incorporate the weighted upperbound $\omega(\cdot)$, rather than the true LM component $\psi(\cdot)$.[11]

4.3 LM upperbound and Max-ARPA

Following Carter et al. (2012) we compute an upperbound on n-gram conditional probabilities by precomputing max-backoff weights stored in a "Max-ARPA" table, an extension of the ARPA format (Jurafsky and Martin, 2000).

A standard ARPA table T stores entries

[10] This constraint prevents items from becoming dead-ends where incomplete derivations require a reordering step larger than d. This is known to prevent many search errors in beam search (Chang and Collins, 2011).

[11] Unlike Aziz et al. (2013), rather than unigrams only, we score all n-grams within a translation rule (including incomplete ones).

$\langle \mathtt{Z}, \mathtt{Z.p}, \mathtt{Z.b} \rangle$, where $\mathtt{Z}$ is an n-gram equal to the concatenation $\mathtt{Pz}$ of a prefix $\mathtt{P}$ with a word $\mathtt{z}$, $\mathtt{Z.p}$ is the conditional probability $p(\mathtt{z}|\mathtt{P})$, and $\mathtt{Z.b}$ is a so-called "backoff" weight associated with $\mathtt{Z}$. The conditional probability of an arbitrary n-gram $p(\mathtt{z}|\mathtt{P})$, whether listed or not, can then be recovered from T by the simple recursive procedure shown in Equation 4, where tail deletes the first word of the string $\mathtt{P}$.

$$p(\mathtt{z}|\mathtt{P}) = \begin{cases} p(\mathtt{z}|\,\mathrm{tail}(\mathtt{P})) & \mathtt{Pz} \notin T \text{ and } \mathtt{P} \notin T \\ p(\mathtt{z}|\,\mathrm{tail}(\mathtt{P})) \times \mathtt{P.b} & \mathtt{Pz} \notin T \text{ and } \mathtt{P} \in T \\ \mathtt{Pz.p} & \mathtt{Pz} \in T \end{cases} \tag{4}$$

The optimistic version (or "max-backoff") q of p is defined as $q(\mathtt{z}|\mathtt{P}) \equiv \max_H p(\mathtt{z}|\mathtt{HP})$, where $\mathtt{H}$ varies over all possible contexts extending the prefix $\mathtt{P}$ to the left. The Max-ARPA table allows to compute $q(\mathtt{z}|\mathtt{P})$ for arbitrary values of $\mathtt{z}$ and $\mathtt{P}$. It is constructed on the basis of the ARPA table T by adding two columns to T: a column $\mathtt{Z.q}$ that stores the value $q(\mathtt{z}|\mathtt{P})$ and a column $\mathtt{Z.m}$ that stores an optimistic version of the backoff weight.

These columns are computed offline in two passes by first sorting T in descending order of n-gram length.[12] In the first pass (Algorithm 1), we compute for every entry in the table an optimistic backoff weight $\mathtt{m}$. In the second pass (Algorithm 2), we compute for every entry an optimistic conditional probability $\mathtt{q}$ by maximising over 1-word history extensions (whose $\mathtt{.q}$ fields are already known due to the sorting of T).

The following **Theorem** holds (see proof below): *For an arbitrary n-gram $Z = Pz$, the probability $q(z|P)$ can be recovered through the procedure shown in Equation 5.*

$$q(\mathtt{z}|\mathtt{P}) = \begin{cases} p(\mathtt{z}|\mathtt{P}) & \mathtt{Pz} \notin T \text{ and } \mathtt{P} \notin T \\ p(\mathtt{z}|\mathtt{P}) \times \mathtt{P.m} & \mathtt{Pz} \notin T \text{ and } \mathtt{P} \in T \\ \mathtt{Pz.q} & \mathtt{Pz} \in T \end{cases} \tag{5}$$

Note that, if $\mathtt{Z}$ is listed in the table, we return its upperbound probability $\mathtt{q}$ directly. When the n-gram is unknown, but its prefix is known, we take into account the optimistic backoff weight $\mathtt{m}$ of the prefix. On the other hand, if both the n-gram and its prefix are unknown, then no additional context could change the score of the n-gram, in which case $q(\mathtt{z}|\mathtt{P}) = p(\mathtt{z}|\mathtt{P})$.

In the sequel, we will need the following definitions. Suppose $\alpha = y_I^J$ is a substring of $\mathbf{y} = y_1^M$. Then $p_{\text{LM}}(\alpha) \equiv \prod_{k=I}^{J} p(y_k|y_1^{k-1})$ is the contribution of α to the true LM score of $\mathbf{y}$. We then obtain an upperbound $q_{\text{LM}}(\alpha)$ to this contribution by defining $q_{\text{LM}}(\alpha) \equiv q(y_I|\epsilon) \prod_{k=I+1}^{J} q(y_k|y_I^{k-1})$.

[12] If an n-gram is listed in T, then all its substrings must also be listed. Certain pruning strategies may corrupt this property, in which case we make missing substrings explicit.

Proof of **Theorem**. Let us first suppose that the length of $\mathtt{P}$ is strictly larger than the order n of the language model. Then for any $\mathtt{H}$, $p(\mathtt{z}|\mathtt{HP}) = p(\mathtt{z}|\mathtt{P})$; this is because $\mathtt{HP} \notin T$ and $\mathtt{P} \notin T$, along with all intermediary strings, hence, by (4), $p(\mathtt{z}|\mathtt{HP}) = p(\mathtt{z}|\,\mathrm{tail}(\mathtt{HP})) = p(\mathtt{z}|\,\mathrm{tail}(\mathrm{tail}(\mathtt{HP}))) = \ldots = p(\mathtt{z}|\mathtt{P})$. Hence $q(\mathtt{z}|\mathtt{P}) = p(\mathtt{z}|\mathtt{P})$, and, because $\mathtt{Pz} \notin T$ and $\mathtt{P} \notin T$, the theorem is satisfied in this case.

Having established the theorem for $|\mathtt{P}| > n$, we now assume that it is true for $|\mathtt{P}| > m$ and prove by induction that it is true for $|\mathtt{P}| = m$. We use the fact that, by the definition of $\mathtt{q}$, we have $q(\mathtt{z}|\mathtt{P}) = \max_{\mathtt{x}\in\Delta} q(\mathtt{z}|\mathtt{xP})$. We have three cases to consider.

First, suppose that $\mathtt{Pz} \notin T$ and $\mathtt{P} \notin T$. Then $\mathtt{xPz} \notin T$ and $\mathtt{xP} \notin T$, hence by induction $q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{P})$ for any $\mathtt{x}$, therefore $q(\mathtt{z}|\mathtt{P}) = p(\mathtt{z}|\mathtt{P})$. We have thus proven the first case.

Second, suppose that $\mathtt{Pz} \notin T$ and $\mathtt{P} \in T$. Then, for any $\mathtt{x}$, we have $\mathtt{xPz} \notin T$, and:

$$\begin{aligned} q(\mathtt{z}|\mathtt{P}) &= \max_{\mathtt{x}\in\Delta} q(\mathtt{z}|\mathtt{xP}) \\ &= \max\Big(\max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\notin T} q(\mathtt{z}|\mathtt{xP}), \max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\in T} q(\mathtt{z}|\mathtt{xP})\Big). \end{aligned}$$

For $\mathtt{xP} \notin T$, by induction, $q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{P})$, and therefore $\max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\notin T} q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{P})$. For $\mathtt{xP} \in T$, we have $q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{xP}) \times \mathtt{xP.m} = p(\mathtt{z}|\mathtt{P}) \times \mathtt{xP.b} \times \mathtt{xP.m}$. Thus, we have:

$$\max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\in T} q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{P}) \times \max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\in T} \mathtt{xP.b} \times \mathtt{xP.m}.$$

But now, because of lines 3 and 4 of Algorithm 1, $\mathtt{P.m} = \max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\in T} \mathtt{xP.b} \times \mathtt{xP.m}$, hence $\max_{\mathtt{x}\in\Delta,\, \mathtt{xP}\in T} q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{P}) \times \mathtt{P.m}$. Therefore, $q(\mathtt{z}|\mathtt{P}) = \max(p(\mathtt{z}|\mathtt{P}), p(\mathtt{z}|\mathtt{P}) \times \mathtt{P.m}) = p(\mathtt{z}|\mathtt{P}) \times \mathtt{P.m}$, where we have used the fact that $\mathtt{P.m} \geq 1$ due to line 1 of Algorithm 1. We have thus proven the second case.

Finally, suppose that $\mathtt{Pz} \in T$. Then, again,

$$\begin{aligned} q(\mathtt{z}|\mathtt{P}) &= \max_{\mathtt{x}\in\Delta} q(\mathtt{z}|\mathtt{xP}) \\ &= \max\Big(\\ &\qquad \max_{\mathtt{x}\in\Delta,\, \mathtt{xPz}\notin T,\, \mathtt{xP}\notin T} q(\mathtt{z}|\mathtt{xP}), \\ &\qquad \max_{\mathtt{x}\in\Delta,\, \mathtt{xPz}\notin T,\, \mathtt{xP}\in T} q(\mathtt{z}|\mathtt{xP}), \\ &\qquad \max_{\mathtt{x}\in\Delta,\, \mathtt{xPz}\in T} q(\mathtt{z}|\mathtt{xP})\ \Big). \end{aligned}$$

For $\mathtt{xPz} \notin T$, $\mathtt{xP} \notin T$, we have $q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{P}) = \mathtt{Pz.p}$, where the last equality is due to the fact that $\mathtt{Pz} \in T$. For $\mathtt{xPz} \notin T$, $\mathtt{xP} \in T$, we have $q(\mathtt{z}|\mathtt{xP}) = p(\mathtt{z}|\mathtt{xP}) \times \mathtt{xP.m} = p(\mathtt{z}|\mathtt{P}) \times \mathtt{xP.b} \times \mathtt{xP.m} = \mathtt{Pz.p} \times \mathtt{xP.b} \times \mathtt{xP.m}$. For $\mathtt{xPz} \in T$, we have $q(\mathtt{z}|\mathtt{xP}) = \mathtt{xPz.q}$. Overall, we thus have:

$$\begin{aligned} q(\mathtt{z}|\mathtt{P}) = \max\Big(& \mathtt{Pz.p}, \\ & \max_{\mathtt{x}\in\Delta,\, \mathtt{xPz}\notin T,\, \mathtt{xP}\in T} \mathtt{Pz.p} \times \mathtt{xP.b} \times \mathtt{xP.m}, \\ & \max_{\mathtt{x}\in\Delta,\, \mathtt{xPz}\in T} \mathtt{xPz.q}\ \Big). \end{aligned}$$

Note that $\mathtt{xPz} \in T \Rightarrow \mathtt{xP} \in T$, and then one can check that Algorithm 2 exactly computes $\mathtt{Pz.q}$ as this maximum over three maxima, hence $\mathtt{Pz.q} = q(\mathtt{z}|\mathtt{P})$.

7:             Pz.q ← max(Pz.q, Pz.p × xP.b × xP.m)
8:         end if
9:     end for
10: end for
```

4.4 Search

The search for the true optimum derivation is illustrated in Algorithm 3. The algorithm takes as input the initial proposal distribution $g^{(0)}(\mathbf{d})$ (see §4.2, Figure 3) and a maximum error ϵ (which we set to a small constant 0.001 rather than zero, to avoid problems with floating point precision). In line 3 we find the optimum derivation $\mathbf{d}$ in $g^{(0)}$ (see §4.5). The variable g^* stores the maximum score w.r.t. the current proposal, while the variable f^* stores the maximum score observed thus far w.r.t. the true model (note that in line 5 we assess the true score of $\mathbf{d}$). In line 6 we start a loop that runs until the error falls below ϵ. This *error* is the difference (in $\log$-domain) between the proxy maximum g^* and the best true score observed thus far f^*.[13] In line 7, we refine the current proposal using evidence from $\mathbf{d}$ (see §4.6). In line 9, we update the maximum derivation searching through the refined proposal. In line 11, we keep track of the best score so far according to the true model, in order to compute the updated gap in line 6.

4.5 Dynamic Programming

Finding the best derivation in a proposal hypergraph is straightforward with standard dynamic programming. We can compute *inside weights* in the *max-times* semiring in time proportional to $O(|V| + |E|)$ (Goodman, 1999). Once inside weights have been computed, finding the Viterbi-derivation starting from the root is straightforward. A simple, though important, optimisation concerns the computation of inside weights. The inside algorithm (Baker, 1979) requires a bottom-up traverse of the nodes in V. To do that, we topologically sort the nodes in V at time $t = 0$ and maintain a sorted list of nodes as we refine g throughout the search – thus avoiding having to recompute the partial ordering of the nodes at every iteration.

[13] Because $g^{(t)}$ upperbounds f everywhere, in optimisation we have a guarantee that the maximum of f must lie in the interval $[f^*, g^*)$ (see Figure 2) and the quantity $g^* - f^*$ is an upperbound on the error that we incur if we early-stop the search at any given time t. This bound provides a principled criterion in trading accuracy for performance (a direction that we leave for future work). Note that most algorithms for approximate search produce solutions with unbounded error.

Algorithm 3 Exact decoding

```
1: function OPTIMISE(g^(0), ε)
2:     t ← 0                                          ▷ step
3:     d ← argmax_d g^(t)(d)
4:     g* ← g^(t)(d)
5:     f* ← f(d)
6:     while (g* − f* ≥ ε) do      ▷ ε is the maximum error
7:         g^(t+1) ← refine(g^(t), d)        ▷ update proposal
8:         t ← t + 1
9:         d ← argmax_d g^(t)(d)             ▷ update argmax
10:        g* ← g^(t)(d)
11:        f* ← max(f*, f(d))        ▷ update "best so far"
12:    end while
13:    return g^(t), d
14: end function
```

4.6 Refinement

If a derivation $\mathbf{d} = \operatorname{argmax}_{\mathbf{d}} g^{(t)}(\mathbf{d})$ is such that $g^{(t)}(\mathbf{d}) \ll f(\mathbf{d})$, there must be in $\mathbf{d}$ at least one n-gram whose upperbound LM weight is far above its true LM weight. We then lower $g^{(t)}$ locally by refining only nonterminal nodes that participate in $\mathbf{d}$. Nonterminal nodes are refined by having their LM states extended one word at a time.[14]

For an illustration, assume we are performing optimisation with a bigram LM. Suppose that in the first iteration a derivation $\mathbf{d}_0 = \operatorname{argmax}_{\mathbf{d}} g^{(0)}(\mathbf{d})$ is obtained. Now consider an edge in $\mathbf{d}_0$

$$[l, C, r, \epsilon]\ \ \alpha y_1 \xrightarrow{w} [l_0, C_0, r_0, \epsilon]$$

where an empty LM state is made explicit (with an empty string ϵ) and αy_1 represents a target phrase. We refine the edge's head $[l_0, C_0, r_0, \epsilon]$ by creating a node based on it, however, with an extended LM state, i.e., $[l_0, C_0, r_0, y_1]$. This motivates a split of the set of incoming edges to the original node, such that, if the target projection of an incoming

[14] The refinement operation is a special case of a general finite-state intersection. However, keeping its effect local to derivations going through a specific node is non-trivial using the general mechanism and justifies a tailored operation.

edge ends in y_1, that edge is reconnected to the new node as below.

$$[l, C, r, \epsilon]\ \ \alpha y_1 \xrightarrow{w} [l_0, C_0, r_0, y_1]$$

The outgoing edges from the new node are reweighted copies of those leaving the original node. That is, outgoing edges such as

$$[l_0, C_0, r_0, \epsilon]\ \ y_2\beta \xrightarrow{w} \left[l', C', r', \gamma'\right]$$

motivate edges such as

$$[l_0, C_0, r_0, y_1]\ \ y_2\beta \xrightarrow{w \otimes w'} \left[l', C', r', \gamma'\right]$$

where $w' = \lambda_\psi {}^{q_{\text{LM}}(y_1 y_2)}/_{q_{\text{LM}}(y_2)}$ is a change in LM probability due to an extended context.

Figure 4 is the logic program that constructs the refined hypergraph in the general case. In comparison to Figure 3, items are now extended to store an LM state. The input is the original hypergraph $G = \langle V, E\rangle$ and a node $\mathbf{v}_0 \in V$ to be refined by left-extending its LM state γ_0 with the word y. In the program, $\left\langle \mathbf{u}\sigma \xrightarrow{w} \mathbf{v} \right\rangle$ with $\mathbf{u}, \mathbf{v} \in V$ and $\sigma \in \Delta^*$ represents an edge in E. An item $[l, C, r, \gamma]_{\mathbf{v}}$ (annotated with a state $\mathbf{v} \in V$) represents a node (in the refined hypergraph) whose signature is equivalent to $\mathbf{v}$ (in the input hypergraph). We start with AXIOMS by copying the nodes in G. In COPY, edges from G are copied unless they are headed by $\mathbf{v}_0$ and their target projections end in $y\gamma_0$ (the extended context). Such edges are processed by REFINE, which instead of copying them, creates new ones headed by a refined version of $\mathbf{v}_0$. Finally, REWEIGHT continues from the refined node with reweighted copies of the edges leaving $\mathbf{v}_0$. The weight update represents a change in LM probability (w.r.t. the upper-bound distribution) due to an extended context.

INPUT
$G = \langle V, E\rangle$
$\mathbf{v}_0 = [l_0, C_0, r_0, \gamma_0] \in V$ where $\gamma_0 \in \Delta^*$
$y \in \Delta$
ITEM $[l, C, r, \gamma \in \Delta^*]$
AXIOMS

$$\frac{}{[l, C, r, \gamma]_{\mathbf{v}}}\ \ \mathbf{v} \in V$$

COPY

$$\frac{[l, C, r, \alpha]_{\mathbf{u}} \quad \left\langle \mathbf{u}\beta \xrightarrow{w} \mathbf{v} \right\rangle}{[l', C', r', \alpha']_{\mathbf{v}} : w} \quad \begin{array}{l} \mathbf{v} \neq \mathbf{v}_0 \vee \alpha\beta \neq \sigma y \gamma_0 \\ \alpha, \alpha', \beta, \sigma \in \Delta^* \end{array}$$

REFINE

$$\frac{[l, C, R, \alpha]_{\mathbf{u}} \quad \left\langle \mathbf{u}\beta \xrightarrow{w} \mathbf{v}_0 \right\rangle}{[l_0, C_0, r_0, y\gamma_0] : w} \quad \begin{array}{l} \alpha\beta = \sigma y \gamma_0 \\ \alpha, \beta, \sigma \in \Delta^* \end{array}$$

REWEIGHT

$$\frac{[l_0, C_0, r_0, y\gamma_0] \quad \left\langle \mathbf{v}_0\sigma \xrightarrow{w} \mathbf{v} \right\rangle}{[l, C, r, \gamma]_{\mathbf{v}} : w \otimes w'}\ \ \sigma, \gamma \in \Delta^*$$

where $w' = \lambda_\psi \dfrac{q_{\text{LM}}(y\gamma_0)}{q_{\text{LM}}(\gamma_0)}$

Figure 4: Local intersection via LM right state refinement. The input is a hypergraph $G = \langle V, E\rangle$, a node $\mathbf{v}_0 \in V$ singly identified by its carry $[l_0, C_0, r_0, \gamma_0]$ and a left-extension y for its LM context γ_0. The program copies most of the edges $\left\langle \mathbf{u}\sigma \xrightarrow{w} \mathbf{v} \right\rangle \in E$. If a derivation goes through $\mathbf{v}_0$ and the string under $\mathbf{v}_0$ ends in $y\gamma_0$, the program refines and reweights it.

5 Experiments

We used the dataset made available by the Workshop on Statistical Machine Translation (WMT) (Bojar et al., 2013) to train a German-English phrase-based system using the Moses toolkit (Koehn et al., 2007) in a standard setup. For phrase extraction, we used both Europarl (Koehn, 2005) and News Commentaries (NC) totalling about 2.2M sentences.[15] For language modelling, in addition to the monolingual parts of Europarl and NC, we added News-2013 totalling about 25M sentences. We performed language model interpolation and *batch-mira* tuning (Cherry and Foster, 2012) using *newstest2010* (2,849 sentence pairs). For tuning we used cube pruning with a large beam size ($k = 5000$) and a distortion limit $d = 4$. Unpruned language models were trained using *lmplz* (Heafield et al., 2013b) which employs modified Kneser-Ney smoothing (Kneser and Ney, 1995). We report results on *newstest2012*.

Our exact decoder produces optimal translation derivations for all the 3,003 sentences in the test set. Table 1 summarises the performance of our novel decoder for language models of order $n = 3$ to $n = 5$. For 3-gram LMs we also varied the distortion limit d (from 4 to 6). We report the average time (in seconds) to build the initial proposal, the total run time of the algorithm, the number of iterations N before convergence, and the size of the hypergraph in the end of the search (in thousands of nodes and thousands of edges).[16]

[15] Pre-processing: tokenisation, truecasing and automatic compound-splitting (German only). Following Durrani et al. (2013), we set the maximum phrase length to 5.

[16] The size of the initial proposal does not depend on LM order, but rather on distortion limit (see Figure 3): on average (in thousands) $|V_0| = 0.6$ and $|E_0| = 27$ with $d = 4$, $|V_0| = 1.3$ and $|E_0| = 70$ with $d = 5$, and $|V_0| = 2.5$ and

n	d	build (s)	total (s)	N	$\|V\|$	$\|E\|$
3	4	1.5	21	190	2.5	159
3	5	3.5	55	303	4.4	343
3	6	10	162	484	8	725
4	4	1.5	50	350	4	288
5	4	1.5	106	555	6.1	450

Table 1: Performance of the exact decoder in terms of: time to *build* $g^{(0)}$, *total* decoding time including *build*, number of *iterations* (N), and number of nodes and edges (in thousands) at the end of the search.

n	Nodes at level m					LM states at level m			
	0	1	2	3	4	1	2	3	4
3	0.4	1.2	0.5	-	-	113	263	-	-
4	0.4	1.6	1.4	0.3	-	132	544	212	-
5	0.4	2.1	2.4	0.7	0.1	142	790	479	103

Table 2: Average number of nodes (in thousands) whose LM state encode an m-gram, and average number of unique LM states of order m in the final hypergraph for different n-gram LMs ($d = 4$ everywhere).

It is insightful to understand how different aspects of the initial proposal impact on performance. Increasing the translation option limit (*tol*) leads to $g^{(0)}$ having more edges (this dependency is linear with *tol*). In this case, the number of nodes is only minimally affected — due to the possibility of a few new segmentations. The maximum phrase length (*mpl*) introduces in $g^{(0)}$ more configurations of reordering constraints ($[l, C]$ in Figure 3). However, not many more, due to C being limited by the distortion limit d. In practice, we observe little impact on time performance. Increasing d introduces many more permutations of the input leading to exponentially many more nodes and edges. Increasing the order n of the LM has no impact on $g^{(0)}$ and its impact on the overall search is expressed in terms of a higher number of nodes being locally intersected.

An increased hypergraph, be it due to additional nodes or additional edges, necessarily leads to slower iterations because at each iteration we must compute inside weights in time $O(|V|+|E|)$. The number of nodes has the larger impact on the number of iterations. OS* is very efficient in ignoring hypotheses (edges) that cannot compete for an optimum. For instance, we observe that running time depends linearly on *tol* only through the computation of inside weights, while the number of iterations is only minimally affected.[17] An increased LM order, for a fixed distortion limit, impacts much more on the number of iterations than on the average running time of a single iteration. Fixing $d = 4$, the average time per iteration is 0.1 ($n = 3$), 0.13 ($n = 4$) and 0.18 ($n = 5$). Fixing a 3-gram LM, we observe 0.1 ($d = 4$), 0.17 ($d = 5$) and 0.31 ($d = 6$). Note the exponential growth of the latter, due to a proposal encoding exponentially many more permutations.

Table 2 shows the average degree of refinement of the nodes in the final proposal. Nodes are shown by level of refinement, where m indicates that they store m words in their carry. The table also shows the number of unique m-grams ever incorporated to the proposal. This table illustrates well how our decoding algorithm moves from a coarse upperbound where every node stores an empty string to a variable-order representation which is sufficient to prove an optimum derivation.

In our approach a complete derivation is optimised from the proxy model at each iteration. We observe that over 99% of these derivations project onto distinct strings. In addition, while the optimum solution may be found early in the search, a certificate of optimality requires refining the proxy until convergence (see §4.1). It turns out that most of the solutions are first encountered as late as in the last 6-10% of the iterations.

We use the optimum derivations obtained with our exact decoder to measure the number of search errors made by beam search and cube pruning with increasing beam sizes (see Table 3). Beam search reaches optimum derivations with beam sizes $k \geq 500$ for all language models tested. Cube pruning, on the other hand, still makes mistakes at $k = 1000$. Table 4 shows translation quality achieved with different beam sizes for cube pruning and compares it to exact decoding. Note that for $k \geq 10^4$ cube pruning converges to optimum

$|E_0| = 178$ with $d = 6$. Observe the exponential dependency on distortion limit, which also leads to exponentially longer running times.

[17] It is possible to reduce the size of the hypergraph throughout the search using the upperbound on the search error $g^* - f^*$ to prune hypotheses that surely do not stand a chance of competing for the optimum (Graehl, 2005). Another direction is to group edges connecting the same nonterminal nodes into one *partial edge* (Heafield et al., 2013a) — this is particularly convenient due to our method only visiting the 1-best derivation from $g(\mathbf{d})$ at each iteration.

k	Beam search			Cube pruning		
	3	4	5	3	4	5
10	938	1294	1475	2168	2347	2377
10^2	19	60	112	613	999	1126
10^3	0	0	0	29	102	167
10^4	0	0	0	0	4	7

Table 3: Beam search and cube pruning search errors (out of 3,003 test samples) by beam size using LMs of order 3 to 5 ($d = 4$).

order	3			4	5
k	$d = 4$	$d = 5$	$d = 6$	$d = 4$	$d = 4$
10	20.47	20.13	19.97	20.71	20.69
10^2	21.14	21.18	21.08	21.73	21.76
10^3	21.27	21.34	21.32	21.89	21.91
10^4	21.29	21.37	21.37	21.92	21.93
OS*	21.29	21.37	21.37	21.92	21.93

Table 4: Translation quality in terms of BLEU as a function of beam size in cube pruning with language models of order 3 to 5. The bottom row shows BLEU for our exact decoder.

derivations in the vast majority of the cases (100% with a 3-gram LM) and translation quality in terms of BLEU is no different from OS*. However, with $k < 10^4$ both model scores and translation quality can be improved. Figure 5 shows a finer view on search errors as a function of beam size for LMs of order 3 to 5 (fixed $d = 4$). In Figure 6, we fix a 3-gram LM and vary the distortion limit (from 4 to 6). Dotted lines correspond to beam search and dashed lines correspond to cube pruning.

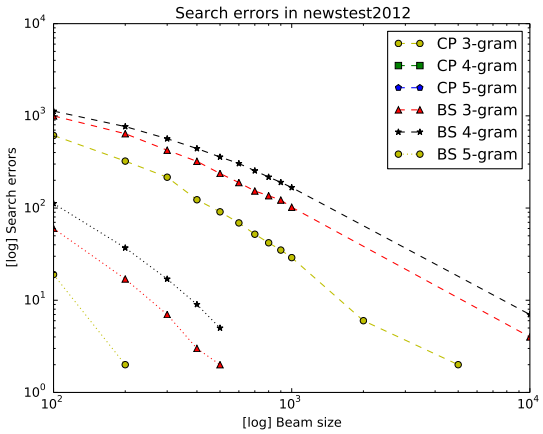

Figure 5: Search errors made by beam search and cube pruning as a function of beam-size.

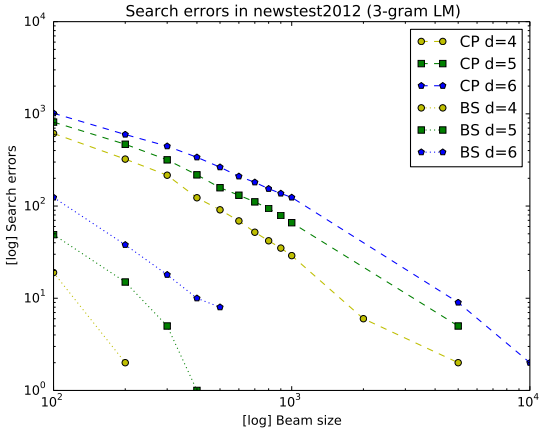

Figure 6: Search errors made by beam search and cube pruning as a function of the distortion limit (decoding with a 3-gram LM).

6 Conclusions and Future Work

We have presented an approach to decoding with unpruned hypergraphs using upperbounds on the language model distribution. The algorithm is an instance of a coarse-to-fine strategy with connections to A* and adaptive rejection sampling known as OS*. We have tested our search algorithm using state-of-the-art phrase-based models employing robust language models. Our algorithm is able to decode all sentences of a standard test set in manageable time consuming very little memory. We have performed an analysis of search errors made by beam search and cube pruning and found that both algorithms perform remarkably well for phrase-based decoding. In the case of cube pruning, we show that model score and translation quality can be improved for beams $k < 10,000$.

There are a number of directions that we intend to investigate to speed up our decoder, such as: (1) error-safe pruning based on search error bounds; (2) use of reinforcement learning to guide the decoder in choosing which n-gram contexts to extend; and (3) grouping edges into partial edges, effectively reducing the size of the hypergraph and ultimately computing inside weights in less time.

Abstract

Recent work by Cherry (2013) has shown that directly optimizing phrase-based reordering models towards BLEU can lead to significant gains. Their approach is limited to small training sets of a few thousand sentences and a similar number of sparse features. We show how the expected BLEU objective allows us to train a simple linear discriminative reordering model with millions of sparse features on hundreds of thousands of sentences resulting in significant improvements. A comparison to likelihood training demonstrates that expected BLEU is vastly more effective. Our best results improve a hierarchical lexicalized reordering baseline by up to 2.0 BLEU in a single-reference setting on a French-English WMT 2012 setup.

1 Introduction

Modeling reordering for phrase-based machine translation has been a long standing problem. Contrary to synchronous context free grammar-based translation models (Wu, 1997; Galley et al., 2004; Galley et al., 2006; Chiang, 2007), phrase-based models (Koehn et al., 2003; Och and Ney, 2004) have no in-built notion of reordering beyond what is captured in a single phrase pair, and the first phrase-based decoders simply scored inter-phrase reorderings using a restricted linear distortion feature, which scores a phrase reordering proportionally to the length of its displacement. While phrase-based models allow in theory completely unrestricted reordering patterns, movements are generally limited to a finite distance for complexity reasons. To address this limitation, extensive prior work focused on richer feature sets, in particular on lexicalized reordering models trained with maximum likelihood-based approaches (Tillmann, 2003; Xiong et al., 2006; Galley and Manning, 2008; Nguyen et al.,2009;§2).

More recently, Cherry (2013) proposed a very effective sparse ordering model relying on a set of only a few thousand indicator features which are trained towards a task-specific metric such as BLEU (Papineni et al., 2002). These features are simply added to the log-linear framework of translation that is trained with the Margin Infused Relaxed Algorithm (MIRA; Chiang et al., 2009) on a small development set of a few thousand sentences. While simple, the approach outperforms the state-of-the-art hierarchical reordering model of Galley and Manning (2008), a maximum likelihood-based model trained on millions of sentences to fit millions of parameters.

Ideally, we would like to scale sparse reordering models to similar dimensions but recent attempts to increase the amount of training data for MIRA was met with little success (Eidelman et al., 2013). In this paper we propose much larger sparse ordering models that combine the scalability of likelihood-based approaches with the higher accuracy of maximum BLEU training (§3). We train on the output of a hierarchical reordering model-based system and scale to millions of features learned on hundreds of thousands of sentences (§4). Specifically, we use the expected BLEU objective function (Rosti et al., 2010; Rosti et al., 2011; He and Deng, 2012; Gao and He, 2013; Gao et al., 2014; Green et al., 2014) which allows us to train models that use training data and feature sets that are two to three orders of magnitudes larger than in previous work (§5).

Our models significantly outperform the state-of-the-art hierarchical lexicalized reordering model on two language pairs and we demonstrate that richer feature sets result in significantly higher accuracy than with a feature set similar to Cherry (2013). We also demonstrate that our

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1250–1260,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

approach greatly benefits from more training data than is typically used for maximum BLEU training. Previous work concluded that sparse reordering models perform better than maximum entropy models, however, the two approaches do not only differ in the objective function but also the type of training data (Cherry, 2013). Our analysis isolates the objective function and shows that expected BLEU optimization is the most important factor to train accurate ordering models. Finally, we compare expected BLEU training to pair-wise ranked optimization (PRO) on a feature set similar to Cherry (2013; §7).

2 Reordering Models

Reordering models for phrase-based translation are typically part of the log-linear framework which forms the basis of many statistical machine translation systems (Och and Ney, 2004).

Formally, we are given K training pairs $\mathcal{D} = (f^{(1)}, e^{(1)})...(f^{(K)}, e^{(K)})$, where each $f^{(i)} \in \mathcal{F}$ is drawn from a set of possible foreign sentences, and each English sentence $e^{(i)} \in \mathcal{E}(f^{(i)})$ is drawn from a set of possible English translations of $f^{(i)}$. The log-linear model is parameterized by m parameters θ where each $\theta_k \in \theta$ is the weight of an associated feature $h_k(f, e)$ such as a language model or a reordering model. Function $h(f, e)$ maps foreign and English sentences to the vector $h_1(f, e)...h_m(f, e)$, and we usually choose translations $\hat{e}$ according to the following decision rule:

$$\hat{e} = \arg\max_{e \in \mathcal{E}(f)} \theta^{\mathsf{T}} h(f, e) \quad (1)$$

In practice, computing $\hat{e}$ exactly is intractable and we resort to an approximate but more efficient beam search (Och and Ney, 2004).

Early phrase-based models simply relied on a linear distortion feature, which measures the distance between the first word of the current source phrase and the last word of the previous source phrase (Koehn et al., 2003; Och and Ney, 2004). Unfortunately, this approach is agnostic to the actual phrases being reordered, and does not take into account that certain phrases are more likely to be reordered than others. This shortcoming led to a range of *lexicalized* reordering models that capture exactly those preferences for individual phrases (Tillmann, 2003; Koehn et al., 2007).

Reordering models generally assume a sequence of English phrases $e = \{\bar{e}_1, \ldots, \bar{e}_n\}$ currently hypothesized by the decoder, a phrase alignment $a = \{a_1, \ldots, a_n\}$ that defines a foreign phrase $\bar{f}_{a_i}$ for each English phrase $\bar{e}_i$, and an *orientation* o_i which describes how a phrase pair should be reordered with respect to the previous phrases. There are typically three orientation types and the exact definition depends on the specific models which we describe below. Orientations can be determined during decoding and from word-aligned training corpora. Most models estimate a probability distribution $p(o_i|pp_i, a_1, \ldots, a_i)$ for the i-th phrase pair $pp_i = \langle \bar{e}_i, \bar{f}_{a_i} \rangle$ and the alignments $a_1, \ldots, a_i$ of the previous target phrases.

Lexicalized Reordering. This model defines the three orientation types based only on the position of the current and previously translated source phrase a_i and a_{i-1}, respectively (Tillmann, 2003; Koehn et al., 2007). The orientation types generally are: monotone (M), indicating that a_{i-1} is directly followed by a_i. swap (S) assumes that a_i precedes a_{i-1}, i.e., the two phrases swap places. Finally, discontinuous (D) indicates that a_i is not adjacent to a_{i-1}. The probability distribution over these reordering events is based on a maximum likelihood estimate:

$$p(o|pp, a_{i-1}, a_i) = \frac{cnt(o, pp)}{cnt(pp)} \quad (2)$$

where $o \in \{M, S, D\}$ and cnt returns smoothed frequency counts over a word-aligned corpus.

Hierarchical Reordering. An extension of the lexicalized reordering model better handles long-distance reordering by conditioning the orientation of the current phrase on a context larger than just the previous phrase (Galley and Manning, 2008). In particular, the hierarchical reordering model does so by building a compact representations of the preceding context using an efficient shift-reduce parser. During translation new phrases get moved on a stack and are then combined with any previous phrase if they are adjacent. Figure 1 shows an illustrative example: when the decoder shifts phrase pp_8 onto the stack, this phrase is then merged with pp_7 (reduce operation), which then can be merged with previous phrases to finally form a hierarchical block h_1. These merge operations stop once we reach a phrase (here, pp_3) that is not contiguous with the current block. Then, as another phrase (pp_9) is hypothesized, the decoder uses the hierarchical block at the top of the stack (h_1) to determine the orientation of the current

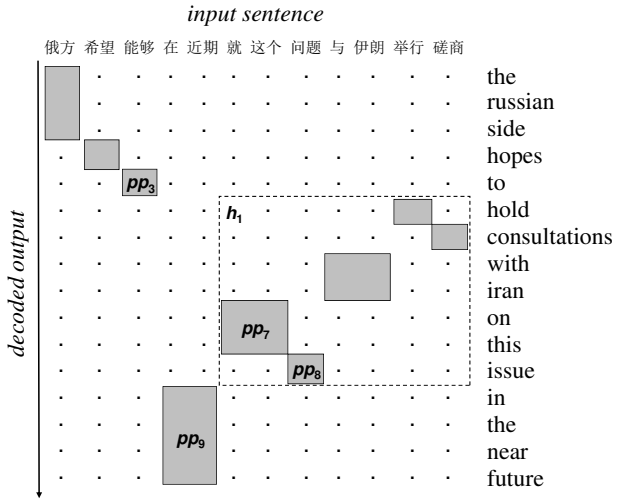

Figure 1: The hierarchical reordering model (HRM) analyzes a non-local context to determine the orientation of the current phrase. For example, the phrase pair pp_9 has a swap orientation ($o_9 = S$) with respect to a hierarchical block (h_1) that comprises the five preceding phrase pairs.

phrase pp_9, which in this case is a swap (S) orientation.[1] The model has the advantage that the orientations computed are more robust to derivational ambiguity of the underlying translation model. A given surface translation may be derived through different phrases but the shift-reduce parser combines them into a single representation which is more consistent with the orientations observed in the word-aligned training data.

Maximum Entropy-based models. The statistics used to estimate the lexicalized and the hierarchical reordering models are based on very sparse estimates, simply because certain phrases are not very frequent. Maximum entropy models address this problem by estimating Eq. 2 through sparse indicator features over phrase pairs instead, but prior work with such models still relies on word aligned corpora for estimation (Xiong et al., 2006; Nguyen et al., 2009). However, recent evaluations of the approach show little gain over the simpler frequency-based estimation method (Cherry, 2013).

Sparse Hierarchical Reordering model. All of the models so far are trained to maximize the likelihood of reordering decisions observed in word aligned corpora. Cherry (2013) argues that it is probably too difficult to learn human reordering patterns through noisy word alignments that were generated by unsupervised methods. Instead, he proposes to learn a discriminative reordering model based on the outputs of the actual machine translation system, adjusting the feature weights to maximize a task-specific objective, which is BLEU in their case. Their model is based on a set of sparse features derived from the hierarchical reordering model which we scale to millions of features (§6).

[1] Galley and Manning (2008) provide a more formal explanation.

3 A Simple Linear Reordering Model

Our reordering model is defined as a simple linear model over the basic orientation types, similar to Cherry (2013). In particular, our model defines score $s_\phi(o, e, f)$ over orientations $o = \{M, S, D\}$, and a sentence pair $\{e, f, a\}$ with alignment a as a linear combination of weighted indicator features:

$$\begin{aligned} s_\phi(o, e, f, a) &= \phi^\mathsf{T} u(o, e, f, a) \\ &= \sum_{i=1}^{I} \phi^\mathsf{T} u(o, pp_i, c_i) \\ &= \sum_{i=1}^{I} s_\phi(o, pp_i, c_i) \end{aligned} \quad (3)$$

where ϕ is a vector of weights, $\{pp_i\}_{i=1}^{I}$ is a set of phrases that decompose the sentence pair $\{e, f, a\}$, and $u(o, pp_i, c_i)$ is a function that maps orientation o, phrase pair pp_i and local context c_i to a sparse vector of indicator features. The local context c_i represents information used by the model that is in addition to the phrase pair. For example, the features of Cherry (2013) condition on the top-stack of the hierarchical shift reduce parser, information that is non-local with respect to the phrase pair. In our experiments, we use features that go beyond the top-stack, in order to condition on various parts of the source and target side contexts (§7).

4 Model Training

Optimization of our model is based on standard stochastic gradient descent (SGD; Bottou, 2004) with an expected BLEU loss $l(\phi)$ which we detail next (§5). The update is:

$$\phi_t = \phi_{t-1} - \mu \frac{\partial l(\phi_{t-1})}{\partial \phi_{t-1}} \quad (4)$$

where ϕ_t and ϕ_{t-1} are model weights at time t and $t-1$ respectively, and μ is a learning rate.

We add the model as a small number of dense features to the log-linear framework of translation

(Eq. 1). Specifically, we extend the m baseline features by a set of new features $h_{m+1}, \ldots, h_{m+j}$, where each represents a linear combination of sparse indicator features corresponding to one of the orientation types. Exposing each orientation as a separate dense feature within the log-linear model is common practice for lexicalized reordering models (Koehn et al., 2005):

$$h_{m+j} = s_\phi(o_j, e, f, a)$$

where $o_j \in \{M, S, D\}$.

The translation model is then parameterized by both θ, the log-linear weights of the baseline features, as well as ϕ, the weights of the reordering model. The reordering model is learned as follows (Gao and He, 2013; Gao et al., 2014):

1. We first train a baseline translation system to learn θ, without the discriminative reordering model, i.e., we set $\theta_{m+1} = 0, \ldots, \theta_{m+j} = 0$.

2. Using these weights, we generate n-best lists for the foreign sentences in the training data using the setup described in the experimental section (§7). The n-best lists serve as an approximation to $\mathcal{E}(f)$, the set of possible translations of f, used in the next step for expected BLEU training of the reordering model (§5).

3. Next, we fix θ, set $\theta_{m+1} = 1, \ldots \theta_{m+j} = 1$ and optimize ϕ with respect to the loss function on the training data using stochastic gradient descent.[2]

4. Finally, we fix ϕ and re-optimize θ in the presence of the discriminative reordering model using Minimum Error Rate Training (MERT; Och 2003; §7).

We found that re-optimizing θ after a few iterations of stochastic gradient descent in step 3 did not improve accuracy.

5 Expected BLEU Objective Function

The expected BLEU objective (Gao and He, 2013; Gao et al., 2014) allows us to efficiently optimize a large scale discriminative reordering model towards the desired task-specific metric, which in our setting is BLEU.

[2]We tuned $\theta_{m+1}, \ldots \theta_{m+j}$ on the development set but found that setting them uniformly to one resulted in faster training and equal accuracy.

Formally, we define our loss function $l(\phi)$ as the negative expected BLEU score, denoted as xBLEU(ϕ), for a given foreign sentence f and a log-linear parameter set θ:

$$\begin{aligned} l(\phi) &= -\text{ xBLEU}(\phi) \\ &= -\sum_{e \in \mathcal{E}(f)} p_{\theta,\phi}(e|f)\, \text{sBLEU}(e, e^{(i)}) \end{aligned} \quad (5)$$

where sBLEU$(e, e^{(i)})$ is a smoothed sentence-level BLEU score with respect to the reference translation $e^{(i)}$, and $\mathcal{E}(f)$ is the generation set approximated by an n-best list. In our experiments we use n-best lists with unique entries and therefore our definitions do not take into account multiple derivations of the same translation. Specifically, our n-best lists are generated by choosing the highest scoring derivation $\hat{e}$ amongst string identical translations e for f. We use a sentence-level BLEU approximation similar to Gao et al. (2014).[3] Finally, $p_{\theta,\phi}(e|f)$ is the normalized probability of translation e given f, defined as:

$$p_{\theta,\phi}(e|f) = \frac{\exp\{\gamma \theta^\mathsf{T} h(f, e)\}}{\sum_{e' \in \mathcal{E}(f)} \exp\{\gamma \theta^\mathsf{T} h(f, e')\}} \quad (6)$$

where $\theta^\mathsf{T} h(f, e)$ includes the discriminative reordering model $h_{m+1}(e, f), \ldots, h_{m+j}(e, f)$ parameterized by ϕ, and $\gamma \in [0, \inf)$ is a tuned scaling factor that flattens the distribution for $\gamma < 1$ and sharpens it for $\gamma > 1$ (Tromble et al., 2008).[4]

Next, we define the gradient of the expected BLEU loss function $l(\phi)$. To simplify our notation we omit the local context c in $s_\phi(o, pp, c)$ (Eq. 3) from now on and assume it to be part of pp. Using the observation that the loss does not explicitly depend on ϕ, we get:

$$\begin{aligned} \frac{\partial l(\phi)}{\partial \phi} &= \sum_{o,pp} \frac{\partial l(\phi)}{\partial s_\phi(o, pp)} \frac{\partial s_\phi(o, pp)}{\partial \phi} \\ &= \sum_{o,pp} -\delta_{o,pp} u(o, pp) \end{aligned}$$

where $\delta_{o,pp}$ is the *error term* for orientation o of phrase pair pp:

$$\delta_{o,pp} = -\frac{\partial l(\phi)}{\partial s_\phi(o, pp)}$$

[3]We found in early experiments that the BLEU+1 approximation used by Liang et al. (2006) and Nakov et. al (2012) worked equally well in our setting.

[4]γ is only used during expected BLEU training.

The error term indicates how the expected BLEU loss changes with the reordering score which we derive in the next section.

Finally, the gradient of the reordering score $s_\phi(o, pp)$ with respect to ϕ is simply given by this:

$$\frac{\partial s_\phi(o, pp)}{\partial \phi} = \frac{\partial \phi^\mathsf{T} u(o, pp)}{\partial \phi} = u(o, pp)$$

5.1 Derivation of the Error Term $\delta_{o,pp}$

We rewrite the loss function (Eq. 5) using Eq. 6 and separate it into two terms $G(\phi)$ and $Z(\phi)$:

$$l(\phi) = -\text{xBLEU}(\phi) = -\frac{G(\phi)}{Z(\phi)} \quad (7)$$
$$= -\frac{\sum_{e \in \mathcal{E}(f)} \exp\{\gamma \theta^\mathsf{T} h(f, e)\} \, \text{sBLEU}(e, e^{(i)})}{\sum_{e' \in \mathcal{E}(f)} \exp\{\gamma \theta^\mathsf{T} h(f, e')\}}$$

Next, we apply the quotient rule of differentiation:

$$\delta_{o,pp} = \frac{\partial \text{xBLEU}(\phi)}{\partial s_\phi(o, pp)} = \frac{\partial (G(\phi)/Z(\phi))}{\partial s_\phi(o, pp)}$$
$$= \frac{1}{Z(\phi)} \left(\frac{\partial G(\phi)}{\partial s_\phi(o, pp)} - \frac{\partial Z(\phi)}{\partial s_\phi(o, pp)} \text{xBLEU}(\phi) \right)$$

The gradients for $G(\phi)$ and $Z(\phi)$ with respect to $s_\phi(o, pp)$ are:

$$\frac{\partial G(\phi)}{\partial s_\phi(o, pp)} = \sum_{e \in \mathcal{E}(f)} \text{sBLEU}(e, e^{(i)}) \frac{\partial \exp\{\gamma \theta^\mathsf{T} h(f, e)\}}{\partial s_\phi(o, pp)}$$
$$\frac{\partial Z(\phi)}{\partial s_\phi(o, pp)} = \sum_{e \in \mathcal{E}(f)} \frac{\partial \exp\{\gamma \theta^\mathsf{T} h(f, e)\}}{\partial s_\phi(o, pp)}$$

By using the following definition:

$$U(\phi, e) = \text{sBLEU}(e, e^{(i)}) - \text{xBLEU}(\phi)$$

together with the chain rule, Eq. 6 and Eq. 7, we can rewrite $\delta_{o,pp}$ as follows:

$$\delta_{o,pp} = \frac{1}{Z(\phi)} \sum_{e \in \mathcal{E}(f)} \left(\frac{\partial \exp\{\gamma \theta^\mathsf{T} h(f, e)\}}{\partial s_\phi(o, pp)} U(\phi, e) \right)$$
$$= \sum_{e \in \mathcal{E}(f)} \left(p_{\theta,\phi}(e|f) \frac{\partial \gamma \theta^\mathsf{T} h(f, e)}{\partial s_\phi(o, pp)} U(\phi, e) \right)$$

Because ϕ is only relevant to the reordering model, represented by $h_{m+1}, \ldots, h_{m+j}$, we have:

$$\frac{\partial \gamma \theta^\mathsf{T} h(f, e)}{\partial s_\phi(o, pp)} = \gamma \lambda_k \frac{\partial h_k(e, f)}{\partial s_\phi(o, pp)}$$
$$= \gamma \lambda_k \mathcal{N}(o, pp, e, f)$$

Figure 2: Algorithm for computing the expected BLEU loss with SGD updates (Eq. 4) based on training data $\mathcal{D}$ and learning rate μ.

where $m + 1 \leq k \leq m + j$ and $\mathcal{N}(o, pp, e, f)$ is the number of times pp with orientation o occurs in the current sentence pair.

This simplifies the error term to:

$$\delta_{o,pp} = \sum_{e \in \mathcal{E}(f)} p_{\theta,\phi}(e|f) \gamma \lambda_k \mathcal{N}(o, pp, e, f) U(\phi, e) \quad (8)$$

where λ_k is the weight of the dense feature summarizing orientation o in the log-linear model. We use Eq. 8 in a simple algorithm to train our model (Figure 2). Our SGD trainer uses a mini-batch size of a single sentence (§7) which entails all hypothesis in the n-best list for this sentence and the parameters are updated after each mini-batch.

6 Feature Sets

Our features are inspired by Cherry (2013) who bases his features on the local phrase-pair $pp = \langle \bar{e}, \bar{f} \rangle$ as well as the top stack of the shift reduce parser of the baseline hierarchical ordering model. We experiment with these variants and extensions:

- SparseHRMLocal: This feature set is exclusively based on the local phrase-pair and

consists of features over the first and last word of both the source and target phrase.[5] We use four different word representations: The word identity itself, but only for the 80 most common source and target language words. The three other word representations are based on Brown clustering with either 20, 50 or 80 classes (Brown et al., 1992). There is one feature for every orientation type.

- SparseHRM: The main feature set of Cherry (2013). This is an extension of SparseHRM-Local adding features based on the first and last word of both the source and the target of the hierarchical block at the top of the stack. There are also features based on the source words *in-between* the current phrase and the hierarchical block at the top of the stack.

- SparseHRM+UncommonWords: This set is identical to SparseHRM, except that word-identity features are not restricted to the 80 most frequent words, but can be instantiated for all words, regardless of frequency.

- SparseHRM+BiPhrases: This augments SparseHRM by phrase-identity features resulting in millions of instances compared to only a few thousand for SparseHRM. We add three features for each possible phrase pair: the source phrase, the target phrase, and the whole phrase pair.

The baseline hierarchical lexicalized reordering model is most similar to SparseHRM+BiPhrases feature set since both have parameters for phrase, orientation pairs.[6] The feature set closest to Cherry (2013) is SparseHRM. However, while Cherry had to severely restrict his features for batch lattice MIRA-based training, our maximum expected BLEU approach can handle millions of features.

7 Experiments

Baseline. We experiment with a phrase-based system similar to Moses (Koehn et al., 2007), scoring translations by a set of common features including maximum likelihood estimates of source given target phrases $p_{MLE}(e|f)$ and vice versa, $p_{MLE}(f|e)$, lexically weighted estimates $p_{LW}(e|f)$ and $p_{LW}(f|e)$, word and phrase-penalties, as well as a linear distortion feature. The baseline uses a hierarchical reordering model with five orientation types, including monotone and swap, described in §2, as well as two discontinuous orientations, distinguishing if the previous phrase is to the left or right of the current phrase. Finally, monotone global indicates that all previous phrases can be combined into a single hierarchical block. The baseline includes a modified Kneser-Ney word-based language model trained on the target-side of the parallel data, which is described below. Log-linear weights are estimated with MERT (Och, 2003). We regard the 1-best output of the phrase-based decoder with the hierarchical reordering model as the baseline accuracy.

Evaluation. We use training and test data from the WMT 2012 campaign and report results on French-English and German-English translation (Callison-Burch et al., 2012). Translation models are estimated on 102M words of parallel data for French-English and 91M words for German-English; between 7.5-8.2M words are newswire, depending on the language pair, and the remainder are parliamentary proceedings. All discriminative reordering models are trained on the newswire subset since we found this portion of the data to be most useful in initial experiments. We evaluate on six newswire domain test sets from 2008, 2010 to 2013 as well as the 2010 system combination test set containing between 2034 to 3003 sentences. Log-linear weights are estimated on the 2009 data set comprising 2525 sentences. We evaluate using BLEU with a single reference.

Discriminative Reordering Model. We use 100-best lists generated by the phrase-based decoder to train the discriminative reordering model. The n-best lists are generated by ten systems, each trained on 90% of the available data in order to decode the remaining 10%. The purpose of this procedure is to avoid a bias introduced by generating n-best lists for sentences on which the translation model was previously trained.[7] Unless otherwise

[5] Phrase-local features allow pre-computation which results in significant speed-ups at run-time. Cherry (2013) shows that local features are responsible for most of his gains.

[6] Although, our model is likely to learn significantly fewer parameters since many phrase, orientation pairs will only be seen in the word-aligned data but not in actual machine translation output.

[7] Later, we found that the bias has only a negligible effect on end-to-end accuracy since we obtained very similar results when decoding with a system trained on all data. This setting increased the training data BLEU score from 27.5 to 37.8. We used a maximum source and target phrase length of 7 words.

mentioned, we train our reordering model on the news portion of the parallel data, corresponding to 136K-150K sentences, depending on the language pair. We tuned the various hyper-parameters on a held-out set, including the learning rate, for which we found a simple setting of 0.1 to be useful. To prevent overfitting, we experimented with ℓ_2 regularization, but found that it did not improve test accuracy. We also tuned the probability scaling parameter γ (Eq. 6) but found $\gamma = 1$ to be very good among other settings. We evaluate the performance on a held-out validation set during training and stop whenever the objective changes less than a factor of 0.0003. For our **PRO experiments**, we tuned three hyper-parameters controlling ℓ_2 regularization, sentence-level BLEU smoothing, and length. The latter is important to eliminate PRO's tendency to produce too short translations (Nakov et al., 2012).

7.1 Scaling the Feature Set

We first compare our baseline, a likelihood trained hierarchical reordering model (HRM; Galley & Manning, 2008), to various expected BLEU trained models, starting with SparseHRMLocal, inspired by Cherry (2013) and compare it to SparseHRM+BiPhrases, a set that is three orders of magnitudes larger.

Our results on French-English translation (Table 1) and German-English translation (Table 2) show that the expected BLEU trained models scale to millions of features and that we outperform the baseline by up to 2.0 BLEU on newstest2012 for French-English and by up to 1.1 BLEU on newstest2011 for German-English.[8] Increasing the size of the feature set improves accuracy across the board: The average accuracy over all test sets improves from 1.0 BLEU for the most basic feature set to 1.5 BLEU for the largest feature set on French-English and from 0.3 BLEU to 0.8 BLEU on German-English.[9] The most comparable setting to Cherry (2013) is the feature set SparseHRM, which we outperform by up to 0.5 BLEU on French-English and by 0.3 BLEU on average on both language pairs, demonstrating the benefit of being able to effectively train large feature sets. Furthermore, the increase in the number of features does not affect runtime, since most

[8] Different to the setups of Galley & Manning (2008) and Cherry (2013) our WMT evaluation framework uses only one instead of four references, which makes our BLEU score improvements not directly comparable.

[9] We attribute smaller improvements on German-English to the low distortion limit of only six words of our system and the more difficult reordering patterns when translating from German which may require more elaborate features.

features can be pre-computed and stored in the phrase-table, only requiring a constant time table-lookup, similar to traditional reordering models.

Another appeal of our approach is that training is very fast given a set of n-best lists for the training data. The SparseHRM model with 4,407 features is trained in only 26 minutes, while the SparseHRM+BiPhrases model with over three million parameters can be trained in just over two hours (136K sentences and 100 epochs in both cases). We attribute this to the training regime (§4), which does not iteratively re-decode the training data for expected BLEU training.[10]

7.2 Varying Training Set Size

Previous work on sparse reordering models was restricted to small data sets (Cherry, 2013) due to the limited ability of standard machine translation optimizers to handle more than a few thousand sentences. In particular, recent attempts to scale the margin-infused relaxation algorithm, a variation which was also used by Cherry (2013), to larger data sets showed that more data does not necessarily help to improve test set accuracy for large feature sets (Eidelman et al., 2013).

In the next set of experiments, we shed light on the advantage of training discriminative reordering models with expected BLEU on large training sets. Specifically, we start off by estimating a reordering model on only 2,000 sentences, similar to the size of the development set used by Cherry (2013), and incrementally increase the amount of training data to nearly three hundred thousand sentences. To avoid overfitting to small data sets we experiment with our most basic feature set SparseHRM-Local, comprising of just over 4,400 types.

For this experiment only, we measure accuracy in a *re-ranking* framework for faster experimentation where we use the 100-best output of the baseline system relying on a likelihood-based hierarchical reordering model. We re-estimate the log-linear weights by running a further iteration of MERT on the n-best list of the development set which is augmented by scores corresponding to the discriminative reordering model. The weights of those features are initially set to one and we use 20 random restarts for MERT. At test time we rescore the 100-best list of the test set using the new set of log-linear weights learned previously.

[10] We would expect better accuracy when iteratively decoding the training data but did not do so in this study for efficiency reasons.

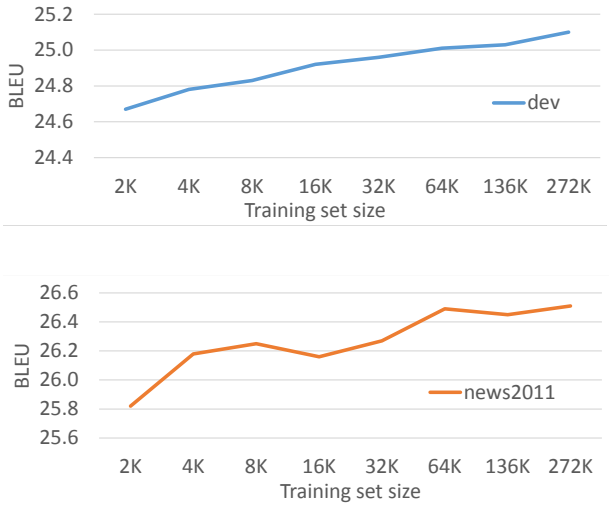

Figure 3: Effect of increasing the training set size from 2,000 to 272,000 sentences measured on the dev set (top) and news2011 (bottom) in an n-best list rescoring setting.

Figure 3 confirms that more training data increases accuracy and that the best model requires a substantially larger amount of training data than what is typically used for maximum BLEU training. We expect an even steeper curve for larger feature sets where more parameters need to be estimated and where the amount of training data is likely to have an even larger effect.

7.3 Likelihood versus BLEU Optimization

Previous research has shown that directly training a reordering model for BLEU can vastly outperform a likelihood trained maximum entropy reordering model (Cherry, 2013). However, the two approaches do not only differ in the objectives used, but also in the type of training data. The maximum entropy reordering model is trained on a word-aligned corpus, trying to learn human reordering patterns, whereas the sparse reordering model is trained on machine translation output, trying to learn from the mistakes made by the actual system. It is therefore not clear how much either one contributes to good accuracy.

Our next experiment teases those two aspects apart and clearly shows the effect of the objective function. Specifically, we compare the traditionally used conditional log-likelihood (CLL) objective to expected BLEU on the French-English translation task in a small feature condition (SparseHRM) of about 9K features and

	dev	2008	2010	sc2010	2011	2012	2013	AllTest

Table 3: French-English results comparing the baseline hierarchical reordering model (HRM) to sparse reordering model trained towards conditional log-likelihood (CLL) and expected BLEU (xBLEU).

	dev	2008	2010	sc2010	2011	2012	2013	AllTest
PRO	24.05	20.90	25.42	25.28	25.79	25.09	26.07	24.94
xBLEU	25.24	21.26	25.99	25.93	26.98	26.34	26.77	25.77

Table 4: French-English results on the SparseHRMLocal feature set when when trained with pair-wise ranked optimization (PRO) and expected BLEU (xBLEU).

a large feature setting of over 3M features (SparseHRM+BiPhrases). In the CLL setting, we maximize the likelihood of the hypothesis with the highest BLEU score in the n-best list of each training sentence.

Our results (Table 3) show that CLL training achieves only a fraction of the gains yielded by the expected BLEU objective. For SparseHRM, CLL improves the baseline by less than 0.2 BLEU on average across all test sets, whereas expected BLEU achieves 1.2 BLEU. Increasing the number of features to 3M (SparseHRM+BiPhrases) results in a slightly better average gain of 0.3 BLEU for CLL but but expected BLEU still achieves a much higher improvement of 1.5 BLEU. Because our gains with likelihood training are similar to what Cherry (2013) reported for his maximum entropy model, we conclude that the objective function is the most important factor to achieving good accuracy.

7.4 Comparison to PRO

In our final experiment we compare expected BLEU training to pair-wise ranked optimization (PRO), a popular off the shelf trainer for machine translation models with large feature sets (Hopkins and May, 2011).[11] Previous work has shown that PRO does not scale to truly large feature sets with millions of types (Yu et al., 2013) and we therefore restrict ourselves to our smallest set (SparseHRMLocal) of just over 4.4K features. We train PRO on the development set comprising of 2,525 sentences, a setup that is commonly used by standard machine translation optimizers. In this setting, PRO directly learns weights for the baseline features (§7) as well as the 4.4K indicator features corresponding to the sparse reordering model. For expected BLEU training we use the full 136K sentences from the training data. The results (Table 4) demonstrate that expected BLEU outperforms a typical setup commonly used to train large feature sets.

8 Conclusion and Future Work

The expected BLEU objective is a simple and effective approach to train large-scale discriminative reordering models. We have demonstrated that it scales to millions of features, which is orders of magnitudes larger than other modern machine translation optimizers can currently handle.

Empirically, our sparse reordering model improves machine translation accuracy across the board, outperforming a strong hierarchical lexicalized reordering model by up to 2.0 BLEU on a French to English WMT2012 setup, where the baseline was trained on over two million sentence pairs. We have shown that scaling to large training sets is crucial to good performance and that the best performance is reached when hundreds of thousands of training sentences are used. Furthermore, we demonstrate that task-specific training towards expected BLEU is much more effective than optimizing conditional log-likelihood as

[11] MIRA is another popular optimizer but as previously mentioned, even the best publicly available implementation does not scale to large training sets (Eidelman et al., 2013).

is usually done. We attribute this to the fact that likelihood is a strict zero-one loss that does not assign credit to partially correct solutions, whereas expected BLEU does.

In future work we plan to extend expected BLEU training to lattices and to evaluate the effect of estimating weights for the dense baseline features as well. Our current training procedure (Gao and He, 2013; Gao et al., 2014) decodes the training data only once. In future work, we would like to compare this to repeated decoding as done by conventional optimization methods as well as other large-scale discriminative training approaches (Yu et al., 2013). We expect this to yield additional accuracy gains.

Abstract

Numerous works in Statistical Machine Translation (SMT) have attempted to identify better translation hypotheses obtained by an initial decoding using an improved, but more costly scoring function. In this work, we introduce an approach that takes the hypotheses produced by a state-of-the-art, reranked phrase-based SMT system, and explores new parts of the search space by applying rewriting rules selected on the basis of posterior phrase-level confidence. In the medical domain, we obtain a 1.9 BLEU improvement over a reranked baseline exploiting the same scoring function, corresponding to a 5.4 BLEU improvement over the original `Moses` baseline. We show that if an indication of which phrases require rewriting is provided, our automatic rewriting procedure yields an additional improvement of 1.5 BLEU. Various analyses, including a manual error analysis, further illustrate the good performance and potential for improvement of our approach in spite of its simplicity.

1 Introduction

The standard configuration of modern phrase-based Statistical Machine Translation (SMT) (Koehn et al., 2003) systems can produce very acceptable results on some tasks. However, early integration of better features to guide the search for the best hypothesis can result in significant improvements, an expression of the complexity of modeling translation quality. For instance, improvements have been obtained by integrating features into decoding that better model semantic coherence at the sentence level (Hasan and Ney, 2009) or syntactic well-formedness (Schwartz et al., 2011). However, early use of such complex features typically comes at a high computational cost. Moreover, some informative features require or are better computed when complete translation hypotheses are available. This is addressed in numerous works on reranking of the highest scored sub-space of hypotheses, on so-called n-best lists (Och et al., 2004; Zhang et al., 2006; Carter and Monz, 2011) or output lattices (Schwenk et al., 2006; Blackwood et al., 2010), where many works specifically target the inclusion of better language modelling capabilities, a well-known weakness of current automatic generation approaches (Knight, 2007).

Another way to improve translation *a posteriori* can be done by rewriting initial hypotheses, for instance in a greedy fashion by including new models (Langlais et al., 2007; Hardmeier et al., 2012), or by specifically modeling a task of automatic post-editing targeting a specific system (Simard et al., 2007; Dugast et al., 2007). While such automatic post-editing may seem to be too limited, notably because of the limited initial diversity considered and the fact that it may be in some instances agnostic to the internals of the initial system, it has been shown to potentially improve accuracy of the new translation hypotheses (Parton et al., 2012) and to offer very high oracle performance (Marie and Max, 2013).

However, an important issue for such approaches is their capacity to only rewrite *incorrect* parts of the translation hypotheses and to use appropriate replacement candidates. Many works have tackled the issue of word to *n*-gram confidence estimation in SMT output (Zens and Ney, 2006; Ueffing and Ney, 2007; Bach et al., 2011; de Gispert et al., 2013), and some attempts have been made to exploit confidence estimates for lattice rescoring (Blackwood et al., 2010) or *n*-best reranking (Bach et al., 2011; Luong et al., 2014b).

In this work, we present an approach in which

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1261–1272,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

new complete hypotheses are produced by rewriting existing hypotheses, and are scored using complex models that could not be used during the initial decoding. We will use as competitive baselines systems that rerank the output of an initial decoder using the complete set of available features, and will show that we manage to improve their translation. The difference between our approach and the reranking baseline lies in the manner in which we expand our training data, as well as in our use of high-confidence rewritings to obtain new translation hypotheses. Importantly, this work will only exploit simple confidence estimates corresponding to phrase-based posteriors, which do not require that large sets of human-annotated data be available as in other works (Bach et al., 2011; Luong et al., 2014b).

The remainder of this paper is organized as follows. Section 2 is devoted to the description of our approach, with details on our rewriting approach (2.1), additional features (2.2), rewriting phrase table (2.3), and training examples (2.4). Section 3 presents experiments. We first describe our experimental setup (3.1) and our baseline systems (3.2). We then report results when naive rewriting is performed and then with confidence-based rewriting (3.3). We next devote a significant part of the paper in section 4 to report further results and analyses: an analysis of the performance of our system depending on the quality of initial hypotheses (4.1); a semi-oracle experiment where correct phrases are known (4.2); an oracle experiment where only correct rewriting decisions are made (4.3); a manual error analysis of the main configurations studied in this work (4.4); and, finally, a study of the performance of our approach on a more difficult translation task (4.5). Related work is discussed in section 5 and we conclude and introduce our future work in section 6.

2 Description of the approach

2.1 Rewriting of translation hypotheses

Langlais *et al* (2007) proposed a greedy search procedure to improve translations by reusing the same translation table and scoring function that were used during an initial phrase-based decoding. In our approach, we rewrite hypotheses by using the same greedy search algorithm, adding more complex models and using the most-confident bi-phrases according to the initial decoder's search space. To select the hypothesis to rewrite for each sentence, we produce a n-best list of the initial decoder and rerank this list with a new, better informed scoring function (see section 2.2). The one-best hypothesis obtained after reranking is then rewritten by our system (denoted as `rewriter`). In this way, we ensure that the hypothesis that was rewritten had been so far the best one according to the initial decoding best subspace and the new models used.

At each iteration, new hypotheses are obtained from a current hypothesis by applying one rewriting operation on bi-phrases. The set of all new hypotheses is called the neighborhood of the current hypothesis. Focusing in this work on *local rewriting*, we used the following set of operations (N denotes the number of bi-phrases, T the maximum number of entries per source phrase in a rewriting phrase table (see 2.3), and S the average number of tokens per source phrase)[1]:

1. `replace` ($\mathcal{O}(N.T)$): replaces the translation of a source phrase with another translation from the rewriting phrase table;

2. `split` ($\mathcal{O}(N.S.T^2)$): splits a source phrase into all possible sets of two (contiguous) phrases, and uses `replace` on each of the resulting phrases;

3. `merge` ($\mathcal{O}(T.N)$): merges two contiguous source phrases and uses `replace` on the resulting new phrase.

This rewriting algorithm is described in pseudo-code in Algorithm 1.

Algorithm 1 `rewriter` Algorithm

Require: *source* a sentence to translate

```
nbestList ← TRANSLATE(source)
oneBest ← RERANK(nbestList)
sCurrent ← GET_SCORE(oneBest)
loop
   hypothesesSet ← NEIGHBORHOOD(oneBest)
   newOneBest ← RANK(hypothesesSet)
   s ← GET_SCORE(newOneBest)
   if s ≤ sCurrent then
      return oneBest
   else
      oneBest ← newOneBest
      sCurrent ← s
   end if
end loop
```

[1] Complexity is expressed in terms of the maximum number of hypotheses that will be considered given some hypothesis to rewrite.

The produced hypotheses are then ranked according to a new, better informed scoring function (see 2.2). At the next iteration, the hypothesis now ranked at the top of the list is rewritten, and search terminates when no better hypothesis is found.

Such a greedy search has several obvious limitations, in particular it can only perform a limited exploration of the search space, a situation that can be improved by using a beam (see Section 3.3). However, associated with a small and precise rewriting phrase table, this approach only visits small numbers of more-confident hypotheses, which is a critical property given the cost of computing the new scoring function used.

2.2 Reranking and features

The rerankings of the hypotheses sets describe in this work are all performed with `kb-mira` (Cherry and Foster, 2012) using the initial features set of the decoder in conjunction with the following additional features:[2]

- **`SOUL` models**: `SOUL` models are structured output layer neural network language models (LMs) which have been shown to be useful in reranking tasks, for instance for WMT evaluations (Allauzen et al., 2013; Pécheux et al., 2014). `SOUL` scoring being too costly to be integrated during decoding, it fits perfectly the `reranker` scenario, which furthermore enables to use larger contexts for *n*-grams. We used both monolingual (Le et al., 2011) and bilingual (Le et al., 2012) `SOUL` 10-gram models, which were trained on the WMT'12 data.

- **POS language model**: part-of-speech (POS) LMs have been shown to yield improvements in *n*-best list reranking (Carter and Monz, 2011). In this work, we trained a 6-gram POS LM using Witten-Bell smoothing.

- **IBM1** : the IBM1 scores ($p(e|f)$ and $p(f|e)$) of the complete hypothesis (Och et al., 2004).

- **phrase-based confidence score** : bi-phrases are associated to a posterior probability, inspired from *n*-gram posterior probability estimation as defined in (de Gispert et al., 2013). Let E be the set of all hypotheses in the space of translation hypotheses defined by the n-best list used for source sentence f, and E_α be the subset of E such that word alignments in sentence pairs (e', f), $\forall e' \in E_\alpha$, allow us to extract bi-phrase α. Let also $H(e, f)$ be the score assigned by a baseline decoder (denoted as `1-pass Moses` henceforth) to sentence pair (e, f). We use the following posterior probability for α:

$$P(\alpha|F) = \frac{\sum_{e' \in E_\alpha} exp(H(e', f))}{\sum_{e'' \in E} exp(H(e'', f))} \quad (1)$$

Then, the logarithms of each phrase's confidence score are summed to use as a confidence score for the complete hypothesis.

[2]Note that we did not try to explore the independant contribution of each feature in this work.

2.3 Rewriting phrase table

Taking the whole translation table of the decoder as a rewriting phrase table to perform the greedy search produces very large neighborhoods that `rewriter` cannot handle due to the cost of the models that have to be computed. We tried two different approaches to extract a rewriting phrase table from the translation table of the system.

We first tried a naive approach where the rewriting phrase table of `rewriter` for the test set uses the phrase table of `1-pass Moses`, filtered to keep the k best entries according to the direct translation model. We denote such a configuration `rpt`k`pef`.

Our second approach consists in extracting the rewriting phrase table containing bi-phrases that were the most probable according to the set of all models used in `1-pass Moses`. Selection of bi-phrases for each sentence is done in a binary fashion, depending on their presence in k-best lists of `1-pass Moses` for a given value of k. This configuration will be denoted `conf`k.

2.4 Training examples

We tried several sets of examples to train the ranker of `rewriter`. We used the 1,000-best list of the development set produced by `1-pass Moses` during its tuning. In other configurations we mixed *a*) the neighborhood of the `reranker` n-best hypotheses computed by our system on the development set using a rewriting phrase table containing the bi-phrases found in the k-best list produced by `1-pass Moses`; and *b*) the neighborhood of the one-best hypotheses of `reranker` using a rewriting phrase table containing the 10-best translations from the `1-pass Moses` translation table according to the direct translation

model. Both neighborhoods are produced by a single iteration of rewriter. We denote respectively these sets of hypotheses n-bestNeigh and 10PefNeigh. Our intuition behind the constitution of these training sets is that the ranker of rewriter needs, in order to perform well, training examples that will be similar to hypotheses that it actually generates.

3 Experiments

3.1 Experimental setup

We used two datasets from two different domains: the data provided for the WMT'14 medical translation task[3] (Medical) and a smaller task using the TED talks[4] (TED Talks) data of the IWSLT evaluation campaigns. For the Medical task we used only the English to French translation direction, and both translation directions, English to French and French to English, for the TED Talks task. In this work, the main part of our experiments uses Medical, and TED Talks will be used at a later stage to study a lower-quality situation (cf. 4.5). For the Medical task, initial decodings were produced using a LM trained on all WMT'14 monolingual and bilingual medical data, while for the TED Talks task we used a much larger LM trained on all the data provided for WMT'13[5]. Both are 4-gram LMs estimated with Kneser-Ney smoothing (Chen and Goodman, 1998). For the 6-gram POS LMs used (see 2.2), we used the same data as used for the token-based LM for Medical, and the concatenation of the News Commentaries and Europarl sub-parts of the WMT'13 data for TED Talks. Table 1 provides relevant statistics about the data used.

Tasks	Corpus	Sentences	Tokens (en-fr)
Medical	train	4.9M	78M - 91M
	dev	500	10k - 12k
	test	1,000	21k - 26k
	LM		- 146M
TED Talks	train	107 758	2M - 2.2M
	dev	934	20k - 20k
	test	1,664	31k - 34k
	LM		6B - 2.5B

Table 1: Corpora used in this work.

[4] https://wit3.fbk.eu/mt.php?release=2013-01

[5] http://www.statmt.org/wmt13

We first built a state-of-the-art phrase-based SMT system using Moses (Koehn et al., 2003) with standard settings. We tuned its parameters towards BLEU (Papineni et al., 2002) on the tuning dataset using the kb-mira implementation available in Moses with default parameters.

Our results will be compared using BLEU and TER (Snover et al., 2006) to *a*) the initial best translation produced by the Moses decoder (1-pass Moses) and *b*) the best translation obtained by reranking the 1,000-best list of 1-pass Moses (reranker). Since reranker implements a well-documented approach and uses types of features commonly used in reranking tasks we will consider it as our main baseline. It was trained using kb-mira on the 1,000-best of the development data decoded by 1-pass Moses.

In our experiments, rewriter rewrites the one-best hypothesis[6] produced by reranker using the operators Replace, Split and Merge as described in section 2.1.

3.2 Baseline results

Table 2 gives the results of the 1-pass Moses decoding for the Medical task and the reranking results of reranker applied to the 1-pass Moses 1,000-best list.

1-pass Moses obtains a score of 38.2 BLEU on the test set, which can be considered as a good baseline system.[7] reranker outperforms 1-pass Moses by 3.5 BLEU, indicating a strong performance of the features used on this task. In particular, SOUL is known to be a useful feature for reranking n-best lists on highly-inflected languages such as French. Note also that the SOUL models we used were trained on the WMT'12 monolingual and bilingual data and so were better informed than the models used during the 1-pass Moses decoding.[8] Moreover, as can be seen on Figure 1, the 1,000-best oracle reveals a large potential for improvement over the one-best (+12.4 BLEU). We further observe that the reranked list of reranker shows a much faster potential for translation improvement.

[6] Note that we will also provide results where a beam of *k*-best hypotheses are rewritten.

[7] Distribution of error types on a sub-part of the test set will be provided in section 4.4.

[8] However, SOUL considers only a small sample of the training data for training. For instance, the training of the French monolingual model used roughly only 1% (895K sentences) of all the WMT'12 data.

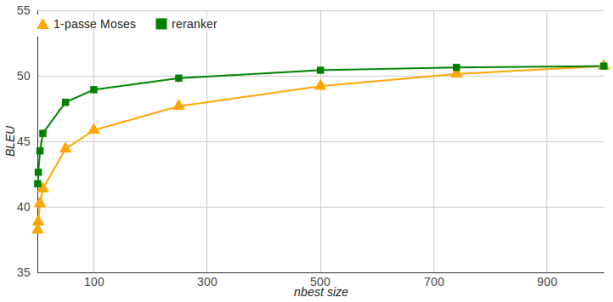

Figure 1: n-best list oracle for `1-pass Moses` and `reranker`

3.3 `rewriter` results

Results for the different rewriting phrase tables and training examples are given in Table 2. First, concerning the rewriting phrase table, for the k=5 (`rpt5pef`) and k=10 (`rpt10pef`) configurations[9] a decrease of 0.7-0.8 BLEU over `reranker` is obtained. This illustrates that naive rewritings applied on the test set cannot be used with our training regime to improve translation quality.

In the next experiments, we used a `conf`k rewriting table. Table 2[10] shows the results of `rewriter` when rewriting the one-best hypothesis from `reranker` for various values of k to define the k-best list from which the rewriting table is built. Various training sets are also considered in the table.

The `1-pass Moses` 1,000-best configuration reused the same set of hypotheses used to train `reranker`. For this configuration, `rewriter` loses 2.6 BLEU over `reranker` on the test set with `conf10k`. Of course, this training data set is of a quite different nature compared to the hypotheses built by `rewriter`.

In the 10pefNeigh training, the ranker is trained with the neighborhoods produced by the first iteration of `rewriter` on the development set with a rewriting phrase table containing only the k-best translations for each source phrase according to the direct translation model. This configuration improves over the previous one by 1.7 BLEU, but is still 0.9 BLEU below `reranker`. Adding the neighborhoods of the `reranker` n-best hypotheses produced with a `conf10k` rewriting phrase table to the training data does not improve over the previous situation for $n = 10$, but increasing n to 30 and then 50 produces strong improvements on the test set (resp. +1.4 and +1.6 BLEU). Considering a larger neighborhood obtained by rewriting the best $n = 90$ hypotheses does not yield further gains. We denote from now on `opti` our best configuration thus far, considering the performance on the development set and having the largest confidence-based rewriting phrase table considered.

Letting `rewriter` perform a beam search on the 10-best hypotheses of the test set, further gains are obtained, corresponding now to an improvement of +1.9 BLEU over our `reranker` baseline, or +5.4 BLEU over `1-pass Moses`.[11] Furthermore, although taking the bi-phrases from the 10,000-best is our best configuration, it is interesting to note that taking bi-phrases from the 10-best only already yields a moderate improvement of +0.6 BLEU over `reranker`. Figure 2a shows that up to $k = 10,000$ higher value of k to extract the rewriting phrase table increase the BLEU score on the test set. [12] We did not experiment with higher values of k, but plan to use the output lattice produced by `1-pass Moses` to compute efficiently posteriors for larger sets of bi-phrases (de Gispert et al., 2013).

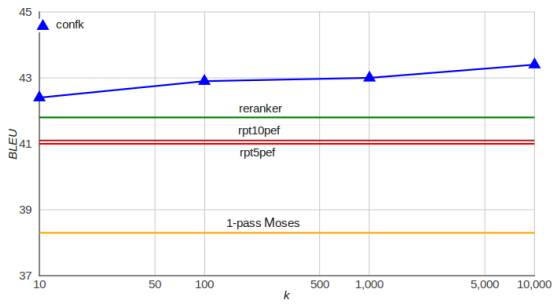
As illustrated on Figure 2b, `rewriter` mostly improves the BLEU score during the three first iterations and then converges at the ninth iteration. However, it is important to note that not all sentences are actually improved by our system. As illustrated on Figure 3a, `opti` improves 40.8% of the sentences of the test set but degrades 29.2% of them according to sentence-BLEU (Lin and Och, 2004). It is certainly the case that more informative confidence features may help idenfity more precisely which fragments of the translations should really undergo rewriting. We will investigate the exploitation of an oracle phrase-based confidence measure in Section 4.2.

[9] We did not experiment with higher values of k because of the computationnal cost of the features used by `reranker`. Indeed, adding more phrase translations increases the size of the neighborhoods corresponding to many additional n-grams to score by `SOUL`, the most expensive model.

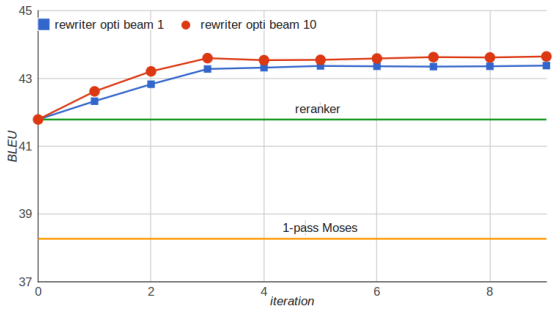
[10] In Table 2 the number of unique bi-phrases for the `rpt` rewriting phrase tables is computed by considering only source phrases appearing in the test set, for the n-best Neighborhood configurations we merged the phrase tables of each sentence into one and count just as one unique entry bi-phrases appearing several times.

[11] Using a beam becomes quickly prohibitive: using 12 threads, 25 mn vs. 3h were needed for the test set for the configurations of size 1 and 10, respectively.

[12] Note that even for $k = 10,000$ the computed neighborhoods are still quite small with an average of 116 hypotheses for each hypothesis to rewrite per iteration, against an average of 788 hypotheses for the `rpt10pef` configuration.



(a) Results of `rewriter` with `rpt5pef`, `rpt10pef` and different values of k for `confk`



(b) Iterations of `rewriter` on test with `opti` and two beam sizes : 1 and 10.

Figure 2: Performance of `rewriter` depending on the type of the rewriting phrase table and the number of iterations and beam sizes.

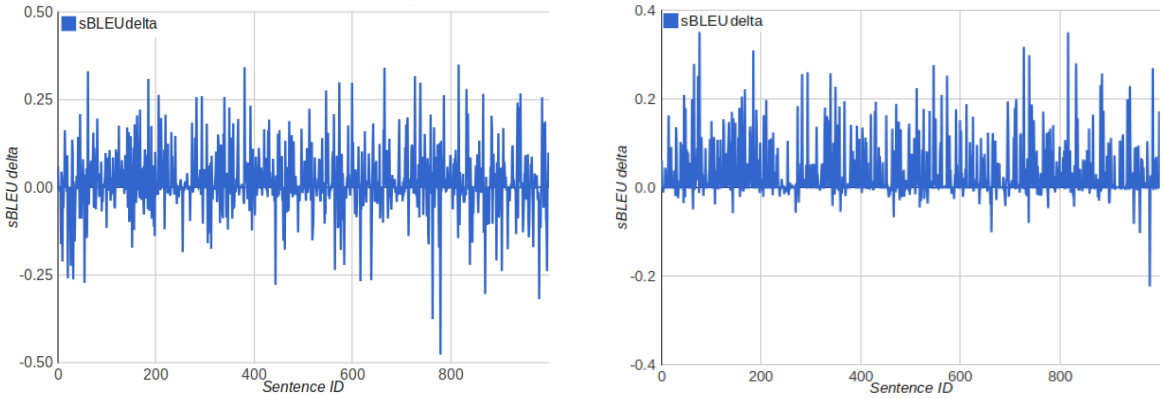
4 Analysis of confidence-based rewriting

4.1 Performance of `rewriter` depending on the quality of initial hypotheses

The first question we address in our analysis of `rewriter` is whether its performance depends on the difficulty of each individual sentence. As a proxy of sentence difficulty we used sentence-BLEU of `1-pass Moses`, and used it to divide the sentences of the test set into quartiles. Figure 4 shows that `reranker` improves more over `1-pass Moses` and that at the same time `rewriter` improves more over `reranker` as the sentences are more difficult. In particular, `rewriter` obtains a 8.6 BLEU improvement over `1-pass Moses` on the more difficult quartile, but only a 1.3 BLEU improvement on the least difficult quartile. We hypothesize that better performance may be achieved if adapting the training and rewriting of `rewriter` to sentences of varying quality, which may, for instance, be estimated with off-the-shelf estimators (Specia et al., 2013).

4.2 Semi-oracle experiments: rewriting only incorrect fragments

We observed in section 3.3 that our `opti` configuration, which obtains strong improvements in translation quality (as given by corpus-BLEU), in fact degrades (as given by sentence-BLEU) a significant proportion of sentences. To further analyze these results, we simulate a situation where oracle confidence information is available at the phrase-level: in particular, `rewriter` is prevented from rewriting bi-phrases whose target phrase appears exactly in the reference transla-



(a) automatic (b) semi-oracle

Figure 3: sBLEU delta, for each sentence, between the `reranker` one-best to rewrite and its automatic (3a) or semi-oracle (3b) rewriting computed by `rewriter` with the `opti` configuration.

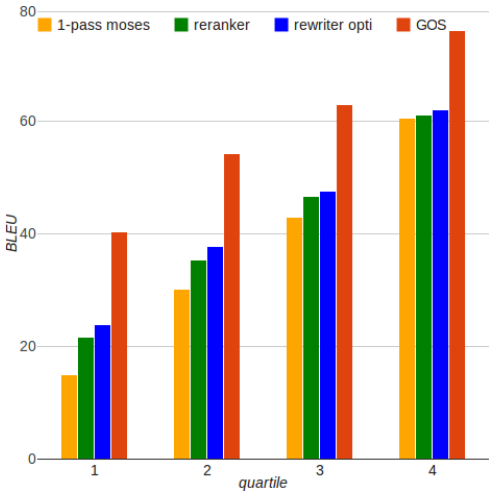


Figure 4: Source sentences were divided into quartiles according to sBLEU of the `1-pass Moses` system. For each quartile we reported the performance of `1-pass Moses`, `reranker`, `rewriter`, `GOS`.

tion.[13] Furthermore, this "freezing" of bi-phrases can be repeated after each iteration of `rewriter`.

Thus, we now have an oracle situation for choosing which source phrases may be rewritten, but the rest of the rewriting procedure is still fully automatic. Moreover, we purposefully did not adapt the training procedure to this new configuration, and reused `opti` as is. Results, reported in Table 3, indicate that an additional 1.5 BLEU is obtained from `opti`, or 3.1 BLEU from `reranker` and 6.6 BLEU from `1-pass Moses`. The use of a larger beam of size 10 did not improve those results any further. At the first iteration, `rewriter` "froze" approximatively 65.6% of the bi-phrases, and 70.5% at the last iteration, demonstrating the ability of `rewriter` to find good rewritings that match the reference translation. Looking at Figure 3b, we now find that, as expected, only a limited number of sentences are now degraded by `rewriter`. The large improvements obtained clearly underlines the important role that better confidence estimates could play in our framework.

System	test	
	BLEU	TER
`reranker`	41.8	41.6
`opti`	43.4	40.4
`semi-oracle`, beam 1	$44.9_{(+1.5)}$	$39.2_{(-1.2)}$
`semi-oracle`, beam 10	$44.9_{(+1.5)}$	$39.0_{(-1.4)}$

Table 3: Results for the semi-oracle using `opti`.

4.3 Oracle experiments: making only the correct decisions

We now turn to the situation where only rewritings that actually improve translation performance would be made. In practice, we use a simple solution: we resort to greedy oracle search (`GOS`) (Marie and Max, 2013), where sentence-BLEU is maximized using rewritings from the `opti` phrase table. At each iteration the rewriting in the neighborhood that maximizes sentence-BLEU is selected until convergence.

Results for this greedy search oracle appear in the last column of Table 2 and allow us to put in perspective the individual potential of the var-

[13] This is obviously not an optimal solution.

ious tested configurations. We can first notice that the rpt5pef phrase table allows the oracle to reach 50.6 BLEU, 8.1 BLEU below the oracle value obtained with conf10k, although rpt5pef contains twice as many bi-phrases. The same conclusion can be made about rpt10pef, which is 3.9 BLEU higher than rpt5pef but contains nearly twice as many bi-phrases. Finally, although conf10k contains approximatively four times fewer bi-phrases than rpt10pef, its oracle value is 4.2 BLEU higher. This points out the fact that conf10k is a lot more precise rewriting phrase table for the translations to rewrite, as well as the fact that rpt5pef and rpt10pef are much noisier and consequently difficult to use efficiently by our automatic rewriting procedure.

4.4 Manual error analysis

In the previous sections, we have shown that our automatic rewriting procedure can improve translation quality over both an initial Moses baseline, and a reranked baseline using the same features as our procedure. We have further shown in section 4.3 that much larger improvements could be obtained by using an oracle procedure.

We now focus on the four following configurations: 1-pass Moses, reranker, rewriter and GOS. Although this four configurations are well separated both in terms of BLEU and TER scores, it is informative to look more precisely into what makes their results different. We performed a small-scale manual error analysis of these four configurations. A French native speaker annotated 70 translation hypotheses using an error typology adapted from (Vilar et al., 2006).

Results of the manual error analysis are reported in Table 4. The most significant results are for the *disamb(iguation)* and *form* error types, the former being more related to translation accuracy, and the later to fluency. In both cases, we first observe a strong reduction of errors between 1-pass Moses and reranker, which demonstrates the positive impact of the features used on these levels. Then, another, similar reduction is obtained between reranker and rewriter, demonstrating that our reranking procedure manages to identify more precise and fluent hypotheses. Finally, a further reduction is found between rewriter and GOS, indicating that our proposed local, greedy rewriting can still be improved, notably by using more informative features and better confidence estimates.

The other types of error categories are less informative. We find no clear differences in error types attributable to style issues, which seem to be irrecoverable even for GOS. reranker and rewriter both improve on order-related errors over 1-pass Moses, but our local rewriting unsurprisingly did not fix any of these errors. Finally, reranker and rewriter decreased slightly the number of extra words from 1-pass Moses, while GOS sometimes artificially introduces extra words.

4.5 Lower-quality SMT experiments

We now turn to the question of how our rewriting system fares on a more difficult task, and used TED Talks, 6 BLEU below Medical for the English to French direction, for this purpose. In the same way as we did for Medical, we first tried to find the best training configuration for the ranker of the rewriting system. For this task, mixing the n-best neighborhood and 10pefNeigh with n=10 seemed to be sufficient to have no more improvement on the development set by increasing n for both language directions, so we used this training configuration. As for the rewriting phrase table used on the test set, we simply selected conf10k as in the Medical task. Results are reported in Table 5 for French to English and English to French.

We first observe that reranker performed similarly for the two translation directions, by improving 1-pass Moses by 0.5 BLEU. The smaller improvements may be partly attributed to the better LM used in 1-pass Moses, implying a better early modeling of grammaticality, but also by the fact that models such as SOUL and POS LMs rely on accurate contexts and are therefore more apt to help in choosing translations among generally better candidates.

Finally, rewriter obtains smaller but consistent improvements over reranker: +0.4 BLEU for translation into English, and +0.9 BLEU for translation into French. The smaller improvement in the former situation may be attributed to the nature of the target language which has a simpler agreement system. Consequently, the form-related errors discussed in Section 4.4 are possibly less subject to improvement here.

	extra	*missing*	*incorrect*				*unknown*	
	word	word	disamb	form	style	order	word	**all**

5 Related work

Reranking of translation hypotheses n-best list reranking was extensively studied in (Och et al., 2004), using features not used in the initial decoder such as IBM1 scores (which also proved useful for word-level confidence estimation (Blatz et al., 2004)) and generative syntactic models. While the experiments in (Och et al., 2004) did not show any clear contribution of syntactic information used in this manner, the later work by Carter and Monz (2011) managed to successfully exploit syntactic features using discriminative language modeling for n-best reranking. Gimpel *et al.* (2013) outperformed n-best reranking by generating, with an expensive but simple method, diverse hypotheses used as training data. Recently, Luong *et al.* (2014b) reranked n-best lists using confidence scores at the hypothesis level computed from word-level confidence measures learnt from roughly 10,000 SMT system outputs annotated by humans.

Rewriting of translation hypotheses Langlais *et al.* (2007) described a greedy search decoder, first introduced in (Germann et al., 2001), able to improve translations produced by a dynamic programming decoder using the same scoring function and translation table. However, the more recent work by Arun *et al.* (2010) using a Gibbs sampler for approximating maximum translation decoding showed the adequacy of the approximations made by state-of-the-art decoders for finding the best translation in their search space. Other works were more directly targeted at automatic post-editing of SMT output, and approached the problem as one of second-pass translation between automatic predictions and correct translations (Simard et al., 2007; Dugast et al., 2007). The recent work of Zhu *et al.* (2013) attempts to repair translations by exploiting confidence estimates for examples derived from the similarity between source words in the input text and in training examples. Luong *et al.* (2014a) obtained improvements by computing word confidence estimation, trained on human annotated data, and large sets of lexical, syntactic and semantic features, for the words in the n-best list produced during a first-pass decoding, and performing a second-pass decoding exploiting these new scores.

Confidence estimation of Machine Translation The Word Posterior Probability (WPP) proposed by Ueffing and Ney (2007), derived from information from the n-best list produced by a decoder, proved to be useful for estimating word-level confidence. Bach *et al.* (2011) worked on the issue of predicting sentence-level and word-level MT errors by using WPP and other features derived from the source context, the source-target alignment, and dependency structures, but relied on a significantly large manually annotated corpus of MT errors. De Gispert *et al.* (2013) calculate k-

gram posterior probabilities from n-best lists or word lattices, and demonstrated that they were reasonably accurate indications of whether specific k-grams would be found or not in human reference translations. Finally, the work of Blackwood *et al.* (2010) proposed to segment translation lattices according to confidence measures over the maximum likelihood translation hypothesis to focus on regions with potential translation errors. Hypothesis space constraints based on monolingual coverage are then applied to the low confidence regions to improve translation fluency.

6 Conclusions and perspectives

In this paper, we have described an approach that improves translations *a posteriori* by applying simple local rewritings. We have shown that the quality of phrase-level confidence estimates has a direct impact of the amplitude of the improvements that can be obtained, as well as the initial quality of the rewritten hypotheses. We have used a very simple definition for confidence estimates under the form of phrase posteriors estimated from n-best lists from an initial decoder, which obtained good empirical performance, in spite of not requiring large human-annotated datasets as in other approaches (Bach et al., 2011; Luong et al., 2014b).

Our work could be extended in several directions. First, we could use a larger set of rewriting operations (Langlais et al., 2007), including the `rewrite` (*sic*) operation introduced in (Marie and Max, 2013) that paraphrases source phrases and then translates them.

We could also possibly consider any phrase segmentation compatible with a specific word alignment rather than rely on specific phrase segmentations. This would allow us to attain faster some rewritings that could otherwise require several rewriting iterations and may never be attained by the greedy procedure.

More features could also be used, for instance to model more fine-grained syntax (Post, 2011) or document-level lexical coherence (Hardmeier et al., 2012). However, anticipating that some features might be very expensive to compute, we could adapt our procedure to work in several passes: initial passes would tend to restrict the search space more and more using an initial set of features, before a more expensive pass would concentrate on a limited number of hypotheses. Figure 1 indeed already showed a much faster oracle improvement between `1-pass Moses` and `reranker` for n-best list of small sizes.

Another avenue for improvement lies in the possibility to perform the training of our `rewriter` by providing it with more reference translations. As these are typically not readily available, we could resort to targeted paraphrasing (Madnani and Dorr, 2013) to rewrite reference translations into acceptable paraphrases that reuse n-grams from the best hypotheses of the system so far. Contrarily to (Madnani and Dorr, 2013), we could bias the paraphrasing table so that it only contains paraphrases that correspond to target phrases of high confidence values, which would add new n-grams likely of being produced by `rewriter`.

It is furthermore worth noticing that our work proposes a potential answer to an original question: contrarily to typical works on sub-sentencial MT confidence estimation, which predict whether a word or phrase is correct or not, our `rewriter` system could be used to determine automatically whether a rewriting system *could* (if asked to) attempt to improve locally a translation, or whether a human post-editor should already tackle working on improving it. As we showed in our manual error analysis in section 4.4, there are in fact many instances of errors that could not be recovered by our approach, be it because of its local rewriting strategy or of the bilingual resources or models used, so that some knowledge would have to be provided as hard constraints by a human translator, as hinted in (Crego et al., 2010). We could then finally have our `rewriter` system work in a turn-based fashion in collaboration with a human translator, fixing errors or making improvements that are being made possible by the last edits from the translator.

Abstract

We present methods to control the lexicon size when learning a Combinatory Categorial Grammar semantic parser. Existing methods incrementally expand the lexicon by greedily adding entries, considering a single training datapoint at a time. We propose using corpus-level statistics for lexicon learning decisions. We introduce *voting* to globally consider adding entries to the lexicon, and *pruning* to remove entries no longer required to explain the training data. Our methods result in state-of-the-art performance on the task of executing sequences of natural language instructions, achieving up to 25% error reduction, with lexicons that are up to 70% smaller and are qualitatively less noisy.

1 Introduction

Combinatory Categorial Grammar (Steedman, 1996, 2000, CCG, henceforth) is a commonly used formalism for semantic parsing – the task of mapping natural language sentences to formal meaning representations (Zelle and Mooney, 1996). Recently, CCG semantic parsers have been used for numerous language understanding tasks, including querying databases (Zettlemoyer and Collins, 2005), referring to physical objects (Matuszek et al., 2012), information extraction (Krishnamurthy and Mitchell, 2012), executing instructions (Artzi and Zettlemoyer, 2013b), generating regular expressions (Kushman and Barzilay, 2013), question-answering (Cai and Yates, 2013) and textual entailment (Lewis and Steedman, 2013). In CCG, a lexicon is used to map words to formal representations of their meaning, which are then combined using bottom-up operations. In this paper we present learning techniques to explicitly control the size of the CCG lexicon, and show that this results in improved task performance and more compact models.

$$
\begin{array}{l}
\textbf{\textit{chair}} \vdash \boldsymbol{N} : \boldsymbol{\lambda x.\mathrm{chair(x)}} \\
\textbf{\textit{chair}} \vdash \boldsymbol{N} : \boldsymbol{\lambda x.\mathrm{sofa(x)}} \\
\textit{chair} \vdash AP : \lambda a.\mathrm{len(a,3)} \\
\textit{chair} \vdash NP : \mathcal{A}(\lambda x.\mathrm{corner(x)}) \\
\textit{chair} \vdash ADJ : \lambda x.\mathrm{hall(x)}
\end{array}
$$

Figure 1: Lexical entries for the word *chair* as learned with no corpus-level statistics. Our approach is able to correctly learn only the top two bolded entries.

In most approaches for inducing CCGs for semantic parsing, lexicon learning and parameter estimation are performed jointly in an online algorithm, as introduced by Zettlemoyer and Collins (2007). To induce the lexicon, words extracted from the training data are paired with CCG categories one sample at a time (for an overview of CCG, see §2). Joint approaches have the potential advantage that only entries participating in successful parses are added to the lexicon. However, new entries are added greedily and these decisions are never revisited at later stages. In practice, this often results in a large and noisy lexicon.

Figure 1 lists a sample of CCG lexical entries learned for the word *chair* with a greedy joint algorithm (Artzi and Zettlemoyer, 2013b). In the studied navigation domain, the word *chair* is often used to refer to chairs and sofas, as captured by the first two entries. However, the system also learns several spurious meanings: the third shows an erroneous usage of *chair* as an adverbial phrase describing action length, while the fourth treats it as a noun phrase and the fifth as an adjective. In contrast, our approach is able to correctly learn only the top two lexical entries.

We present a *batch* algorithm focused on controlling the size of the lexicon when learning CCG semantic parsers (§3). Because we make updates only after processing the entire training set, we

*This research was carried out at Google.

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

can take corpus-wide statistics into account before each lexicon update. To explicitly control the size of the lexicon, we adopt two complementary strategies: *voting* and *pruning*. First, we consider the lexical evidence each sample provides as a vote towards potential entries. We describe two voting strategies for deciding which entries to add to the model lexicon (§4). Second, even though we use voting to only conservatively add new lexicon entries, we also prune existing entries if they are no longer necessary for parsing the training data. These steps are incorporated into the learning framework, allowing us to apply stricter criteria for lexicon expansion while maintaining a single learning algorithm.

We evaluate our approach on the robot navigation semantic parsing task (Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013b). Our experimental results show that we outperform previous state of the art on executing sequences of instructions, while learning significantly more compact lexicons (§6 and Table 3).

2 Task and Inference

To present our lexicon learning techniques, we focus on the task of executing natural language navigation instructions (Chen and Mooney, 2011). This domain captures some of the fundamental difficulties in recent semantic parsing problems. In particular, it requires learning from weakly-supervised data, rather than data annotated with full logical forms, and parsing sentences in a situated environment. Additionally, successful task completion requires interpreting and executing multiple instructions in sequence, requiring accurate models to avoid cascading errors. Although this overview centers around the aforementioned task, our methods are generalizable to any semantic parsing approach that relies on CCG.

We approach the navigation task as a situated semantic parsing problem, where the meaning of instructions is represented with lambda calculus expressions, which are then deterministically executed. Both the mapping of instructions to logical forms and their execution consider the current state of the world. This problem was recently addressed by Artzi and Zettlemoyer (2013b) and our experimental setup mirrors theirs. In this section, we provide a brief background on CCG and describe the task and our inference method.

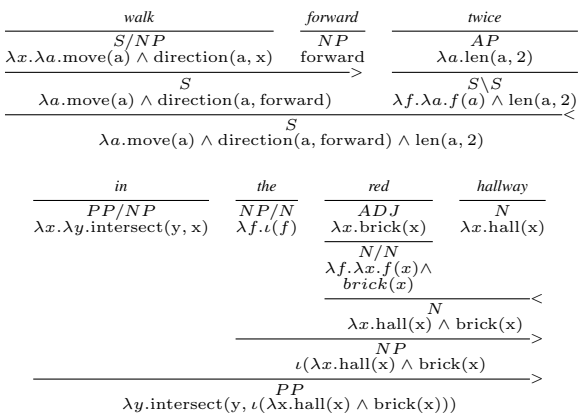

Figure 2: Two CCG parses. The top shows a complete parse with an adverbial phrase (AP), including unary type shifting and forward ($>$) and backward ($<$) application. The bottom fragment shows a prepositional phrase (PP) with an adjective (ADJ).

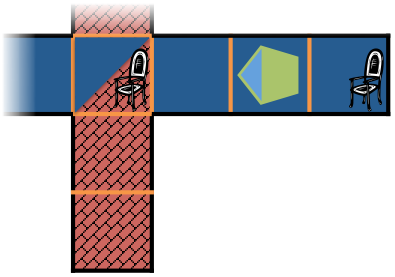
2.1 Combinatory Categorial Grammar

CCG is a linguistically-motivated categorial formalism for modeling a wide range of language phenomena (Steedman, 1996; Steedman, 2000). In CCG, parse tree nodes are categories, which are assigned to strings (single words or n-grams) and combined to create a complete derivation. For example, $S/NP : \lambda x.\lambda a.\text{move(a)} \wedge \text{direction(a, x)}$ is a CCG category describing an imperative verb phrase. The syntactic type S/NP indicates the category is expecting an argument of type NP on its right, and the returned category will have the syntax S. The directionality is indicated by the forward slash $/$, where a backward slash $\backslash$ would specify the argument is expected on the left. The logical form in the category represents its semantic meaning. For example, $\lambda x.\lambda a.\text{move(a)} \wedge \text{direction(a, x)}$ in the category above is a function expecting an argument, the variable x, and returning a function from events to truth-values, the semantic representation of imperatives. In this domain, the conjunction in the logical form specifies conditions on events. Specifically, the event must be a *move* event and have a specified *direction*.

A CCG is defined by a lexicon and a set of combinators. The lexicon provides a mapping from strings to categories. Figure 2 shows two CCG parses in the navigation domain. Parse trees are read top to bottom. Parsing starts by matching categories to strings in the sentence using the lexicon. For example, the lexical entry *walk* $\vdash$ S/NP : $\lambda x.\lambda a.\text{move(a)} \wedge \text{direction(a, x)}$ pairs the string *walk* with the example category above. Each intermediate parse node is constructed by applying

one of a small set of binary CCG combinators or unary operators. For example, in Figure 2 the category of the span *walk forward* is combined with the category of *twice* using backward application ($<$). Parsing concludes with a logical form that captures the meaning of the complete sentence.

We adopt a factored representation for CCG lexicons (Kwiatkowski et al., 2011), where entries are dynamically generated by combining *lexemes* and *templates*. A lexeme is a pair that consists of a natural language string and a set of logical constants, while the template contains the syntactic and semantic components of a CCG category, abstracting over logical constants. For example, consider the lexical entry $\textit{walk} \vdash S/NP : \lambda x.\lambda a.\text{move(a)} \wedge \text{direction(a, x)}$. Under the factored representation, this entry can be constructed by combining the lexeme $\langle \textit{walk}, \{\text{move}, \text{direction}\}\rangle$ and the template $\lambda v_1.\lambda v_2.[S/NP : \lambda x.\lambda a.v_1(a) \wedge v_2(a, x)]$. This representation allows for better generalization over unseen lexical entries at inference time, allowing for pairings of templates and lexemes not seen during training.



facing the chair in the intersection move forward twice

$\langle$LEFT$\rangle$

go to the end of the hall
$\lambda x.move(a) \wedge \text{to(a, } \iota(\lambda x.\text{end(x, } \iota(\lambda y.\text{hall(y)}))))$
$\langle$FORWARD, FORWARD$\rangle$

Figure 3: Fragment of a map and instructions for the navigation domain. The fragment includes two intersecting hallways (red and blue), two chairs and an agent facing left (green pentagon), which follows instructions such as these listed below. Each instruction is paired with a logical form representing its meaning and its execution in the map.

2.2 Situated Log-Linear CCGs

We use a CCG to parse sentences to logical forms, which are then executed. Let $\mathcal{S}$ be a set of states, $\mathcal{X}$ be the set of all possible sentences, and $\mathcal{E}$ be the space of executions, which are $\mathcal{S} \rightarrow \mathcal{S}$ functions. For example, in the navigation task from Artzi and Zettlemoyer (2013b), $\mathcal{S}$ is a set of positions on a map, as illustrated in Figure 3. The map includes an agent that can perform four actions: LEFT, RIGHT, MOVE, and NULL. An execution e is a sequence of actions taken consecutively. Given a state $s \in \mathcal{S}$ and a sentence $x \in \mathcal{X}$, we aim to find the execution $e \in \mathcal{E}$ described in x. Let $\mathcal{Y}$ be the space of CCG parse trees and $\mathcal{Z}$ the space of all possible logical forms. Given a sentence x we generate a CCG parse $y \in \mathcal{Y}$, which includes a logical form $z \in \mathcal{Z}$. An execution e is then generated from z using a deterministic process.

Parsing with a CCG requires choosing appropriate lexical entries from an often ambiguous lexicon and the order in which operations are applied. In a situated scenario such choices must account for the current state of the world. In general, given a CCG, there are many parses for each sentence-state pair. To discriminate between competing parses, we use a situated log-linear CCG, inspired by Clark and Curran (2007).

Let $\textsc{Gen}(x, s; \Lambda) \subset \mathcal{Y}$ be the set of all possible CCG parses given the sentence x, the current state s and the lexicon Λ. In $\textsc{Gen}(x, s; \Lambda)$, multiple parse trees may have the same logical form; let $\mathcal{Y}(z) \subset \textsc{Gen}(x, s; \Lambda)$ be the subset of such parses with the logical form z at the root. Also, let $\theta \in \mathbb{R}^d$ be a d-dimensional parameter vector. We define the probability of the logical form z as:

$$p(z|x, s; \theta, \Lambda) = \sum_{y \in \mathcal{Y}(z)} p(y|x, s; \theta, \Lambda) \quad (1)$$

Above, we marginalize out the probabilities of all parse trees with the same logical form z at the root. The probability of a parse tree y is defined as:

$$p(y|x, s; \theta, \Lambda) = \frac{e^{\theta \cdot \phi(x,s,y)}}{\sum_{y' \in \textsc{Gen}(x,s;\Lambda)} e^{\theta \cdot \phi(x,s,y')}} \quad (2)$$

Where $\phi(x, s, y) \in \mathbb{R}^d$ is a feature vector. Given a logical form z, we deterministically map it to an execution $e \in \mathcal{E}$. At inference time, given a sentence x and state s, we find the best logical form z^* (and its corresponding execution) by solving:

$$z^* = \arg\max_z \; p(z|x, s; \theta, \Lambda) \quad (3)$$

The above $\arg\max$ operation sums over all trees $y \in \mathcal{Y}(z)$, as described in Equation 1. We use a CKY chart for this computation. The chart signature in each span is a CCG category. Since exact inference is prohibitively expensive, we follow previous work and perform bottom-up beam search, maintaining only the k-best categories for each span in the chart. The logical form z^* is taken from the k-best categories at the root of the chart. The partition function in Equation 2 is approximated by summing the inside scores of all categories at the root. We describe the choices of hyperparameters and details of our feature set in §5.

3 Learning

Learning a CCG semantic parser requires inducing the entries of the lexicon Λ and estimating parsing parameters θ. We describe a batch learning algorithm (Figure 4), which explicitly attempts to induce a compact lexicon, while fully explaining the training data. At training time, we assume access to a set of N examples $\mathcal{D} = \left\{d^{(i)}\right\}_1^N$, where each datapoint $d^{(i)} = \langle x^{(i)}, s^{(i)}, e^{(i)} \rangle$, consists of an instruction $x^{(i)}$, the state $s^{(i)}$ where the instruction is issued and its execution demonstration $e^{(i)}$. In particular, we know the correct execution for each state and instruction, but we do not know the correct CCG parse and logical form. We treat the choices that determine them, including selection of lexical entries and parsing operators, as latent. Since there can be many logical forms $z \in \mathcal{Z}$ that yield the same execution $e^{(i)}$, we marginalize over the logical forms (using Equation 1) when maximizing the following regularized log-likelihood:

$$\mathscr{L}(\theta, \Lambda, \mathcal{D}) = \sum_{d^{(i)} \in \mathcal{D}} \sum_{z \in \mathcal{Z}(e^{(i)})} p(z|x^{(i)}, s^{(i)}; \theta, \Lambda) - \frac{\gamma}{2}\|\theta\|_2^2 \quad (4)$$

Where $\mathcal{Z}(e^{(i)})$ is the set of logical forms that result in the execution $e^{(i)}$ and the hyperparameter γ is a regularization constant. Due to the large number of potential combinations,[1] it is impractical to consider the complete set of lexical entries, where all strings (single words and n-grams) are associated with all possible CCG categories. Therefore, similar to prior work, we gradually expand the lexicon during learning. As a result, the parameter space changes throughout training whenever the lexicon is modified. The learning problem involves jointly finding the best set of parameters and lexicon entries. In the remainder of this section, we describe how we optimize Equation 4, while explicitly controlling the lexicon size.

[1]For the navigation task, given the set of CCG category templates (see §2.1) and parameters used there would be between 7.5-10.2M lexical entries to consider, depending on the corpus used (§5).

Algorithm 1 Batch algorithm for maximizing $\mathscr{L}(\theta, \Lambda, \mathcal{D})$. See §3.1 for details.

Input: Training dataset $\mathcal{D} = \left\{d^{(i)}\right\}_1^N$, number of learning iterations T, seed lexicon Λ_0, a regularization constant γ, and a learning rate μ. VOTE is defined in §4.

Algorithm 2 GENENTRIES: Algorithm to generate lexical entries from one training datapoint. See §3.2 for details.

Input: Single datapoint $d = \langle x, s, e \rangle$, current model parameters θ and lexicon Λ.
Output: Datapoint-specific lexicon entries λ.

» Augment lexicon with sentence-specific entries.
$\Lambda_+ \leftarrow \Lambda \cup \textsc{GenLex}(d, \Lambda, \theta)$
» Get max-scoring parses producing correct execution.
$\boldsymbol{y}_+ \leftarrow \textsc{GenMax}(x, s, e; \Lambda_+, \theta)$
» Extract lexicon entries from max-scoring parses.
$\lambda \leftarrow \bigcup_{y \in \boldsymbol{y}_+} \textsc{Lex}(y)$
return λ

Algorithm 3 COMPUTEUPDATE: Algorithm to compute the gradient and the set of lexical entries to prune for one datapoint. See §3.3 for details.

Input: Single datapoint $d = \langle x, s, e \rangle$, current model parameters θ and lexicon Λ.
Output: $\langle \lambda_-, \Delta \rangle$, lexical entries to prune for d and gradient.

» Get max-scoring correct parses given Λ and θ.
$\boldsymbol{y}_+ \leftarrow \textsc{GenMax}(x, s, e; \Lambda, \theta)$
» Create the set of entries to prune.
$\lambda_- \leftarrow \Lambda \setminus \bigcup_{y \in \boldsymbol{y}_+} \textsc{Lex}(y)$
» Compute gradient.
$\Delta \leftarrow \mathbb{E}(y \mid x, s, e; \theta, \Lambda) - \mathbb{E}(y \mid x, s; \theta, \Lambda)$
return $\langle \lambda_-, \Delta \rangle$

Figure 4: Our learning algorithm and its subroutines.

3.1 Optimization Algorithm

We present a learning algorithm to optimize the data log-likelihood, where both lexicon learning and parameter updates are performed in *batch*, i.e., after observing all the training corpus. The batch formulation enables us to use information from the entire training set when updating the model lexicon. Algorithm 1 presents the outline of our optimization procedure. It takes as input a training dataset $\mathcal{D}$, number of iterations T, seed lexicon Λ_0, learning rate μ and regularization constant γ.

Learning starts with initializing the model lexicon Λ using Λ_0 (line 1). In lines 2-9, we run T iterations; in each, we make two passes over the corpus, first to generate lexical entries, and second to compute gradient updates and lexical entries to prune. To generate lexical entries (lines 3-4) we use the subroutine GENENTRIES to independently generate entries for each datapoint, as described in §3.2. Given the entries for each datapoint, we vote on which to add to the model lexicon. The subroutine VOTE (line 5) chooses a subset of the proposed entries using a particular voting strategy (see §4). Given the updated lexicon, we process the corpus a second time (lines 6-7). The subroutine COMPUTEUPDATE, as described in §3.3, computes the gradient update for each datapoint $d^{(i)}$, and also generates the set of lexical entries not included in the max-scoring parses of $d^{(i)}$, which are candidates for pruning. We prune from the model lexicon all lexical entries not used in any correct parse (line 8). During this pruning step, we ensure that no entries from Λ_0 are removed from Λ. Finally, the gradient updates are accumulated to update the model parameters (line 9).

3.2 Lexical Entries Generation

For each datapoint $d = \langle x, s, e \rangle$, the subroutine GENENTRIES, as described in Algorithm 2, generates a set of potential entries. The subroutine uses the function GENLEX, originally proposed by Zettlemoyer and Collins (2005), to generate lexical entries from sentences paired with logical forms. We use the weakly-supervised variant of Artzi and Zettlemoyer (2013b). Briefly, GENLEX uses the sentence and expected execution to generate new lexemes, which are then paired with a set of templates factored from Λ_0 to generate new lexical entries. For more details, see §8 of Artzi and Zettlemoyer (2013b).

Since GENLEX over-generates entries, we need to determine the set of entries that participate in max-scoring parses that lead to the correct execution e. We therefore create a sentence-specific lexicon Λ_+ by taking the union of the GENLEX-generated entries for the current sentence and the model lexicon (line 1). We define $\textsc{GenMax}(x, s, e; \Lambda_+, \theta)$ to be the set of all max-scoring parses according to the parameters θ that are in $\textsc{Gen}(x, s; \Lambda_+)$ and result in the correct execution e (line 2). In line 3 we use the function $\textsc{Lex}(y)$, which returns the lexical entries used in the parse y, to compute the set of all lexical entries used in these parses. This final set contains all newly generated entries for this datapoint and is returned to the optimization algorithm.

3.3 Pruning and Gradient Computation

Algorithm 3 describes the subroutine COMPUTEUPDATE that, given a datapoint d, the current model lexicon Λ and model parameters θ, returns the gradient update and the set of lexical entries to prune for d. First, similar to GENENTRIES we compute the set of correct max-scoring parses using GENMAX (line 1). This time, however, we do not use a sentence-specific lexicon, but instead use the model lexicon that has been expanded with all voted entries. As a result, the set of max-scoring parses producing the correct execution may be different compared to GENENTRIES. $\textsc{Lex}(y)$ is then used to extract the lexical entries from these parses, and the set difference (λ_-) between the model lexicon and these entries is set to be pruned (line 2). Finally, the partial derivative for the datapoint is computed using the difference of two expected feature vectors, according to two distributions (line 3): (a) parses conditioned on the correct execution e, the sentence x, state s and the model, and (b) all parses not conditioned on the execution e. The derivatives are approximate due to the use of beam search, as described in §2.2.

4 Global Voting for Lexicon Learning

Our goal is to learn compact and accurate CCG lexicons. To this end, we globally reason about adding new entries to the lexicon by *voting* (VOTE, Algorithm 1, line 5), and remove entries by *pruning* the ones no longer required for explaining the training data (Algorithm 1, line 8). In voting, each datapoint can be considered as attempting to influence the learning algorithm to update the model lexicon with the entries required to parse it. In this

	Round 1	Round 2	Round 3	Round 4
$d^{(1)}$	⟨*chair*, {chair}⟩ 1/3 ⟨*chair*, {hatrack}⟩ 1/3 ⟨*chair*, {turn, direction}⟩ 1/3	⟨*chair*, {chair}⟩ 1/2 ⟨*chair*, {hatrack}⟩ 1/2	⟨*chair*, {chair}⟩ 1	⟨*chair*, {chair}⟩ 1
$d^{(2)}$	⟨*chair*, {chair}⟩ 1/2 ⟨*chair*, {hatrack}⟩ 1/2	⟨*chair*, {chair}⟩ 1/2 ⟨*chair*, {hatrack}⟩ 1/2	⟨*chair*, {chair}⟩ 1	⟨*chair*, {chair}⟩ 1
$d^{(3)}$	⟨*chair*, {chair}⟩ 1/2 ⟨*chair*, {easel}⟩ 1/2	⟨*chair*, {chair}⟩ 1/2 ⟨*chair*, {easel}⟩ 1/2	⟨*chair*, {chair}⟩ 1/2 ⟨*chair*, {easel}⟩ 1/2	⟨*chair*, {chair}⟩ 1
$d^{(4)}$	⟨*chair*, {easel}⟩ 1	⟨*chair*, {easel}⟩ 1	⟨*chair*, {easel}⟩ 1	⟨*chair*, {easel}⟩ 1
Votes	⟨*chair*, {chair}⟩ 1 1/3 ⟨*chair*, {easel}⟩ 1 1/2 ⟨*chair*, {hatrack}⟩ 5/6 ⟨*chair*, {turn, direction}⟩ 1/3	⟨*chair*, {chair}⟩ 1 1/2 ⟨*chair*, {easel}⟩ 1 1/2 ⟨*chair*, {hatrack}⟩ 1	⟨*chair*, {chair}⟩ 2 1/2 ⟨*chair*, {easel}⟩ 1 1/2	**⟨*chair*, {chair}⟩** 3 ⟨*chair*, {easel}⟩ 1
Discard	⟨*chair*, {turn, direction}⟩	⟨*chair*, {hatrack}⟩	⟨*chair*, {easel}⟩	

Figure 5: Four rounds of CONSENSUSVOTE for the string *chair* for four training datapoints. For each datapoint, we specify the set of lexemes generated in the Round 1 column, and update this set after each round. At the end, the highest voted new lexeme according to the final votes is returned. In this example, MAXVOTE and CONSENSUSVOTE lead to different outcomes. MAXVOTE, based on the initial sets only, will select ⟨*chair*, {easel}⟩.

section we describe two alternative voting strategies. Both strategies ensure that new entries are only added when they have wide support in the training data, but count this support in different ways. For reproducibility, we also provide step-by-step pseudocode for both methods in the supplementary material.

Since we only have access to executions and treat parse trees as latent, we consider as correct all parses that produce correct executions. Frequently, however, incorrect parses spuriously lead to correct executions. Lexical entries extracted from such spurious parses generalize poorly. The goal of voting is to eliminate such entries.

Voting is formulated on the factored lexicon representation, where each lexical entry is factored into a lexeme and a template, as described in §2.1. Each lexeme is a pair containing a natural language string and a set of logical constants.[2] A lexeme is combined with a template to create a lexical entry. In our lexicon learning approach only new lexemes are generated, while the set of templates is fixed; hence, our voting strategies reason over lexemes and only create complete lexicon entries at the end. Decisions are made for each string independently of all other strings, but considering all occurrences of that string in the training data.

In lines 3-4 of Algorithm 1 GENENTRIES is used to propose new lexical entries for each training datapoint $d^{(i)}$. For each $d^{(i)}$ a set $\lambda^{(i)}$, that includes all lexical entries participating in parses that lead to the correct execution, is generated. In these sets, the same string can appear in multiple lexemes. To normalize its influence, each datapoint is given a vote of 1.0 for each string, which is distributed uniformly among all lexemes containing the same string.

For example, a specific $\lambda^{(i)}$ may consist of the following three lexemes: $\langle$*chair*, {chair}$\rangle$, $\langle$*chair*, {hatrack}$\rangle$, $\langle$*face*, {post, front, you}$\rangle$. In this set, the phrase *chair* has two possible meanings, which will therefore each receive a vote of 0.5, while the third lexeme will be given a vote of 1.0. Such ambiguity is common and occurs when the available supervision is insufficient to discriminate between different parses, for example, if they lead to identical executions.

Each of the two following strategies reasons over these votes to globally select the best lexemes. To avoid polluting the model lexicon, both strategies adopt a conservative approach and only select at most one lexeme for each string in each training iteration.

4.1 Strategy 1: MAXVOTE

The first strategy for selecting voted lexical entries is straightforward. For each string it simply aggregates all votes and selects the new lexeme with the most votes. A lexeme is considered new if it is not already in the model lexicon. If no such single lexeme exists (e.g., no new entries were used in correctly executing parses or in the case of a tie) no lexeme is selected in this iteration.

A potential limitation of MAXVOTE is that the votes for all rejected lexemes are lost. However, it is often reasonable to re-allocate these votes to other lexemes. For example, consider the sets of lexemes for the word *chair* in the Round 1 col-

[2] Recall, for example, that in one lexeme the string *walk* may be paired with the set of constants {move, direction}.

umn of Figure 5. Using MAXVOTE on these sets will select the lexeme $\langle \textit{chair}, \{\text{easel}\}\rangle$, rather than the correct lexeme $\langle \textit{chair}, \{\text{chair}\}\rangle$. This occurs when the datapoints supporting the correct lexeme distribute their votes over many spurious lexemes.

4.2 Strategy 2: CONSENSUSVOTE

Our second strategy CONSENSUSVOTE aims to capture the votes that are lost in MAXVOTE. Instead of discarding votes that do not go to the maximum scoring lexeme, voting is done in several rounds. In each round the lowest scoring lexeme is discarded and votes are re-assigned uniformly to the remaining lexemes. This procedure is continued until convergence. Finally, given the sets of lexemes in the last round, the votes are computed and the new lexeme with most votes is selected.

Figure 5 shows a complete voting process for four training datapoints. In each round, votes are aggregated over the four sets of lexemes, and the lexeme with the fewest votes is discarded. For each set of lexemes, the discarded lexeme is removed, unless it will lead to an empty set.[3] In the example, while $\langle \textit{chair}, \{\text{easel}\}\rangle$ is discarded in Round 3, it remains in the set of $d^{(4)}$. The process converges in the fourth round, when there are no more lexemes to discard. The final sets include two entries: $\langle \textit{chair}, \{\text{chair}\}\rangle$ and $\langle \textit{chair}, \{\text{easel}\}\rangle$. By avoiding wasting votes on lexemes that have no chance of being selected, the more widely supported lexeme $\langle \textit{chair}, \{\text{chair}\}\rangle$ receives the most votes, in contrast to Round 1, where $\langle \textit{chair}, \{\text{easel}\}\rangle$ was the highest voted one.

5 Experimental Setup

To isolate the effect of our lexicon learning techniques we closely follow the experimental setup of previous work (Artzi and Zettlemoyer, 2013b, §9) and use its publicly available code.[4] This includes the provided beam-search CKY parser, two-pass parsing for testing, beam search for executing sequences of instructions and the same seed lexicon, weight initialization and features. Finally, except the optimization parameters specified below, we use the same parameter settings.

Data For evaluation we use two related corpora: SAIL (Chen and Mooney, 2011) and ORACLE (Artzi and Zettlemoyer, 2013b). Due to how the original data was collected (MacMahon et al., 2006), SAIL includes many wrong executions and about 30% of all instruction sequences are infeasible (e.g., instructing the agent to walk into a wall). To better understand system performance and the effect of noise, ORACLE was created with the subset of valid instructions from SAIL paired with their gold executions. Following previous work, we use a held-out set for the ORACLE corpus and cross-validation for the SAIL corpus.

Systems We report two baselines. Our batch baseline uses the same regularized algorithm, but updates the lexicon by adding all entries without voting and skips pruning. Additionally, we added post-hoc pruning to the algorithm of Artzi and Zettlemoyer (2013b) by discarding all learned entries that are not participating in max-scoring correct parses at the end of training. For ablation, we study the influence of the two voting strategies and pruning, while keeping the same regularization setting. Finally, we compare our approach to previous published results on both corpora.

Optimization Parameters We optimized the learning parameters using cross validation on the training data to maximize recall of complete sequence execution and minimize lexicon size. We use 10 training iterations and the learning rate $\mu = 0.1$. For SAIL we set the regularization parameter $\gamma = 1.0$ and for ORACLE $\gamma = 0.5$.

Full Sequence Inference To execute sequences of instructions we use the beam search procedure of Artzi and Zettlemoyer (2013b) with an identical beam size of 10. The beam stores states, and is initialized with the starting state. Instructions are executed in order, each is attempted from all states currently in the beam, the beam is then updated and pruned to keep the 10-best states. At the end, the best scoring state in the beam is returned.

Evaluation Metrics We evaluate the end-to-end task of executing complete sequences of instructions against an oracle final state. In addition, to better understand the results, we also measure task completion for single instructions. We repeated

[3] This restriction is meant to ensure that discarding lexemes will not change the set of sentences that can be parsed. In addition, it means that the total amount of votes given to a string is invariant between rounds. Allowing for empty sets will change the sum of votes, and therefore decrease the number of datapoints contributing to the decision.

[4] Their implementation, based on the University of Washington Semantic Parsing Framework (Artzi and Zettlemoyer, 2013a), is available at `http://yoavartzi.com/navi`.

Table 2: Our final results compared to previous work on the SAIL and ORACLE corpora. We report mean precision (P), recall (R), harmonic mean (F1) and lexicon size results and standard deviation between runs (in parenthesis) when appropriate. *Our Approach* stands for batch learning with a consensus voting and pruning. Bold numbers represent the best performing method on a given metric.

each experiment five times and report mean precision, recall,[5] harmonic mean (F1) and lexicon size. For held-out test results we also report standard deviation. For the baseline online experiments we shuffled the training data between runs.

6 Results

Table 1 shows ablation results for 5-fold cross-validation on the ORACLE training data. We evaluate against the online learning algorithm of Artzi and Zettlemoyer (2013b), an extension of it to include post-hoc pruning and a batch baseline. Our best sequence execution development result is obtained with CONSENSUSVOTE and pruning. The results provide a few insights. First, simply switching to batch learning provides mixed results: precision increases, but recall drops and the learned lexicon is larger. Second, adding pruning results in a much smaller lexicon, and, especially in batch learning, boosts performance. Adding voting further reduces the lexicon size and provides additional gains for sequence execution. Finally, while MAXVOTE and CONSENSUSVOTE give comparable performance on their own, CONSENSUSVOTE results in more precise and compact models when combined with pruning.

Table 2 lists our test results. We significantly outperform previous state of the art on both corpora when evaluating sequence accuracy. In both scenarios our lexicon is 60-70% smaller. In contrast to the development results, single sentence performance decreases slightly compared to Artzi and Zettlemoyer (2013b). The discrepancy between single sentence and sequence results might be due to the beam search performed when executing sequences of instructions. Models with more compact lexicons generate fewer logical forms for each sentence: we see a decrease of roughly 40% in our models compared to Artzi and Zettlemoyer (2013b). This is especially helpful during sequence execution, where we use a beam size of 10, resulting in better sequences of executions. In general, this shows the potential benefit of using more compact models in scenarios that incorporate reasoning about parsing uncertainty.

To illustrate the types of errors avoided with voting and pruning, Table 3 describes common error classes and shows example lexical entries for batch trained models with CONSENSUSVOTE and pruning and without. Quantitatively, the mean number of entries per string on development folds

[5]Recall is identical to accuracy as reported in prior work.

String	# lexical entries		Example categories
	Batch baseline	With voting and pruning	
The algorithm often treats common bigrams as multiword phrases, and later learns the more general separate entries. Without pruning the initial entries remain in the lexicon and compete with the correct ones during inference.			
octagon carpet	45	0	~~$N : \lambda x.\text{wall(x)}$~~ ~~$N : \lambda x.\text{hall(x)}$~~ ~~$N : \lambda x.\text{honeycomb(x)}$~~
carpet	51	5	$N : \lambda x.\text{hall(x)}$ ~~$N/N : \lambda f.\lambda x.x == \text{argmin(f, }\lambda\text{y.dist(y))}$~~
octagon	21	5	$N : \lambda x.\text{honeycomb(x)}$ ~~$N : \lambda x.\text{cement(x)}$~~ $ADJ : \lambda x.\text{honeycomb(x)}$
We commonly see in the lexicon a long tail of erroneous entries, which compete with correctly learned ones. With voting and pruning we are often able to avoid such noisy entries. However, some noise still exists, e.g., the entry for "intersection".			
intersection	45	7	$N : \lambda x.\text{intersection(x)}$ ~~$S\backslash N : \lambda f.\text{intersect(you, (f))}$~~ $AP : \lambda a.len(a, 1)$ ~~$N/NP : \lambda x.\lambda y.\text{intersect(y, x)}$~~
twice	46	2	$AP : \lambda a.\text{len(a, 2)}$ ~~$AP : \lambda a.\text{pass(a, }\mathcal{A}\text{(}\lambda\text{x.empty(x)))}$~~ ~~$AP : \lambda a.\text{pass(a, }\mathcal{A}\text{(}\lambda\text{x.hall(x)))}$~~
stone	31	5	$ADJ : \lambda x.\text{stone(x)}$ ~~$ADJ : \lambda x.\text{brick(x)}$~~ ~~$ADJ : \lambda x.\text{honeycomb(x)}$~~ ~~$NP/N : \lambda f.\mathcal{A}(f)$~~
Not all concepts mentioned in the corpus are relevant to the task and some of these are not semantically modeled. However, the baseline learner doesn't make this distinction and induces many erroneous entries. With voting the model better handles such cases, either by pairing such words with semantically empty entries or learning no entries for them. During inference the system can then easily skip such words.			
now	28	0	~~$AP : \lambda a.\text{len(a, 3)}$~~ ~~$AP : \lambda a.\text{direction(a, forward)}$~~
only	38	0	~~$N/NP : \lambda x.\lambda y.\text{intersect(y, x)}$~~ ~~$N/NP : \lambda x.\lambda y.\text{front(y, x)}$~~
here	31	8	~~$NP : \text{you}$~~ $S/S : \lambda x.x$ ~~$S\backslash N : \lambda f.\text{intersect(you, }\mathcal{A}\text{(f))}$~~
Without pruning the learner often over-splits multiword phrases and has no way to reverse such decisions.			
coat	25	0	~~$N : \lambda x.\text{intersection(x)}$~~ ~~$ADJ : \lambda x.\text{hatrack(x)}$~~
rack	45	0	~~$N : \lambda x.\text{hatrack(x)}$~~ ~~$N : \lambda x.\text{furniture(x)}$~~
coat rack	55	5	$N : \lambda x.\text{hatrack(x)}$ ~~$N : \lambda x.\text{wall(x)}$~~ ~~$N : \lambda x.\text{furniture(x)}$~~
Voting helps to avoid learning entries for rare words when the learning signal is highly ambiguous.			
orange	20	0	~~$N : \lambda x.\text{cement(x)}$~~ ~~$N : \lambda x.\text{grass(x)}$~~
pics of towers	26	0	~~$N\lambda x.\text{intersection(x)}$~~ ~~$N : \lambda x.\text{hall(x)}$~~

Table 3: Example entries from a learned ORACLE corpus lexicon using batch learning. For each string we report the number of lexical entries without voting (CONSENSUSVOTE) and pruning and with, and provide a few examples. Struck entries were successfully avoided when using voting and pruning.

decreases from 16.77 for online training to 8.11.

Finally, the total computational cost of our approach is roughly equivalent to online approaches. In both approaches, each pass over the data makes the same number of inference calls, and in practice, Artzi and Zettlemoyer (2013b) used 6-8 iterations for online learning while we used 10. A benefit of the batch method is its insensitivity to data ordering, as expressed by the lower standard deviation between randomized runs in Table 2.[6]

7 Related Work

There has been significant work on learning for semantic parsing. The majority of approaches treat grammar induction and parameter estimation separately, e.g. Wong and Mooney (2006), Kate and Mooney (2006), Clarke et al. (2010), Goldwasser et al. (2011), Goldwasser and Roth (2011), Liang et al. (2011), Chen and Mooney (2011), and Chen (2012). In all these approaches the grammar structure is fixed prior to parameter estimation.

Zettlemoyer and Collins (2005) proposed the learning regime most related to ours. Their learner alternates between batch lexical induction and online parameter estimation. Our learning algorithm design combines aspects of previously studied approaches into a batch method, including gradient updates (Kwiatkowski et al., 2010) and using weak supervision (Artzi and Zettlemoyer, 2011). In contrast, Artzi and Zettlemoyer (2013b) use online perceptron-style updates to optimize a margin-based loss. Our work also focuses on CCG lexicon induction but differs in the use of corpus-level statistics through voting and pruning for explicitly controlling the size of the lexicon.

Our approach is also related to the grammar induction algorithm introduced by Carroll and Char-

[6] Results still vary slightly due to multi-threading.

niak (1992). Similar to our method, they process the data using two batch steps: the first proposes grammar rules, analogous to our step that generates lexical entries, and the second estimates parsing parameters. Both methods use pruning after each iteration, to remove unused entries in our approach, and low probability rules in theirs. However, while we use global voting to add entries to the lexicon, they simply introduce all the rules generated by the first step. Their approach also relies on using disjoint subsets of the data for the two steps, while we use the entire corpus.

Using voting to aggregate evidence has been studied for combining decisions from an ensemble of classifiers (Ho et al., 1994; Van Erp and Schomaker, 2000). MAXVOTE is related to approval voting (Brams and Fishburn, 1978), where voters are required to mark if they approve each candidate or not. CONSENSUSVOTE combines ideas from approval voting, Borda counting, and instant-runoff voting. Van Hasselt (2011) described all three systems and applied them to policy summation in reinforcement learning.

8 Conclusion

We considered the problem of learning for semantic parsing, and presented voting and pruning methods based on corpus-level statistics for inducing compact CCG lexicons. We incorporated these techniques into a batch modification of an existing learning approach for joint lexicon induction and parameter estimation. Our evaluation demonstrates that both voting and pruning contribute towards learning a compact lexicon and illustrates the effect of lexicon quality on task performance.

In the future, we wish to study various aspects of learning more robust lexicons. For example, in our current approach, words not appearing in the training set are treated as unknown and ignored at inference time. We would like to study the benefit of using large amounts of unlabeled text to allow the model to better hypothesize the meaning of such previously unseen words. Moreover, our model's performance is currently sensitive to the set of seed lexical templates provided. While we are able to learn the meaning of new words, the model is unable to correctly handle syntactic and semantic structures not covered by the seed templates. To alleviate this problem, we intend to further explore learning novel lexical templates.

Acknowledgements

We thank Kuzman Ganchev, Emily Pitler, Luke Zettlemoyer, Tom Kwiatkowski and Nicholas FitzGerald for their comments on earlier drafts, and the anonymous reviewers for their valuable feedback. We also wish to thank Ryan McDonald and Arturas Rozenas for their valuable input about voting procedures.

Abstract

In this paper, we demonstrate that significant performance gains can be achieved in CCG semantic parsing by introducing a linguistically motivated grammar induction scheme. We present a new morpho-syntactic factored lexicon that models systematic variations in morphology, syntax, and semantics across word classes. The grammar uses domain-independent facts about the English language to restrict the number of incorrect parses that must be considered, thereby enabling effective learning from less data. Experiments in benchmark domains match previous models with one quarter of the data and provide new state-of-the-art results with all available data, including up to 45% relative test-error reduction.

1 Introduction

Semantic parsers map sentences to formal representations of their meaning (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011). One common approach is to induce a probabilistic CCG grammar, which defines the meanings of individual words and phrases and how to best combine them to analyze complete sentences. There has been recent work developing learning algorithms for CCG semantic parsers (Kwiatkowski et al., 2010; Artzi and Zettlemoyer, 2011) and using them for applications ranging from question answering (Cai and Yates, 2013b; Kwiatkowski et al., 2013) to robot control (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013).

One key learning challenge for this style of learning is to induce the CCG lexicon, which lists possible meanings for each phrase and defines a set of possible parses for each sentence. Previous approaches have either hand-engineered a small set of lexical templates (Zettlemoyer and Collins, 2005, 2007) or automatically learned such templates (Kwiatkowski et al., 2010, 2011). These methods are designed to learn grammars that overgenerate; they produce spurious parses that can complicate parameter estimation.

In this paper, we demonstrate that significant gains can instead be achieved by using a more constrained, linguistically motivated grammar induction scheme. The grammar is restricted by introducing detailed syntactic modeling of a wider range of constructions than considered in previous work, for example introducing explicit treatments of relational nouns, Davidsonian events, and verb tense. We also introduce a new lexical generalization model that abstracts over systematic morphological, syntactic, and semantic alternations within word classes. This includes, for example, the facts that verbs in relative clauses and nominal constructions (e.g., "flights departing NYC" and "departing flights") should be infinitival while verbs in phrases (e.g., "What flights depart at noon?") should have tense. These grammar modeling techniques use universal, domain-independent facts about the English language to restrict word usage to appropriate syntactic contexts, and as such are potentially applicable to any semantic parsing application.

More specifically, we introduce a new *morpho-syntactic*, factored CCG lexicon that imposes our grammar restrictions during learning. Each lexical entry has (1) a word stem, automatically constructed from Wiktionary, with part-of-speech and morphological attributes, (2) a lexeme that is learned

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1284–1295,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

and pairs the stem with semantic content that is invariant to syntactic usage, and (3) a lexical template that specifies the remaining syntactic and semantic content. The full set of templates is defined in terms of a small set of base templates and template transformations that model morphological variants such as passivization and nominalization of verbs. This approach allows us to efficiently encode a general grammar for semantic parsing while also eliminating large classes of incorrect analyses considered by previous work.

We perform experiments in two benchmark semantic parsing datasets: GeoQuery (Zelle and Mooney, 1996) and ATIS (Dahl et al., 1994). In both cases, our approach achieves state-of-the-art performance, including a nearly 45% relative error reduction on the ATIS test set. We also show that the gains increase with less data, including matching previous model's performance with less than 25% of the training data. Such gains are particularly practical for semantic parsers; they can greatly reduce the amount of data that is needed for each new application domain.

2 Related Work

Grammar induction methods for CCG semantic parsers have either used hand-engineered lexical templates, e.g. (Zettlemoyer and Collins, 2005, 2007; Artzi and Zettlemoyer, 2011), or algorithms to learn such templates directly from data, e.g. (Kwiatkowski et al., 2010, 2011). Here, we extend the first approach, and show that better lexical generalization provides significant performance gains.

Although CCG is a common choice for semantic parsers, many other formalisms have been studied, including DCS trees (Liang et al., 2011), integer linear programs (Clarke et al., 2010), and synchronous grammars (Wong and Mooney, 2007; Jones et al., 2012; Andreas et al., 2013). All of these approaches build complete meaning representations for individual sentences, but the data we use has also been studied in related work on cross-sentence reasoning (Miller et al., 1996; Zettlemoyer and Collins, 2009) and modeling semantic interpretation as a tagging problem (Tur et al., 2013; Heck et al., 2013). Although we focus on full analysis with CCG, the general idea of using linguistic constraints to improve learning is broadly applicable.

Semantic parsers are also commonly learned from a variety of different types of supervision, including logical forms (Kate and Mooney, 2006; Wong and Mooney, 2007; Muresan, 2011; Kwiatkowski et al., 2012), question-answer pairs (Clarke et al., 2010; Liang et al., 2011), conversational logs (Artzi and Zettlemoyer, 2011), distant supervision (Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013b), sentences paired with system behavior (Goldwasser and Roth, 2011; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013b), and even from database constraints with no explicit semantic supervision (Poon, 2013). We learn from logical forms, but CCG learning algorithms have been developed for each case above, making our techniques applicable.

There has been significant related work that influenced the design of our morpho-syntactic grammars. This includes linguistics studies of relational nouns (Partee and Borschev, 1998; de Bruin and Scha, 1988), Davidsonian events (Davidson, 1967), parsing as abduction (Hobbs et al., 1988), and other more general theories for lexicons (Pustejovsky, 1991) and CCG (Steedman, 2011). It also includes work on using morphology in CCG syntactic parsing (Honnibal et al., 2010) and more broad-coverage semantics in CCG (Bos, 2008; Lewis and Steedman, 2013). However, our work is unique in studying the use of related ideas for semantic parsing.

Finally, there has also been recent progress on semantic parsing against large, open domain databases such as Freebase (Cai and Yates, 2013a; Kwiatkowski et al., 2013; Berant et al., 2013). Unfortuantely, existing Freebase datasets are not a good fit to test our approach because the sentences they include have relatively simple structure and can be interepreted accurately using only factoid lookups with no database joins (Yao and Van Durme, 2014). Our work focuses on learning more syntactically rich models that support compositional reasoning.

3 Background

Lambda Calculus We represent the meanings of sentences, words and phrases with

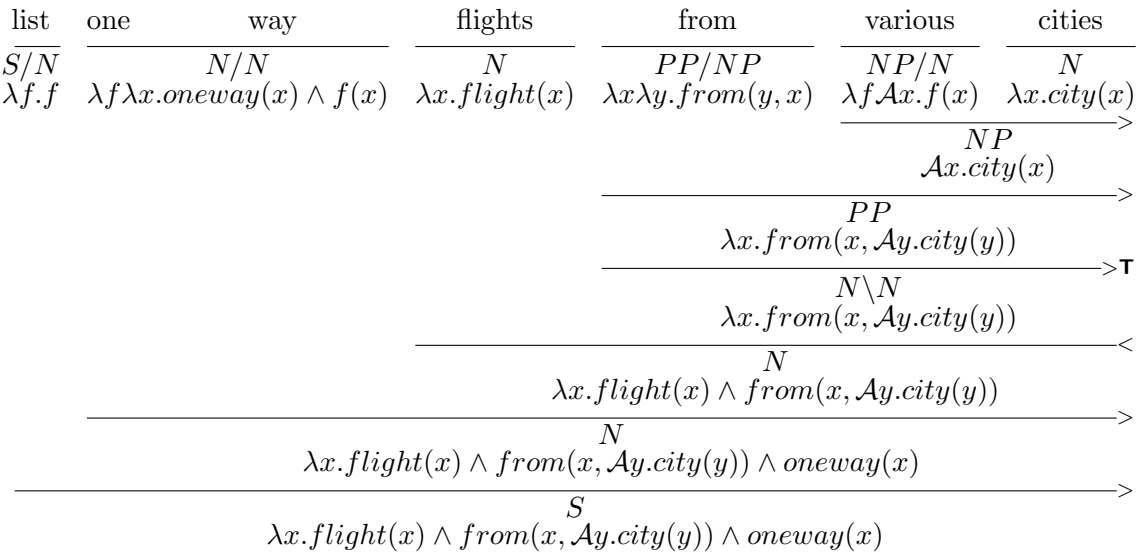

Figure 1: An example CCG parse.

lambda calculus logical expressions. We use a version of the typed lambda calculus (Carpenter, 1997), in which the basic types include entities, events, truth values and numbers. Function types are assigned to lambda expressions. The expression $\lambda x.flight(x)$ with type $\langle e, t\rangle$ takes an entity and returns a truth value, and represents a set of flights.

Combinatory Categorial Grammar CCG (Steedman, 1996, 2000) is a formalism that tightly couples syntax and semantics, and can be used to model a wide range of linguistic phenomena. A traditional CCG grammar includes a lexicon Λ with lexical entries like the following:

$$\begin{aligned}&flights \vdash N : \lambda x.flight(x)\\ &from \vdash PP/NP : \lambda y.\lambda x.from(x, y)\\ &cities \vdash N : \lambda x.city(x)\end{aligned}$$

where a lexical item $w \vdash X : h$ has words w, syntactic category X, and logical expression h.

CCG uses a small set of *combinatory rules* to jointly build syntactic parses and semantic representations. Two common combinatory rules are forward ($>$) and backward ($<$) *application*:

$$\begin{array}{llll} X/Y : f & Y : g & \Rightarrow & X : f(g) \quad (>)\\ Y : g & X\backslash Y : f & \Rightarrow & X : f(g) \quad (<)\end{array}$$

CCG also includes combinatory rules of forward ($>$ **B**) and backward ($<$ **B**) *composition*:

$$\begin{array}{ll} X/Y : f \quad Y/Z : g \Rightarrow X/Z : \lambda x.f(g(x)) & (> \mathbf{B})\\ Y\backslash Z : g \quad X\backslash Y : f \Rightarrow X\backslash Z : \lambda x.f(g(x)) & (< \mathbf{B})\end{array}$$

These rules apply to build syntactic and semantic derivations concurrently.

In this paper, we also implement type raising rules for compact representation of PP (prepositional phrase) and AP (adverbial phrase).

$$\begin{array}{ll} PP : g \Rightarrow N\backslash N : \lambda f\lambda x.f(x) \wedge g(x) & (\mathbf{T})\\ AP : g \Rightarrow S\backslash S : \lambda f\lambda e.f(e) \wedge g(e) & (\mathbf{T})\\ AP : g \Rightarrow S/S : \lambda f\lambda e.f(e) \wedge g(e) & (\mathbf{T})\end{array}$$

Figure 1 shows an example CCG parse (Steedman, 1996, 2000) where the lexical entries are listed across the top and the output lambda-calculus meaning representation is at the bottom. This meaning is a function (denoted by $\lambda x...$) that defines a set of flights with certain properties and includes a generalized Skolem constant (Steedman, 2011) ($\mathcal{A}y...$) that performs existential quantification. Following recent work (Artzi and Zettlemoyer, 2013b), we use meaning representations that model a variety of linguistic constructions, for example including Skolem constants for plurals and Davidson quantifiers for events, which we will introduce briefly throughout this paper as they appear.

Weighted CCGs A weighted CCG grammar is defined as $G = (\Lambda, \Theta)$, where Λ is a CCG lexicon and $\Theta \in \mathbb{R}^d$ is a d-dimensional parameter vector, which will be used to rank the parses allowed under Λ.

For a sentence x, G produces a set of candi-

date parse trees $Y = \mathsf{Y}(x; G)$. Given a feature vector $\Phi \in \mathbb{R}^d$, each parse tree y for sentence x is scored by $\mathsf{S}(y; \Theta) = \theta \cdot \phi(x, y)$. The output logical form $\hat{z}$ is then defined to be at the root of the highest-scoring parse $\hat{y}$:

$$\hat{y} = \arg \max_{y \in \mathsf{Y}(x;G)} \mathsf{S}(y; \Theta) \quad (1)$$

We use existing CKY-style parsing algorithms for this computation, implemented with UW SPF (Artzi and Zettlemoyer, 2013a). Section 7 describes the set of features we use in the learned models.

Learning with GENLEX We will also make use of an existing learning algorithm (Zettlemoyer and Collins, 2007) (ZC07). We first briefly review the ZC07 algorithm, and describe our modifications in Section 7.

Given a set of training examples $D = \{(x_i, z_i) : i = 1...n\}$, x_i being the ith sentence and z_i being its annotated logical form, the algorithm learns a set of parameters Θ for the grammar, while also inducing the lexicon Λ.

The ZC07 learning algorithm uses a function $\mathsf{GENLEX}(x, z)$ to define a set of lexical entries that could be used to parse the sentence x to construct the logical form z. For each training example (x, z), $\mathsf{GENLEX}(x, z)$ maps all substrings x to a set of potential lexical entries, generated by exhaustively pairing the logical constants in z using a set of hand-engineered templates. The example is then parsed with this much bigger lexicon and lexical entries from the highest scoring parses are added to Λ. The parameters Θ used to score parses are updated using a perceptron learning algorithm.

4 Morpho-Syntactic Lexicon

This section defines our morpho-syntactic lexical formalism. Table 1 shows examples of how lexemes, templates, and morphological transformations are used to build lexical entries for example verbs. In this section, we formally define each of these components and show how they are used to specify the space of possible lexical entries that can be built for each input word. In the following two sections, we will provide more discussion of the complete sets of templates (Section 5) and transformations (Section 6).

Verb, Noun, Preposition, Pronoun, Adjective, Adverb, Conjunction, Numeral, Symbol, Proper Noun, Interjection, Expression

Table 2: Part-of-Speech types

POS	**A**ttribute	**V**alues
Noun	Number	singular, plural
Verb	Person	first, second, third
Verb	Voice	active, passive
Verb	Tense	present, past
Verb	Aspect	simple, progressive, perfect
Verb	Participle	present participle, past participle
Adj, Adv, Det	Degree of comparison	comparative, superlative

Table 3: Morphological attributes and values.

We build on the factored CCG lexicon introduced by Kwiatkowski et al. (2011) but (a) further generalize lexemes to represent word stems, (b) constrain the use of templates with widely available syntactic information, and (c) efficiently model common morphological variations between related words.

The first step, given an input word w, is to do morphological and part-of-speech analysis with the **morpho-syntactic function** F. F maps a word to a set of possible morpho-syntactic representations, each containing a triple (s, p, m) of word stem s, part-of-speech p and morphological category m. For example, F maps the word $flies$ to two possible representations:

$$F(flies) = \{(fly, \text{Noun}, (plural)),$$
$$(fly, \text{Verb}, (third, singular, simple, present))\}$$

for the plural noun and present-tense verb senses of the word. F is defined based on the stems, part-of-speech types, and morphological attributes marked for each definition in Wiktionary. [1] The full sets of possible part-of-speech and morphological types required for our domains are shown in Table 2 and Table 3.

Each morpho-syntactic analysis $a \in F(w)$ is then paired with lexemes based on stem match. A **lexeme** $(s, \vec{c})$ pairs a word stem s with a list of logical constants $\vec{c} = [c_1 \dots c_k]$. Table 1 shows the words 'depart', 'departing', 'departure', which are all assigned the lexeme $(depart, [depart])$. In general, there can

[1] www.wiktionary.com

Word	Lexeme : Base Template	Trans	Lexical entry
depart	$(depart, [depart])$:	I	$depart \vdash S\backslash NP : \lambda x\lambda e.depart(e, x)$
departing		I	$departing \vdash S\backslash NP : \lambda x\lambda e.depart(e, x)$
departing	$\xi \vdash S\backslash NP : \lambda x\lambda e.v_1(e, x)$	f_{pres}	$departing \vdash PP : \lambda x\lambda e.depart(e, x)$
departure		f_{nom}	$departure \vdash N : \lambda x\lambda e.depart(e, x)$
use	$(use, [airline])$:	I	$use \vdash S\backslash NP/NP : \lambda x\lambda y\lambda e.airline(e, y, x)$
using		I	$using \vdash S\backslash NP/NP : \lambda x\lambda y\lambda e.airline(e, y, x)$
using	$\xi \vdash S\backslash NP/NP : \lambda x\lambda y\lambda e.v_1(e, y, x)$	f_{pres}	$using \vdash PP/NP : \lambda x\lambda e.airline(e, y, x)$
use		f_{nom}	$use \vdash N/NP : \lambda x\lambda y\lambda e.airline(e, y, x)$

Trans	Template Transformation
f_{pres}	$\xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash PP/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1)$
f_{nom}	$\xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash N/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1)$

Table 1: Lexical entries constructed by combining a *lexeme*, *base template*, and *transformation* for the intransitive verb 'depart' and the transitive verb 'use'.

be many different lexemes for each stem, that vary in the selection of which logical constants are included.

Given analysis (s, p, m) and lexeme $(s, \vec{c})$, we can use a **lexical template** to construct a **lexical entry**. Each template has the form:

$$\lambda(\xi, \vec{v}).[\xi \vdash X : h_{\vec{v}}]$$

where ξ and $\vec{v}$ are variables that abstract over the words and logical constants that will be used to define a lexical entry with syntax X and templated logical form $h_{\vec{v}}$.

To instantiate a template, ξ is filled with the original word w and the constants in $\vec{c}$ replace the variables $\vec{v}$. For example, the template $\lambda(\xi, \vec{v}).[\xi \vdash S\backslash NP : \lambda x\lambda e.v_1(e, x)]$ could be used with the word 'departing' and the lexeme $(depart, [depart])$ to produce the lexical entry $departing \vdash S\backslash NP : \lambda x\lambda e.depart(e, x)$. When clear from context, we will omit the function signature $\lambda_p(\xi, \vec{v})$. for all templates, as seen in Table 1.

In general, there can be many applicable templates, which we organize as follows. Each final template is defined by applying a **morphological transformation** to one of a small set of possible **base templates**. The pairing is found based on the morphological analysis (s, p, m), where each base template is associated with part-of-speech p and each transformation is indexed by the morphology m. A transformation f_m is a function:

$$\mathsf{f}_m(\lambda_p(\xi, \vec{v}).[\xi \vdash X : h_{\vec{v}}]) = \lambda_p(\xi, \vec{v}).[\xi \vdash X' : h'_{\vec{v}}]$$

that takes the base template as input and produces a new template to model the inflected form specified by m.

For example, both base templates in Table 1 are for verbs. The template $\xi \vdash S\backslash NP : \lambda x\lambda e.v_1(e, x)$ can be translated into three other templates based on the transformations I, f_{pres}, and f_{nom}, depending on the analysis of the original words. These transformations generalize across word type; they can be used for the transitive verb 'use' as well as the intransitive 'depart.' Each resulting template, potentially including the original input if the identity transformation I is available, can then be used to make an output lexical entry, as we described above.

5 Lexical Templates

The templates in our lexicon, as introduced in Section 4, model the syntactic and semantic aspects of lexical entries that are shared within each word class. Previous approaches have also used hand-engineered lexical templates, as described in Section 2, but we differ by (1) using more templates allowing for more fine grained analysis and (2) using word class information to restrict template use, for example ensuring that words which cannot be verbs are never paired with templates designed for verbs. This section describes the templates used during learning, first presenting those designed to model grammatical sentences and then a small second set designed for more elliptical spoken utterances.

Base Forms Table 4 lists the primary template set, where each row shows an example with a sentence illustrating its use. Templates are also grouped by the word classes, including adjectives, adverbs, prepositions, and several types of nouns and verbs. While there is not enough space to discuss each row, it is worth

word class	example usage	base template
Noun phrase	Boston	$\xi \vdash NP : v$
Noun (regular)	What **flight** is provided by delta?	$\xi \vdash N : \lambda x.v(x)$
Noun (relation)	I need **fares** of flights	$\xi \vdash N/PP : \lambda x\lambda y.v(x,y)$
	delta **schedule**	$\xi \vdash N\backslash(N/N) : \lambda f\lambda x.v(\mathcal{A}y.f(\lambda z.true, y), x)$
Noun (function)	**size** of California	$\xi \vdash NP/NP : \lambda x.v(x)$
$V_{intrans}$	What flights **depart** from New York?	$\xi \vdash S\backslash NP : \lambda x\lambda e.v(e,x)$
V_{trans}	Which airlines **serve** Seattle (active verb)	$\xi \vdash S\backslash NP/NP : \lambda x\lambda y\lambda e.v(e,y,x)$
	What airlines **have** flights (passive verb)	$\xi \vdash S\backslash NP/NP : \lambda x\lambda y\lambda e.v(e,x,y)$
$V_{ditrans}$	They **give** him a book	$\xi \vdash S\backslash NP/NP/NP : \lambda x\lambda y\lambda z\lambda e.v(e,z,y,x)$
$V_{imperson}$	It **costs** $500 to fly to Boston	$\xi \vdash S\backslash NP/NP/NP : \lambda x\lambda y\lambda z\lambda e.v(e,y,x)$
V_{aux}	The flights **have** arrived at Boston	$\xi \vdash S\backslash NP/(S\backslash NP) : \lambda f.f$
		$\xi \vdash S/NP/(S/NP) : \lambda f.f$
	Does delta provide flights from Seattle?	$\xi \vdash S/S : \lambda f.f$
V_{copula}	The flights **are** from Boston	$\xi \vdash S\backslash NP/PP : \lambda f\lambda x.f(x)$
	What flight **is** cheap?	$\xi \vdash S\backslash NP/(N/N) : \lambda f\lambda x.f(\lambda y.true, x)$
	Alaska **is** the state with the most rivers	$\xi \vdash S\backslash NP/NP : \lambda x\lambda y.equals(y,x)$
Adjective	I need a **one way** flight	$\xi \vdash N/N : \lambda f\lambda x.f(x) \wedge v(x)$
	Boston flights **round trip**	$\xi \vdash PP : \lambda x.v(x)$
	How **long** is mississippi?	$\xi \vdash DEG : \lambda x.v(x)$
Preposition	List flights **from** Boston	$\xi \vdash PP/NP : \lambda x\lambda y.v(y,x)$
	List flights that go **to** Dallas	$\xi \vdash AP/NP : \lambda x\lambda e.v(e,x)$
	List flights **between** Dallas and Boston	$\xi \vdash PP/NP/NP : \lambda x\lambda y\lambda z.v_1(z,x) \wedge v_2(z,y)$
	What flights leave **between** 8am and 9am?	$\xi \vdash AP/NP/NP : \lambda x\lambda y\lambda e.v_1(e,x) \wedge v_2(e,y)$
Adverb	Which flight departs **daily**?	$\xi \vdash AP : \lambda e.v(e)$
	How **early** does the flight arrive?	$\xi \vdash DEG : \lambda x.v(x)$
Determiner	Which airline has **a** flight from Boston?	$\xi \vdash NP/N : \lambda f\mathcal{A}x.f(x)$

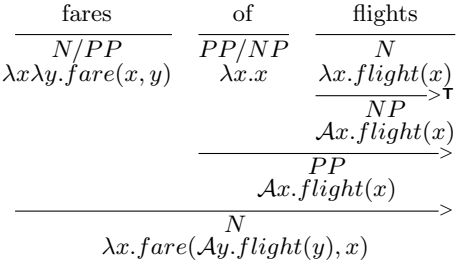
Table 4: Base templates that define different syntactic roles.

type	example usage	base template
$t_{elliptical}$	flights **Newark** to Cleveland	$\xi \vdash PP : \lambda x.P(x,v)$
	flights arriving **2pm**	$\xi \vdash AP : \lambda e.P(e,v)$
	american airline from Denver	$\xi \vdash N : \lambda x.P(x,v)$
$t_{metonymy}$	List **airlines** from Seattle	$\xi \vdash N/PP : \lambda f\lambda x.v(x) \wedge P(\mathcal{A}y.f(y),x))$
	Shat **airlines** depart from Seattle?	$\xi \vdash N/(S\backslash NP) : \lambda f\lambda x.v(x) \wedge P(\mathcal{A}y.f(y),x)$
	fares from miami to New York	$\xi \vdash N/PP : \lambda f\lambda x.v(\mathcal{A}y.f(y),x)$

Table 5: Base templates for ungrammatical linguistic phenomena

considering nouns as an illustrative example.

We model nouns as denoting a set of entities that satisfy a given property. Regular nouns are represented using unary predicates. Relational nouns syntactically function as regular nouns but semantically describe sets of entities that have some relationship with a complement (Partee and Borschev, 1998). For example, the relational noun *fare* describes a binary relationship between flights and their price information, as we see in this parse:



This analysis differs from previous approaches (Zettlemoyer and Collins, 2007), where relational nouns were treated as regular nouns and prepositions introduced the binary relationship. The relational noun model reduces lexical ambiguity for the prepositions, which are otherwise highly polysemous.

Adjectives are nominal modifiers that take a noun or a noun phrase as an argument and add properties through conjunction. Prepositions take nominal objects and function as adjectival modifiers for nouns or adverbial modifiers for verbs. Verbs can be subcategorized by their grammatical structures into transitive (V_{trans}), intransitive ($V_{intrans}$), impersonal ($V_{imperson}$), auxiliary (V_{aux}) and copula (V_{copula}). Adverbs are verb modifiers defining aspects like time, rate and duration. The adoption of event semantics allows adverbial modifiers to be represented by predicates and

linked by the shared events. Determiners precede nouns or noun phrases and distinguish a reference of the noun. Following the generalized Skolem terms, we model determiners, including indefinite and definite articles, as a $\langle\langle e,t\rangle,e\rangle$ function that selects a unique individual from a $\langle e,t\rangle$-typed function defining a singleton set.

Missing Words The templates presented so far model grammatically correct input. However, in dialogue domains such as ATIS, speakers often omit words. For example, speakers can drop the preposition "from" in "flights from Newark to Cleveland" to create the elliptical utterance "flights Newark to Cleveland". We address this issue with the templates $t_{elliptical}$ illustrated in Table 5. Each of these adds a binary relation P to a lexeme with a single entity typed constant. For our example, the word "Newark" could be assigned the lexical item $Newark \vdash PP : \lambda x.from(x, newark)$ by selecting the first template and $P = from$.

Another common problem is the use of metonymy. In the utterance "What airlines depart from New York?", the word "airlines" is used to reference flight services operated by a specific airline. This is problematic because the word "depart" needs to modify an event of type *flight*. We solve this with the $t_{metonymy}$ templates in Table 5. These introduce a binary predicate P that would, in the case of our example, map airlines on to the flights that they operate.

The templates in Table 5 handle the major cases of missing words seen in our data and are more efficient than the approach taken by (Zettlemoyer and Collins, 2007) who introduced complex type shifting rules and relaxed the grammar to allow every word order.

6 Morphological Transformations

Finally, the morpho-syntactic lexicon introduces morphological transformations, which are functions from base lexical templates to lexical templates that model the syntactic and semantic variation as the word is inflected. These transformations allow us to compactly model, for example, the facts that argument order is reversed when moving from active to passive forms of the same verb, and that the subject can be omitted. To the best of our knowledge, we are the first to study such transformations for semantic parsing.

Table 6 shows the transformations. Each row groups a set of transformations by linguistic category, including singular vs. plural number, active vs. passive voice, and so on, and also includes example sentences where the output templates could be used. Again, for space, we do not detail the motivation for every class, but it is worth looking at some of the alternations for verbs and nouns as our prototypical example.

Some verbs can act as noun modifiers. For example, the present participle "using" modifies "flights" in "flights *using* twa". To model this variation, we use the transformation $\mathsf{f}_{present\_part}$, a mapping that changes the root of the verb signature $S\backslash NP$ to PP:

$$\mathsf{f}_{present\_part} : \xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash PP/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1)$$

where $\mathcal{T} = [\epsilon, NP, NP/NP]$ instantiates this rule for verbs that take different sets of arguments, effectively allowing any verb that is in its finite or -ing form to behave syntactically like a prepositional phrase.

Intransitive present participles can also act as prenominal adjectival modifiers as in "the *departing* flight". We add a second mapping that maps the intransitive category $S\backslash NP$ to the noun modifier N/N.

$$\mathsf{f}_{present\_part} : \quad \xi \vdash S\backslash NP : \lambda x\lambda e.v(e, x) \rightarrow \quad \xi \vdash N/N : \lambda f\lambda x\lambda e.f(x) \wedge v(e, x)$$

Finally, verbal nouns have meanings derived from actions typically described by verbs but syntactically function as nouns. For example, *landing* in the phrase "landing from jfk" is the gerundive use of the verb *land*. We add the following mapping to $\mathsf{f}_{present\_part}$ and $\mathsf{f}_{nominal}$:

$$\xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash N/\mathcal{T} : \lambda x_1..x_n\lambda e.v(e, x_n..x_1)$$

with $\mathcal{T}$ from above. This allows for reuse of the same meaning across quite different syntactic constructs, including for example "flights that *depart* from Boston" and "*departure* from Boston."

Template transformations f_m	Example usage
Plural Number (f_{plural})	
I	**flight** → early **flights**
$\xi \vdash N : \lambda x.v(x) \rightarrow \xi \vdash NP : \mathcal{A}x.v(x)$	**city** → flights to **cities**
Singular Number ($\mathsf{f}_{singular}$)	
I	**flight** → **flight**
Possessive ($\mathsf{f}_{possess}$)	
$\xi \vdash NP : v \rightarrow \xi \vdash N/N : \lambda f \lambda x.f(x) \wedge P(x, v)$	**delta** → **delta's** flights
$\xi \vdash N : \lambda x.v(x) \rightarrow \xi \vdash N/N : \lambda f \lambda x.f(x) \wedge P(x, \mathcal{A}y.v(y))$	**airline** → **airline's** flights
Passive Voice ($\mathsf{f}_{passive}$)	
$\xi \vdash \mathcal{Y}/NP : \lambda x_1..x_n \lambda e.v(e, x_1..x_n) \rightarrow \xi \vdash \mathcal{Y}/PP : \lambda x_1..x_n \lambda e.v(e, x_n..x_1)$	**serves** →is **served** by
$\xi \vdash \mathcal{Y}/NP : \lambda x_1..x_n \lambda e.v(e, x_1, .., x_n) \rightarrow \xi \vdash \mathcal{Y} : \lambda x_1..x_{n-1} \lambda e.v(e, x_{n-1}..x_1)$	**name** →city **named** Austin
Present Participle ($\mathsf{f}_{present}$)	
$\xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n \lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash PP/\mathcal{T} : \lambda x_1..x_n \lambda e.v(e, x_n..x_1)$	**use** →flights **using** twa
$\xi \vdash S\backslash NP : \lambda x \lambda e.v(e, x) \rightarrow \xi \vdash N/N : \lambda f \lambda x \lambda e.f(x) \wedge v(e, x)$	**arrive** →**arriving** flights
$\xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n \lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash N/\mathcal{T} : \lambda x_1..x_n \lambda e.v(e, x_n..x_1)$	**land** → **landings** at jfk
Past Participle (f_{past})	
$\xi \vdash S\backslash NP/NP : \lambda x_1..x_n \lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash PP/PP : \lambda x_1..x_n \lambda e.v(e, x_1..x_n)$	**use** → plane **used** by
Nominalization ($\mathsf{f}_{nominal}$)	
$\xi \vdash S\backslash NP/\mathcal{T} : \lambda x_1..x_n \lambda e.v(e, x_n..x_1) \rightarrow \xi \vdash N/\mathcal{T} : \lambda x_1..x_n \lambda e.v(e, x_n..x_1)$	**depart** → **departure**
Comparative (f_{comp})	
$\xi \vdash DEG : \lambda x.v(x) \rightarrow \xi \vdash PP/PP : \lambda x \lambda y.v(y) < v(x)$	**short** → **shorter**
$\xi \vdash DEG : \lambda x.v(x) \rightarrow \xi \vdash PP/PP : \lambda x \lambda y.v(y) > v(x)$	**long** → **longer**
Superlative (f_{super})	
$\xi \vdash DEG : \lambda x.v(x) \rightarrow \xi \vdash NP/N : \lambda f.argmin(\lambda x.f(x), \lambda x.v(x))$	**short** → **shortest**
$\xi \vdash DEG : \lambda x.v(x) \rightarrow \xi \vdash NP/N : \lambda f.argmax(\lambda x.f(x), \lambda x.v(x))$	**long** → **longest**

Table 6: Morphological transformations with examples. $\mathcal{T} = [\epsilon, NP, NP/NP]$ and $\mathcal{Y} = [S\backslash NP, S\backslash NP/NP]$ allow a single transformation to generalize across word type.

Nouns can be inflected by number to denote singular and plural forms or by adding an apostrophe to mark a possessive case. The transformation function $\mathsf{f}_{\mathsf{singular}}$ is an identity transformation. Plurals may have different interpretations: one is the generic $\langle e, t \rangle$ set representation, which requires no transformation on the base, or plurals can occur without overt determiners (bare plurals), but semantically imply quantification. We create a plural to singular type shifting rule which implements the $\langle \langle e, t \rangle, e \rangle$ skolem function to select a unique individual from the set. The possessive transformation $\mathsf{f}_{\mathsf{possess}}$ transfers the base template to a noun modifier, and adds a binary predicate P that encodes the relation.

There are also a number of instances of the identity transformation function I, which does not change the base template. Because the semantics we are constructing was designed to answer questions against a static database, it does not need to represent certain phenomena to return the correct answer. This includes more advanced variants of person, tense, aspect, and potentially many others. Ideally, these morphological attributes should add semantic modifiers to the base meaning, for example, tense can constrain the time at which an event occurs. However, none of our domains support such reasoning, so we assign the identity transformation, and leave the exploration of these issues to future work.

7 Learning

One advantage of our morpho-syntactic, factored lexicon is that it can be easily learned with small modifications to existing algorithms (Zettlemoyer and Collins, 2007). We only need to modify the GENLEX procedure that defines the space of possible lexical entries. For each training example (x, z), $\mathsf{GENLEX}(x, z, F)$ first maps each substring in the sentence x into the morphological representation (s, p, c) using F introduced in Section 4. A candidate lexeme set L' is then generated by exhaustively pairing the word stems with all subsets of the logical constants from z. Lexical templates are applied to the lexemes in L' to generate candidate lexical entries for x. Finally, the lexemes that participate in the top scoring correct parse of x are added to the permanent lexicon.

Initialization Following standard practice, we compile an initial lexicon Λ_0, which consists of a list of domain independent lexical

items for function words, such as interrogative words and conjunctions. These lexical items are mostly semantically vacuous and serve particular syntactic functions that are not generalizable to other word classes. We also initialize the lexemes with a list of NP entities complied from the database, e.g., (*Boston*, [*bos*]).

Features We use two types of features in the model for discriminating parses. Four *lexical* features are fired on each lexical item: $\phi_{(s,\vec{c})}$ for the lexeme, ϕ_{t_p} for the base template, ϕ_{t_m} for the morphologically modified template, and ϕ_l for the complete lexical item. We also compute the standard *logical expression* features (Zettlemoyer and Collins, 2007) on the root semantics to track the pairwise predicate-argument relations and the co-occuring predicate-predicate relations in conjunctions and disjunctions.

8 Experimental Setup

Data and Metrics We evaluate performance on two benchmark semantic parsing datasets, Geo880 and ATIS. We use the standard data splits, including 600/280 train/test for Geo880 and 4460/480/450 train/develop/test for ATIS. To support the new representations in Section 5, we systematically convert annotations with existential quantifiers, temporal events and relational nouns to new logical forms with equivalent meanings. All systems are evaluated with exact match accuracy, the percentage of fully correct logical forms.

Initialization We assign positive initial weights to the indicator features for entries in the initial lexicon, as defined in Section 7, to encourage their use. The elliptical template and metonymy template features are initialized with negative weights to initially discourage word skipping.

Comparison Systems We compare performance with all recent CCG grammar induction algorithms that work with our datasets. This includes methods that used a limited set of hand-engineered templates for inducing the lexicon, ZC05 (Zettlemoyer and Collins, 2005) and ZC07 (Zettlemoyer and Collins, 2007), and those that learned grammar structure by automatically splitting the labeled logical forms, UBL (Kwiatkowski et al., 2010) and FUBL (Kwiatkowski et al., 2011). We also compare the state-of-the-art for Geo880 (DCS (Liang et al., 2011) and DCS+ which includes an engineered seed lexicon) and ATIS (which is ZC07). Finally, we include results for GUSP (Poon, 2013), a recent unsupervised approach for ATIS.

System	Test
ZC05	79.3
ZC07	86.1
UBL	87.9
FUBL	88.6
DCS	87.9
FULL	90.4
DCS$^+$	91.1

Table 7: Exact-match Geo880 test accuracy.

System	Dev	Test
ZC07	74.4	84.6
UBL	65.6	71.4
FUBL	81.9	82.8
GUSP	-	83.5
TEMP-ONLY	85.5	87.2
FULL	87.5	91.3

Table 8: Exact-match accuracy on the ATIS development and test sets.

System Variants We report results for a complete approach (Full), and variants which use different aspects of the morpho-syntactic lexicon. The TEMP-ONLY variant learned with the templates from Section 5 but, like ZC07, does not use any word class information to restrict their use. The TEMP-POS removes morphology from the lexemes, but includes the word class information from Wiktionary. Finally, we also include DCS$^+$, which initialize a set of words with POS tag JJ, NN, and NNS.

9 Results

Full Models Tables 7 and 8 report the main learning results. Our approach achieves state-of-the-art accuracies on both datasets, demonstrating that our new grammar induction scheme provides a type of linguistically motivated regularization; restricting the algorithm to consider a much smaller hypothesis space allows to learn better models.

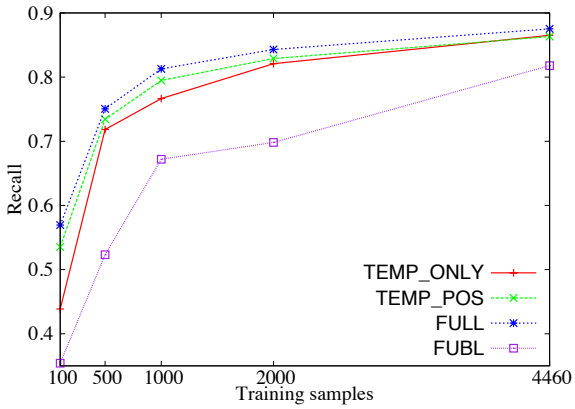


Figure 2: ATIS Learning Curve

On Geo880 the full method edges out the best systems by 2% absolute on the test set, as compared to other systems with no domain-specific lexical initialization. Although DCS requires less supervision, it also uses external signals including a POS tagger.

We see similarly strong results for ATIS, outperforming FUBL on the ATIS development set by 6.8%, and improving the accuracy on the test set by 7.9% over the previous best system ZC07. Unlike FUBL, which excels at the development set but trails ZC07's templated grammar by almost 2 points on the test set, our approach demonstrates consistent improvements on both. Additionally, although the unsupervised model (GUSP) rivals previous approaches, we are able to show that more careful use of supervision open a much wider performance gap.

Learning Curve with Ablations Figure 2 presents a learning curve for the ATIS domain, demonstrating that the learning improvements become even more dramatic for smaller training set sizes. Our model outperforms FUBL by wide margins, matching its final accuracy with only 22% of the total training examples. Our full model also consistently beats the variants with fewer word class restrictions, although by smaller margins. Again, these results further highlight the benefit of importing external syntactic resources and enforcing linguistically motivated constraints during learning.

Learned Lexicon The learned lexicon is also more compact. Table 9 summarizes statistics on unique lexical entries required to parse the ATIS development set. The morpho-syntactic model uses 80.3% of the lexical entries and 63.7% of the lexemes that FUBL needs, while increase performance by nearly 7 points. Upon inspection, our model achieves better lexical decomposition by learning shorter lexical units, for example, the adoption of Davidsonian events allows us to learn unambiguous adverbial modifiers, and the formal modeling of nominalized nouns and relational nouns treats prepositions as syntactic modifiers, instead of being encoded in the semantics. Such restrictions generalize to a much wider variety of syntactic contexts.

System	Lexical Entries	Lexemes
FUBL	1019	721
Our Approach	818	495

Table 9: Lexicon size comparison on the ATIS dev set (460 unique tokens).

10 Summary and Future Work

We demonstrated that significant performance gains can be achieved in CCG semantic parsing by introducing a more constrained, linguistically motivated grammar induction scheme. We introduced a morpho-syntactic factored lexicon that uses domain-independent facts about the English language to restrict the number of incorrect parses that must be considered and demonstrated empirically that it enables effective learning of complete parsers, achieving state-of-the-art performance.

Because our methods are domain independent they should also benefit other semantic parsing applications and other learning algorithms that use different types of supervision, as we hope to verify in future work. We would also like to study how to generalize these gains to languages other than English, by inducing more of the syntactic structure.

Abstract

We present a model for the automatic semantic analysis of requirements elicitation documents. Our target semantic representation employs *live sequence charts*, a multi-modal visual language for scenario-based programming, which can be directly translated into executable code. The architecture we propose integrates sentence-level and discourse-level processing in a generative probabilistic framework for the analysis and disambiguation of individual sentences in context. We show empirically that the discourse-based model consistently outperforms the sentence-based model when constructing a system that reflects all the static (entities, properties) and dynamic (behavioral scenarios) requirements in the document.

1 Introduction

Requirements elicitation is a process whereby a system analyst gathers information from a stakeholder about a desired system (software or hardware) to be implemented. The knowledge collected by the analyst may be *static*, referring to the conceptual model (the entities, their properties, the possible values) or *dynamic*, referring to the behavior that the system should follow (who does what to whom, when, how, etc). A stakeholder interested in the system typically has a specific static and dynamic domain in mind, but he or she cannot necessarily prescribe any formal models or code artifacts. The term *requirements elicitation* we use here refers to a piece of discourse in natural language, by means of which a stakeholder communicates their desiderata to the system analyst.

The role of a system analyst is to understand the different requirements and transform them into formal constructs, formal diagrams or executable code. Moreover, the analyst needs to consolidate the different pieces of information to uncover a single shared domain. Studies in software engineering aim to develop intuitive symbolic systems with which human agents can encode requirements that would then be unambiguously translated into a formal model (Fuchs and Schwitter, 1995; Bryant and Lee, 2002).

More recently, Gordon and Harel (2009) defined a natural fragment of English that can be used for specifying requirements which can be effectively translated into *live sequence charts* (LSC) (Damm and Harel, 2001; Harel and Marelly, 2003), a formal language for specifying the dynamic behavior of reactive systems. However, the grammar that underlies this language fragment is highly ambiguous, and all disambiguation has to be conducted manually by a human agent. Indeed, it is commonly accepted that the more natural a controlled language fragment is, the harder it is to develop an unambiguous translation mechanism (Kuhn, 2014).

In this paper we accept the ambiguity of requirements descriptions as a premise, and aim to answer the following question: can we automatically recover a formal representation of the complete system — one that *best* reflects the human-perceived interpretation of the entire document? Recent advances in natural language processing, with an eye to semantic parsing (Zettlemoyer and Collins, 2005; Liang et al., 2011; Artzi and Zettlemoyer, 2013; Liang and Potts, 2014), use different formalisms and various kinds of learning signals for statistical semantic parsing. In particular, the model of Lei et al. (2013) induces input parsers from format descriptions. However, rarely do these models take into account the entire document's context.

The key idea we promote here is that discourse context provides substantial disambiguating information for sentence analysis. We suggest a novel

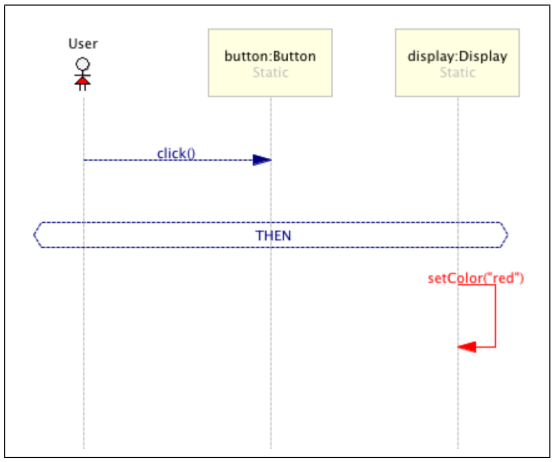

Figure 1: An LSC scenario: "When the user clicks the button, the display color must change to red."

model for integrated sentence-level and discourse-level processing, in a joint generative probabilistic framework. The input for the requirements elicitation task is given in a simplified, yet highly ambiguous, fragment of English, as specified in Gordon and Harel (2009). The output, in contrast, is a sequence of unambiguous and well-formed *live sequence charts* (LSC) (Damm and Harel, 2001; Harel and Marelly, 2003) describing the dynamic behavior of the system, tied to a single shared code-base called a *system model* (SM).

Our solution takes the form of a *hidden markov model* (HMM) where emission probabilities reflect the grammaticality and interpretability of textual requirements via a *probabilistic grammar* and transition probabilities model the overlap between SM snapshots of a single, shared, domain. Using efficient viterbi decoding, we search for the best sequence of domain snapshots that has most likely generated the entire requirements document. We empirically show that such an integrated model consistently outperforms a sentence-based model learned from the same set of data.

The remainder of this document is organized as follows. In Section 2 we describe the task, and spell out our formal assumptions concerning the input and the output. In Section 3 we present our target semantic representation and a specially tailored notion of *grounding* for anchoring the requirements in a code-base. In Section 4 we develop our sentence-based and discourse-based models, and in Section 5 we evaluate the models on various case studies. In Section 6 we discuss applications and future extensions, and in Section 7 we summarize and conclude.

2 Parsing Requirements Elicitation Documents: Task Description

There is an inherent discrepancy between the input and the output of the software engineering process. The input, system requirements, is specified in a natural, informal, language. The output, the system, is ultimately implemented in a formal unambiguous programming language. Can we automatically recover such a formal representation of a complete system from a set of requirements? In this work we explore this challenge empirically.

The Input. We assume a *scenario-based programming* paradigm (a.k.a *behavioral programming* (BP) (Harel et al., 2012)) in which system development is seen as a process whereby humans describe the expected behavior of the system by means of "short-stories", formally called *scenarios* (Harel, 2001). We further assume that a given requirements document describes exactly one system, and that each sentence describes a single, possibly complex, scenario. The requirements we aim to parse are given in a simplified form of English (specifically, the English fragment described in Gordon and Harel (2009)). Contrary to strictly formal specification languages, which are closed and unambiguous, this fragment of English employs an open-ended lexicon and exhibits extensive syntactic and semantic ambiguity.[1]

The Output. Our target semantic representation employs *live sequence charts* (LSC), a diagrammatic formal language for scenario-based programming (Damm and Harel, 2001). Formally, LSCs are an extension of the well-known UML message sequence diagrams (Harel and Maoz, 2006), and they have a direct translation into executable code (Harel and Marelly, 2003).[2] Using LSC diagrams for software modelling enjoys the advantages of being easily learnable (Harel and Gordon, 2009), intuitively interpretable (Eitan et al., 2011) and straightforwardly amenable to execution (Harel et al., 2002) and verification (Harel et al., 2013). The LSC language is particularly suited for representing natural language requirements, since its basic formal constructs, *scenarios*, nicely align with *events*, the primitive objects of Neo-Davidsonian Semantics (Parsons, 1990).

[1] Formally, this variant may be viewed as a CNL of degree P2 E3 N4 S4 with properties C,F,W,A (Kuhn, 2014, pp 6-12).

[2] It can be shown that the execution semantics of the LSC language is embedded in a fragment of a branching temporal logic called CTL* (Kugler et al., 2005).

Live Sequence Charts and Code Artifacts. A *live sequence chart* (LSC) is a diagram that describes a possible or necessary run of a specified system. In a single LSC diagram, entities are represented as vertical lines called *lifelines*, and interactions between entities are represented using horizontal arrows between lifelines called *messages*, connecting a sender to a receiver. Messages may refer to other entities (or properties of entities) as arguments. Time in LSCs proceeds from top to bottom, imposing a partial order on the execution of messages. LSC messages can be *hot* (red, "must happen") or *cold* (blue, "may happen"). A message may have an execution status, which designates it as *monitored* (dashed arrow, "wait for") or *executed* (full arrow, "execute"). The LSC language also encompasses conditions and control structures, and it allows defining requirements in terms of the negation of charts. Figure 1 illustrates the LSC for the scenario "When the user clicks the button, the display color must change to red.". The respective *system model* (SM) is a code-base hierarchy containing the classes USER, BUTTON, DISPLAY, the method BUTTON.CLICK() and the property DISPLAY.COLOR.

3 Formal Settings

In the text-to-code generation task, we aim to implement a prediction function $f : \mathcal{D} \rightarrow \mathcal{M}$, such that $D \in \mathcal{D}$ is a piece of discourse consisting of an ordered set of requirements $D = d_1, d_2...d_n$, and $f(D) = M \in \mathcal{M}$ is a code-base hierarchy that grounds the semantic interpretation of D; we denote this by $M \triangleright \mathbf{sem}(d_1, ..., d_n)$. We now define the objects D, M, and describe how to construct the semantic interpretation function ($\mathbf{sem}(.)$). We then spell out the notion of grounding ($\triangleright$).

Surface Structures: Let Σ be a finite lexicon and let $\mathcal{L}_{req} \subseteq \Sigma^*$ be a language for specifying requirements. We assume the sentences in $\mathcal{L}_{req}$ have been generated by a context-free grammar $G = \langle \mathcal{N}, \Sigma, S \in \mathcal{N}, \mathcal{R} \rangle$, where $\mathcal{N}$ is a set of non-terminals, Σ is the aforementioned lexicon, $S \in \mathcal{N}$ is the start symbol and $\mathcal{R}$ is a set of context-free rules $\{A \rightarrow \alpha | A \in \mathcal{N}, \alpha \in (\mathcal{N} \cup \Sigma)^*\}$. For each utterance $u \in \mathcal{L}_{req}$, we can find a sequential application of rules that generates it: $u = r_1 \circ ... \circ r_k$; $\forall i : r_i \in \mathcal{R}$. We call such a sequence a *derivation* of u. These derivations may be graphically depicted as parse trees, where the utterance u defines the sequence of tree terminals in the leaves.

We define $\mathcal{T}_{req}$ to be the set of trees strongly generated by G, and utilize an auxiliary yield function $yield : \mathcal{T}_{req} \rightarrow \mathcal{L}_{req}$ returning the leaves of the given tree $t \in .\mathcal{L}_{req}$. Different parse-trees can generate the same utterance, so the task of analyzing the structure of an utterance $u \in \mathcal{L}_{req}$ is modeled via a function $syn : \mathcal{L}_{req} \rightarrow \mathcal{T}_{req}$ that returns the correct, human-perceived, parse of u.

Semantic Structures: Our target semantic representation of a requirement $d \in \mathcal{L}_{req}$ is a diagrammatic structure called a *live sequence chart* (LSC). The LSC formal definition we provide here is based on the appendix of Harel and Marelly (2003), but rephrased in set-theoretic, event-based, terms. We defined this alternative formalization in order to make LSCs compatible with Neo-Davidsonian, event-based, semantic theories. As a result, this form of LSC formalization is well-suited for representing the semantics of natural language utterances.

Let us assume that L is a dictionary of entities (lifelines), A is a dictionary of actions, P is a dictionary of attribute names and V a dictionary of attribute values. The set of simple events in the LSC formal system is defined as follows:

$$E_{active} \subset L \times A \times L \times (L \times P \times V)^*$$

$$\times \{hot, cold\} \times \{executed, monitored\}$$

where $e = \langle l_1, a, l_2, \{l_i : p_i : v_i\}_{i=3}^k, temp, exe \rangle$ and $l_i \in L, a \in A, p_i \in P, temp \in \{hot, cold\}$, $exe \in \{executed, monitored\}$. The event e is called a *message* in which an action a is carried over from a sender l_1 to a receiver l_2.[3] The set $\{l_i : p_i : v_i\}_{i=3}^k$ depicts a set of attribute:value pairs provided as arguments to action a. The temperature $temp$ marks the modality of the action (may, must), and the status exe distinguishes actions to be taken from actions to be waited for.

An event e can also refer to a state, where a logical expression is being evaluated over a set of property:value pairs. We call such an event a *condition*, and specify the set of possible conditions as follows:

$$E_{cond} \subset Exp \times (L \times P \times V)^*$$

$$\times \{hot, cold\} \times \{executed, monitored\}$$

[3] The LSC language also distinguishes static lifelines from dynamically-bound lifelines. For brevity, we omit this from the formal description of events, and simply assert that it may be listed as one of the properties of the relevant lifeline.

Specifically, $e = \langle exp, \{l : p : v\}_{i=0}^{k}, temp, exe\rangle$ is a condition to be evaluated, where $l_i \in L, p_i \in P, v_i \in V, temp \in \{hot, cold\}$ and $exe \in \{executed, monitored\}$ are as specified above. The condition $exp \in Exp$ is a first-order logic formula using the usual operators $(\vee, \wedge, \rightarrow, \neg, \exists, \forall)$. The set $\{l : p : v\}_{i=0}^{k}$ depicts a (possibly empty) set of attribute:value pairs that participates as predicates in exp. Executing a condition, that is, evaluating the logical expression specified by exp, also has a modality (may/must) and an execution status (performed/waited for).

The LSC language further allows us to define more complex events by combining partially ordered sets of events with control structures.

$$E_{complex} \subset N \times E_{cond} \times$$

$$\{\langle E_c, <\rangle | \langle E_c, <\rangle \textit{ is a poset }\}$$

N is a set of non-negative integers, E_{cond} is a set of conditions as described above, and each element $\langle E_c, <\rangle$ is a partially ordered set of events. This structure allows us to derive three kinds of control structures:

- $e = \langle \#, \emptyset, \langle E, <\rangle\rangle$ is a loop in which $\langle E, <\rangle$ is executed $\#$ times.
- $e = \langle 0, cond, \langle E, <\rangle\rangle$ is a conditioned execution. If $cond$ holds, $\langle E, <\rangle$ is executed.
- $e = \langle \#, \{cond\}_{i=1}^{\#}, \{\langle E_c, <\rangle\}_{i=1}^{\#}\rangle$ is a switch: in case i, if the condition i holds, $\langle E_c, <\rangle_i$ is executed.

Definition 1 (LSC) An LSC $c = \langle E, <\rangle$ is a partially ordered set of events such that

$$\forall e \in E : e \in E_{active} \vee e \in E_{cond} \vee e \in E_{complex}$$

Grounded Semantics: The information represented in the LSC provides the recipe for a rigorous construction of the code-base that will implement the program. This code-base is said to *ground* the semantic representation. For example, if our target programming language is an Object-Oriented programming language such as Java, then the code-base will include the objects, the methods and the properties that are minimally required for executing the scenario that is represented by the LSC. We refer to this code-base as a *system model* (henceforth, SM), and define it as follows.

Definition 2: (SM) Let L_m be a set of implemented objects, A_m a set of implemented methods, P_m a set of arguments and V_m argument values. We further define the auxiliary functions $methods : A_m \rightarrow L_m$, $props : P_m \rightarrow L_m$ and $values : V_m \rightarrow L_m \times P_m$, for identifying the entity $l \in L_m$ that implements the method $a \in A_m$, the entity $l \in L_m$ that contains the property $p \in P_m$, and the entity property $\langle l, p\rangle \in L_m \times P_m$ that assumes that value $v \in V_m$, respectively. A *system model* (SM) is a tuple m representing the implemented architecture.

$$m = \langle L_m, A_m, P_m, V_m, methods, props, values\rangle$$

Analogously to *interpretation* functions in logic and natural language semantics, we assume here an *implementation* function, denoted $[[.]]$, which maps each formal entity in the LSC semantic representation to its instantiation in the code-base. Using this function we define a notion of grounding that captures the fact that a certain code-base permits the execution of a given LSC c.

Definition 3(a): (Grounding) Let $\mathcal{M}$ be the set of system models and let $\mathcal{C}$ be the set of LSC charts. We say that m *grounds* $c = \langle E, <\rangle$, and write $m \triangleright c$, if $\forall e \in E : m \triangleright e$, where:

- if $e \in E_{active}$ then
  $m \triangleright e \Leftrightarrow$
  $[[l_1]], [[l_2]] \in L$ &
  $[[a]] \in methods([[l_2]])$ &
  $\forall i : \langle l : p : v\rangle_i \Rightarrow [[l]] \in L_m \& [[p]] \in props[[l]] \& v \in values([[l]], [[p]])$
- if $e \in E_{cond}$ then
  $m \triangleright e \Leftrightarrow$
  $\forall i : \langle l : p : v\rangle_i \Rightarrow [[l]] \in L_m \& [[p]] \in props[[l]] \& v \in values([[l]], [[p]])$
- if $e = \langle \#, e_s, \langle E_c, <\rangle \in E_{complex}$ then
  $m \triangleright e \Leftrightarrow m \triangleright e_s$ & $\forall e' \in E_c : m \triangleright e'$

We have thus far defined how the semantics of a single LSC can be grounded in a single SM. In the real world, however, a requirements document typically contains multiple different requirements, but it is interpreted as a complete whole. The desired SM is then one that represents a single domain shared by all the specified requirements. Let us then assume a document $\mathbf{d} = d_1, ..., d_n$ containing n requirements, where $\forall i : d_i \in \mathcal{L}_{req}$, and

let $\sqcup$ be a unification operation that returns the formal unification of two SMs if such exists, and an empty SM otherwise. We define a discourse interpretation function $\mathbf{sem}(\mathbf{d})$ that returns a single SM for the entire document, where different mentions across sentences may share the same reference. The discourse interpretation function $\mathbf{sem}$ can be as simple as unifying all individual SMs for d_i, and asserting that all elements that have the same name in different SMs refer to a single element in the overall SM. Or, it can be as complex as taking into account synonyms ("*clicks* the button" and "*presses* the button"), anaphora ("when the user clicks the *button*, *it* changes colour"), binding ("when the user clicks *any* button, *this* button is highlighted"), and so on. We can now define the grounding of an entire requirements document.

Definition 3(b): (Grounding) Let $\mathbf{d} = d_1...d_n$ be a requirements document and let $\mathbf{m} = m_1...m_n$ be a sequence of system models. $M = \langle \mathbf{m}, \sqcup \rangle$ is a sequence of models and a unification operation, and $M \triangleright \mathbf{sem}(\mathbf{d})$ if and only if $\forall i : m_i \triangleright sem(d_i)$ and $((m_1 \sqcup m_2).... \sqcup m_n) \triangleright \mathbf{sem}(d_1, ..., d_n)$.

In this work we assume that $\mathbf{sem}(\mathbf{d})$ is a simple discourse interpretation function, where entities, methods, properties, etc. that are referred to using the same name in different local SMs refer to a single element in the overall code-base. This simple assumption already carries a substantial amount of disambiguating information concerning individual requirements. For example, assume that we have seen a "click" method over a "button" object in sentence i. This may help us disambiguate future attachment ambiguity, favoring structures where a "button" is attached to "click" over other attachment alternatives. Our goal is then to model discourse-level context for supporting the accurate semantic analysis of individual requirements.

4 Probabilistic Modeling

In this section we set out to explicitly model the requirement's *context*, formally captured as a document-level SM, in order to support the accurate disambiguation of the requirements' *content*. We first specify our probabilistic *content* model, a sentence-level model which is based on a probabilistic grammar augmented with compositional semantic rules. We then specify our probabilistic *context* model, a document-level sequence model that takes into account the content as well as the relation between SMs at different time points.

4.1 Sentence-Based Modeling

The task of our sentence-based model is to learn a function that maps each requirement sentence to its correct LSC diagram and SM snapshot. In a nutshell, we do this via a (partially lexicalized) probabilistic context-free grammar augmented with a semantic interpretation function.

More formally, given a discourse $D = d_1...d_n$ we think of each d_i as having been generated by a *probabilistic context-free grammar* (PCFG) G. The syntactic analysis of d_i may be ambiguous, so we first implement a syntactic analysis function $syn : \mathcal{L}_{req} \rightarrow \mathcal{T}_{req}$ using a probabilistic model that selects the most likely syntax tree t of each d individually. We can simplify $syn(d)$, with d constant with respect to the maximization:

$$\begin{aligned} syn(d) &= \mathit{argmax}_{t \in \mathcal{T}_{req}} P(t|d) \\ &= \mathit{argmax}_{t \in \mathcal{T}_{req}} \frac{P(t,d)}{p(d)} \\ &= \mathit{argmax}_{t \in \mathcal{T}_{req}} P(t,d) \\ &= \mathit{argmax}_{t \in \{t | t \in \mathcal{T}_{req}, yield(t)=d\}} P(t) \end{aligned}$$

Because of the context-freeness assumption, it holds that $P(t) = \prod_{r \in der(t)} P(r)$, where $der(t)$ returns the rules that derive t. The resulting probability distribution $P : \mathcal{T}_{req} \rightarrow [0, 1]$ defines a probabilistic language model over all requirements $d \in \mathcal{L}_{req}$, i.e., $\sum_{d \in \mathcal{L}_{req}} \sum_{t \in \mathcal{T}_{req}, yield(t)=d} P(t) = 1$.

We assume a function $sem : \mathcal{T} \rightarrow \mathcal{C}$ mapping syntactic parse trees to semantic constructs in the LSC language. Syntactic parse trees are complex entities, assigning structures to the flat sequences of words. The principle of compositionality asserts that the meaning of a complex syntactic entity is a function of the meaning of its parts and their mode of combination. Here, the semantics of a tree $t \in \mathcal{T}_{req}$ is derived compositionally from the interpretation of the rules in the grammar G. We overload the sem notation to define $sem : \mathcal{R} \rightarrow \mathcal{C}$ as a function assigning rules to LSC constructs (events or parts of events),[4] with $\hat{\circ}$ merging the resulting sets of events. Our sentence-based compositional semantics is summarized as:

$$sem(u) = sem(syn(u)) = sem(r_1 \circ ... \circ r_n) =$$

$$sem(r_1)\hat{\circ}...\hat{\circ}sem(r_n) = c_1\hat{\circ}...\hat{\circ}c_n = c$$

[4]Here, it suffices to say that sem maps edges in the syntax tree to functions in the API of an existing LSC editor. For example: $sem(NP \rightarrow DET\ NN) = fCreateObject(DET.sem, NN.sem)$. We specify the function sem in the supplementary materials. The code of sem is available as part of *PlayGo* (`www.playgo.co`).

For a single chart c, one can easily construct an implementation for every entity, action and property in the chart. Then, by design, we get an SM m such that $m \triangleright c$. To construct the SM of the entire discourse in the sentence-based model we simply return $f(d_1, ..., d_n) = \sqcup_{i=1}^{n} m_i$ where $\forall i : m_i \triangleright sem(syn(d_i))$ and $\sqcup$ unifies different mentions of the same string to a single element.

4.2 Discourse-Based Modeling

We assume a given document $D \in \mathcal{D}$ and aim to find the most probable system model $M \in \mathcal{M}$ that satisfies the requirements. We assume that M reflects a single domain that the stakeholders have in mind, and we are provided with an ambiguous natural language evidence, an elicited discourse D, in which they convey it. We instantiate this view as a *noisy channel* model (Shannon, 1948), which provides the foundation for many NLP applications, such as speech recognition (Bahl et al., 1983) and machine translation (Brown et al., 1993).

According to the noisy channel model, when a signal is received it does not uniquely identify the message being sent. A probabilistic model is then used to decode the original message. In our case, the signal is the discourse and the message is the overall system model. In formal terms, we want to find a model M that maximises the following:

$$f(D) = argmax_{M \in \mathcal{M}} P(M|D)$$

We can simplify further, using Bayes law, where D is constant with respect to the maximisation.

$$\begin{aligned} f(D) &= argmax_{M \in \mathcal{M}} P(M|D) \\ &= argmax_{M \in \mathcal{M}} \frac{P(D|M) \times P(M)}{P(D)} \\ &= argmax_{M \in \mathcal{M}} P(D|M) \times P(M) \end{aligned}$$

We would thus like to estimate two types of probability distributions, $P(M)$ over the source and $P(D|M)$ over the channel.

Both M and D are structured objects with complex internal structure. In order to assign probabilities to objects involving such complex structures it is customary to break them down into simpler, more basic, events. We know that $D = d_1, d_2, ..., d_n$ is composed of n individual sentences, each representing a certain aspect of the model M. We assume a sequence of *snapshots* of M that correspond to the timestamps $1...n$, that is: $m_1, m_2, ..., m_n \in \mathcal{M}$ where $\forall i : m_i \triangleright sem(d_i)$. The complete SM is given by the union of the different snapshots reflected in different requirements, i.e., $M = \bigsqcup_i m_i$. We then rephrase:

$$\begin{aligned} P(M) &= P(m_1, ..., m_n) \\ P(D|M) &= P(d_1, ..., d_n | m_1, ..., m_n) \end{aligned}$$

These events may be seen as points in a high dimensional space. In actuality, they are too complex and would be too hard to estimate directly. We then define two independence assumptions. First, we assume that a system model snapshot at time i depends only on k previous snapshots (a stationary distribution). Secondly, we assume that each sentence i depends only on the SM snapshot at time i. We now get:

$$\begin{aligned} P(m_1...m_n) &\approx \textstyle\prod_i P(m_i|m_{i-1}...m_{i-k}) \\ P(d_1...d_n|m_1...m_n) &\approx \textstyle\prod_i P(d_i|m_i) \end{aligned}$$

Furthermore, assuming bi-gram transitions, our objective function is now represented as follows:

$$f(D) = argmax_{M \in \mathcal{M}} \prod_{i=1}^{n} P(m_i|m_{i-1}) P(d_i|m_i)$$

Note that m_0 may be empty if the system is implemented from scratch, and non-empty if the requirements assume an existing code-base, which makes $p(m_1|m_0)$ a non-trivial transition.

4.3 Training and Decoding

Our model is in essence a Hidden Markov Model in which states capture SM snapshots, state-transition probabilities model transitions between SM snapshots, and emission probabilities model the verbal description of each state. To implement this, we need to implement a decoding algorithm that searches through all possible state sequences, and a training algorithm that can automatically learn the values of the still rather complex parameters $P(m_i|m_{i-1}), P(d_i|m_i)$ from data.

$$f(D) = \underbrace{argmax_{M \in \mathcal{M}}}_{decoding} \prod_{i=1}^{n} \underbrace{P(m_i|m_{i-1}) P(d_i|m_i)}_{training}$$

Training: We assume a supervised training setting in which we are given a set of examples annotated by a human expert. For instance, these can be requirements an analyst has formulated and encoded using an LSC editor, while manually providing disambiguating information. We are provided with a set of pairs $\{D_i, M_i\}_{i=1}^{n}$ containing n documents, where each of the pairs in $i = 1..n$ is a

tuple set $\{d_{ij}, t_{ij}, c_{ij}, m_{ij}\}_{j=1}^{n_i}$. For all i, j, it holds that $t_{ij} = syn(d_{ij})$, $c_{ij} = sem(t_{ij})$, and $m_{ij} \triangleright sem(syn(d_{ij}))$. The union of the n_i SM snapshots yields the entire model $\sqcup_j m_{i_j} = M_i$, that satisfies the set of requirements $M_i \triangleright \mathbf{sem}(d_{i1}, ..., d_{in_i})$.

(i) Emission Parameters Our emission parameters $P(d_i|m_i)$ represent the probability of a verbal description of a requirement given an SM snapshot which grounds the semantics of the description. A single SM may result from different syntactic derivations. We calculate this probability by marginalizing over the syntactic trees that are grounded in the same SM snapshot.

$$\frac{P(d,m)}{P(m)} = \frac{\sum_{t \in \{t|yield(t)=d, m \triangleright sem(t)\}} P(t)}{\sum_{t \in \{t|t \in \mathcal{T}_{req}, m \triangleright sem(t)\}} P(t)}$$

The probability of $P(t)$ is estimated using a treebank PCFG (Charniak, 1996), based on all pairs $\langle d_{ij}, t_{ij} \rangle$ in the annotated corpus. We estimate rule probabilities using maximum-likelihood estimates, and use simple smoothing for unknown lexical items, using rare-words distributions.

(ii) Transition Parameters Our transition parameters $P(m_i|m_{i-1})$ represent the amount of overlap between the SM snapshots. We look at the current and the previous system model, and aim to estimate how likely the current SM is given the previous one. There are different assumptions that may underly this probability distribution, reflecting different principles of human communication.

We first define a generic estimator as follows:

$$\hat{P}(m_i|m_j) = \frac{gap(m_i, m_j)}{\sum_{m_j} gap(m_i, m_j)}$$

where $gap(.)$ quantifies the information sharing between SM snapshots. Regardless of the implementation of gap, it can be easily shown that $\hat{P}$ is a conditional probability distribution where $\hat{P} : \mathcal{M} \times \mathcal{M} \rightarrow [0, 1]$ and, for all $m_i, m_j, : \sum_{m_j} \hat{P}(m_i|m_j) = 1$. (For efficiency reasons, we consider $\mathcal{M}$ to be a restricted universe that is considered be the decoder, as specified shortly.)

We define different gap implementations, reflecting different assumptions about the discourse. Our first assumption here is that different SM snapshots refer to the same conceptual world, so there should be a large overlap between them. We call this the **max-overlap** assumption. A second assumption is that, in collaborative communication, a new requirement will only be stated if it provides new information, akin to Grice (1975). This is the **max-expansion** assumption. An additional assumption prefers "easy" transitions over "hard" ones, this is the **min-distance** assumption. The different gap calculations are listed in Table 1.

Transition:	$gap(m_{curr}, m_{prev})$
max-overlap	$\frac{\lvert set(m_{curr}) \cap set(m_{prev}) \rvert}{\lvert set(m_{curr}) \rvert}$
max-expansion	$1 - \frac{\lvert set(m_{curr}) \cap set(m_{prev}) \rvert}{\lvert set(m_{prev}) \cup set(m_{curr}) \rvert}$
min-distance	$1 - \frac{ted(m_{prev}, m_{curr})}{\lvert set(m_{prev}) \rvert + \lvert set(m_{curr}) \rvert}$

Table 1: Quantifying the gap between snapshots. $set(m_i)$ is a set of nodes marked by path to root.

Decoding An input document contains n requirements. Our decoding algorithm considers the N-best syntactic analyses for each requirement. At each time step $i = 1...n$ we assume N, states representing the semantics of the N best syntax trees, retrieved via a CKY chart parser. Thus, setting $N = 1$ is equal to a sentence-based model, in which for each sentence we simply select the most likely tree according to a probabilistic grammar, and construct a semantic representation for it.

For each document of length n, we assume that our entire universe of system models $\mathcal{M}$ is composed of $N \times n$ SM snapshots, reflecting the N most-likely analyses of n sentences, as provided by the probabilistic syntactic model. (As shall be seen shortly, even with this restricted[5] universe approximating $\mathcal{M}$, our discourse-based model provides substantial improvements over a sentence-based model).

Our discourse-based model is an HMM where each requirement is an observed signal, and each $i = 1..N$ is a state representing the SM that grounds the i_th best tree. Because of the Markov independence assumption our setup satisfies the *optimal subproblem* and *overlapping problem* properties, and we can use efficient *viterbi* decoding to exhaustively search through the different state sequences, and find the most probable sequence that has generated the sequence of requirements according to our discourse-based probabilistic model.

[5]This restriction is akin to pseudo-likelihood estimation, as in Arnold and Strauss (1991). In pseudo-likelihood estimation, instead of normalizing over the entire set of elements, one uses a subset that reflects only the possible outcomes. Here, instead of summing SM probabilities over all possible sentences in the language, we sum up the SM analyses of the sentences observed in the document only. This estimation could also be addressed via, e.g., sampling methods.

The overall complexity decoding a document with n sentences of which max length is l, using a grammar G of size $|G|$ and a fixed N, is given by:

$$O(n \times l^3 \times |G|^3 + l^2 \times N^2 \times n + n^3 \times N^2)$$

We can break this expression down as follows: (i) In $O(n \times l^3 \times |G|^3)$ we generate N best trees for each one of the n requirements, using a CKY chart (Younger, 1967). (ii) In $O(l^2 \times N^2 \times n)$ we create the universe $\mathcal{M}$ based on the N best trees of the n requirements, and calculate $N \times N$ transitions. (iii) In $O((N \times n)^2 \times n) = O(N^2 \times n^3)$ we decode the $n \times N$ grid using Viterbi (1967) decoding.

5 Experiments

Goal. We set out to evaluate the accuracy of a semantic parser for requirements documents, in the two modes of analysis presented above. Our evaluation methodology is as standardly assumed in machine learning and NLP: given a set of annotated examples — that is, given a set of requirements documents, where each requirement is annotated with its correct LSC representation and each document is associated with a complete SM — we partition this set into a *training set* and a *test set* that are disjoint. We train our statistical model on the examples in the training set and automatically analyze the requirements in the test set. We then compare the predicted semantic analyses of the test set with the human-annotated (henceforth, *gold*) semantic analyses of this test set, and empirically quantify our prediction accuracy.

Metrics. Our semantic LSC objects have the form of a tree (reflecting the sequence of nested events in our scenarios). Therefore, we can use standard tree evaluation metrics, such as ParseEval (Black et al., 1992), to evaluate the accuracy of the prediction. Overall, we define three metrics to evaluate the accuracy of the LSC trees:

> **POS:** the POS metric is the percentage of part-of-speech tags predicted correctly.
> **LSC-F1:** F1 is the harmonic means of the precision and recall of the predicted tree.
> **LSC-EM:** EM is 1 if the predicted tree is an exact match to the gold tree, and 0 otherwise.

In the case of SM trees, as opposed to the LSC trees, we cannot assume identity of the yield between the gold and parse trees for the same sentence,[6] so we cannot use ParseEval. Therefore, we implement a distance-based metrics in the spirit of Tsarfaty et al. (2012). Then, to evaluate the accuracy of the SM, we use two kinds of scores:

> **SM-TED:** TED is the normalized edit distance between the predicted and gold SM trees, subtracted from a unity.
> **SM-EM:** EM is 1 if the predicted SM is an exact match with the gold SM, 0 otherwise.

System	#Scenarios	avg sentence length

Table 3: Sentence-Based modeling: Accuracy results on the *Phone* development set.

Data. We have a small seed of correctly annotated requirements-specification case studies that describe simple reactive systems in the LSC language. Each document contains a sequence of requirements, each of which is annotated with the correct LSC diagram. The entire program is grounded in a java implementation. As training data, we use the case studies provided by Gordon and Harel (2009). Table 2 lists the case studies and basic statistics concerning these data.

As our annotated seed is quite small, it is hard to generalize from it to unseen examples. In particular, we are not guaranteed to have observed all possible structures that are theoretically permitted by the assumed grammar. To cope with this, we create a synthetic set of examples using the grammar of Gordon and Harel (2009) in generation mode, and randomly generate trees $t \in \mathcal{T}_{req}$.

The grammar we use to generate the synthetic examples clearly *over-generates*. That is to say, it creates many trees that do not have a sound interpretation. In fact, only 3000 our of 10000 generated examples turn out to have a sound semantic interpretation grounded in an SM. Nonetheless, these data allow us to smooth the syntactic distributions that are observed in the seed, and increase the coverage of the grammar learned from it.

[6] This is because the LSC trees are predicted bottom up and the SM trees are predicted top-down.

Results. Table 3 presents the results for parsing the *Phone* document, our development set, with the sentence-based model, varying the training data. We see that despite the small size of the seed, adding it to our set if synthetics examples substantially improves results over a model trained on synthetic examples only.

In our next experiment, we provide empirical upper-bounds and lower-bounds for the discourse-based model. Table 4 presents the results of the discourse-based model for $N > 1$ on the *Phone* example. *Gen-Only* presents the results of the discourse-based model with a PCFG learned from synthetic trees only, incorporating transitions obeying the **max-overlap** assumption. Already here, we see a mild improvement for $N > 1$ relative to the $N = 1$ results, indicating that even a weak signal such as the overlap between neighboring sentences already improves sentence disambiguation in context. We next present the results of an *Oracle* experiment, where every requirement is assigned the highest scoring tree in terms of LSC-F1 with respect to the gold tree, keeping the same transitions. Again we see that results improve with N, indicating that the syntactic model alone does not provide optimal disambiguation. These results provides an upper bound on the parser performance for each N. *Gen+Seed* presents results of the discourse-based model where the PCFG interpolates the seed set and the synthetic train set, with **max-overlap** transitions. Here, we see larger improvements over the synthetic-only PCFG. That is, modeling grammaticality of individual sentences improves the interpretation of the document.

Next we compare the performance for different implementations of the $gap(m_i, m_j)$ function. We estimate probability distributions that reflect each of the assumptions we discussed, and add an additional method called **hybrid**, in which we interpolate the **max-expansion** and **max-overlap** estimates (equal weights). In Table 5, the trend from the previous experiment persists. Notably, the **hybrid** model provides a larger error reduction than its components used separately, indicating that in order to capture discourse context we may need to balance possibly conflicting factors. In **no emissions** we rely solely on the probability of state transitions, and again increasing N leads to improvement. This result confirms that *context* is indispensable for sentence interpretation — even when probabilities for the sentence's semantics (*content*) are entirely absent.

Table 4: Discourse-Based Modeling: Accuracy results on the *Phone* dev set. The Oracle selects the highest scoring LSC tree among the N-candidates, providing an upper bound on accuracy. Gen-Only selects the most probable tree, relying on synthetic examples only, providing a lower bound.

We finally perform a cross-fold experiment in which we leave one document out as a test set and take the rest as our seed. The results are provided in Table 6. The discourse-based model outperforms the sentence-based model $N = 1$ in all cases. Moreover, the drop in $N = 128$ for *Phone* seems incidental to this set, and the other cases level off beforehand. Despite our small seed, the persistent improvement on all metrics is consistent with our hypothesis that modeling the interpretation process within the discourse has substantial benefits for automatic understanding of the text.

6 Applications and Discussion

The statistical models we present here are applied in the context of *PlayGo*,[7] a comprehensive tool for behavioral, scenario-based, programming. PlayGo now provides two modes of *playing-in* natural language requirements: interactive play-in, where a user manually disambiguates the analyses of the requirements (Gordon and Harel, 2009), and statistical play-in, where disambiguation decisions are taken using our discourse-based model.

The fragment of English we use is very expressive. It covers not only entities and predicates, but also temporal and aspectual information, modalities, and program flow. Beyond that, we assume an open-ended lexicon. Overall, we are not

only translating English sentences into executable LSCs — we provide a fully generative model for translating a complete document (text) into a complete system model (code).

This text-to-code problem may be thought of as a machine translation (MT) problem, where one aims to translate sentences in English to the formal language of LSCs. However, standard statistical MT techniques rely on the assumption that textual requirements and code are aligned at a sentence level. Creating a formal model that aligns text and code on a sentence-by-sentence basis is precisely our technical contribution in Section 3.

To our knowledge, modeling syntax and discourse processing via a fully joint generative model, where a discourse level HMM is interleaved with PCFG sentence-based emissions, is novel. By plugging in different models for $p(d|m)$, different languages may be parsed. This method may further be utilized for relating content and context in other tasks: parsing and document-level NER, parsing and document-level IE, etc. To do so, one only needs to redefine the PCFG (emissions) and state-overlap (transition) parameters, as appropriate for their data.[8]

7 Conclusion

The requirements understanding task presents an exciting challenge for CL/NLP. We ought to automatically discover the entities in the discourse, the actions they take, conditions, temporal constraints, and execution modalities. Furthermore, it requires us to extract a single ontology that satisfies all individual requirements. The contributions of this paper are three-fold: we formalize the text-to-code prediction task, propose a semantic representation with well-defined grounding, and empirically evaluate models for this prediction. We show consistent improvement of discourse-based over sentence-based models, in all case studies. In the future, we intend to extend this model for interpreting requirements in un-restricted, or less-restricted, English, endowed with a more sophisticated discourse interpretation function.

Semantic Parsing with Relaxed Hybrid Trees

Wei Lu
Information Systems Technology and Design
Singapore University of Technology and Design
luwei@sutd.edu.sg

Abstract

We propose a novel model for parsing natural language sentences into their formal semantic representations. The model is able to perform integrated lexicon acquisition and semantic parsing, mapping each atomic element in a complete semantic representation to a contiguous word sequence in the input sentence in a recursive manner, where certain overlappings amongst such word sequences are allowed. It defines distributions over the novel *relaxed hybrid tree* structures which jointly represent both sentences and semantics. Such structures allow tractable dynamic programming algorithms to be developed for efficient learning and decoding. Trained under a discriminative setting, our model is able to incorporate a rich set of features where certain unbounded long-distance dependencies can be captured in a principled manner. We demonstrate through experiments that by exploiting a large collection of simple features, our model is shown to be competitive to previous works and achieves state-of-the-art performance on standard benchmark data across four different languages. The system and code can be downloaded from http://statnlp.org/research/sp/.

1 Introduction

Semantic parsing, the task of transforming natural language sentences into formal representations of their underlying semantics, is one of the classic goals for natural language processing and artificial intelligence. This area of research recently has received a significant amount of attention. Various models have been proposed over the past few years (Zettlemoyer and Collins, 2005; Kate and Mooney, 2006; Wong and Mooney, 2006; Lu et al., 2008; Jones et al., 2012).

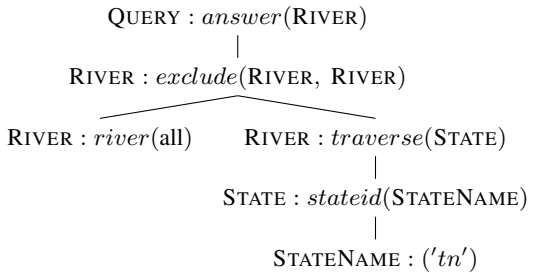

Figure 1: An example tree-structured semantic representation (above) and its corresponding natural language sentence.

Following previous research efforts, we perform semantic parsing under a setting where the semantics for complete sentences are provided as training data, but detailed word-level semantic information is not explicitly given during the training phase. As one example, consider the following natural language sentence paired with its corresponding semantic representation:

What rivers do not run through Tennessee ?
$answer(exclude(river(all), traverse(stateid('tn'))))$

The training data consists of a set of sentences paired with semantic representations. Our goal is to learn from such pairs a model, which can be effectively used for parsing novel sentences into their semantic representations.

Certain assumptions about the semantics are typically made. One common assumption is that the semantics can be represented as certain recursive structures such as trees, which consist of atomic semantic units as tree nodes. For example, the above semantics can be converted into an equivalent tree structure as illustrated in Figure 1. We will provide more details about such tree structured semantic representations in Section 2.1.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1308–1318,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

Currently, most state-of-the-art approaches that deal with such tree structured semantic representations either cast the semantic parsing problem as a statistical string-to-string transformation problem (Wong and Mooney, 2006), which ignores the potentially useful structural information of the tree, or employ latent-variable models to capture the correspondences between words and tree nodes using a generative approach (Lu et al., 2008; Jones et al., 2012). While generative models can be used to flexibly model the correspondences between individual words and semantic nodes of the tree, such an approach is limited to modeling local dependencies and is unable to flexibly incorporate a large set of potentially useful features.

In this work, we propose a novel model for parsing natural language into tree structured semantic representations. Specifically, we propose a novel *relaxed hybrid tree* representation which jointly encodes both natural language sentences and semantics; such representations can be effectively learned with a latent-variable discriminative model where long-distance dependencies can be captured. We present dynamic programming algorithms for efficient learning and decoding. With a large collection of simple features, our model reports state-of-the-art results on benchmark data annotated with four different languages.

Furthermore, although we focus our discussions on semantic parsing in this work, our proposed model is a general. Essentially our model is a discriminative string-to-tree model which recursively maps overlapping contiguous word sequences to tree nodes at different levels, where efficient dynamic programming algorithms can be used. Such a model may find applications in other areas of natural language processing, such as statistical machine translation and information extraction.

2 Background

2.1 Semantics

Various semantic formalisms have been considered for semantic parsing. Examples include the tree-structured semantic representations (Wong and Mooney, 2006), the lambda calculus expressions (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007), and dependency-based compositional semantic representations (Liang et al., 2013). In this work, we specifically focus on the tree-structured representations for semantics.

Each semantic representation consists of semantic units as its tree nodes, where each semantic unit is of the following form:

$$m_a \equiv \tau_a : p_\alpha(\tau_b*) \quad (1)$$

Here m_a is used to denote a complete semantic unit, which consists of its semantic type τ_a, its function symbol p_α, as well as an argument list τ_b* (we assume there are at most two arguments for each semantic unit). In other words, each semantic unit can be regarded as a function which takes in other semantics of specific types as arguments, and returns new semantics of a particular type. For example, in Figure 1, the semantic unit at the root has a type QUERY, a function name $answer$, and a single argument type RIVER.

2.2 Joint Representations

Semantic parsing models transform sentences into their corresponding semantics. It is therefore essential to make proper assumptions about joint representations for language and semantics that capture how individual words and atomic semantic units connect to each other. Typically, different existing models employ different assumptions for establishing such connections, leading to very different definitions of joint representations. We survey in this section various representations proposed by previous works.

The WASP semantic parser (Wong and Mooney, 2006) essentially casts the semantic parsing problem as a string-to-string transformation problem by employing a statistical phrase-based machine translation approach with synchronous grammars (Chiang, 2007). Therefore, one can think of the joint representation for both language and semantics as a synchronous derivation tree consisting of those derivation steps for transforming sentences into target semantic representation strings. While this joint representation is flexible, allowing blocks of semantic structures to map to word sequences, it does not fully exploit the structural information (tree) as conveyed by the semantics.

The KRISP semantic parser (Kate and Mooney, 2006) makes use of Support Vector Machines with string kernels (Lodhi et al., 2002) to recursively map contiguous word sequences into semantic units to construct a tree structure. Our *relaxed hybrid tree* structures also allow input word sequences to map to semantic units in a recursive manner. One key distinction, as we will see, is that our structure distinguishes words which are imme-

diately associated with a particular semantic unit, from words which are remotely associated.

The SCISSOR model (Ge and Mooney, 2005) performs integrated semantic and syntactic parsing. The model parses natural language sentences into semantically augmented parse trees whose nodes consist of both semantic and syntactic labels and then builds semantic representations based on such augmented trees. Such a joint representation conveys more information, but requires language-specific syntactic analysis.

The *hybrid tree* model (Lu et al., 2008) is based on the assumption that there exists an underlying generative process which jointly produces both the sentence and the semantic tree in a top-down recursive manner. The generative process results in a hybrid tree structure which consists of words as leaves and semantic units as nodes. An example hybrid tree structure is shown in Figure 2 (a). Such a representation allows each semantic unit to map to a possibly *discontiguous* sequence of words. The model was shown to be effective empirically, but it implicitly assumes that both the sentence and semantics exhibit certain degree of structural similarity that allows the hybrid tree structures to be constructed.

UBL (Kwiatkowski et al., 2010) is a semantic parser based on restricted higher-order unification with CCG (Steedman, 1996). The model can be used to handle both tree structured semantic representations and lambda calculus expressions, and assumes there exist CCG derivations as joint representations in which each semantic unit is associated with a contiguous word sequence where overlappings amongst word sequences are not allowed.

Jones et al. (2012) recently proposed a framework that performs semantic parsing with tree transducers. The model learns representations that are similar to the hybrid tree structures using a generative process under a Bayesian setting. Thus, their representations also potentially present similar issues as the ones mentioned above.

Besides these supervised approaches, recently there are also several works that take alternative learning approaches to (mostly task-dependent) semantic parsing. Poon and Domingos (2009) proposed a model for unsupervised semantic parsing that transforms dependency trees into semantic representations using Markov logic (Richardson and Domingos, 2006). Clarke et al. (2010) proposed a model that learns a semantic parser for answering questions without relying on semantic annotations. Goldwasser et al. (2011) took an unsupervised approach for semantic parsing based on self-training driven by confidence estimation. Liang et al. (2013) proposed a model for learning the dependency-based compositional semantics (DCS) which can be used for optimizing the end-task performance. Artzi and Zettlemoyer (2013) proposed a model for mapping instructions to actions with weak supervision.

Symbol	Description
$\mathbf{n}$	A complete natural language sentence
$\mathbf{m}$	A complete semantic representation
$\mathbf{h}$	A complete latent joint representation (or, a *relaxed hybrid tree* for our work)
$\mathcal{H}(\mathbf{n}, \mathbf{m})$	A complete set of latent joint representations that contain the $(\mathbf{n}, \mathbf{m})$ pair exactly
n, n_a	A contiguous sequence of words
w, w_k	A natural language word
m, m_a	A semantic unit
h, h_a	A node in the relaxed hybrid tree
Φ	The feature vector
ϕ_k	The k-th feature
Λ	The weight vector (model parameters)
λ_k	The weight for the k-th feature ϕ_k

Table 1: Notation Table

3 Approach

We discuss our approach to semantic parsing in this section. The notation that we use in this paper is summarized in Table 1.

3.1 Model

In standard supervised syntactic parsing, one typically has access to a complete syntactic parse tree for each sentence in the training phase, which exactly tells the correct associations between words and syntactic labels. In our problem, however, each sentence is only paired with a complete semantic representation where the correct associations between words and semantic units are unavailable. We thus need to model such information with latent variables.

For a given $\mathbf{n}$-$\mathbf{m}$ pair (where $\mathbf{n}$ is a complete natural language sentence, and $\mathbf{m}$ is a complete semantic representation), we assume there exists a latent joint representation $\mathbf{h}$ that consists of both $\mathbf{n}$ and $\mathbf{m}$ which tells the correct associations between words and semantic units in such a pair. We use $\mathcal{H}(\mathbf{n}, \mathbf{m})$[1] to denote the set of all such possible

[1]We will give a concrete definition of $\mathcal{H}(\mathbf{n}, \mathbf{m})$ used for this work, which is the complete set of all possible *relaxed hybrid tree* structures for the $\mathbf{n}$-$\mathbf{m}$ pair, when we discuss our own joint representations later in Section 3.2.

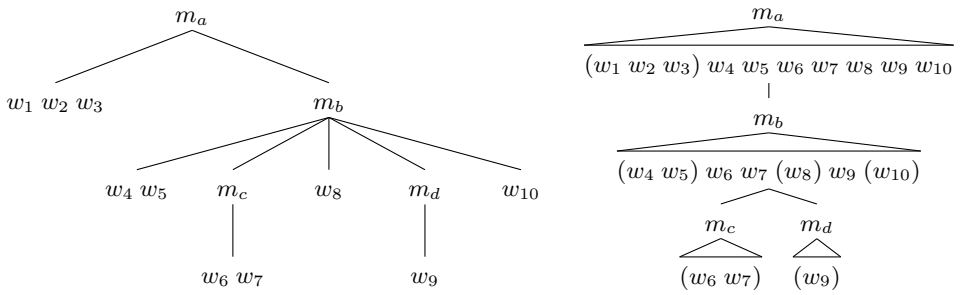

Figure 2: Two different ways of jointly representing sentences and their semantics. The hybrid tree representation of Lu et al. (2008) (left), and our novel *relaxed hybrid tree* representation (right). In our representation, a word w can be either *immediately* associated with its parent m (the words which appear inside the parenthesis), or *remotely* associated with m (the words that do not appear inside the parenthesis, and will also appear under a subtree rooted by one of m's children).

latent joint representations that contain both $\mathbf{n}$ and $\mathbf{m}$ exactly.

Given the joint representations, to model how the data is generated, one can either take a generative approach which models the joint probability distribution over $(\mathbf{n}, \mathbf{m}, \mathbf{h})$ tuples, or a discriminative approach which models the distribution over $(\mathbf{m}, \mathbf{h})$ tuples given the observation $\mathbf{n}$. Following several previous research efforts (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010; Liang et al., 2013), in this work we define a discriminative model using a log-linear approach:

$$P(\mathbf{m}, \mathbf{h}|\mathbf{n}; \Lambda) = \frac{e^{\Lambda \cdot \Phi(\mathbf{n}, \mathbf{m}, \mathbf{h})}}{\sum_{\mathbf{m}', \mathbf{h}' \in \mathcal{H}(\mathbf{n}, \mathbf{m}')} e^{\Lambda \cdot \Phi(\mathbf{n}, \mathbf{m}', \mathbf{h}')}} \quad (2)$$

Here $\Phi(\mathbf{n}, \mathbf{m}, \mathbf{h})$ is a function defined over the tuple $(\mathbf{n}, \mathbf{m}, \mathbf{h})$ that returns a vector consisting of counts of features associated with the tuple, and Λ is a vector consisting of feature weights, which are the parameters of the model.

In practice, we are only given the $\mathbf{n}$-$\mathbf{m}$ pairs but the latent structures are not observed. We therefore consider the following marginal probability:

$$P(\mathbf{m}|\mathbf{n}; \Lambda) = \sum_{\mathbf{h} \in \mathcal{H}(\mathbf{n}, \mathbf{m})} P(\mathbf{m}, \mathbf{h}|\mathbf{n}; \Lambda)$$
$$= \frac{\sum_{\mathbf{h} \in \mathcal{H}(\mathbf{n}, \mathbf{m})} e^{\Lambda \cdot \Phi(\mathbf{n}, \mathbf{m}, \mathbf{h})}}{\sum_{\mathbf{m}', \mathbf{h}' \in \mathcal{H}(\mathbf{n}, \mathbf{m}')} e^{\Lambda \cdot \Phi(\mathbf{n}, \mathbf{m}', \mathbf{h}')}} \quad (3)$$

The above probability is defined for a particular $\mathbf{n}$-$\mathbf{m}$ pair. The complete log-likelihood objective for the training set is:

$$\mathcal{L}(\Lambda) = \sum_i \log P(\mathbf{m}_i|\mathbf{n}_i; \Lambda) - \kappa||\Lambda||^2$$
$$= \sum_i \log \sum_{\mathbf{h} \in \mathcal{H}(\mathbf{n}_i, \mathbf{m}_i)} P(\mathbf{m}_i, \mathbf{h}|\mathbf{n}_i; \Lambda) - \kappa||\Lambda||^2 \quad (4)$$

where $(\mathbf{n}_i, \mathbf{m}_i)$ refers to the i-th instance in the training set. Note that here we introduce the additional regularization term $-\kappa \cdot ||\Lambda||^2$ to control over-fitting, where κ is a positive scalar.

Our goal is to maximize this objective function by tuning the model parameters Λ. Let's assume $\Lambda = \langle \lambda_1, \lambda_2, \ldots, \lambda_N \rangle$, where N is the total number of features (or the total number of parameters). Differentiating with respect to λ_k, the weight associated with the k-th feature ϕ_k, yields:

$$\frac{\partial \mathcal{L}(\Lambda)}{\partial \lambda_k} = \sum_i \sum_{\mathbf{h}} \mathbf{E}_{P(\mathbf{h}|\mathbf{n}_i, \mathbf{m}_i; \Lambda)}[\phi_k(\mathbf{n}_i, \mathbf{m}_i, \mathbf{h})]$$
$$- \sum_i \sum_{\mathbf{m}, \mathbf{h}} \mathbf{E}_{P(\mathbf{m}, \mathbf{h}|\mathbf{n}_i; \Lambda)}[\phi_k(\mathbf{n}_i, \mathbf{m}, \mathbf{h})] - 2\kappa\lambda_k \quad (5)$$

where $\phi_k(\mathbf{n}, \mathbf{m}, \mathbf{h})$ refers to the number of occurrences for the k-th feature in the tuple $(\mathbf{n}, \mathbf{m}, \mathbf{h})$.

Given the objective value (4) and gradients (5), standard methods such as stochastic gradient descent or L-BFGS (Liu and Nocedal, 1989) can be employed to optimize the objective function. We will discuss the computation of the objective function and gradients next.

3.2 Relaxed Hybrid Trees

To allow tractable computation of the values for the objective function (4) and the gradients (5),

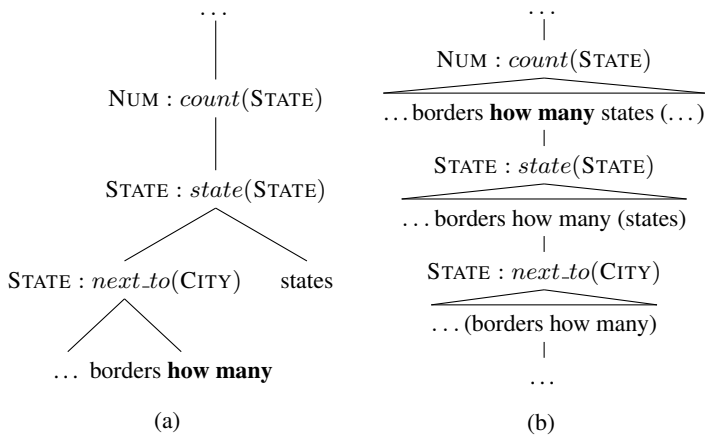

Figure 3: An example hybrid tree and an example *relaxed hybrid tree* representation. When the correct latent structure can not be found, the dependency between the words "how many" and the semantic unit "NUM : $count$(STATE)" can not be captured if the hybrid tree is used, whereas with our relaxed hybrid tree representation, such a dependency can still be captured.

certain restrictions on the latent structures ($\mathbf{h}$) will need to be imposed. We define in this section the set of all valid latent structures $\mathcal{H}(\mathbf{n}, \mathbf{m})$ for the $(\mathbf{n}, \mathbf{m})$ pair so that some efficient dynamic programming algorithms can be deployed.

We introduce our novel *relaxed hybrid tree* representations which jointly encode both natural language sentences and the tree-structured semantics. A *relaxed hybrid tree* $\mathbf{h}$ defined over $(\mathbf{n}, \mathbf{m})$ is a tree whose nodes are (n, m) pairs, where each n is a contiguous sequence of words from $\mathbf{n}$, and each m is a semantic unit (a tree node) from $\mathbf{m}$. For any two nodes $h_a \equiv (n_a, m_a)$ and $h_b \equiv (n_b, m_b)$ that appear in the relaxed hybrid tree $\mathbf{h}$, if h_a is the parent of h_b in $\mathbf{h}$, then m_a must also be the parent of m_b in $\mathbf{m}$, and n_a must contain n_b. If the lowest common ancestor of h_a and h_b in $\mathbf{h}$ is neither h_a nor h_b, then n_a and n_b do not share any common word. Note that words that appear at different positions in $\mathbf{n}$ are regarded as different words, regardless of their string forms.

Figure 2 (b) shows an example *relaxed hybrid tree* structure that we consider. Assume we would like to jointly represent both the natural language sentence $\mathbf{n} \equiv w_1 w_2 \ldots w_{10}$ and its corresponding semantic representation $\mathbf{m} \equiv m_a(m_b(m_c, m_d))$. In the given example, the semantic unit m_a maps to the complete sentence, m_b maps to the sequence $w_4 w_5 \ldots w_{10}$, m_c maps to $w_6 w_7$, and m_d maps to w_9. Certain words such as w_4 and w_{10} that appear directly below the semantic unit m_b but do not map to any of m_b's child semantic units are highlighted with parentheses "()", indicating they are *immediately associated* with m_b. These words play unique roles in the sub-tree rooted by m_b and are expected to be semantically closely related to m_b. Note that each word is immediately associated with *exactly one* semantic unit.

As a comparison, we also show an example hybrid tree representation (Lu et al., 2008) in Figure 2 (a) that has similar words-semantics correspondences. Different from our representation, the hybrid tree representation assumes each natural language word only maps to a single semantic unit (which is its immediate parent), and each semantic unit maps to a possibly discontiguous sequence of words. We believe that such a representation is overly restrictive, which might exhibit problems in cases where natural language sentences are highly non-isomorphic to their semantic tree structures. Under our relaxed hybrid tree representations, words that are immediately associated with a particular semantic unit now can also be *remotely associated* with all its parent semantic units as well. Essentially, our representation allows us to capture certain *unbounded* dependencies – for any word, as long as it appears below a certain semantic unit (in the relaxed hybrid tree), we can always capture the dependency between the two, regardless of which actual semantic unit that word is immediately associated with. Such an important relaxation allows some long-distance dependencies to be captured, which can potentially alleviate the sentence-semantics non-isomorphism issue reported in several earlier semantic parsing works (Kate and Mooney, 2006;

Wong and Mooney, 2007).

To better illustrate the differences, we show a concrete example in Figure 3, where the correct latent structure showing the correspondences between words and semantic units can not be found with the hybrid tree model. As a result, the hybrid tree model will fail to capture the correct dependency between the words "how many" and the semantic unit "NUM : $count$(STATE)". On the other hand, with our relaxed hybrid tree representation, such a dependency can still be captured, since these words will still be (remotely) associated with the semantic unit.

Such a relaxed hybrid tree representation, when further constrained with the word association patterns that we will introduce next, allows both the objective function (4) and the gradients of (5) to be computed through the dynamic programming algorithms to be presented in Section 4.

3.3 Word Association Patterns

As we have mentioned above, in the relaxed hybrid tree structures, each word w under a certain semantic unit m can either appear directly below m only (immediately associated with m), or can also appear in a subtree rooted by one of m's child semantic unit (remotely associated with m).

We allow several different ways for word associations and define the allowable patterns for semantic units with different number of arguments in Table 2. Such patterns are defined so that our model is amendable to dynamic programming algorithms to be discussed in Sec 4. In this table, $\mathbf{w}$ refers to a contiguous sequence of natural language words that are immediately associated with the current semantic unit, while $\mathbf{X}$ and $\mathbf{Y}$ refers to a sequence of natural language words that the first and second child semantic unit will map to, respectively.

For example, in Figure 2 (b), the word sequence directly below the semantic unit m_a follows the pattern $\mathbf{wX}$ (since the word sequence $w_1w_2w_3$ is immediately associated with m_a, and the remaining words are remotely associated with m_a), and the word sequence below m_b follows $\mathbf{wXwYw}$[2].

The word association patterns are similar to those *hybrid patterns* used in hybrid trees. One key difference is that we disallow the unary pattern $\mathbf{X}$. The reason is, when computing the partition function in Equation 3, inclusion of pattern $\mathbf{X}$ will result in relaxed hybrid trees consisting of an infinite number of nodes. However, this issue does not come up in the original *hybrid tree* models due to their generative setting, where the training process does not involve such a partition function.

#Args	Word Association Patterns
0	$\mathbf{w}$
1	$\mathbf{wX}$, $\mathbf{Xw}$, $\mathbf{wXw}$
2	$\mathbf{XY}$, $\mathbf{YX}$, $\mathbf{wXY}$, $\mathbf{wYX}$, $\mathbf{XwY}$, $\mathbf{YwX}$ $\mathbf{XYw}$, $\mathbf{YXw}$, $\mathbf{wXwY}$, $\mathbf{wYwX}$ $\mathbf{wXYw}$, $\mathbf{wYXw}$, $\mathbf{XwYw}$, $\mathbf{YwXw}$ $\mathbf{wXwYw}$, $\mathbf{wYwXw}$

Table 2: The complete list of word association patterns. Here #Args means the number of arguments for a semantic unit.

3.4 Features

The features are defined over the $(\mathbf{n}, \mathbf{m}, \mathbf{h})$ tuples. In practice, we define features at each level of the relaxed hybrid tree structure $\mathbf{h}$. In other words, features are defined over (n, m) tuples where n is a contiguous sequence of natural language words (immediately or remotely) associated with the semantic unit m (recall that $\mathbf{h}$ contains both $\mathbf{n}$ and $\mathbf{m}$, and each level of $\mathbf{h}$ simply consists of a semantic unit and a contiguous sequence of words). Each feature over (n, m) is then further decomposed as a product between two indicator feature functions, defined over the natural language words (n) and semantic unit (m) respectively: $\phi(n, m) = \phi^i(n) \times \phi^o(m)$. For each $\phi^i(n)$ we define two types of features: the *local features*, which are defined over immediately associated words only, and the *span features*, which are defined over all (immediately or remotely) associated words to capture long range dependencies.

The local features include word unigrams and bigrams, the word association patterns, as well as character-level features[3] which perform implicit morphological analysis. The span features include word unigrams, bigrams, as well as trigrams. Although our model allows certain more sophisticated features to be exploited, such as word POS features, word similarity features based on the WordNet (Pedersen et al., 2004), we deliberately choose to only include these simple features so

[2]This is based on the assumption that m_c and m_d are the first and second child of m_b in the semantic representation, respectively. If m_d is the first child in the semantic representation and m_c is the second, the pattern should be $\mathbf{wYwXw}$.

[3]For each word, we used all its prefixes (not necessarily linguistically meaningful ones) whose length are greater than 2 as features, for all languages.

as to make a fair comparison with previous works which also did not make use of external resources. For the features defined on m (i.e., $\phi^o(m)$), we include only the string form of m, as well as m's function name as features.

Finally, we also define features over $\mathbf{m}$ only. Such features are defined over semantic unit pairs such as (m_a, m_b) where m_a is the parent node of m_b as in $\mathbf{m}$. They include: 1) concatenation of the string forms of m_a and m_b, 2) concatenation of the string form of m_a and m_b's type, and 3) concatenation of the function names of m_a and m_b.

4 Algorithms

In this section we describe the efficient algorithms used for learning and decoding. The algorithms are inspired by the inside-outside style algorithms used for the generative hybrid tree models (Lu et al., 2008), but are different in the following ways: 1) we need to handle features, including long-distance features, 2) we need to additionally handle the computation of the partition function of Equation (3).

4.1 Learning

The training process involves the computation of the objective function (4) as well as the gradient terms (5).

The objective function (4) (excluding the regularization term which can be trivially computed) is equivalent to the following:

$$\mathcal{L}(\Lambda) = \sum_i \log \sum_{\mathbf{h} \in \mathcal{H}(\mathbf{n}_i, \mathbf{m}_i)} e^{\Lambda \cdot \Phi(\mathbf{n}_i, \mathbf{m}_i, \mathbf{h})} - \sum_i \log \sum_{\mathbf{m}', \mathbf{h}' \in \mathcal{H}(\mathbf{n}_i, \mathbf{m}')} e^{\Lambda \cdot \Phi(\mathbf{n}_i, \mathbf{m}', \mathbf{h}')} \quad (6)$$

In the first term, $\sum_{\mathbf{h} \in \mathcal{H}(\mathbf{n}_i, \mathbf{m}_i)} e^{\Lambda \cdot \Phi(\mathbf{n}_i, \mathbf{m}_i, \mathbf{h})}$ is in fact the sum of the scores (as defined by Φ and Λ) associated with all such latent structures that contain both $\mathbf{m}_i$ and $\mathbf{n}_i$ exactly. The second term is the sum of the scores associated with all the latent structures that contain $\mathbf{n}_i$ exactly. We focus our discussions on the computation of the first part first.

We use $\overset{m_{(p)}}{\underset{w_i \ldots w_j}{\triangle}}$ to denote the combined score of all such latent relaxed hybrid tree structures that contain both the semantic tree rooted by m and the natural language word sequence $w_i \ldots w_j$ that forms the word association pattern p with respect to m. For example, the score of the relaxed hybrid tree in Figure 2 (b) is contained by $\overset{m_{a(\mathbf{wX})}}{\underset{w_1 \ldots w_{10}}{\triangle}}$ (here p = $\mathbf{wX}$ because only $w_1 w_2 w_3$ are immediately associated with m_a).

We give an illustrative example that shows how these scores can be computed efficiently using dynamic programming. Consider the following case when m has at least one child semantic unit:

$$\overset{m_{(\mathbf{wXw})}}{\underset{w_i \ldots w_j}{\triangle}} = \overset{m_{(\mathbf{w})}}{\underset{w_i}{\triangle}} \otimes \overset{m_{(\mathbf{wXw})}}{\underset{w_{i+1} \ldots w_j}{\triangle}}$$

$$+ \overset{m_{(\mathbf{w})}}{\underset{w_i}{\triangle}} \otimes \overset{m_{(\mathbf{Xw})}}{\underset{w_{i+1} \ldots w_j}{\triangle}}$$

Here the symbol $\otimes$ means *extract and compute*, a process that involves 1) extraction of additional features when the two structures on the right-hand side are put together (for example, the local bigram feature "$w_i w_{i+1}$" can be extracted in the above case), and 2) computation of the score for the new structure when the two structures from both sides of $\otimes$ are combined, based on the scores of these structures and newly extracted features.

The above equation holds because for any relaxed hybrid tree contained by the left-hand side, the left-most word w_i is always immediately associated with m. The term $\overset{m_{(\mathbf{wXw})}}{\underset{w_{i+1} \ldots w_j}{\triangle}}$ is presenting a similar but smaller structure to the term on the left-hand side. The other term $\overset{m_{(\mathbf{wX})}}{\underset{w_i \ldots w_j}{\triangle}}$ can also be computed based on similar equations. In other words, such terms can be computed from even smaller similar terms in a recursive manner. A bottom-up dynamic programming algorithm is used for computing such terms.

When the semantic unit m has two child nodes, similar equations can also be established. Here we give an illustrative example:

$$\overset{m_{(\mathbf{wXwYw})}}{\underset{w_i \ldots w_j}{\triangle}} = \sum_{k=i}^{j-1} \overset{m_{(\mathbf{wX})}}{\underset{w_i \ldots w_k}{\triangle}} \otimes \overset{m_{(\mathbf{Yw})}}{\underset{w_{k+1} \ldots w_j}{\triangle}}$$

Finally, we have the following equation:

$$\overset{m}{\underset{w_i \ldots w_j}{\triangle}} = \sum_p \overset{m_{(p)}}{\underset{w_i \ldots w_j}{\triangle}}$$

The left-hand side simply means the combined score for all such relaxed hybrid trees that have (n, m) as the root, where $n \equiv w_i \ldots w_j$. Once the computation for a certain (n, m) pair is done, we

can move up to process such pairs that involve m's parent node.

The above process essentially computes the *inside* score associated with the (n, m) pair, which gives the sum of the scores of all such (incomplete) relaxed hybrid trees that can be constructed with (n, m) as the root. Similar to (Lu et al., 2008), we can also define and compute the *outside* scores for (n, m) (the combined score of such incomplete relaxed hybrid trees that contain (n, m) as one of its leave nodes) in an analogous manner, where the computation of the gradient functions can be efficiently integrated in this process.

Computation of the second part of the objective function (6) involves dynamic programming over a packed forest representation rather than a single tree, which requires an extension to the algorithm described in (Lu et al., 2008). The resulting algorithm is similar to the one used in (Lu and Ng, 2011), which has been used for language generation from packed forest representations of typed λ-calculus expressions.

4.2 Decoding

The decoding phase involves finding the optimal semantic tree $\mathbf{m}^*$ given a new input sentence $\mathbf{n}$:

$$\mathbf{m}^* = \arg\max_{\mathbf{m}} P(\mathbf{m}|\mathbf{n}) \tag{7}$$

This in fact is equivalent to finding the following optimal semantic tree $\mathbf{m}^*$:

$$\mathbf{m}^* = \arg\max_{\mathbf{m}} \sum_{\mathbf{h} \in \mathcal{H}(\mathbf{n},\mathbf{m})} e^{\Lambda \cdot \Phi(\mathbf{n},\mathbf{m},\mathbf{h})} \tag{8}$$

Unfortunately, the summation operation inside the $\arg\max$ prevents us from employing a similar version of the dynamic programming algorithm we developed for learning in Section 4.1. To overcome this difficulty, we instead find the optimal semantic tree using the following equation:

$$\mathbf{m}^* = \arg\max_{\mathbf{m},\mathbf{h} \in \mathcal{H}(\mathbf{n},\mathbf{m})} e^{\Lambda \cdot \Phi(\mathbf{n},\mathbf{m},\mathbf{h})} \tag{9}$$

We essentially replace the $\sum$ operation by the $\max$ operation inside the $\arg\max$. In other words, we first find the best latent relaxed hybrid tree $\mathbf{h}^*$ that contains the input sentence $\mathbf{n}$, and next we extract the optimal semantic tree $\mathbf{m}^*$ from $\mathbf{h}^*$.

This decoding algorithm is similar to the dynamic programming algorithm used for computing the inside score for a given natural language sentence $\mathbf{n}$ (i.e., the algorithm for computing the second term of Equation (6)). The difference here is, at each intermediate step, instead of computing the combined score for all possible relaxed hybrid tree structures (i.e., performing `sum`), we find the single-best relaxed hybrid tree structure (i.e., performing $\max$).

5 Experiments

We present evaluations on the standard GeoQuery dataset which is publicly available. This dataset has been used for evaluations in various semantic parsing works (Wong and Mooney, 2006; Kate and Mooney, 2006; Lu et al., 2008; Jones et al., 2012). It consists of 880 natural language sentences paired with their corresponding formal semantic representations. Each semantic representation is a tree structured representation derived from a Prolog query that can be used to interact with a database of U.S. geography facts for retrieving answers. The original dataset was fully annotated in English, and recently Jones et al. (2012) released a new version of this dataset with three additional language annotations (German, Greek and Thai). For all the experiments, we used the identical experimental setup as described in Jones et al. (2012). Specifically, we trained on 600 instances, and evaluated on the remaining 280.

We note that there exist two different versions of the GeoQuery dataset annotated with completely different semantic representations. Besides the version that we use in this work, which is annotated with tree structured semantic representations, the other version is annotated with lambda calculus expressions (Zettlemoyer and Collins, 2005). Results obtained from these two versions are not comparable.[4] Like many previous works, we focus on tree structured semantic representations for evaluations in this work since our model is designed for handling the class of semantic representations with recursive tree structures.

We used the standard evaluation criteria for judging the correctness of the outputs. Specifically, our system constructs Prolog queries from the output parses, and uses such queries to retrieve answers from the GeoQuery database. An output is considered correct if and only if it retrieves the

[4] Kwiatkowski et al. (2010) showed in Table 3 of their work that the version with tree-structured representations appeared to be more challenging – their semantic parser's performance on this version was substantially lower than that on the lambda calculus version.

System	English		Thai		German		Greek	
	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1

Table 3: Performance on the benchmark data, using four different languages as inputs. RHT: relaxed hybrid tree (this work).

same answers as the gold standard (Jones et al., 2012). We report accuracy scores – the percentage of inputs with correct answers, and F1 measures – the harmonic mean of precision (the proportion of correct answers out of inputs with an answer) and recall (the proportion of correct answers out of all inputs). By adopting such an evaluation method we will be able to directly compare our model's performance against those of the previous works.

The evaluations were conducted under such a setting in order to make comparisons to previous works. We would like to stress that our model is designed for general-purpose semantic parsing that is not only natural language-independent, but also task-independent. We thus distinguish our work from several previous works in the literature which focused on semantic parsing under other assumptions. Specifically, for example, works such as (Liang et al., 2013; Poon and Domingos, 2009; Clarke et al., 2010) essentially performed semantic parsing under different settings where the goal was to optimize the performance of certain downstream NLP tasks such as answering questions, and different semantic formalisms and language-specific features were usually involved.

For all our experiments, we used the L-BFGS algorithm for learning the feature weights, where feature weights were all initialized to zeros and the regularization hyper-parameter κ was set to 0.01. We set the maximum number of L-BFGS steps to 100. When all the features are considered, our model creates over 2 million features for each language on the dataset (English: 2.1M, Thai: 2.3M, German: 2.7M, Greek: 2.6M). Our model requires (on average) a per-instance learning time of 0.428 seconds and a per-instance decoding time of 0.235 seconds, on an Intel machine with a 2.2 GHz CPU. Our implementation is in Java. Here the per-instance learning time refers to the time spent on computing the instance-level log-likelihood as well as the expected feature counts (needed for the gradients).

Table 3 shows the evaluation results of our system as well as those of several other comparable previous works which share the same experimental setup as ours. UBL-S is the system presented in Kwiatkowski et al. (2010) which performs semantic parsing with the CCG based on mapping between graphs, and is the only non-tree based top-performing system. Their system, similar to ours, also uses a discriminative log-linear model where two types of features are defined. WASP is a model based on statistical phrase-based machine translation as we have described earlier. The hybrid tree model (HYBRIDTREE+) performs learning using a generative process which is augmented with an additional discriminative-reranking stage, where certain global features are incorporated (Lu et al., 2008). The Bayesian tree transducer model (TREETRANS) learns under a Bayesian generative framework, using hyper-parameters manually tuned on the German training data.

We can observe from Table 3 that the semantic parser based on relaxed hybrid tree gives competitive performance when all the features (described in Sec 3.4) are used. It significantly outperforms the hybrid tree model that is augmented with a discriminative reranking step. The model reports the best accuracy and F1 scores on English and Thai and best accuracy score on Greek. The scores on German are lower than those of UBL-S and TREETRANS, mainly because the span features appear not to be effective for this language, as we will discuss next.

We report in Table 4 the test set performance when certain types of features are excluded from our system. Such results can help us understand the effectiveness of features of different types. As we can see from the table, in general, all features play essential roles, though their effective-

System	English		Thai		German		Greek

Table 4: Results when certain types of features (local features, span features and character-level features) are excluded.

ness vary across different languages. The local features, which capture local dependencies, are of particular importance. Performance on three languages (English, Thai, and Greek) will drop when such features are excluded. Character-level features are very helpful for the three European languages (English, German, and Greek), but appear to be harmful for Thai. This indicates the character-level features that we propose do not perform effective morphological analysis for this Asian language.[5] The span features, which are able to capture certain long-distance dependencies, also play important roles. Specifically, if such features are excluded, our model's performance on three languages (Greek, English, Thai) will drop. Such features do not appear to be helpful for Thai and appear to be harmful for German. Clearly, such long-distance features are not contributing useful information to the model when these two languages are considered. This is especially the case for German, where we believe such features are contributing substantial noisy information to the model. What underlying language-specific, syntactic properties are generally causing these gaps in the performances? We believe this is an important question that needs to be addressed in future research. As we have mentioned, to make an appropriate comparison with previous works, only simple features are used. We believe that our system's performance can be further improved when additional informative language-specific features can be extracted from effective language tools and incorporated into our system.

6 Conclusions

In this work, we present a new discriminative model for semantic parsing which extends the *hybrid tree* model. Such an extension is similar to the extension of the generative syntactic parser based on probabilistic context-free grammars (PCFG) to the feature-based CRF parser (Finkel et al., 2008), but is slightly more complex due to latent structures. Developed on top of our novel *relaxed hybrid tree* representations, our model allows certain long-distance dependencies to be captured. We also present efficient algorithms for learning and decoding. Experiments on benchmark data show that our model is competitive to previous works and achieves the state-of-the-art performance across several different languages.

Future works include development of efficient algorithms for feature-based semantic parsing with alternative loss functions (Zhou et al., 2013), development of feature-based language generation models (Lu et al., 2009; Lu and Ng, 2011) and multilingual semantic parsers (Jie and Lu, 2014), as well as the development of efficient semantic parsing algorithms for optimizing the performance of certain downstream NLP tasks with less supervision (Clarke et al., 2010; Liang et al., 2013).

Being able to efficiently exploit features defined over individual words, our model also opens up the possibility for us to exploit alternative representations of words for learning (Turian et al., 2010), or to perform joint learning of both distributional and logical semantics (Lewis and Steedman, 2013). Furthermore, as a general string-to-tree structured prediction model, this work may find applications in other areas within NLP.

The system and code can be downloaded from `http://statnlp.org/research/sp/`.

Acknoledgments

The author would like to thank the anonymous reviewers for their helpful comments. This work was supported by SUTD grant SRG ISTD 2013 064.

[5]The character-level features that we introduced are indeed very general. We have conducted several additional experiments, which show that our model's performance for each language can be further improved when certain language-specific character-level features are introduced.

Abstract

The anchor words algorithm performs provably efficient topic model inference by finding an approximate convex hull in a high-dimensional word co-occurrence space. However, the existing greedy algorithm often selects poor anchor words, reducing topic quality and interpretability. Rather than finding an approximate convex hull in a high-dimensional space, we propose to find an exact convex hull in a visualizable 2- or 3-dimensional space. Such low-dimensional embeddings both improve topics and clearly show users why the algorithm selects certain words.

1 Introduction

Statistical topic modeling is useful in exploratory data analysis (Blei et al., 2003), but model inference is known to be NP-hard even for the simplest models with only two topics (Sontag and Roy, 2011), and training often remains a black box to users. Likelihood-based training requires expensive approximate inference such as variational methods (Blei et al., 2003), which are deterministic but sensitive to initialization, or Markov chain Monte Carlo (MCMC) methods (Griffiths and Steyvers, 2004), which have no finite convergence guarantees. Recently Arora et al. proposed the Anchor Words algorithm (Arora et al., 2013), which casts topic inference as statistical recovery using a *separability assumption*: each topic has a specific anchor word that appears only in the context of that single topic. Each anchor word can be used as a unique pivot to disambiguate the corresponding topic distribution. We then reconstruct the word co-occurrence pattern of each non-anchor words as a convex combination of the co-occurrence patterns of the anchor words.

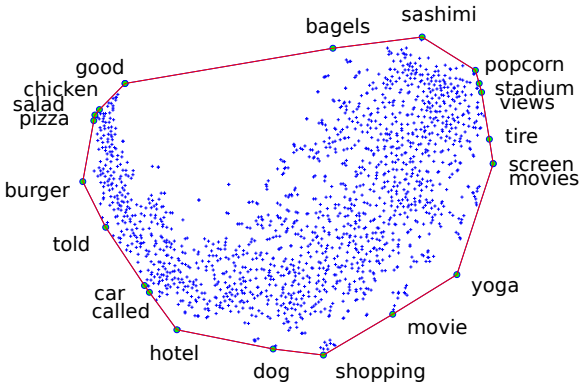

Figure 1: 2D t-SNE projection of a Yelp review corpus and its convex hull. The words corresponding to vertices are anchor words for topics, whereas non-anchor words correspond to the interior points.

This algorithm is fast, requiring only one pass through the training documents, and provides provable guarantees, but results depend entirely on selecting good anchor words. (Arora et al., 2013) propose a greedy method that finds an approximate convex hull around a set of vectors corresponding to the word co-occurrence patterns for each vocabulary word. Although this method is an improvement over previous work that used impractical linear programming methods (Arora et al., 2012), serious problems remain. The method greedily chooses the farthest point from the current subspace until the given number of anchors have been found. Particularly at the early stages

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1319–1328,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

of the algorithm, the words associated with the farthest points are likely to be infrequent and idiosyncratic, and thus form poor bases for human interpretation and topic recovery. This poor choice of anchors noticeably affects topic quality: the anchor words algorithm tends to produce large numbers of nearly identical topics.

Besides providing a separability criterion, anchor words also have the potential to improve topic interpretability. After learning topics for given text collections, users often request a label that summarizes each topic. Manually labeling topics is arduous, and labels often do not carry over between random initializations and models with differing numbers of topics. Moreover, it is hard to control the subjectivity in labelings between annotators, which is open to interpretive errors. There has been considerable interest in automating the labeling process (Mei et al., 2007; Lau et al., 2011; Chuang et al., 2012). (Chuang et al., 2012) propose a measure of *saliency*: a good summary term should be both distinctive specifically to one topic and probable in that topic. Anchor words are by definition optimally distinct, and therefore may seem to be good candidates for topic labels, but greedily selecting extreme words often results in anchor words that have low probability.

In this work we explore the opposite of Arora et al.'s method: rather than finding an approximate convex hull for an exact set of vectors, we find an exact convex hull for an approximate set of vectors. We project the $V \times V$ word co-occurrence matrix to visualizable 2- and 3-dimensional spaces using methods such as t-SNE (van der Maaten and Hinton, 2008), resulting in an input matrix up to 3600 times narrower than the original input for our training corpora. Despite this radically low-dimensional projection, the method not only finds topics that are as good or better than the greedy anchor method, it also finds highly salient, interpretable anchor words and provides users with a clear visual explanation for why the algorithm chooses particular words, all while maintaining the original algorithm's computational benefits.

2 Related Work

Latent Dirichlet allocation (LDA) (Blei et al., 2003) models D documents with a vocabulary V using a predefined number of topics by K. LDA views both $\{A_k\}_{k=1}^K$, a set of K topic-word distributions for each topic k, and $\{W_d\}_{d=1}^D$, a set of D document-topic distributions for each document d, and $\{\mathbf{z}_d\}_{d=1}^D$, a set of topic-assignment vectors for word tokens in the document d, as randomly generated from known stochastic processes. Merging $\{A_k\}$ as k-th column vector of $V \times K$ matrix A, $\{W_d\}$ as d-th column vector of $K \times D$ matrix W, the learning task is to estimate the posterior distribution of latent variables A, W, and $\{\mathbf{z}_d\}$ given $V \times D$ word-document matrix $\hat{M}$, which is the only observed variable where d-th column corresponds to the empirical word frequencies in the training documents d.

(Arora et al., 2013) recover word-topic matrix A and topic-topic matrix $R = \mathbb{E}[WW^T]$ instead of W in the spirit of nonnegative matrix factorization. Though the true underlying word distribution for each document is unknown and could be far from the sample observation $\hat{M}$, the empirical word-word matrix $\hat{Q}$ converges to its expectation $A\mathbb{E}[WW^T]A^T = ARA^T$ as the number of documents increases. Thus the learning task is to approximately recover A and R pretending that the empirical $\hat{Q}$ is close to the true second-order moment matrix Q.

The critical assumption for this method is to suppose that every topic k has a specific anchor word s_k that occurs with non-negligible probability (> 0) only in that topic. The anchor word s_k need not always appear in every document about the topic k, but we can be confident that the document is at least to some degree about the topic k if it contains s_k. This assumption drastically improves inference by guaranteeing the presence of a diagonal sub-matrix inside the word-topic matrix A. After constructing an estimate $\hat{Q}$, the algorithm in (Arora et al., 2013) first finds a set $S = \{s_1, ..., s_K\}$ of K anchor words (K is user-specified), and recovers A and R subsequently based on S. Due to this structure, overall performance depends heavily on the quality of anchor words.

In the matrix algebra literature this greedy anchor finding method is called *QR with row-pivoting*. Previous work classifies a matrix into two sets of row (or column) vectors where the vectors in one set can effectively reconstruct the vectors in another set, called *subset-selection algorithms*. (Gu and Eisenstat, 1996) suggest one important deterministic algorithm. A randomized algorithm provided by (Boutsidis et al., 2009) is the state-of-the art using a pre-stage that selects the

candidates in addition to (Gu and Eisenstat, 1996). We found no change in anchor selection using these algorithms, verifying the difficulty of the anchor finding process. This difficulty is mostly because anchors must be nonnegative convex bases, whereas the classified vectors from the subset selection algorithms yield unconstrained bases.

The t-SNE model has previously been used to display high-dimensional embeddings of words in 2D space by Turian.[1] Low-dimensional embeddings of topic spaces have also been used to support user interaction with models: (Eisenstein et al., 2011) use a visual display of a topic embedding to create a navigator interface. Although t-SNE has been used to visualize the *results* of topic models, for example by (Lacoste-Julien et al., 2008) and (Zhu et al., 2009), we are not aware of any use of the method as a fundamental component of topic inference.

3 Low-dimensional Embeddings

Real text corpora typically involve vocabularies in the tens of thousands of distinct words. As the input matrix $\hat{Q}$ scales quadratically with V, the Anchor Words algorithm must depend on a low-dimensional projection of $\hat{Q}$ in order to be practical. Previous work (Arora et al., 2013) uses random projections via either Gaussian random matrices (Johnson and Lindenstrauss, 1984) or sparse random matrices (Achlioptas, 2001), reducing the representation of each word to around 1,000 dimensions. Since the dimensionality of the compressed word co-occurrence space is an order of magnitude larger than K, we must still approximate the convex hull by choosing extreme points as before.

In this work we explore two projection methods: PCA and t-SNE (van der Maaten and Hinton, 2008). Principle Component Analysis (PCA) is a commonly-used dimensionality reduction scheme that linearly transforms the data to new coordinates where the largest variances are orthogonally captured for each dimension. By choosing only a few such principle axes, we can represent the data in a lower dimensional space. In contrast, t-SNE embedding performs a non-linear dimensionality reduction preserving the local structures. Given a set of points $\{\mathbf{x}_i\}$ in a high-dimensional space X, t-SNE allocates probability mass for each pair of points so that pairs of similar (closer) points become more likely to co-occur than dissimilar (distant) points.

[1] http://metaoptimize.com/projects/wordreprs/

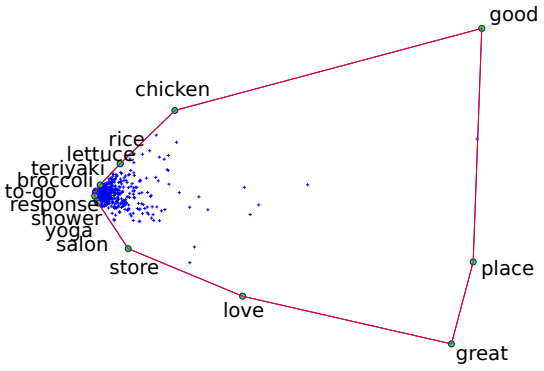

Figure 2: 2D PCA projections of a Yelp review corpus and its convex hulls.

$$p_{j|i} = \frac{\exp(-d(\mathbf{x}_i, \mathbf{x}_j)^2/2\sigma_i^2)}{\sum_{k \neq i} \exp(-d(\mathbf{x}_i, \mathbf{x}_k)^2/2\sigma_i^2)} \quad (1)$$

$$p_{ij} = \frac{p_{j|i} + p_{i|j}}{2N} \quad \text{(symmetrized)} \quad (2)$$

Then it generates a set of new points $\{\mathbf{y}_i\}$ in low-dimensional space Y so that probability distribution over points in Y behaves similarly to the distribution over points in X by minimizing KL-divergence between two distributions:

$$q_{ij} = \frac{(1 + \|\mathbf{y}_i - \mathbf{y}_j\|^2)^{-1}}{\sum_{k \neq l}(1 + \|\mathbf{y}_k - \mathbf{y}_l\|^2)^{-1}} \quad (3)$$

$$min\ KL(P||Q) = \sum_{i \neq j} p_{ij} \log \frac{p_{ij}}{q_{ij}} \quad (4)$$

Instead of approximating a convex hull in such a high-dimensional space, we select the exact vertices of the convex hull formed in a low-dimensional projected space, which can be calculated efficiently. Figures 1 and 2 show the convex hulls for 2D projections of $\hat{Q}$ using t-SNE and PCA for a corpus of Yelp reviews. Figure 3 illustrates the convex hulls for 3D t-SNE projection for the same corpus. Anchor words correspond to the vertices of these convex hulls. Note that we present the 2D projections as illustrative examples only; we find that three dimensional projections perform better in practice.

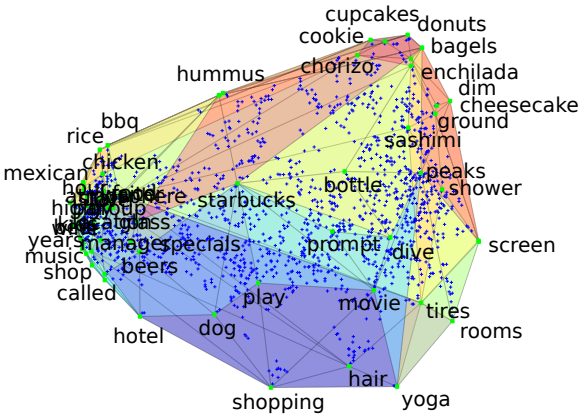

Figure 3: 3D t-SNE projection of a Yelp review corpus and its convex hull. Vertices on the convex hull correspond to anchor words.

In addition to the computational advantages, this approach benefits anchor-based topic modeling in two aspects. First, as we now compute the exact convex hull, the number of topics depends on the dimensionality of the embedding, v. For example in the figures, 2D projection has 21 vertices, whereas 3D projection supports 69 vertices. This implies users can easily tune the granularity of topic clusters by varying $v = 2, 3, 4, ...$ without increasing the number of topics by one each time. Second, we can effectively visualize the thematic relationships between topic anchors and the rest of words in the vocabulary, enhancing both interpretability and options for further vocabulary curation.

4 Experimental Results

We find that radically low-dimensional t-SNE projections are effective at finding anchor words that are much more salient than the greedy method, and topics that are more distinctive, while maintaining comparable held-out likelihood and semantic coherence. As noted in Section 1, the previous greedy anchor words algorithm tends to produce many nearly identical topics. For example, 37 out of 100 topics trained on a 2008 political blog corpus have *obama, mccain, bush, iraq* or *palin* as their most probable word, including 17 just for *obama*. Only 66% of topics have a unique top word. In contrast, the t-SNE model on the same dataset has only one topic whose most probable word is *obama*, and 86% of topics have a unique top word (*mccain* is the most frequent top word, with five topics).

We use three real datasets: business reviews from the Yelp Academic Dataset,[2] political blogs from the 2008 US presidential election (Eisenstein and Xing, 2010), and New York Times articles from 2007.[3] Details are shown in Table 1. Documents with fewer than 10 word tokens are discarded due to possible instability in constructing $\hat{Q}$. We perform minimal vocabulary curation, eliminating a standard list of English stopwords[4] and terms that occur below frequency cutoffs: 100 times (Yelp, Blog) and 150 times (NYT). We further restrict possible anchor words to words that occur in more than three documents. As our datasets are not artificially synthesized, we reserve 5% from each set of documents for held-out likelihood computation.

Name	Documents	Vocab.	Avg. length
Yelp	20,000	1,606	40.6
Blog	13,000	4,447	161.3
NYT	41,000	10,713	277.8

Table 1: Statistics for datasets used in experiments

Unlike (Arora et al., 2013), which presents results on synthetic datasets to compare performance across different *recovery* methods given increasing numbers of documents, we are are interested in comparing *anchor finding* methods, and are mainly concerned with semantic quality. As a result, although we have conducted experiments on synthetic document collections,[5] we focus on real datasets for this work. We also choose to compare only anchor finding algorithms, so we do not report comparisons to likelihood-based methods, which can be found in (Arora et al., 2013).

For both PCA and t-SNE, we use three-dimensional embeddings across all experiments. This projection results in matrices that are 0.03% as wide as the original $V \times V$ matrix for the NYT dataset. Without low-dimensional embedding, each word is represented by a V-dimensional vector where only several terms are non-zero due to the sparse co-occurrence patterns. Thus a ver-

[2] https://www.yelp.com/academic_dataset

[3] http://catalog.ldc.upenn.edu/LDC2008T19

[4] We used the list of 524 stop words included in the Mallet library.

[5] None of the algorithms are particularly effective at finding synthetically introduced anchor words possibly because there are other candidates around anchor vertices that approximate the convex hull to almost the same degree.

tex captured by the greedy anchor-finding method is likely to be one of many eccentric vertices in very high-dimensional space. In contrast, t-SNE creates an effective dense representation where a small number of pivotal vertices are more clearly visible, improving both performance and interpretability.

Note that since we can find an *exact* convex hull in these spaces,[6] there is an upper bound to the number of topics that can be found given a particular projection. If more topics are desired, one can simply increase the dimensionality of the projection. For the greedy algorithm we use sparse random projections with 1,000 dimensions with 5% negative entries and 5% positive entries. PCA and t-SNE choose (49, 32, 47) and (69, 77, 107) anchors, respectively for each of three Yelp, Blog, and NYTimes datasets.

4.1 Anchor-word Selection

We begin by comparing the behavior of low-dimensional embeddings to the behavior of the standard greedy algorithm. Table 2 shows ordered lists of the first 12 anchor words selected by three algorithms: t-SNE embedding, PCA embedding, and the original greedy algorithm. Anchor words selected by t-SNE (*police, business, court*) are more general than anchor words selected by the greedy algorithm (*cavalry, al-sadr, yiddish*). Additional examples of anchor words and their associated topics are shown in Table 3 and discussed in Section 4.2.

#	t-SNE	PCA	Greedy
1	police	beloved	cavalry
2	bonds	york	biodiesel
3	business	family	h/w
4	day	loving	kingsley
5	initial	late	mourners
6	million	president	pcl
7	article	people	carlisle
8	wife	article	al-sadr
9	site	funeral	kaye
10	mother	million	abc's
11	court	board	yiddish
12	percent	percent	great-grandmother

Table 2: The first 12 anchor words selected by three algorithms for the NYT corpus.

The Gram-Schimdt process used by Arora et al. greedily selects anchors in high-dimensional space. As each word is represented within V-dimensions, finding the word that has the next most distinctive co-occurrence pattern tends to prefer overly eccentric words with only short, intense bursts of co-occurring words. While the bases corresponding to these anchor words could be theoretically relevant for the original space in high-dimension, they are less likely to be equally important in low-dimensional space. Thus projecting down to low-dimensional space can rearrange the points emphasizing not only uniqueness, but also longevity, achieving the ability to form measurably more specific topics.

Concretely, neither *cavalry, al-sadr, yiddish* nor *police, business, court* are full representations of New York Times articles, but the latter is a much better basis than the former due to its greater generality. We see the effect of this difference in the specificity of the resulting topics (for example in 17 *obama* topics). Most words in the vocabulary have little connection to the word *cavalry*, so the probability $p(z|w)$ does not change much across different w. When we convert these distributions into $P(w|z)$ using the Bayes' rule, the resulting topics are very close to the corpus distribution, a

Type	#	HR	Top Words (**Yelp**)

Table 3: Example t-SNE topics and their most similar topics across algorithms. The Greedy algorithm can find similar topics, but the anchor words are much less salient.

[6] In order to efficiently find an exact convex hull, we use the *Quickhull* algorithm.

unigram distribution $p(w)$.

$$p(w|z = k_{cavalry}) \propto p(z = k_{cavalry}|w)p(w)$$
$$\approx p(w)$$

This lack of specificity results in the observed similarity of topics.

4.2 Quantitative Results

In this section we compare PCA and t-SNE projections to the greedy algorithm along several quantitative metrics. To show the effect of different values of K, we report results for varying numbers of topics. As the anchor finding algorithms are deterministic, the anchor words in a K-dimensional model are identical to the first K anchor words in a $(K+1)$-dimensional model. For the greedy algorithm we select anchor words in the order they are chosen. For the PCA and t-SNE methods, which find anchors jointly, we sort words in descending order by their distance from their centroid.

Recovery Error. Each non-anchor word is approximated by a convex combination of the K anchor words. The projected gradient algorithm (Arora et al., 2013) determines these convex coefficients so that the gap between the original word vector and the approximation becomes minimized. As choosing a good basis of K anchor words decreases this gap, Recovery Error (RE) is defined by the average ℓ_2-residuals across all words.

$$RE = \frac{1}{V}\sum_{i=1}^{V} \|\bar{Q}_i - \sum_{k=1}^{K} p(z_1 = k|w_1 = i)\bar{Q}_{S_k}\|_2 \quad (5)$$

Recovery error decreases with the number of topics, and improves substantially after the first 10–15 anchor words for all methods. The t-SNE method has slightly better performance than the greedy algorithm, but they are similar. Results for recovery with the original, unprojected matrix (not shown) are much worse than the other algorithms, suggesting that the initial anchor words chosen are especially likely to be uninformative.

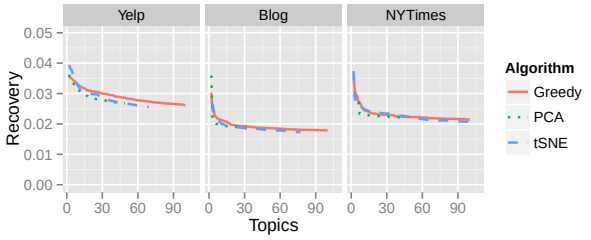

Figure 4: Recovery error is similar across algorithms.

Normalized Entropy. As shown previously, if the probability of topics given a word is close to uniform, the probability of that word in topics will be close to the corpus distribution. Normalized Entropy (NE) measures the entropy of this distribution relative to the entropy of a K-dimensional uniform distribution:

$$NE = \frac{1}{V}\sum_{i=1}^{V} \frac{H(z|w = i)}{\log K}. \quad (6)$$

The normalized entropy of topics given word distributions usually decreases as we add more topics, although both t-SNE and PCA show a dip in entropy for low numbers of topics. This result indicates that words become more closely associated with particular topics as we increase the number of topics. The low-dimensional embedding methods (t-SNE and PCA) have consistently lower entropy.

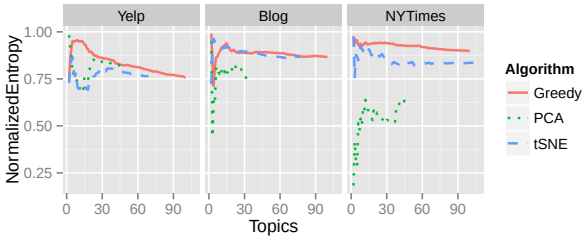

Figure 5: Words have higher topic entropy in the greedy model, especially in NYT, resulting in less specific topics.

Topic Specificity and **Topic Dissimilarity.** We want topics to be both specific (that is, not overly general) and different from each other. When there are insufficient number of topics, $p(w|z)$ often resembles the corpus distribution $p(w)$, where high frequency terms become the top words contributing to most topics. Topic Specificity (TS) is defined by the average KL divergence from each topic's conditional distribution to the corpus distribution.[7]

$$TS = \frac{1}{K}\sum_{k=1}^{K} KL\big(p(w|z = k) \;||\; p(w)\big) \quad (7)$$

[7]We prefer *specificity* to (AlSumait et al., 2009)'s term *vacuousness* because the metric increases as we move away from the corpus distribution.

One way to define the distance between multiple points is the minimum radius of a ball that covers every point. Whereas this is simply the distance form the centroid to the farthest point in the Euclidean space, it is an itself difficult optimization problem to find such centroid of distributions under metrics such as KL-divergence and Jensen-Shannon divergence. To avoid this problem, we measure Topic Dissimilarity (TD) viewing each conditional distribution $p(w|z)$ as a simple V-dimensional vector in $\mathbb{R}^V$. Recall $a_{ik} = p(w = i|z = k)$,

$$TD = \max_{1 \le k \le K} \| \frac{1}{K} \sum_{k'=1}^{K} a_{*k'} - a_{*k} \|_2. \quad (8)$$

Specificity and dissimilarity increase with the

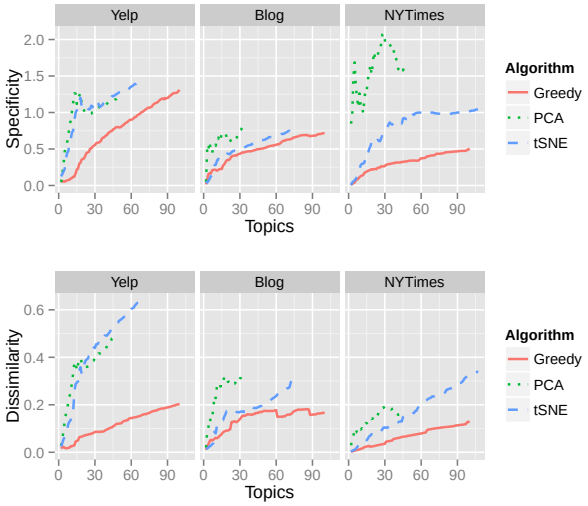

Figure 6: Greedy topics look more like the corpus distribution and more like each other.

number of topics, suggesting that with few anchor words, the topic distributions are close to the overall corpus distribution and very similar to one another. The t-SNE and PCA algorithms produce consistently better specificity and dissimilarity, indicating that they produce more useful topics early with small numbers of topics. The greedy algorithm produces topics that are closer to the corpus distribution and less distinct from each other (17 *obama* topics).

Topic Coherence is known to correlate with the semantic quality of topic judged by human annotators (Mimno et al., 2011). Let $\mathcal{W}_k^{(T)}$ be T most probable words (i.e., top words) for the topic k.

$$TC = \sum_{w_1 \neq w_2 \in \mathcal{W}_k^{(T)}} \log \frac{D(w_1, w_2) + \epsilon}{D(w_1)} \quad (9)$$

Here $D(w_1, w_2)$ is the co-document frequency, which is the number of documents in $\mathcal{D}$ consisting of two words w_1 and w_2 simultaneously. $D(w)$ is the simple document frequency with the word w. The numerator contains smoothing count ϵ in order to avoid taking the logarithm of zero. Coherence scores for t-SNE and PCA are worse

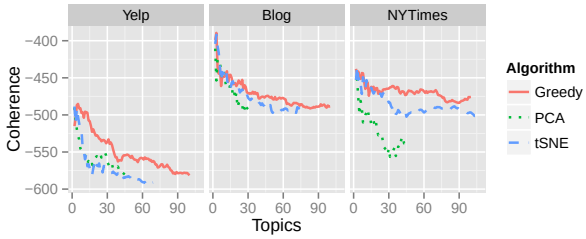

Figure 7: The greedy algorithm creates more coherent topics (higher is better), but at the cost of many overly general or repetitive topics.

than those for the greedy method, but this result must be understood in combination with the Specificity and Dissimilarity metrics. The most frequent terms in the overall corpus distribution $p(w)$ often appear together in documents. Thus a model creating many topics similar to the corpus distribution is likely to achieve high Coherence, but low Specificity by definition.

Saliency. (Chuang et al., 2012) define saliency for topic words as a combination of distinctiveness and probability within a topic. Anchor words are distinctive by construction, so we can increase saliency by selecting more probable anchor words. We measure the probability of anchor words in two ways. First, we report the zero-based rank of anchor words within their topics. Examples of this metric, which we call "hard" rank are shown in Table 3. The hard rank of the anchors in the PCA and t-SNE models are close to zero, while the anchor words for the greedy algorithm are much lower ranked, well below the range usually displayed to users. Second, while hard rank measures the perceived difference in rank of contributing words, position may not fully capture the relative importance of the anchor word. "Soft" rank quantifies the average log ratio between probabilities of the

prominent word w_k^* and the anchor word s_k.

$$SR = \frac{1}{K}\sum_{k=1}^{K} \log \frac{p(w = w_k^* | z = k)}{p(w = s_k | z = k)} \quad (10)$$

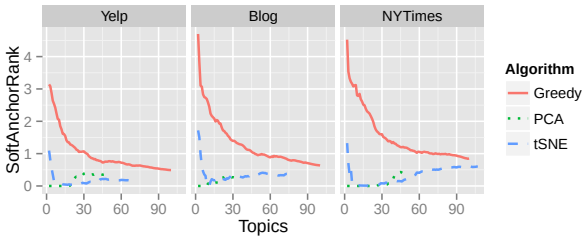

Figure 8: Anchor words have higher probability, and therefore greater salience, in t-SNE and PCA models (1 $\approx$ one third the probability of the top ranked word).

Lower values of soft rank (Fig. 8 indicate that the anchor word has greater relative probability to occur within a topic. As we increase the number of topics, anchor words become more prominent in topics learned by the greedy method, but t-SNE anchor words remain relatively more probable within their topics as measured by soft rank.

Held-out Probability. Given an estimate of the topic-word matrix A, we can compute the marginal probability of held-out documents under that model. We use the left-to-right estimator introduced by (Wallach et al., 2009), which uses a sequential algorithm similar to a Gibbs sampler. This method requires a smoothing parameter for document-topic Dirichlet distributions, which we set to $\alpha_k = 0.1$. We note that the greedy algorithm run on the original, unprojected matrix has better held-out probability values than t-SNE for the Yelp corpus, but as this method does not scale to realistic vocabularies we compare here to the sparse random projection method used in (Arora et al., 2013). The t-SNE method appears to do best, particularly in the NYT corpus, which has a larger vocabulary and longer training documents. The length of individual held-out documents has no correlation with held-out probability.

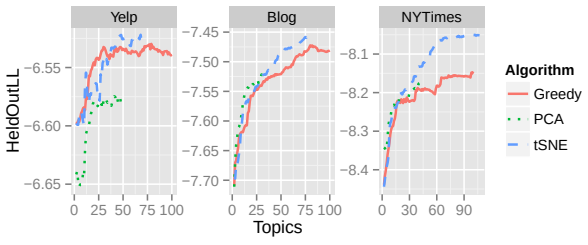

Figure 9: t-SNE topics have better held-out probability than greedy topics.

We emphasize that Held-out Probability is sensitive to smoothing parameters and should only be used in combination with a range of other topic-quality metrics. In initial experiments, we observed significantly worse held-out performance for the t-SNE algorithm. This phenomenon was because setting the probability of anchor words to zero for all but their own topics led to large negative values in held-out log probability for those words. As t-SNE tends to choose more frequent terms as anchor words, these "spikes" significantly affected overall probability estimates. To make the calculation more fair, we added 10^{-5} to any zero entries for anchor words in the topic-word matrix A across *all* models and renormalized.

Because t-SNE is a stochastic model, different initializations can result in different embeddings. To evaluate how steady anchor word selection is, we ran five random initializations for each dataset. For the Yelp dataset, the number of anchor words varies from 59 to 69, and 43 out of those are shared across at least four trials. For the Blog dataset, the number of anchor words varies from 80 to 95, with 56 shared across at least four trials. For the NYT dataset, this number varies between 83 and 107, with 51 shared across at least four models.

4.3 Qualitative Results

Table 3 shows topics trained by three methods (t-SNE, PCA, and greedy) for all three datasets. For each model, we select five topics *at random* from the t-SNE model, and then find the closest topic from each of the other models. If anchor words present in the top eight words, they are shown in boldface.

A fundamental difference between anchor-based inference and traditional likelihood-based inference is that we can give an *order* to topics according to their contribution to word co-occurrence convex hull. This order is intrinsic to the original algorithm, and we heuristically give orders to t-SNE and PCA based on their contributions. This order is listed as # in the previous table. For all but one topic, the closest topic from the greedy model has a higher order number than

the associated t-SNE topic. As shown above, the standard algorithm tends to pick less useful anchor words at the initial stage; only the later, higher ordered topics are specific.

The most clear distinction between models is the rank of anchor words represented by Hard Rank for each topic. Only one topic corresponding to (*initial*) has the anchor word which does not coincide with the top-ranked word. For the greedy algorithm, anchor words are often tens of words down the list in rank, indicating that they are unlikely to find a connection to the topic's semantic core. In cases where the anchor word is highly ranked (*unbelievers*, *parenthood*) the word is a good indicator of the topic, but still less decisive.

t-SNE and PCA are often consistent in their selection of anchor words, which provides useful validation that low-dimensional embeddings discern more relevant anchor words regardless of linear vs non-linear projections. Note that we are only varying the anchor selection part of the Anchor Words algorithm in these experiments, recovering topic-word distributions in the same manner given anchor words. As a result, any differences between topics with the same anchor word (for example *chicken*) are due to the difference in either the number of topics or the rest of anchor words. Since PCA suffers from a crowding problem in lower-dimensional projection (see Figure 2) and the problem could be severe in a dataset with a large vocabulary, t-SNE is more likely to find the proper number of anchors given a specified granularity.

5 Conclusion

One of the main advantages of the anchor words algorithm is that the running time is largely independent of corpus size. Adding more documents would not affect the size of the co-occurrence matrix, requiring more times to construct the co-occurrence matrix at the beginning. While the inference is scalable depending only on the size of the vocabulary, finding quality anchor words is crucial for the performance of the inference.

(Arora et al., 2013) presents a greedy anchor finding algorithm that improves over previous linear programming methods, but finding quality anchor words remains an open problem in spectral topic inference. We have shown that previous approaches have several limitations. Exhaustively finding anchor words by eliminating words that are reproducible by other words (Arora et al., 2012) is impractical. The anchor words selected by the greedy algorithm are overly eccentric, particularly at the early stages of the algorithm, causing topics to be poorly differentiated. We find that using low-dimensional embeddings of word co-occurrence statistics allows us to approximate a better convex hull. The resulting anchor words are highly *salient*, being both distinctive and probable. The models trained with these words have better quantitative and qualitative properties along various metrics. Most importantly, using radically low-dimensional projections allows us to provide users with clear visual explanations for the model's anchor word selections.

An interesting property of using low-dimensional embeddings is that the number of topics depends only on the projecting dimension. Since we can efficiently find an exact convex hull in low-dimensional space, users can achieve topics with their preferred level of granularities by changing the projection dimension. We do not insist this is the "correct" number of topics for a corpus, but this method, along with the range of metrics described in this paper, provides users with additional perspective when choosing a dimensionality that is appropriate for their needs.

We find that the t-SNE method, besides its well-known ability to produce high quality layouts, provides the best overall anchor selection performance. This method consistently selects higher-frequency terms as anchor words, resulting in greater clarity and interpretability. Embeddings with PCA are also effective, but they result in less well-formed spaces, being less effective in held-out probability for sufficiently large corpora.

Anchor word finding methods based on low-dimensional projections offer several important advantages for topic model users. In addition to producing more salient anchor words that can be used effectively as topic labels, the relationship of anchor words to a visualizable word co-occurrence space offers significant potential. Users who can see why the algorithm chose a particular model will have greater confidence in the model and in any findings that result from topic-based analysis. Finally, visualizable spaces offer the potential to produce interactive environments for semi-supervised topic reconstruction.

Acknowledgments

We thank David Bindel and the anonymous reviewers for their valuable comments and suggestions, and Laurens van der Maaten for providing his t-SNE implementation.

Weakly-Supervised Learning with Cost-Augmented Contrastive Estimation

Kevin Gimpel **Mohit Bansal**

{kgimpel,mbansal}@ttic.edu

Abstract

We generalize contrastive estimation in two ways that permit adding more knowledge to unsupervised learning. The first allows the modeler to specify not only the *set* of corrupted inputs for each observation, but also *how bad* each one is. The second allows specifying structural preferences on the latent variable used to explain the observations. They require setting additional hyperparameters, which can be problematic in unsupervised learning, so we investigate new methods for unsupervised model selection and system combination. We instantiate these ideas for part-of-speech induction without tag dictionaries, improving over contrastive estimation as well as strong benchmarks from the PASCAL 2012 shared task.

1 Introduction

Unsupervised NLP aims to discover useful structure in unannotated text. This structure might be part-of-speech (POS) tag sequences (Merialdo, 1994), morphological segmentation (Creutz and Lagus, 2005), or syntactic structure (Klein and Manning, 2004), among others. Unsupervised systems typically improve when researchers incorporate knowledge to bias learning to capture characteristics of the desired structure.[1]

There are many successful examples of adding knowledge to improve learning without labeled examples, including: sparsity in POS tag distributions (Johnson, 2007; Ravi and Knight, 2009; Ganchev et al., 2010), short attachments for dependency parsing (Smith and Eisner, 2006), agreement of word alignment models (Liang et al., 2006), power law effects in lexical distributions (Blunsom and Cohn, 2010; Blunsom and Cohn, 2011), multilingual constraints (Smith and Eisner, 2009; Ganchev et al., 2009; Snyder et al., 2009; Das and Petrov, 2011), and orthographic cues (Spitkovsky et al., 2010c; Spitkovsky et al., 2011b), *inter alia*.

Contrastive estimation (CE; Smith and Eisner, 2005) is a general approach to weakly-supervised learning with a particular way of incorporating knowledge. CE increases the likelihood of the observations at the expense of those in a particular **neighborhood** of each observation. The neighborhood typically contains corrupted versions of the observations. The latent structure is marginalized out for both the observations and their corruptions; the intent is to learn latent structure that helps to explain why the observation was generated rather than any of the corrupted alternatives.

In this paper, we present a new objective function for weakly-supervised learning that generalizes CE by including two types of **cost functions**, one on observations and one on output structures. The first (§4) allows us to specify not only the set of corrupted observations, but also *how bad* each corruption was. We use n-gram language models to measure the severity of each corruption.

The second (§5) allows us to specify preferences on desired output structures, regardless of the input sentence. For POS tagging, we attempt to learn language-independent tag frequencies by computing counts from treebanks for 11 languages not used in our POS induction experiments. For example, we encourage tag sequences that contain adjacent nouns and penalize those that contain adjacent adpositions.

We consider several unsupervised ways to set hyperparameters for these cost functions (§7), including the recently-proposed log-likelihood estimator of Bengio et al. (2013). We also circumvent

[1] We note that doing so strains the definition of the term *unsupervised*. Hence we will use the term *weakly-supervised* to refer to methods that do not explicitly train on labeled examples for the task of interest, but do use some form of task-specific knowledge.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1329–1341,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

hyperparameter selection via system combination, developing a novel voting scheme for POS induction that aligns tag identifiers across runs.

We evaluate our approach, which we call **cost-augmented contrastive estimation (CCE)**, on POS induction without tag dictionaries for five languages from the PASCAL shared task (Gelling et al., 2012). We find that CCE improves over both standard CE as well as strong baselines from the shared task. In particular, our final average accuracies are better than all entries in the shared task that use the same number of tags.

2 Related Work

Weakly-supervised techniques can be roughly categorized in terms of whether they influence the model, the learning procedure, or explicitly target the output structure. Examples abound in NLP; we focus on those that have been applied to POS tagging.

There have been many efforts at biasing models, including features (Smith and Eisner, 2005a; Berg-Kirkpatrick et al., 2010), sparse priors (Johnson, 2007; Goldwater and Griffiths, 2007; Toutanova and Johnson, 2007), sparsity in tag transition distributions (Ravi and Knight, 2009), small models via minimum description length criteria (Vaswani et al., 2010; Poon et al., 2009), a one-tag-per-type constraint (Blunsom and Cohn, 2011), and power law effects via Bayesian nonparametrics (Van Gael et al., 2009; Blunsom and Cohn, 2010; Blunsom and Cohn, 2011).

We focus below on efforts that induce bias into the learning (§2.1) or more directly in the output structure (§2.2), as they are more closely related to our contributions in this paper.

2.1 Biasing Learning

Some unsupervised methods do not change the model or attempt to impose structural bias; rather, they change the learning. This may involve optimizing a different objective function for the same model, e.g., by switching from soft to hard EM (Spitkovsky et al., 2010b). Or it may involve changing the objective during learning via annealing (Smith and Eisner, 2004) or more general multi-objective techniques (Spitkovsky et al., 2011a; Spitkovsky et al., 2013).

Other learning modifications relate to automatic data selection, e.g., choosing examples for generative learning (Spitkovsky et al., 2010a) or automatically generating negative examples for discriminative unsupervised learning (Li et al., 2010; Xiao et al., 2011).

CE does both, automatically generating negative examples and changing the objective function to include them. Our observation cost function alters CE's objective function, sharpening the effective distribution of the negative examples.

2.2 Structural Bias

Our output cost function is used to directly specify preferences on desired output structures. Several others have had similar aims. For dependency grammar induction, Smith and Eisner (2006) favored short attachments using a fixed-weight feature whose weight was optionally annealed during learning. Their bias could be implemented as an output cost function in our framework.

Posterior regularization (PR; Ganchev et al., 2010) is a general framework for declaratively specifying preferences on model outputs. Naseem et al. (2010) proposed universal syntactic rules for unsupervised dependency parsing and used them in a PR regime; we use analogous universal tag sequences in our cost function.

Our output cost is similar to posterior regularization. The difference is that we specify preferences via an arbitrary cost function on output structures, while PR uses expectation constraints on posteriors of the model. We compare to the PR tag induction system of Graça et al. (2011) in our experiments, improving over it in several settings.

2.3 Exploiting Resources

Much of the work mentioned above also benefits from leveraging existing resources. These may be curated or crowdsourced resources like the Wiktionary (Li et al., 2012), or traditional annotated treebanks for languages other than those under investigation (Cohen et al., 2011). In this paper, we use tag statistics from treebanks for 11 languages to impose our structural bias for a different set of languages used in our POS induction experiments.

Substantial recent work has improved many NLP tasks by leveraging multilingual or parallel text (Cohen and Smith, 2009; Snyder et al., 2009; Wang and Manning, 2014), including unsupervised POS tagging (Naseem et al., 2009; Das and Petrov, 2011; Täckström et al., 2013; Ganchev and Das, 2013). This sort of multilingual guidance could also be captured by particular output cost functions, though we leave this to future work.

3 Unsupervised Structure Learning

We consider a structured unsupervised learning setting. We use $\mathcal{X}$ to denote our set of possible structured inputs, and for a particular $\boldsymbol{x} \in \mathcal{X}$, we use $\mathcal{Y}(\boldsymbol{x})$ to denote the set of valid structured outputs for $\boldsymbol{x}$. We are given a dataset of inputs $\{\boldsymbol{x}^{(i)}\}_{i=1}^{N}$. To map inputs to outputs, we start by building a model of the joint probability distribution $p_{\boldsymbol{\theta}}(\boldsymbol{x}, \boldsymbol{y})$. We use a log-linear parameterization with feature vector $\boldsymbol{f}$ and weight vector $\boldsymbol{\theta}$:

$$p_{\boldsymbol{\theta}}(\boldsymbol{x}, \boldsymbol{y}) = \frac{\exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{y})\right\}}{\sum_{\boldsymbol{x}' \in \mathcal{X}, \boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}')\right\}}$$

where the sum in the denominator ranges over all possible inputs and all valid outputs for them.

In this paper, we consider ways of learning the parameters $\boldsymbol{\theta}$. Given $\boldsymbol{\theta}$, at test time we output a $\boldsymbol{y}$ for a new $\boldsymbol{x}$ using, e.g., Viterbi or minimum Bayes risk decoding; we use the latter in this paper.

3.1 EM and Contrastive Estimation

We start by reviewing two ways of choosing $\boldsymbol{\theta}$. The expectation-maximization algorithm (EM; Dempster et al., 1977) finds a local optimum of the marginal (log-)likelihood of the observations $\{\boldsymbol{x}^{(i)}\}_{i=1}^{N}$. The marginal log-likelihood is a sum over all $\boldsymbol{x}^{(i)}$ of the **gain function** $\gamma_{\text{EM}}(\boldsymbol{x}^{(i)})$:

$$\begin{aligned}
\gamma_{\text{EM}}(\boldsymbol{x}^{(i)}) &= \log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} p_{\boldsymbol{\theta}}(\boldsymbol{x}^{(i)}, \boldsymbol{y}) \\
&= \log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y})\right\} \\
&\quad - \underbrace{\log \sum_{\boldsymbol{x}' \in \mathcal{X}, \boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}')\right\}}_{Z(\boldsymbol{\theta})}
\end{aligned}$$

The difficulty is the final term, $\log Z(\boldsymbol{\theta})$, which requires summing over all possible inputs and all valid outputs for them. This summation is typically intractable for structured problems, and may even diverge. For this reason, EM is typically only used to train log-linear model weights when $Z(\boldsymbol{\theta}) = 1$, e.g., for hidden Markov models, probabilistic context-free grammars, and models composed of locally-normalized log-linear models (Berg-Kirkpatrick et al., 2010), among others.

There have been efforts at approximating the summation over elements of $\mathcal{X}$, whether by limiting sequence length (Haghighi and Klein, 2006), only summing over observations in the training data (Riezler, 1999), restricting the observation space based on the task (Dyer et al., 2011), or using Gibbs sampling to obtain an unbiased sample of the full space (Della Pietra et al., 1997; Rosenfeld, 1997).

Contrastive estimation (CE) addresses this challenge by using a **neighborhood** function $\mathcal{N} : \mathcal{X} \rightarrow 2^{\mathcal{X}}$ that generates a set of inputs that are "corruptions" of an input $\boldsymbol{x}$; $\mathcal{N}(\boldsymbol{x})$ always includes $\boldsymbol{x}$. Using shorthand $\mathcal{N}_i$ for $\mathcal{N}(\boldsymbol{x}^{(i)})$, CE corresponds to maximizing the sum over inputs $\boldsymbol{x}^{(i)}$ of the gain

$$\begin{aligned}
\gamma_{\text{CE}}(\boldsymbol{x}^{(i)}) &= \log \Pr(\boldsymbol{x}^{(i)} \mid \mathcal{N}_i) \\
&= \log \frac{\sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} p_{\boldsymbol{\theta}}(\boldsymbol{x}^{(i)}, \boldsymbol{y})}{\sum_{\boldsymbol{x}' \in \mathcal{N}_i} \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} p_{\boldsymbol{\theta}}(\boldsymbol{x}', \boldsymbol{y}')} \\
&= \log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y})\right\} - \\
&\quad \log \sum_{\boldsymbol{x}' \in \mathcal{N}_i} \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}')\right\}
\end{aligned}$$

Two $\log Z(\boldsymbol{\theta})$ terms cancel out, leaving the summation over input/output pairs in the neighborhood instead of the full summation over pairs.

Two desiderata govern the choice of $\mathcal{N}$. One is to make the summation over its elements computationally tractable. If $\mathcal{N}(\boldsymbol{x}) = \mathcal{X}$ for all $\boldsymbol{x} \in \mathcal{X}$, we obtain EM, so a smaller neighborhood typically must be used in practice. The second consideration is to target learning for the task of interest. For POS tagging and dependency parsing, Smith and Eisner (2005a, 2005b) used neighborhood functions that corrupted the observations in systematic ways, e.g., their TRANS1 neighborhood contains the original sentence along with those that result from transposing a single pair of adjacent words. The intent was to force the learner to explain why the given sentences were observed at the expense of the corrupted sentences.

Next we present our modifications to contrastive estimation. Both can be viewed as adding specialized cost functions that penalize some part of the structured input/output pair.

4 Modeling Corruption Costs

While CE allows us to specify a set of corrupted $\boldsymbol{x}$ for each $\boldsymbol{x}^{(i)}$ via the neighborhood function $\mathcal{N}$, it says nothing about how bad each corruption is. The same type of corruption might be harmful in one context and not harmful in another.

This fact was suggested as the reason why certain neighborhoods did not work as well for POS

tagging as others (Smith and Eisner, 2005a). One poorly-performing neighborhood consisted of sentences in which a single word of the original was deleted. Deleting a single word in a sentence might not harm grammaticality. By contrast, neighborhoods that transpose adjacent words led to better results. These kinds of corruptions are expected to be more frequently harmful, at least for languages with relatively rigid word order. However, there may still be certain transpositions that are benign, at least for grammaticality.

To address this, we introduce an **observation cost function** $\Delta : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}_{\geq 0}$ that indicates how much two observations differ. Using Δ, we define the following gain function $\gamma_{\mathrm{CCE}_1}(\boldsymbol{x}^{(i)}) =$

$$\log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y})\right\} -$$
$$\log \sum_{\boldsymbol{x}' \in \mathcal{N}_i} \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}') + \Delta(\boldsymbol{x}^{(i)}, \boldsymbol{x}')\right\}$$

The function Δ inflates the score of neighborhood entries with larger differences from the observed $\boldsymbol{x}^{(i)}$. This gain function is inspired by ideas from structured large-margin learning (Taskar et al., 2003; Tsochantaridis et al., 2005), specifically softmax-margin (Povey et al., 2008; Gimpel and Smith, 2010). Softmax-margin extends conditional likelihood by allowing the user to specify a cost function to give partial credit for structures that are partially correct. Conditional likelihood, by contrast, treats all incorrect structures equally.

While softmax-margin uses a cost function to specify how two *output* structures differ, our gain function γ_{CCE_1} uses a cost function Δ to specify how two *inputs* differ. But the motivations are similar: since poor structures have their scores artificially inflated by Δ, learning pays more attention to them, choosing weights that penalize them more than the lower-cost structures.

4.1 Observation Cost Functions

What types of cost functions should we consider? For efficient inference, we want to ensure that Δ decomposes additively across parts of the corrupted input $\boldsymbol{x}'$ in the same way as the features; we assume unigram and bigram features in this paper.

In addition, the choice of the observation cost function Δ is tied to the choice of neighborhood function. In our experiments, we use neighborhoods that change the *order* of words in the observation but not the *set* of words. Our first cost function simply counts the number of novel bigrams introduced when corrupting the original:

$$\Delta_I(\boldsymbol{x}^{(i)}, \boldsymbol{x}) = \alpha \sum_{j=1}^{|\boldsymbol{x}|+1} \mathbb{I}\Big[x_{j-1}x_j \notin 2\mathrm{grams}(\boldsymbol{x}^{(i)})\Big]$$

where x_j is the jth word of sentence $\boldsymbol{x}$, x_0 is the start-of-sentence marker, $x_{|\boldsymbol{x}|+1}$ is the end-of-sentence marker, $2\mathrm{grams}(\boldsymbol{x})$ returns the set of bigrams in $\boldsymbol{x}$, $\mathbb{I}[]$ returns 1 if its argument is true and 0 otherwise, and α is a constant to be tuned. We call this cost function MATCH. Only $\boldsymbol{x}^{(i)}$ (which is always contained in $\mathcal{N}_i$) is guaranteed to have cost 0. In the TRANS1 neighborhood, corrupted sequences will be penalized more if their transpositions occur in the middle of the sentence rather than at the beginning or end.

We also consider a version that weights the indicator by the negative log probability of the novel bigram: $\Delta_{LM}(\boldsymbol{x}^{(i)}, \boldsymbol{x}) =$

$$\alpha \sum_{j=1}^{|\boldsymbol{x}|+1} -\log \mathrm{P}(x_j | x_{j-1}) \mathbb{I}\Big[x_{j-1}x_j \notin 2\mathrm{grams}(\boldsymbol{x}^{(i)})\Big]$$

where $\mathrm{P}(x_j|x_{j-1})$ is obtained from a bigram language model. Among novel bigrams in the corruption $\boldsymbol{x}$, if the second word is highly surprising conditioned on the first, the bigram will incur high cost. We refer to $\Delta_{LM}(\boldsymbol{x}^{(i)}, \boldsymbol{x})$ as MATLM.

5 Expressing Structural Preferences

Our second modification to CE allows us to specify structural preferences for outputs $\boldsymbol{y}$. We first note that there exist objective functions for *supervised* structure prediction that never require computing the feature vector for the true output $\boldsymbol{y}^{(i)}$. Examples include Bayes risk (Kaiser et al., 2000; Povey and Woodland, 2002) and structured ramp loss (Do et al., 2008). These two objectives do, however, need to compute a cost function $\mathrm{cost}(\boldsymbol{y}^{(i)}, \boldsymbol{y})$, which requires the true output $\boldsymbol{y}^{(i)}$. We start with the following form of structured ramp loss from Gimpel and Smith (2012), transformed here to a gain function:

$$\max_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \Big(\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y}) - \mathrm{cost}(\boldsymbol{y}^{(i)}, \boldsymbol{y})\Big) -$$
$$\max_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \Big(\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y}') + \mathrm{cost}(\boldsymbol{y}^{(i)}, \boldsymbol{y}')\Big) \quad (1)$$

Maximizing this gain function for supervised learning corresponds to increasing the model score

of outputs that have both high model score ($\boldsymbol{\theta}^\top \boldsymbol{f}$) and low cost, while decreasing the model score of outputs with high model score and *high* cost.

For unsupervised learning, we do not have $\boldsymbol{y}^{(i)}$, so we simply drop $\boldsymbol{y}^{(i)}$ from the cost function. The result is an **output cost function** $\pi : \mathcal{Y} \rightarrow \mathbb{R}_{\geq 0}$ which captures our *a priori* knowledge about desired output structures. The value of $\pi(\boldsymbol{y})$ should be large for outputs $\boldsymbol{y}$ that are far from the ideal. In this paper, we consider POS induction and use intrinsic evaluation; however, in a real-world scenario, the output cost function could use signals derived from the downstream task in which the tags are being used.

Given π, we convert each max to a $\log \sum \exp$ in Eq. 1 and introduce the contrastive neighborhood into the second term, defining our new gain function $\gamma_{\mathrm{CCE}_2}(\boldsymbol{x}^{(i)}) =$

$$\log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y}) - \pi(\boldsymbol{y})\right\} -$$
$$\log \sum_{\boldsymbol{x}' \in \mathcal{N}_i} \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}') + \pi(\boldsymbol{y}')\right\}$$

Gimpel (2012) found that using such "softened" versions of the ramp losses worked better than the original versions (e.g., Eq. 1) when training machine translation systems.

5.1 Output Cost Functions

The output cost π should capture our desiderata about $\boldsymbol{y}$ for the task of interest. We consider universal POS tag subsequences analogous to the universal syntactic rules of Naseem et al. (2010). In doing so, we use the universal tags of Petrov et al. (2012): NOUN, VERB, ADJ (adjective), ADV (adverb), PRON (pronoun), DET (determiner), ADP (pre/postposition), NUM (numeral), CONJ (conjunction), PRT (particle), '.' (punctuation), and X (other).

We aimed for a set of rules that would be robust across languages. So, we used treebanks for 11 languages from the CoNLL 2006/2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007) other than those used in our POS induction experiments. In particular, we used Arabic, Bulgarian, Catalan, Czech, English, Spanish, German, Hungarian, Italian, Japanese, and Turkish. We replicated shorter treebanks a sufficient number of times until they were a similar size as the largest treebank. Then we counted gold POS tag unigrams and bigrams from the concatenation.

tag unigram	count	cost
X	50783	3.83
NUM	174613	2.59

NOUN .	504897	0

Table 1: Counts and costs for universal tags based on treebanks for 11 languages not used in POS induction experiments.

Where $\#(y)$ is the count of tag y in the treebank concatenation, the cost of y is

$$u(y) = \log\left(\frac{\max_{y'} \#(y')}{\#(y)}\right)$$

and, where $\#(\langle y_1, y_2\rangle)$ is the count of tag bigram $\langle y_1, y_2\rangle$, the cost of $\langle y_1, y_2\rangle$ is

$$u(\langle y_1, y_2\rangle) = 10 \times \log\left(\frac{\max_{\langle y_1', y_2'\rangle} \#(\langle y_1', y_2'\rangle)}{\#(\langle y_1, y_2\rangle)}\right)$$

We use a multiplier of 10 in order to exaggerate count differences among bigrams, which generally are closer together than unigram counts. In Table 1, we show counts and costs for all tag unigrams and selected tag bigrams.[2]

Given these costs for individual tag unigrams and bigrams, we use the following π function, which we call UNIV:

$$\pi(\boldsymbol{y}) = \beta \sum_{j=1}^{|\boldsymbol{y}|+1} u(y_j) + u(\langle y_{j-1}, y_j\rangle)$$

where β is a constant to be tuned and y_j is the jth tag of $\boldsymbol{y}$. We define y_0 to be the beginning-of-sentence marker and $y_{|\boldsymbol{y}|+1}$ to be the end-of-sentence marker (which has unigram cost 0).

Many POS induction systems use one-tag-per-type constraints (Blunsom and Cohn, 2011; Gelling et al., 2012), which often lead to higher

[2]The complete tag bigram list is provided in the supplementary material.

$$\max_{\boldsymbol{\theta}} \sum_{i=1}^{N} \log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y})\right\} - \log \sum_{\boldsymbol{x}' \in \mathcal{N}_i} \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}')\right\} \quad (2)$$

$$\max_{\boldsymbol{\theta}} \sum_{i=1}^{N} \log \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}^{(i)})} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}^{(i)}, \boldsymbol{y}) - \pi(\boldsymbol{y})\right\} - \log \sum_{\boldsymbol{x}' \in \mathcal{N}_i} \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x}')} \exp\left\{\boldsymbol{\theta}^\top \boldsymbol{f}(\boldsymbol{x}', \boldsymbol{y}') + \Delta(\boldsymbol{x}^{(i)}, \boldsymbol{x}') + \pi(\boldsymbol{y}')\right\} \quad (3)$$

Figure 1: Contrastive estimation (Eq. 2) and cost-augmented contrastive estimation (Eq. 3). L2 regularization terms ($\frac{C}{2}\sum_{j=1}^{|\boldsymbol{\theta}|}\theta_j^2$) are not shown here but were used in our experiments.

accuracies even though the gold standard is not constrained in this way. This constraint can be encoded as an output cost function, though it would require approximate inference (Poon et al., 2009).

6 Cost-Augmented CE

We extended the objective function underlying CE by defining two new types of cost functions, one on observations (§4) and one on outputs (§5). We combine them into a single objective, which we call **cost-augmented contrastive estimation** (CCE), shown as Eq. 3 in Figure 1.

If the cost functions Δ and π factor in the same way as the features $\boldsymbol{f}$, then it is straightforward to implement CCE atop an existing CE implementation. The additional terms in the cost functions can be implemented as features with fixed weights (albeit where the weight differs depending on the context).

7 Model Selection

Our modifications give increased flexibility, but require setting new hyperparameters. In addition to the choice of the cost functions, each has a weight: α for Δ and β for π. We need ways to set these weights that do not require labeled data.

Smith and Eisner (2005a) chose the hyperparameter values that yielded the best CE objective on held-out development data. We use their strategy, though we experiment with two others as well.[3] In particular, we estimate held-out data log-likelihood via the method of Bengio et al. (2013) and also consider ways of combining outputs from multiple models.

7.1 Estimating Held-Out Log-Likelihood

Bengio et al. (2013) recently proposed ways to efficiently estimate held-out data log-likelihood for generative models. They showed empirically that a simple, biased version of their conservative sampling-based log-likelihood (CSL) estimator can be useful for model selection.

The biased CSL requires a Markov chain on the variables in the model (i.e., $\boldsymbol{x}$ and $\boldsymbol{y}$) as well as the ability to compute $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y})$. It generates consecutive samples of $\boldsymbol{y}$ from a Markov chain initialized at each $\boldsymbol{x}$ in a development set D, with S Markov chains run for each $\boldsymbol{x}$. We compute and sum $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y}^j)$ for each sampled $\boldsymbol{y}^j$, then sum over all $\boldsymbol{x}$ in D. The result is a biased estimate for the log-likelihood of D. Bengio et al. showed that these biased estimates could give the same model ranking as unbiased estimates, though more efficiently. They also showed that taking the single, initial sample from the S Markov chains resulted in the same model ranking as using many samples from each chain. We follow suit here.

Our Markov chain is a blocked Gibbs sampler in which we alternate between sampling from $p_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{x})$ and $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y})$. Since we only use a single sample from each Markov chain and initialize each chain to $\boldsymbol{x}$, this simply amounts to drawing S samples from $p_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{x})$. To sample from $p_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{x})$, we use the exact algorithm obtained by running the backward algorithm and then performing left-to-right sampling of tags using the local features and requisite backward terms to define the local tag distributions.

We then compute $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y})$ for each sampled $\boldsymbol{y}$. If there are no features in $\boldsymbol{f}$ that look at more than one word (which is the case with the features used in our experiments), then this probability factors:

$$p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y}) = \prod_{k=1}^{|\boldsymbol{y}|} p_{\boldsymbol{\theta}}(x_k|y_k)$$

This is easily computable assuming that we have normalization constants $Z(y)$ cached for each tag y. To compute each $Z(y)$, we sum over all words observed in the training data (replacing some with a special UNK token; see below). We can then compute likelihoods for individual words and mul-

[3] When using their strategy for CCE, we compute the CE criterion only, omitting the costs. We do so because the weights of the cost terms can have a large impact on the magnitude of the objective, making it difficult to do a fair comparison of models with different cost weights.

tiply them across the words in the sentence to compute $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y})$.

To summarize, we get a log-likelihood estimate for development set $D = \{\boldsymbol{x}^{(i)}\}_{i=1}^{|D|}$ by sampling S times from $p_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{x}^{(i)})$ for each $\boldsymbol{x}^{(i)}$, getting samples $\{\{\boldsymbol{y}^{(i),j}\}_{j=1}^{S}\}_{i=1}^{|D|}$, then we compute

$$\sum_{i=1}^{|D|} \sum_{j=1}^{S} \log p_{\boldsymbol{\theta}}(\boldsymbol{x}^{(i)}|\boldsymbol{y}^{(i),j})$$

We used values of $S \in \{1, 10, 100\}$, finding that the ranking of models was consistent across S values. We used $S = 10$ in all results reported below.

We note that this estimator was originally presented for generative models, and that (C)CE is not a generative training criterion. It seeks to maximize the conditional probability of an observation given its neighborhood. Nonetheless, when implementing our log-likelihood estimator, we treat the model as a generative model, computing the $Z(y)$ constants by summing over all words in the vocabulary.

7.2 System Combination

We can avoid choosing a single model by combining the outputs of multiple models via system combination. We decode test data by using posterior decoding. To combine the outputs of multiple models, we find the max-posterior tag under each model, then choose the highest vote-getter, breaking ties arbitrarily.

However, when doing POS induction without a tag dictionary, the tags are simply unique identifiers and may not have consistent meaning across runs. To address this, we propose a novel voting scheme that is inspired by the widely-used 1-to-1 accuracy metric for POS induction (Haghighi and Klein, 2006). This metric maps system tags to gold tags to maximize accuracy with the constraint that each gold tag is mapped to at most once. The optimal mapping can be found by solving a maximum weighted bipartite matching problem.

We adapt this idea to map tags between two systems, rather than between system tags and gold tags. Given k systems that we want to combine, we choose one to be the **backbone** and map the remaining $k - 1$ systems' outputs to the backbone.[4] After mapping each system's output to the backbone system, we perform simple majority voting among all k systems. To choose the backbone, we consider each of the k systems in turn as backbone and maximize the sum of the weights of the weighted bipartite matching solutions found. This is a heuristic that attempts to choose a backbone that is similar to all other systems. We found that highly-weighted matchings often led to high POS tagging accuracy metrics. We call this voting scheme ALIGN. To see the benefit of ALIGN, we also compare to a simple scheme (NAÏVE) that performs majority voting without any tag mapping.

[4]We use the LEMON C++ toolkit (Dezs et al., 2011) to solve the maximum weighted bipartite matching problems.

8 Experiments

Task and Datasets We consider POS induction without tag dictionaries using five freely-available datasets from the PASCAL shared task (Gelling et al., 2012).[5] These include Danish (DA), using the Copenhagen Dependency Treebank v2 (Buch-Kromann et al., 2007); Dutch (NL), using the Alpino treebank (Bouma et al., 2001); Portuguese (PT), using the Floresta Sintá(c)tica treebank (Afonso et al., 2002); Slovene (SL), using the jos500k treebank (Erjavec et al., 2010); and Swedish (SV), using the Talbanken treebank (Nivre et al., 2006). We use their provided training, development, and test sets.

Evaluation We fix the number of tags in our models to 12, which matches the number of universal tags from Petrov et al. (2012). We use both many-to-1 (M-1) and 1-to-1 (1-1) accuracy as our evaluation metrics, using the universal tags for the gold standard (which was done for the official evaluation for the shared task).[6] We note that our π function assigns identities to tags (e.g., tag 1 is assumed to be NOUN), so we could use actual tagging accuracy when training with the π cost function. But we use M-1 and 1-1 accuracy to enable easier comparison both among different settings and to prior work.

Baselines From the shared task, we compare to all entries that used 12 tags. These include

[5]`http://wiki.cs.ox.ac.uk/InducingLinguisticStructure/SharedTask`

[6]It is common to use a greedy algorithm to compute 1-to-1 accuracy, e.g., as in the shared task scoring script (`http://www.dcs.shef.ac.uk/~tcohn/wils/eval.tar.gz`), though the optimal mapping can be computed efficiently via the maximum weighted bipartite matching algorithm, as stated above. We use the shared task scorer for all results here for ease of comparison. When we instead evaluate using the optimal mapping, we find that accuracies are usually only slightly higher than those found by the greedy algorithm.

BROWN clusters (Brown et al., 1992), clusters obtained using the `mkcls` tool (Och, 1995), and the featurized HMM with sparsity constraints trained using posterior regularization (PR), described by Graça et al. (2011). The PR system achieved the highest average 1-1 accuracy in the shared task.

We restrict our attention to systems that use 12 tags because the M-1 and 1-1 metrics are highly dependent upon the number of hypothesized tags. In general, using more tags leads to higher M-1 and lower 1-1 (Gelling et al., 2012). By keeping the number of tags fixed, we hope to provide a cleaner comparison among approaches.

We compare to two other baselines: an HMM trained with 500 iterations of EM and an HMM trained with 100 iterations of stepwise EM (Liang and Klein, 2009). We used random initialization as done by Liang and Klein: we set each parameter in each multinomial to $\exp\{1 + c\}$, where $c \sim U[0, 1]$, then normalized to get probability distributions. For stepwise EM, we used minibatch size 3 and stepsize reduction power 0.7.

For all models we trained, including both baselines and CCE, we used only the training data during training and used the unannotated development data for certain model selection criteria. No labels were used except for final evaluation on the test data. Therefore, we need a way to handle unknown words in test data. When running EM and stepwise EM, while reading in the final 10% of sentences in the training set, we replace novel words with the special token UNK. We then replace unknown words in test data with UNK.

8.1 CCE Setup

Features We use standard indicator features on tag-tag transitions and tag-word emissions, the spelling features from Smith and Eisner (2005a), and additional emission features based on Brown clusters. The latter features are simply indicators for tag-cluster pairs—analogous to tag-word emissions in which the word is replaced by its Brown cluster identifier. We run Brown clustering (Liang, 2005) on the POS training data for each language, once with 12 clusters and once with 40, then add tag-cluster emission features for each clustering and one more for their conjunction.[7]

Learning We solve Eq. 2 and Eq. 3 by running LBFGS until convergence on the training data, up to 100 iterations. We tag the test data with minimum Bayes risk decoding and evaluate.

We use two neighborhood functions:

- TRANS1: the original sentence along with all sentences that result from doing a single transposition of adjacent words.
- SHUFF10: the original sentence along with 10 random permutations of it.

We use L2 regularization, adding $\frac{C}{2}\sum_{j=1}^{|\boldsymbol{\theta}|}\theta_j^2$ to the objectives shown in Figure 1. We use a fixed (untuned) $C = 0.0001$ for all experiments reported below.[8] We initialize each CE model by sampling weights from $\mathcal{N}(0, 1)$.

Cost Functions The cost functions Δ and π have constants α and β which balance their contributions relative to the model score and must be tuned. We consider the ways proposed in Section 7, namely tuning based on the contrastive estimation criterion computed on development data (CE), the log-likelihood estimate on development data with $S = 10$ (LL), and our two system combination algorithms: naïve voting (NAÏVE) and aligned voting (ALIGN), both of which use as input the 4 system outputs whose hyperparameters led to the highest values for the CE criterion on development data.

We used $\alpha \in \{3 \times 10^{-4}, 10^{-3}, 3 \times 10^{-3}, 0.01, 0.03, 0.1, 0.3\}$ and $\beta \in \{3 \times 10^{-6}, 10^{-5}, 3 \times 10^{-5}, 10^{-4}, 3 \times 10^{-4}\}$. Setting $\alpha = \beta = 0$ gives us CE, which we also compare to. When using both MATLM and UNIV simultaneously, we first choose the best two α values by the LL criterion and the best two β values by the CE criterion when using only those individual costs. This gives us 4 pairs of values; we run experiments with these pairs and choose the pair to report using each of the model selection criteria. For system combination, we use the 4 system outputs resulting from these 4 pairs.

For training bigram language models for the MATLM cost, we use the language's POS training data concatenated with its portion of the Europarl v7 corpus (Koehn, 2005) and the text of its

[7] To handle unknown words: for words that only appear in the final 10% of training sentences, we replace them with UNK when firing their tag-word emission features. We use special Brown cluster identifiers reserved for UNK. But we still use all spelling features derived from the actual word type. For unknown words at test time, we use the UNK emission feature, the Brown cluster features with the special UNK cluster identifiers, and the word's actual spelling features.

[8] In subsequent experiments we tried $C \in \{0.01, 0.001\}$ for the baseline CE setting and found minimal differences.

Table 2: Results for observation cost functions. The CE baseline corresponds to rows where cost="none". Other rows are CCE. Best score for each column and each neighborhood is bold.

Wikipedia. The word counts for the Wikipedias used range from 18M for Slovene to 1.9B for Dutch. We used modified Kneser-Ney smoothing as implemented by SRILM (Stolcke, 2002).

8.2 Results

We present two sets of results. First we compare our MATCH and MATLM observation cost functions for our two neighborhoods and two ways of doing model selection. Then we do a broader comparison, comparing both types of costs and their combination to our full set of baselines.

Observation Cost Functions In Table 2, we show results for observation cost functions. We note that the TRANS1 neighborhood works much better than the SHUFF10 neighborhood, but we find that using cost functions can close the gap in certain cases, particularly for Dutch and Slovene for which the SHUFF10 MATLM scores approach or exceed the TRANS1 scores without a cost.

Since the SHUFF10 neighborhood exhibits more diversity than TRANS1, we expect to see larger gains from using observation cost functions. We do in fact see larger gains in M-1, e.g., average improvements are 1.6-2.6 for SHUFF10 and 0.4-1.3 for TRANS1, though 1-1 gains are closer.

For TRANS1, while MATCH does reach a slightly higher average M-1 than MATLM, the latter does much better in 1-1 (49.9 vs. 47.6 when using LL for model selection). For SHUFF10, MATLM consistently does better than MATCH. Nonetheless, we suspect MATCH works as well as it does because it at least differentiates the observation (which is always part of the neighborhood) from the corruptions.

We find that the LL model selection criterion consistently works better than the CE criterion for model selection. When using LL model selection and fixing the neighborhood, all average scores are better than their CE baselines. For M-1, the average improvement is 1.0 to 2.6 points, and for 1-1 the average improvement ranges from 0.4 to 2.7.

We find the best overall performance when using MATLM with LL model selection with the TRANS1 neighborhood, and we report this setting in our subsequent experiments.

Output Cost Function Table 3 shows results when using our UNIV output cost function, as well as our full set of baselines. All (C)CE experiments used the TRANS1 neighborhood.

We find that our contrastive estimation baseline (cost="none") has a higher average M-1 (61.8) than all results from the shared task, but its average 1-1 accuracy is lower than that reached by posterior regularization, the best system in the shared task according to 1-1. Using an observation cost function increases both M-1 and 1-1: MATLM yields an average 1-1 of 49.9, nearing the 50.1 of PR while exceeding it in M-1 by nearly 2 points.

When using the UNIV cost function, we see some variation in performance across model selection criteria, but we find improvements in both M-1 and 1-1 accuracy under most settings. When doing model selection via ALIGN voting, we roughly match the average 1-1 of PR, and when using the CE criterion, we beat it by 1 point on average (51.3 vs. 50.1).

Combined Costs When using the UNIV cost, we find that model selection via CE works better than LL. So for the combined costs, we took the two best MATLM weights (α values) according to LL and the two best UNIV weights (β values) according to CE and ran combined cost experiments (MATCHLM+UNIV) with the four pairs of hyperparameters. Then from among these four,

Table 3: Unsupervised POS tagging accuracies for five languages, showing results for three systems from the PASCAL shared task as well as three other baselines (EM, stepwise EM, and contrastive estimation). All (C)CE results use the TRANS1 neighborhood. The best score in each column is bold.

we again chose results by CE, LL, and both voting schemes.

The results are shown in the lower part of Table 3. We find different trends in M-1 and 1-1 depending on whether we use CE or LL for model selection, which may be due to our limited hyperparameter search stemming from computational constraints. However, by comparing NAÏVE to ALIGN, we see a consistent benefit from aligning tags before voting, leading to our highest average accuracies. In particular, using MATCHLM+UNIV and ALIGN, we improve over CE by 2.5 in M-1 and 4.5 in 1-1, also improving over the best results from the shared task.

9 Conclusion

We have shown how to modify contrastive estimation to use additional sources of knowledge, both in terms of observation and output cost functions. We adapted a recently-proposed technique for estimating the log-likelihood of held-out data, finding it to be effective as a model selection criterion when using observation cost functions. We improved tagging accuracy by using weak supervision in the form of universal tag frequencies. We proposed a system combination method for POS induction systems that consistently performs better than naïve voting and circumvents hyperparameter selection. We reported results on par with or exceeding the best systems from the PASCAL 2012 shared task.

Contrastive estimation has been shown effective for numerous NLP tasks, including dependency grammar induction (Smith and Eisner, 2005b), bilingual part-of-speech induction (Chen et al., 2011), morphological segmentation (Poon et al., 2009), and machine translation (Xiao et al., 2011). The hope is that our contributions can benefit these and other applications of weakly-supervised learning.

Abstract

We introduce a reinforcement learning-based approach to simultaneous machine translation—producing a translation while receiving input words—between languages with drastically different word orders: from verb-final languages (e.g., German) to verb-medial languages (English). In traditional machine translation, a translator must "wait" for source material to appear before translation begins. We remove this bottleneck by predicting the final verb in advance. We use reinforcement learning to learn when to trust predictions about unseen, future portions of the sentence. We also introduce an evaluation metric to measure expeditiousness and quality. We show that our new translation model outperforms batch and monotone translation strategies.

1 Introduction

We introduce a simultaneous machine translation (MT) system that predicts unseen verbs and uses reinforcement learning to learn when to trust these predictions and when to wait for more input.

Simultaneous translation is producing a partial translation of a sentence before the input sentence is complete, and is often used in important diplomatic settings. One of the first noted uses of human simultaneous interpretation was the Nuremberg trials after the Second World War. Siegfried Ramler (2009), the Austrian-American who organized the translation teams, describes the linguistic predictions and circumlocutions that translators would use to achieve a tradeoff between translation latency and accuracy. The audio recording technology used by those interpreters sowed the seeds of technology-assisted interpretation at the United Nations (Gaiba, 1998).

Performing real-time translation is especially difficult when information that comes early in the target language (the language you're translating *to*) comes late in the source language (the language you're translating *from*). A common example is when translating from a verb-final (SOV) language (e.g., German or Japanese) to a verb-medial (SVO) language, (e.g., English). In the example in Figure 1, for instance, the main verb of the sentence (in **bold**) appears at the end of the German sentence. An offline (or "batch") translation system waits until the end of the sentence before translating anything. While this is a reasonable approach, it has obvious limitations. Real-time, interactive scenarios—such as online multilingual video conferences or diplomatic meetings—require comprehensible partial interpretations *before* a sentence ends. Thus, a significant goal in interpretation is to make the translation as **expeditious** as possible.

We present three components for an SOV-to-SVO simultaneous MT system: a reinforcement learning framework that uses predictions to create expeditious translations (Section 2), a system to predict how a sentence will end (e.g., predicting the main verb; Section 4), and a metric that balances quality and expeditiousness (Section 3). We combine these components in a framework that learns *when* to begin translating sections of a sentence (Section 5).

Section 6 combines this framework with a

Figure 1: An example of translating from a verb-final language to English. The verb, in **bold**, appears at the end of the sentence, preventing coherent translations until the final source word is revealed.

translation system that produces simultaneous translations. We show that our data-driven system can successfully predict unseen parts of the sentence, learn when to trust them, and outperform strong baselines (Section 7).

While some prior research has approached the problem of simultaneous translation—we review these systems in more detail in Section 8—no current model learns *when* to definitively begin translating chunks of an incomplete sentence. Finally, in Section 9, we discuss the limitations of our system: it only uses the most frequent source language verbs, it only applies to sentences with a single main verb, and it uses an idealized translation system. However, these limitations are not insurmountable; we describe how a more robust system can be assembled from these components.

2 Decision Process for Simultaneous Translation

Human interpreters learn strategies for their profession with experience and practice. As words in the source language are observed, a translator—human or machine—must decide whether and how to translate, while, for certain language pairs, simultaneously predicting future words. We would like our system to do the same. To this end, we model simultaneous MT as a Markov decision process (MDP) and use reinforcement learning to effectively combine predicting, waiting, and translating into a coherent strategy.

2.1 States: What is, what is to come

The **state** s_t represents the current view of the world given that we have seen t words of a source language sentence.[1] The state contains information both about what is known and what is predicted based on what is known. To compare the system to a human translator in a decision-making process, the state is akin to the translator's cognitive state. At any given time, we have *knowledge* (observations) and *beliefs* (predictions) with varying degrees of certainty: that is, the state contains the revealed words $x_{1:t}$ of a sentence; the state also contains predictions about the remainder of the sentence: we predict the next word in the sentence and the final verb.

More formally, we have a prediction at time t of the next source language word that will appear, $n_{t+1}^{(t)}$, and for the final verb, $v^{(t)}$. For example, given the partial observation "`ich bin mit dem`", the state might contain a prediction that the next word, $n_{t+1}^{(t)}$, will be "`Zug`" and that the final verb $v^{(t)}$ will be "`gefahren`".

We discuss the mechanics of next-word and verb prediction further in Section 4; for now, consider these black boxes which, after observing every new source word x_t, make predictions of future words in the source language. This representation of the state allows for a richer set of actions, described below, permitting simultaneous translations that outpace the source language input[2] by predicting the future.

2.2 Actions: What our system can do

Given observed and hypothesized input, our simultaneous translation system must decide when to translate them. This is expressed in the form of four actions: our system can **commit** to a partial translation, predict the **next word** and use it to update the translation, predict the **verb** and use it to update the translation, or **wait** for more words.

We discuss each of these actions in turn before describing how they come together to incrementally translate an entire sentence:

Wait Waiting is the simplest action. It produces no output and allows the system to receive more input, biding its time, so that when it does choose to translate, the translation is based on more information.

Commit Committing produces translation output: given the observed source sentence, produce the best translation possible.

[1] We use t to evoke a discrete version of time. We only allow actions after observing a complete source word.

[2] Throughout, "input" refers to source language input, and "output" refers to target language translation.

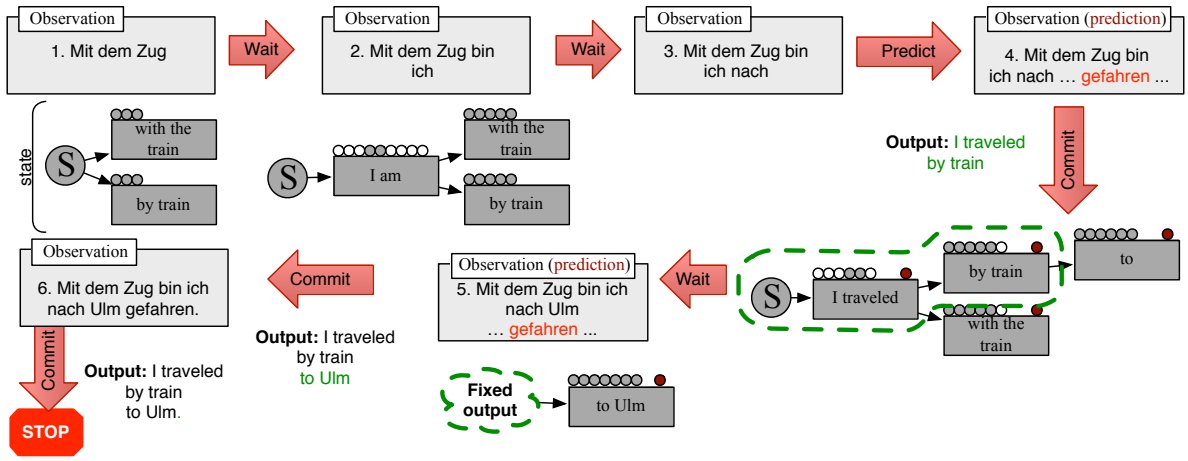

Figure 2: A simultaneous translation from source (German) to target (English). The agent chooses to wait until after (3). At this point, it is sufficiently confident to predict the final verb of the sentence (4). Given this additional information, it can now begin translating the sentence into English, constraining future translations (5). As the rest of the sentence is revealed, the system can translate the remainder of the sentence.

Next Word The **next word** action takes a prediction of the next source word and produces an updated translation based on that prediction, i.e., appending the predicted word to the source sentence and translating the new sentence.

Verb Our system can also predict the source sentence's final verb (the last word in the sentence). When our system takes the **verb** action, it uses its verb prediction to update the translation using the prediction, by placing it at the end of the source sentence.

We can recreate a traditional batch translation system (interpreted temporally) by a sequence of **wait** actions until all input is observed, followed by a **commit** to the complete translation. Our system can **commit** to partial translations if it is confident, but producing a good translation early in the sentence often depends on missing information.

2.3 Translation Process

Having described the state, its components, and the possible actions at a state, we present the process in its entirety. In Figure 2, after each German word is received, the system arrives at a new *state*, which consists of the source input, target translation so far, and predictions of the unseen words. The translation system must then take an *action* given information about the current state. The action will result in receiving and translating more source words, transitioning the system to the next state. In the example, for the first few source-language words, the translator lacks the confidence to produce any output due to insufficient information at the state. However, after State 3, the state shows high confidence in the predicted verb "gefahren". Combined with the German input it has observed, the system is sufficiently confident to act on that prediction to produce English translation.

2.4 Consensus Translations

Three straightforward actions—**commit**, **next word**, and **verb**—all produce translations. These rely black box access to a translation (discussed in detail in Section 6): that is, given a source language sentence fragment, the translation system produces a target language sentence fragment.

Because these actions can happen more than once in a sentence, we must form a single consensus translation from all of the translations that we might have seen. If we have only one translation or if translations are identical, forming the consensus translation is trivial. But how should we resolve conflicting translations?

Any time our system chooses an action that

produces output, the observed input (plus extra predictions in the case of **next-word** or **verb**), is passed into the translation system. That system then produces a complete translation of its input fragment.

Any new words—i.e., words whose target index is greater than the length of any previous translation—are appended to the previous translation.[3] Table 1 shows an example of forming these consensus translations.

Now that we have defined how states evolve based on our system's actions, we need to know how to select which actions to take. Eventually, we will formalize this as a learned policy (Section 5) that maps from states to actions. First, however, we need to define a reward that measures how "good" an action is.

3 Objective: What is a good simultaneous translation?

Good simultaneous translations must optimize two objectives that are often at odds, i.e., producing translations that are, in the end, accurate, and producing them in pieces that are presented expeditiously. While there are existing automated metrics for assessing translation quality (Papineni et al., 2002; Banerjee and Lavie, 2005; Snover et al., 2006), these must be modified to find the necessary compromise between translation quality and expeditiousness. That is, a good metric for simultaneous translation must achieve a balance between translating chunks early and translating accurately. All else being equal, maximizing either goal in isolation is trivial: for accurate translations, use a **batch** system and wait until the sentence is complete, translating it all at once; for a maximally expeditious translation, create **monotone** translations, translating each word as it appears, as in Tillmann et al. (1997) and Pytlik and Yarowsky (2006). The former is not simultaneous at all; the latter is mere word-for-word replacement and results in awkward, often unintelligible translations of distant language pairs.

Once we have predictions, we have an expanded array of possibilities, however. On one extreme, we can imagine a **psychic** translator—one that can completely translate an imagined sentence after one word is uttered—as an unobtainable system. On the other extreme is a standard **batch** translator, which waits until it has access to the utterer's complete sentence before translating anything.

Again, we argue that a system can improve on this by *predicting* unseen parts of the sentence to find a better tradeoff between these conflicting goals. However, to evaluate and optimize such a system, we must measure where a system falls on the continuum of accuracy versus expeditiousness.

Consider partial translations in a two-dimensional space, with time (quantized by the number of source words seen) increasing from left to right on the x axis and the BLEU score (including brevity penalty against the reference length) on the y axis. At each point in time, the system may add to the consensus translation, changing the precision (Figure 3). Like an ROC curve, a good system will be high and to the left, optimizing the area under the curve: the ideal system would produce points as high as possible immediately. A translation which is, in the end, accurate, but which is less expeditious, would accrue its score more slowly but outperform a similarly expeditious system which nevertheless translates poorly.

An idealized psychic system achieves this, claiming all of the area under the curve, as it would have a perfect translation instantly, having no need of even waiting for future input.[4] A batch system has only a narrow (but tall) sliver to the right, since it translates nothing until all of the words are observed.

Formally, let Q be the score function for a partial translation, $\boldsymbol{x}$ the sequentially revealed source words $x_1, x_2, \ldots, x_T$ from time step 1 to T, and $\boldsymbol{y}$ the partial translations $y_1, y_2, \ldots, y_T$, where T is the length of the source language input. Each incremental translation y_t has a BLEU-n score with respect to a reference $\boldsymbol{r}$. We apply the usual BLEU brevity penalty to all the incremental translations (initially empty) to

[3] Using constrained decoding to enforce consistent translation prefixes would complicate our method but is an appealing extension.

[4] One could reasonably argue that this is not ideal: a fluid conversation requires the prosody and timing between source and target to match exactly. Thus, a psychic system would provide too much information too quickly, making information exchange unnatural. However, we take the information-centric approach: more information faster is better.

Pos	Input	Intermediate	Consensus
1			
2	Er	He_1	He_1
3	Er wurde *gestaltet*	It_1 was_2 designed_3	He_1 was_2 designed_3
4		It_1 was_2 designed_3	He_1 was_2 designed_3
5	Er wurde gestern renoviert	It_1 was_2 renovated_3 yesterday_4	He_1 was_2 designed_3 yesterday_4

Table 1: How intermediate translations are combined into a consensus translation. Incorrect translations (e.g., "he" for an inanimate object in position 3) and incorrect predictions (e.g., incorrectly predicting the verb *gestaltet* in position 5) are kept in the consensus translation. When no translation is made, the consensus translation remains static.

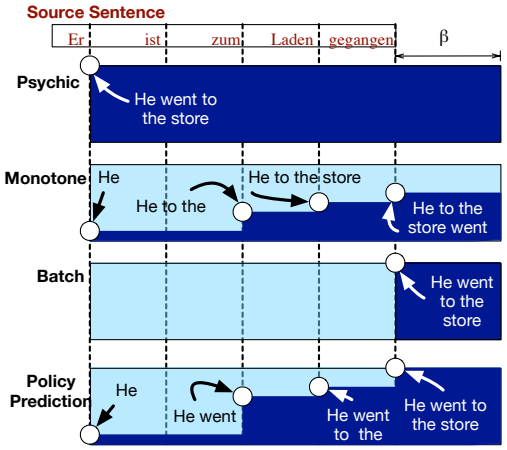

Figure 3: Comparison of LBLEU (the area under the curve given by Equation 1) for an impossible psychic system, a traditional batch system, a monotone (German word order) system, and our prediction-based system. By correctly predicting the verb "gegangen" (to go), we achieve a better overall translation more quickly.

obtain **latency-bleu** (LBLEU),

$$Q(\boldsymbol{x}, \boldsymbol{y}) = \frac{1}{T} \sum_t \text{BLEU}(y_t, r) + T \cdot \text{BLEU}(y_T, r) \quad (1)$$

The LBLEU score is a word-by-word integral across the input source sentence. As each source word is observed, the system receives a reward based on the BLEU score of the partial translation. LBLEU, then, represents the sum of these T rewards at each point in the sentence. The score of a simultaneous translation is the sum of the scores of all individual segments that contribute to the overall translation.

We multiply the final BLEU score by T to ensure good final translations in learned systems to compensate for the implicit bias toward low latency.[5]

4 Predicting Verbs and Next Words

The **next** and **verb** actions depend on predictions of the sentence's next word and final verb; this section describes our process for predicting verbs and next words given a partial source language sentence.

The prediction of the next word in the source language sentence is modeled with a left-to-right language model. This is (naïvely) analogous to how a human translator might use his own "language model" to guess upcoming words to gain some speed by completing, for example, collocations before they are uttered. We use a simple bigram language model for next-word prediction. We use Heafield et al. (2013).

For verb prediction, we use a generative model that combines the prior probability of a particular verb v, $p(v)$, with the likelihood of the source context at time t given that verb (namely, $p(x_{1:t} \mid v)$), as estimated by a smoothed Kneser-Ney language model (Kneser and Ney, 1995). We use Pauls and Klein (2011). The prior probability $p(v)$ is estimated by simple relative frequency estimation. The context, $x_{1:t}$, consists of all words observed. We model $p(x_{1:t} \mid v)$ with verb-specific n-gram language models. The predicted verb $v^{(t)}$ at time t is then:

$$\arg\max_v p(v) \prod_{i=1}^{t} p(x_i \mid v, x_{i-n+1:i-1}) \quad (2)$$

[5] One could replace T with a parameter, β, to bias towards different kinds of simultaneous translations. As $\beta \to \infty$, we recover batch translation.

where $x_{i-n+1:i-1}$ is the $n-1$-gram context. To narrow the search space, we consider only the 100 most frequent final verbs, where a "final verb" is defined as the sentence-final sequence of verbs and particles as detected by a German part-of-speech tagger (Toutanova et al., 2003).[6]

5 Learning a Policy

We have a framework (states and actions) for simultaneous machine translation and a metric for assessing simultaneous translations. We now describe the use of reinforcement learning to learn a **policy**, a mapping from states to actions, to maximize LBLEU reward.

We use imitation learning (Abbeel and Ng, 2004; Syed et al., 2008): given an optimal sequence of actions, learn a generalized policy that maps states to actions. This can be viewed as a cost-sensitive classification (Langford and Zadrozny, 2005): a state is represented as a feature vector, the loss corresponds to the quality of the action, and the output of the classifier is the action that should be taken in that state.

In this section, we explain each of these components: generating an optimal policy, representing states through features, and learning a policy that can generalize to new sentences.

5.1 Optimal Policies

Because we will eventually learn policies via a classifier, we must provide training examples to our classifier. These training examples come from an **oracle policy** π^* that demonstrates the optimal sequence—i.e., with maximal LBLEU score—of actions for each sequence. Using dynamic programming, we can determine such actions for a fixed translation model.[7] From this oracle policy, we generate training examples for a supervised classifier. State s_t is represented as a tuple of the observed words $x_{1:t}$, predicted verb $v^{(t)}$, and the predicted word $n_{t+1}^{(t)}$. We represent the state to a classifier as a feature vector $\phi(x_{1:t}, n_{t+1}^{(t)}, v^{(t)})$.

[6]This has the obvious disadvantage of ignoring morphology and occasionally creating duplicates of common verbs that have may be associated with multiple particles; nevertheless, it provides a straightforward verb to predict.

[7]This is possible for the limited class of consensus translation schemes discussed in Section 2.4.

5.2 Feature Representation

We want a feature representation that will allow a classifier to generalize beyond the specific examples on which it is trained. We use several general classes of features: features that describe the input, features that describe the possible translations, and features that describe the quality of the predictions.

Input We include both a bag of words representation of the input sentence as well as the most recent word and bigram to model word-specific effects. We also use a feature that encodes the length of the source sentence.

Prediction We include the identity of the predicted verb and next word as well as their respective probabilities under the language models that generate the predictions. If the model is confident in the prediction, the classifier can learn to more so trust the predictions.

Translation In addition to the state, we include features derived from the possible actions the system might take. This includes a bag of words representation of the target sentence, the score of the translation (decreasing the score is undesirable), the score of the current consensus translation, and the difference between the current and potential translation scores.

5.3 Policy Learning

Our goal is to learn a classifier that can accurately mimic the oracle's choices on previously unseen data. However, at test time, when we run the learned policy classifier, the learned policy's state distribution may deviate from the optimal policy's state distribution due to imperfect imitation, arriving in states not on the oracle's path. To address this, we use SEARN (Daumé III et al., 2009), an iterative imitation learning algorithm. We learn from the optimal policy in the first iteration, as in standard supervised learning; in the following iterations, we run an interpolated policy

$$\pi_{k+1} = \epsilon\pi_k + (1-\epsilon)\pi^*, \qquad (3)$$

with k as the iteration number and ϵ the mixing probability. We collect examples by asking the policy to label states on its path. The interpolated policy will execute the optimal action with probability $1-\epsilon$ and the learned

policy's action with probability ϵ. In the first iteration, we have $\pi_0 = \pi^*$.

Mixing in the learned policy allows the learned policy to slowly change from the oracle policy. As it trains on these no-longer-perfect state trajectories, the state distribution at test time will be more consistent with the states used in training.

SEARN learns the policy by training a cost-sensitive classifier. Besides providing the optimal action, the oracle must also assign a cost to an action

$$\mathcal{C}(a_t, \boldsymbol{x}) \equiv Q(\boldsymbol{x}, \pi^*(x_t)) - Q(\boldsymbol{x}, a_t(x_t)), \quad (4)$$

where $a_t(x_t)$ represents the translation outcome of taking action a_t. The cost is the regret of not taking the optimal action.

6 Translation System

The focus of this work is to show that given an effective batch translation system and predictions, we can learn a policy that will turn this into a simultaneous translation system. Thus, to separate translation errors from policy errors, we perform experiments with a nearly optimal translation system we call an *omniscient* translator.

More realistic translation systems will naturally lower the objective function, often in ways that make it difficult to show that we can effectively predict the verbs in verb-final source languages. For instance, German to English translation systems often drop the verb; thus, predicting a verb that will be ignored by the translation system will not be effective.

The omniscient translator translates a source sentence correctly once it has been fed the appropriate source words as input. There are two edge cases: empty input yields an empty output, while a complete, correct source sentence returns the correct, complete translation. Intermediate cases—where the input is either incomplete or incorrect—require using an alignment. The omniscient translator assumes as input a reference translation r, a partial source language input $x_{1:t}$ and a corresponding partial output y. In addition, the omniscient translator assumes access to an *alignment* between r and x. In practice, we use the HMM aligner (Vogel et al., 1996; Och and Ney, 2003).

We first consider incomplete but correct inputs. Let $y = \tau(x_{1:t})$ be the translator's output given a partial source input $x_{1:t}$ with translation y. Then, $\tau(x_{1:t})$ produces all target words y_j if there is a source word x_i in the input aligned to those words—i.e., $(i, j) \in a_{x,y}$—*and* all preceding target words can be translated. (That translations must be contiguous is a natural requirement for human recipients of translations). In the case where y_j is unaligned, the closest aligned target word to y_j that has a corresponding alignment entry is aligned to x_i; then, if x_i is present in the input, y_j appears in the output. Thus, our omniscient translation system will always produce the correct output given the correct input.

However, our learned policy can make wrong predictions, which can produce partial translations y that do *not* match the reference. In this event, an incorrect source word $\tilde{x}_i$ produces incorrect target words $\tilde{y}_j$, for all j: $(i, j) \in a_{x,y}$. These $\tilde{y}_j$ are sampled from the IBM Model 1 lexical probability table multiplied by the source language model $\tilde{y}_j \sim \text{Mult}(\theta_{\tilde{x}_i}) p_{LM}(\tilde{\boldsymbol{x}})$.[8] Thus, even if we predict the correct verb using a **next word** action, it will be in the wrong position and thus generate a translation from the lexical probabilities. Since translations based on Model 1 probabilities are generally inaccurate, the omniscient translator will do very well when given correct input but will produce very poor translations otherwise.

7 Experiments

In this section, we describe our experimental framework and results from our experiments. From aligned data, we derive an omniscient translator. We use monolingual data in the source language to train the verb predictor and the next word predictor. From these features, we compute an optimal policy from which we train a learned policy.

7.1 Data sets

For translation model and policy training, we use data from the German-English Parallel "de-news" corpus of radio broadcast news (Koehn, 2000), which we lower-cased and stripped of

[8] If a policy chooses an incorrect unaligned word, it has no effect on the output. Alignments are position-specific, so "wrong" refers to position and type.

punctuation. A total of 48,601 sentence pairs are randomly selected for building our system. Of these, we use 70% (34,528 pairs) for training word alignments.

For training the translation policy, we restrict ourselves to sentences that end with one of the 100 most frequent verbs (see Section 4). This results in a data set of 4401 training sentences and 1832 test sentences from the de-news data. We did this to narrow the search space (from thousands of possible, but mostly very infrequent, verbs).

We used 1 million words of news text from the Leipzig Wortschatz (Quasthoff et al., 2006) German corpus to train 5-gram language models to predict a verb from the 100 most frequent verbs.

For next-word prediction, we use the 18,345 most frequent German bigrams from the training set to provide a set of candidates in a language model trained on the same set. We use frequent bigrams to reduce the computational cost of finding the completion probability of the next word.

7.2 Training Policies

In each iteration of SEARN, we learn a multi-class classifier to implement the policy. The specific learning algorithm we use is AROW (Crammer et al., 2013). In the complete version of SEARN, the cost of each action is calculated as the highest expected reward starting at the current state minus the actual roll-out reward. However, computing the full roll-out reward is computationally very expensive. We thus use a surrogate binary cost: if the predicted action is the same as the optimal action, the cost is 0; otherwise, the cost is 1. We then run SEARN for five iterations. Results on the development data indicate that continuing for more iterations yields no benefit.

7.3 Policy Rewards on Test Set

In Figure 4, we show performance of the optimal policy *vis-à-vis* the learned policy, as well as the two baseline policies: the batch policy and the monotone policy. The x-axis is the percentage of the source sentence seen by the model, and the y-axis is a smoothed average of the reward as a function of the percentage of the sentence revealed. The monotone policy's performance is close to the optimal policy for

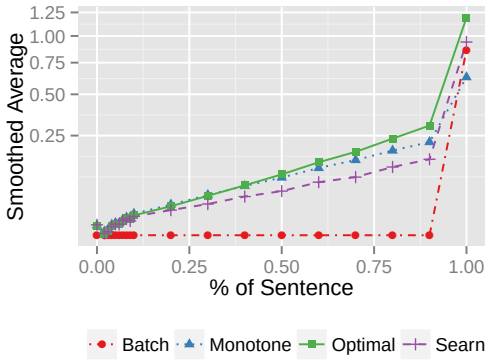

Figure 4: The final reward of policies on German data. Our policy outperforms all baselines by the end of the sentence.

Figure 5: Histogram of actions taken by the policies.

the first half of the sentence, as German and English have similar word order, though they diverge toward the end. Our learned policy outperforms the monotone policy toward the end and of course outperforms the batch policy throughout the sentence.

Figure 5 shows counts of actions taken by each policy. The batch policy always commits at the end. The monotone policy commits at each position. Our learned policy has an action distribution similar to that of the optimal policy, but is slightly more cautious.

7.4 What Policies Do

Figure 6 shows a policy that, predicting incorrectly, still produces sensible output. The policy correctly intuits that the person discussed

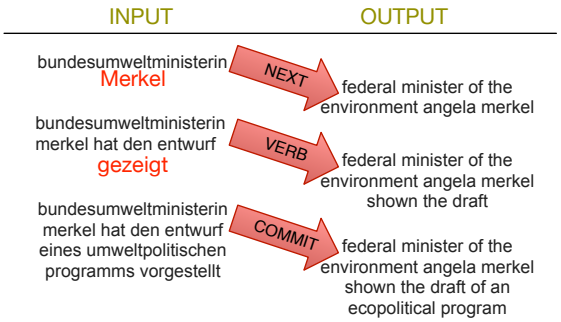

Figure 6: An imperfect execution of a learned policy. Despite choosing the wrong verb "gezeigt" (showed) instead of "vorgestellt" (presented), the translation retains the meaning.

is Angela Merkel, who was the environmental minister at the time, but the policy uses an incorrectly predicted verb. Because of our poor translation model (Section 6), it renders this word as "shown", which is a poor translation. However, it is still comprehensible, and the overall policy is similar to what a human would do: intuit the subject of the sentence from early clues and use a more general verb to stand in for a more specific one.

8 Related Work

Just as MT was revolutionized by statistical learning, we suspect that simultaneous MT will similarly benefit from this paradigm, both from a systematic system for simultaneous translation and from a framework for learning how to incorporate predictions.

Simultaneous translation has been dominated by rule and parse-based approaches (Mima et al., 1998a; Ryu et al., 2006). In contrast, although Verbmobil (Wahlster, 2000) performs incremental translation using a statistical MT module, its incremental decision-making module is rule-based. Other recent approaches in speech-based systems focus on waiting until a pause to translate (Sakamoto et al., 2013) or using word alignments (Ryu et al., 2012) between languages to determine optimal translation units.

Unlike our work, which focuses on prediction and learning, previous strategies for dealing with SOV-to-SVO translation use rule-based methods (Mima et al., 1998b) (for instance, passivization) to buy time for the translator to hear more information in a spoken context—or use phrase table and reordering probabilities to decide where to translate with less delay (Fujita et al., 2013). Oda et al. (2014) is the most similar to our work on the translation side. They frame word segmentation as an optimization problem, using a greedy search and dynamic programming to find segmentation strategies that maximize an evaluation measure. However, unlike our work, the direction of translation was from *from* SVO to SVO, obviating the need for verb prediction. Simultaneous translation is more straightforward for languages with compatible word orders, such as English and Spanish (Fügen, 2008).

To our knowledge, the only attempt to specifically predict verbs or any late-occurring terms (Matsubara et al., 2000) uses pattern matching on what would today be considered a small data set to predict English verbs for Japanese to English simultaneous MT.

Incorporating verb predictions into the translation process is a significant component of our framework, though n-gram models strongly prefer highly frequent verbs. Verb prediction might be improved by applying the insights from psycholinguistics. Ferreira (2000) argues that verb lemmas are required early in sentence production—prior to the first noun phrase argument—and that multiple possible syntactic hypotheses are maintained in parallel as the sentence is produced. Schriefers et al. (1998) argues that, in simple German sentences, non-initial verbs do not need lemma planning at all. Momma et al. (2014), investigating these prior claims, argues that the abstract relationship between the internal arguments and verbs triggers *selective* verb planning.

9 Conclusion and Future Work

Creating an effective simultaneous translation system for SOV to SVO languages requires not only translating partial sentences, but also effectively predicting a sentence's verb. Both elements of the system require substantial refinement before they are usable in a real-world system.

Replacing our idealized translation system is the most challenging and most important next step. Supporting multiple translation hypotheses and incremental decoding (Sankaran

et al., 2010) would improve both the efficiency and effectiveness of our system. Using data from human translators (Shimizu et al., 2014) could also add richer strategies for simultaneous translation: passive constructions, reordering, etc.

Verb prediction also can be substantially improved both in its scope in the system and how we predict verbs. Verb-final languages also often place verbs at the end of clauses, and also predicting these verbs would improve simultaneous translation, enabling its effective application to a wider range of sentences. Instead predicting an *exact* verb early (which is very difficult), predicting a semantically close or a more general verb might yield interpretable translations.

A natural next step is expanding this work to other languages, such as Japanese, which not only has SOV word order but also requires tokenization and morphological analysis, perhaps requiring sub-word prediction.

Abstract

The task of unsupervised induction of probabilistic context-free grammars (PCFGs) has attracted a lot of attention in the field of computational linguistics. Although it is a difficult task, work in this area is still very much in demand since it can contribute to the advancement of language parsing and modelling. In this work, we describe a new algorithm for PCFG induction based on a principled approach and capable of inducing accurate yet compact artificial natural language grammars and typical context-free grammars. Moreover, this algorithm can work on large grammars and datasets and infers correctly even from small samples. Our analysis shows that the type of grammars induced by our algorithm are, in theory, capable of modelling natural language. One of our experiments shows that our algorithm can potentially outperform the state-of-the-art in unsupervised parsing on the WSJ10 corpus.

1 Introduction

The task of unsupervised induction of PCFGs has attracted a lot of attention in the field of computational linguistics. This task can take the form of either parameter search or structure learning. In parameter search, a CFG is fixed and the focus is on assigning probabilities to this grammar using Bayesian methods (Johnson et al., 2007) or maximum likelihood estimation (Lari and Young, 1990). In structure learning, the focus is on building the right grammar rules from scratch. We take the latter approach.

Unsupervised structure learning of (P)CFGs is a notoriously difficult task (de la Higuera, 2010; Clark and Lappin, 2010), with theoretical results showing that in general it is either impossible to achieve (Gold, 1967; de la Higuera, 1997) or requires impractical resources (Horning, 1969; Yang, 2012). At the same time, it is well known that context-free structures are needed for better language parsing and modelling, since less expressive models (such as HMMs) are not good enough (Manning and Schütze, 2001; Jurafsky and Martin, 2008). Moreover, the trend is towards unsupervised (rather than supervised) learning methods due to the lack in most languages of annotated data and the applicability in wider domains (Merlo et al., 2010). Thus, despite its difficulty, unsupervised PCFG grammar induction (or induction of other similarly expressive models) is still an important task in computational linguistics.

In this paper, we describe a new algorithm for PCFG induction based on a principled approach and capable of inducing accurate yet compact grammars. Moreover, this algorithm can work on large grammars and datasets and infers correctly even from small samples. We show that our algorithm is capable of achieving competitive results in both unsupervised parsing and language modelling of typical context-free languages and artificial natural language grammars. We also show that the type of grammars we propose to learn are, in theory, capable of modelling natural language.

2 Preliminaries

2.1 Grammars and Languages

A *context-free grammar* (CFG) is a 4-tuple $\langle N, \Sigma, P, I \rangle$, where N is the set of non-terminals, Σ the set of terminals, P the set of production rules and I a set of starting non-terminals (i.e. multiple starting non-terminals are possible). The language generated from a particular non-terminal A is $L(A) = \{w | A \stackrel{*}{\Rightarrow} w\}$ and the language generated by a grammar G is $L(G) = \bigcup_{S \in I} L(S)$. A CFG is in *Chomsky Normal Form (CNF)* if ev-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1353–1362,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ery production rule is of the form $N \rightarrow NN$ or $N \rightarrow \Sigma$.

A *probabilistic context-free grammar* (PCFG) is a CFG with a probability value assigned to every rule and every starting non-terminal. The probability of a leftmost derivation from a PCFG is the product of the starting non-terminal probability and the production probabilities used in the derivation. The probability of a string generated by a PCFG is the sum of all its leftmost derivations' probabilities. The stochastic language generated from a PCFG G is $(L(G), \phi_G)$, where ϕ_G is the distribution over Σ^* defined by the probabilities assigned to the strings by G. For a PCFG to be *consistent*, the probabilities of the strings in its stochastic language must add up to 1 (Wetherell, 1980). Any PCFG mentioned from now onwards is assumed to be consistent.

2.2 Congruence Relations

A *congruence relation* $\sim$ on Σ^* is any equivalence relation on Σ^* that respects the following condition: if $u \sim v$ and $x \sim y$ then $ux \sim vy$. The congruence classes of a congruence relation are simply its equivalence classes. The congruence class of $w \in \Sigma^*$ w.r.t. a congruence relation $\sim$ is denoted by $[w]_\sim$. The set of *contexts* of a substring w with respect to a language L, denoted $Con(w, L)$, is $\{(l, r) \in \Sigma^* \times \Sigma^* \mid lwr \in L\}$. Two strings u and v are *syntactically congruent* with respect to L, written $u \equiv_L v$, if $Con(u, L) = Con(v, L)$. This is a congruence relation on Σ^*. The *context distribution* of a substring w w.r.t. a stochastic language (L, ϕ), denoted $C_w^{(L,\phi)}$, is a distribution whose support is all the possible contexts over alphabet Σ (i.e. $\Sigma^* \times \Sigma^*$) and is defined as follows:

$$C_w^{(L,\phi)}(l, r) = \frac{\phi(lwr)}{\sum_{l',r' \in \Sigma^*} \phi(l'wr')}$$

Two strings u and v are *stochastically congruent* with respect to (L, ϕ), written $u \cong_{(L,\phi)} v$, if $C_u^{(L,\phi)}$ is equal to $C_v^{(L,\phi)}$. This is a congruence relation on Σ^*.

2.3 Congruential Grammars

Clark (2010a) defines *Congruential CFGs* (C-CFGs) as being all the CFGs G which, for any non-terminal A, if $u \in L(A)$ then $L(A) \subseteq [u]_{\equiv_{L(G)}}$ (where $[u]_{\equiv_{L(G)}}$ is the syntactic congruence class of u w.r.t. the language of G). This class of grammars was defined with learnability in mind. Since these grammars have a direct relationship between congruence classes and the non-terminals, their learnability is reduced to that of finding the correct congruence classes (Clark, 2010a).

This class of grammars is closely related to the class of NTS-grammars (Boasson and Sénizergues, 1985). Any C-CFG is an NTS-grammar but not vice-versa. However, it is not known whether languages generated by C-CFGs are all NTS-languages (Clark, 2010a). Note that NTS-languages are a subclass of deterministic context-free languages and contain the regular languages, the substitutable (Clark and Eyraud, 2007) and k-l-substitutable context-free languages (Yoshinaka, 2008), the very simple languages and other CFLs such as the Dyck language (Boasson and Sénizergues, 1985).

We define a slightly more restrictive class of grammars, which we shall call *Strongly Congruential CFGs* (SC-CFGs). A CFG G is a SC-CFG if, for any non-terminal A, if $u \in L(A)$ then $L(A) = [u]_{\equiv_{L(G)}}$. The probabilistic equivalent of this is the class of *Strongly Congruential PCFGs* (SC-PCFGs), defined as all the PCFGs G which, for any non-terminal A, if $u \in L(A)$ then $L(A) = [u]_{\cong_{(L(G),\phi)}}$. In other words, the non-terminals (i.e. syntactic categories in natural language) of these grammars directly correspond to classes of substitutable strings (i.e. substitutable words and phrases in NL). One may ask whether this is too strict a restriction for natural language grammars. We argue that it is not, for the following reasons.

First of all, this restriction complies with the approach taken by American structural linguists for the identification of syntactic categories, as shown by Rauh (2010): *"[Zellig and Fries] identified syntactic categories as distribution classes, employing substitution tests and excluding semantic properties of the items analysed. Both describe syntactic categories exclusively on the basis of their syntactic environments and independently of any inherent properties of the members of these categories"*.

Secondly, we know that such grammars are capable of describing languages generated by grammars that contain typical natural language grammatical structures (see Section 4.1; artificial natural language grammars NL1-NL7, taken from various sources, generate languages which can be described by SC-PCFGs).

3 Algorithm

COMINO (our algorithm) induces SC-PCFGs from a positive sample S. The steps involved are:

1. Inducing the stochastically congruent classes of all the substrings of S
2. Selecting which of the induced classes are non-terminals and subsequently building a CFG.
3. Assigning probabilities to the induced CFG.

The approach we take is very different from traditional grammar induction approaches, in which grouping of substitutable substrings is done incrementally as the same groups are chosen to represent non-terminals. We separate these two task so that learning takes place in the grouping phase whilst selection of non-terminals is done independently by solving a combinatorial problem.

For the last step, the standard EM-algorithm for PCFGs (Lari and Young, 1990) is used. In Sections 3.1 and 3.2, the first and second steps of the algorithm are described in detail. We analyse our algorithm in Section 3.3.

3.1 Inducing the Congruence Classes

We describe in Algorithm 1 how the congruence classes are induced.

Algorithm 1: Learn Congruence Classes

Input: A multiset S; parameters: n, d, i; distance function `dist` on local contexts of size k

Output: The congruence classes $\mathcal{CC}$ over the substrings of S

1 $Subs \leftarrow$ Set of all substrings of S ;
2 $\mathcal{CC} \leftarrow \{\{w\} \mid w \in Subs\}$;
3 **while** *True* **do**
4 $\quad Pairs \leftarrow \{(x, y) \mid x, y \in \mathcal{CC},\ x \neq y, |S|_x \geq n\ ,\ |S|_y \geq n\}$;
5 $\quad$ **if** $|Pairs| = 0$ **then exitloop** ;
6 $\quad$ Order $Pairs$ based on $\texttt{dist}_k$;
7 $\quad (x, y) \leftarrow Pairs[0]$;
8 $\quad init = \{[w]_{\mathcal{CC}} \mid w \in S\}$;
9 $\quad$ **if** $\texttt{dist}_k(x, y) \geq d$ **and** $|init| \leq i$ **then exitloop** ;
10 $\quad \mathcal{CC} \leftarrow \texttt{Merge}(x, y, \mathcal{CC})$;
11 **end**
12 **return** $\mathcal{CC}$;

At the beginning, each substring (or phrase for natural language) in the sample is assigned its own congruence class (line 2). Then, pairs of *frequent* congruence classes are *merged* together depending on the *distance* between their *empirical context distribution*, which is calculated on *local contexts*. The following points explain each keyword:

- The *empirical context distribution* of a substring w is simply a probability distribution over all the contexts of w, where the probability for a context (l, r) is the number of occurrences of lwr in the sample divided by the number of occurrences of w. This is extended to congruence classes by treating each substring in the class as one substring (i.e. the sum of occurrences of lw_ir, for all w_i in the class, divided by the sum of occurrences of all w_i).
- Due to the problem of sparsity with contexts (in any reasonably sized corpus of natural language, very few phrases will have more than one occurrence of the same context), only *local contexts* are considered. The local contexts of w are the pairs of first k symbols (or words for natural language) preceding and following w. The lower k is, the less sparsity is a problem, but the empirical context distribution is less accurate. For natural language corpora, k is normally set to 1 or 2.
- A *frequent* congruence class is one whose substring occurrences in the sample add up to more than a pre-defined threshold n. Infrequent congruence classes are ignored due to their unreliable empirical context distribution. However, as more merges are made, more substrings are added to infrequent classes, thus increasing their frequency and eventually they might be considered as frequent classes.
- A *distance* function `dist` between samples of distributions over contexts is needed by the algorithm to decide which is the closest pair of congruence classes, so that they are merged together. We used L1-Distance and Pearson's chi-squared test for experiments in Sections 4.1 and 4.2 respectively.
- After each *merge*, other merges are logically deduced so as to ensure that the relation re-

mains a congruence[1]. In practice, the vast majority of the merges undertaken are logically deduced ones. This clearly relieves the algorithm from taking unnecessary decisions (thus reducing the chance of erroneous decisions). On the downside, one bad merge can have a disastrous ripple effect. Thus, to minimize as much as possible the chance of this happening, every merge undertaken is the best possible one at that point in time (w.r.t. the distance function used). The same idea is used in DFA learning (Lang et al., 1998).

This process is repeated until either 1) no pairs of frequent congruence classes are left to merge (line 5) or 2) the smallest distance between the candidate pairs is bigger or equal to a pre-defined threshold d and the number of congruence classes containing strings from the sample is smaller or equal to a pre-defined threshold i (line 9).

The first condition of point 2 ensures that congruence classes which are sufficiently close to each other are merged together. The second condition of point 2 ensures that the hypothesized congruence classes are generalized enough (i.e. to avoid undergeneralization). For natural language examples, one would expect that a considerable number of sentences are grouped into the same class because of their similar structure. Obviously, one can make use of only one of these conditions by assigning the other a parameter value which makes it trivially true from the outset (0 for d and $|Subs|$ for i).

3.2 Building the Context-Free Grammar

Deciding which substrings are constituents (in our case, this translates into choosing which congruence classes correspond to non-terminals) is a problematic issue and is considered a harder task than the previous step (Klein, 2004). A path followed by a number of authors consists in using an Ockham's razor or Minimal Description Length principle approach (Stolcke, 1994; Clark, 2001; Petasis et al., 2004). This generally leads to choosing as best hypothesis the one which best compresses the data. Applying this principle in our case would mean that the non-terminals should be assigned in such a way that the grammar built is *the smallest possible* one (in terms of the number of non-terminals and/or production rules) consistent with the congruence classes. To our knowledge, only local greedy search is used by systems in the literature which try to follow this approach.

We propose a new method for tackling this problem. We show that all the possible SC-CFGs in CNF consistent with the congruence classes directly correspond to all the solutions of a boolean formula built upon the congruence classes, where the variables of this formula correspond to non-terminals (and, with some minor adjustments, production rules as well). Thus, finding the smallest possible grammar directly translates into finding a solution which has the smallest possible amount of true variables. Finding a minimal solution for this type of formula is a known NP-Hard problem (Khanna et al., 2000). However, sophisticated linear programming solvers (Berkelaar et al., 2008) can take care of this problem. For small examples (e.g. all the examples in Table 1), these solvers are able to find an exact solution in a few seconds. Moreover, these solvers are capable of finding good approximate solutions to larger formulas containing a few million variables.

The formula contains one variable per congruence class. All variables corresponding to congruence classes containing strings from the sample are assigned the value `True` (since there must be a starting non-terminal that generates these strings). All variables corresponding to congruence classes containing symbols from Σ are assigned the value `True` (since for every $a \in \Sigma$, there must be a rule $A \rightarrow a$). Finally, and most importantly, for every congruence class $[w]$ and for every string w in $[w]$ ($|w| = n$), the following conditional statement is added to the formula:

$$v(w) \Rightarrow (v(w_{1,1}) \wedge v(w_{2,n})) \vee (v(w_{1,2}) \wedge v(w_{3,n})) \vee \ldots \vee (v(w_{1,n-1}) \wedge v(w_{n,n}))$$

where $v(x)$ is the variable corresponding to the congruence class $[x]$ and $w_{i,j}$ is the substring of w from the i^{th} to the j^{th} symbol of w. This statement is representing the fact that if a congruence class $[w]$ is chosen as a non-terminal then for each string in $w \in [w]$, there must be at least one CNF rule $A \rightarrow BC$ that generates w and thus there must be at least one division of w into $w_{1,k}w_{k+1,n}$ such that B corresponds to $[w_{1,k}]$ and C corresponds to $[w_{k+1,n}]$.

The grammar extracted from the solution of this

[1] for example, if a congruence class contains the phrases "the big" and "that small", and another class contains "dog barked" and "cat meowed", it can be logically deduced that the phrases "the big dog barked","the big cat meowed", "that small dog barked" and "that small cat meowed" should be in the same class.

formula is made up of all the possible CNF production rules built from the chosen non-terminals. The starting non-terminals are those which correspond to congruence classes that contain at least one string from the sample.

The following is a run of the whole process on a simple example:

Sample $\{ab, aabb, aaabbb\}$

Congruence Classes

$1 : [a]$, $2 : [b]$, $3 : [ab, aabb, aaabbb]$, $4 : [aa]$, $5 : [bb]$, $6 : [aab, aaabb]$, $7 : [abb, aabbb]$, $8 : [aaa]$, $9 : [bbb]$, $10 : [aaab]$, $11 : [abbb]$

Boolean Formula

There is one conditional statement per substring. For example, $X_6 \Rightarrow (X_1 \wedge X_3) \vee (X_4 \wedge X_2)$ represents the two possible ways aab in congruence class 6 can be split ($a|ab$, $aa|b$).

Variables X_1, X_2 and X_3 are true.

$X_3 \Rightarrow (X_1 \wedge X_2)$
$X_3 \Rightarrow (X_1 \wedge X_7) \vee (X_4 \wedge X_5) \vee (X_6 \wedge X_2)$
$X_3 \Rightarrow (X_1 \wedge X_7) \vee (X_4 \wedge X_{11}) \vee (X_8 \wedge X_9) \vee (X_{10} \wedge X_5) \vee (X_6 \wedge X_2)$
$X_4 \Rightarrow (X_1 \wedge X_1)$
$X_5 \Rightarrow (X_2 \wedge X_2)$
$X_6 \Rightarrow (X_1 \wedge X_3) \vee (X_4 \wedge X_2)$
$X_6 \Rightarrow (X_1 \wedge X_3) \vee (X_4 \wedge X_7) \vee (X_8 \wedge X_5) \vee (X_{10} \wedge X_2)$
$X_7 \Rightarrow (X_1 \wedge X_5) \vee (X_3 \wedge X_2)$
$X_7 \Rightarrow (X_1 \wedge X_{11}) \vee (X_4 \wedge X_9) \vee (X_6 \wedge X_5) \vee (X_3 \wedge X_2)$
$X_8 \Rightarrow (X_1 \wedge X_4) \vee (X_4 \wedge X_1)$
$X_9 \Rightarrow (X_2 \wedge X_5) \vee (X_5 \wedge X_2)$
$X_{10} \Rightarrow (X_1 \wedge X_6) \vee (X_4 \wedge X_3) \vee (X_8 \wedge X_2)$
$X_{11} \Rightarrow (X_1 \wedge X_9) \vee (X_3 \wedge X_5) \vee (X_7 \wedge X_2)$

Solution

Running the solver on this formula will return the following true variables that make up a minimal solution: X_1, X_2, X_3 and X_7.

Grammar

For every statement $x \Rightarrow \ldots \vee (y \wedge z) \vee \ldots$ where x,y and z are true, a production rule $x \rightarrow yz$ is added. So, the following grammar is built:

X_3 is the starting non-terminal
$X_3 \rightarrow X_1X_7 \mid X_1X_2 \quad X_7 \rightarrow X_3X_2$
$X_1 \rightarrow a \quad X_2 \rightarrow b$

3.3 Analysis

In the first phase of the algorithm, we are grouping all the substrings of the sample S according to the congruence relation $\cong_{(L,\phi)}$, where (L, ϕ) is the target stochastic language (for natural language, this is the language model). To do so, we are assuming that S was i.i.d. generated from (L, ϕ). In the second phase, we are representing the space of all CFGs consistent with the classes obtained in phase one as different solutions to a boolean formula. Here we introduce our bias in favour of smaller grammars by finding a minimal solution to the formula. In the last phase, probabilities are assigned to the grammar obtained in phase two using the standard MLE algorithm for PCFGs.

Unlike many other systems, in our case the hypothesis space of grammars is well-defined. This allows us to analyse our algorithm in a theoretical framework and obtain theoretical learnability results. Moreover, this gives us an idea on the types of syntactical features our system is capable of learning.

Assuming our algorithm always takes correct merge decisions, the sample required for identification needs only to be structurally complete w.r.t. the target grammar (i.e. every production rules is used at least once in the generation of the sample). This means that, in theory, our algorithm can work with very small samples (polynomial size w.r.t. the number of rules in the target grammar).

Some approaches in the literature assume that whenever a particular substring is a constituent in some sentence, then it is automatically a constituent in all other sentences (whenever it does not overlap with previously chosen constituents) (van Zaanen, 2001; Clark, 2001; Adriaans et al., 2000). In reality, this is clearly not the case. A simple experiment on the WSJ10 corpus reveals that only 16 of the most frequent 1009 POS sequences (occurring 10 or more times in the sample) which are at least once constituents, are in fact always constituents. This assumption does not hold for ambiguous grammars in our class.

The approach we take to solve the smallest grammar problem can be extended to other classes of grammars. A similar formula can be built for grammars whose non-terminals have a one-to-one correspondence with congruence classes containing features of their language (Clark, 2010b).

4 Experiments and Discussion

4.1 Experiments on Artificial Data

We tested our system on 11 typical context-free languages and 9 artificial natural language grammars taken from 4 different sources (Stolcke, 1994; Langley and Stromsten, 2000; Adriaans et al., 2000; Solan et al., 2005). The 11 CFLs include 7 described by unambiguous grammars:

UC1: $a^n b^n$ **UC2**: $a^n b^n c^m d^m$ **UC3**: $a^n b^m$ $n \geq m$ **UC4**: $a^p b^q$, $p \neq q$ **UC5**: Palindromes over alphabet $\{a, b\}$ with a central marker **UC6**:Palindromes over alphabet $\{a, b\}$ without a central marker **UC7**: Lukasiewicz language ($S \rightarrow aSS|b$)

and 4 described by ambiguous grammars:

AC1: $|w|_a = |w|_b$ **AC2**: $2|w|_a = |w|_b$ **AC3**: Dyck language **AC4**: Regular expressions.

The 9 artificial natural language grammars are:

NL1: Grammar 'a', Table 2 in (Langley and Stromsten, 2000) **NL2**: Grammar 'b', Table 2 in (Langley and Stromsten, 2000) **NL3**: Lexical categories and constituency, pg 96 in (Stolcke, 1994) **NL4**: Recursive embedding of constituents, pg 97 in (Stolcke, 1994) **NL5**: Agreement, pg 98 in (Stolcke, 1994) **NL6**: Singular/plural NPs and number agreement, pg 99 in (Stolcke, 1994) **NL7**: Experiment 3.1 grammar in (Adriaans et al., 2000) **NL8**: Grammar in Table 10 (Adriaans et al., 2000) **NL9**: TA1 grammar in (Solan et al., 2005).

The quality of the learned model depends on its capacity to predict the correct structure (parse trees) on the one hand and to predict the correct sentence probabilities on the other (i.e. assigns a probability distribution close to the target one). To evaluate parse trees, we follow suggestions given by van Zaanen and Geertzen (2008) and use micro-precision and micro-recall over all the non-trivial brackets. We take the harmonic mean of these two values to obtain the Unlabelled brackets F_1 score (UF_1). The learned distribution can be evaluated using perplexity (when the target distribution is not known) or some similarity metric between distributions (when the target distribution is known). In our case, the target distribution is

Table 2: Relative Entropy and UF_1 results of our system COMINO vs ADIOS and ABL respectively. Best results are highlighted, close results (i.e. with a difference of at most 0.1 for relative entropy and 1% for UF_1) are both highlighted

known. We chose relative entropy[2] as a good measure of distance between distributions.

Our UF_1 results over test sets of one thousand strings were compared to results obtained by ABL (van Zaanen, 2001), which is a system whose primary aim is that of finding good parse trees (rather than identifying the target language). Although ABL does not obtain state-of-the-art results on natural language corpora, it proved to be the best system (for which an implementation is readily available) for unsupervised parsing of sentences generated by artificial grammars. Results are shown in Table 1.

We calculated the relative entropy on a test set of one million strings generated from the target grammar. We compared our results with ADIOS (Solan et al., 2005), a system which obtains competitive results on language modelling (Waterfall et al., 2010) and whose primary aim is of correctly identifying the target language (rather than finding good parse trees). Results are shown in Table 1.

For the tests in the first section of Table 1 (i.e. above the first dashed line), our algorithm was capable of exactly identifying the structure of the target grammar. Notwithstanding this, the bracketing results for these tests did not always yield perfect scores. This happened whenever the target grammar was ambiguous, in which case the most probable parse trees of the target and learned grammar can be different, thus leading to incorrect bracketing. For the tests in the second section of Table 1 (i.e. between the two dashed lines), our algorithm was capable of exactly identifying the target language (but not the grammar). In all of these cases, the induced grammar was slightly smaller than the target one. For the remaining tests, our algorithm did not identify the target language. In fact, it always overgeneralised. The 3 typical CFLs UC3, UC4 and UC6 are not identified because they are not contained in our subclass of CFLs. Inspite of this, the relative entropy results obtained are still relatively good. Overall, it is fair to say that the results obtained by our system, for both language modelling and unsupervised parsing on artificial data, are competitive with the results obtained by other methods.

[2]The relative entropy (or Kullback-Leibler divergence) between a target distribution D and a hypothesized distribution D' is defined as $\sum_{w \in \Sigma^*} ln\Big(\frac{D(w)}{D'(w)}\Big) D(w)$. Add-one smoothing is used to solve the problem of zero probabilities.

4.2 Natural Language Experiments

We also experimented on natural language corpora. For unsupervised parsing, we tested our system on the WSJ10 corpus, using POS tagged sentences as input. Due to time efficiency, we changed the algorithm for finding congruence classes. Instead of always choosing the best possible merge w.r.t. the distance function, a distance threshold is set and all congruence classes whose distance is smaller than the threshold are merged. Also, we changed the distance function from L1-Distance to Pearson's χ^2 test.

In a first experiment (vaguely similar to the one done by Luque and López (2010)), we constructed the best possible SC-CFG consistent with the merges done in the first phase and assigned probabilities to this grammar using Inside-Outside. In other words, we ran the second phase of our system in a supervised fashion by using the treebank to decide which are the best congruence classes to choose as non-terminals. The CNF grammar we obtained from this experiment (COMINO-UBOUND) gives very good parsing results which outperform results from state-of-the-art systems DMV+CCM (Klein, 2004), U-DOP (Bod, 2006a), UML-DOP (Bod, 2006b) and Incremental (Seginer, 2007) as shown in Table 2. Moreover, the results obtained are very close to the best results one can ever hope to obtain from any CNF grammar on WSJ10 (CNF-UBOUND) (Klein, 2004). However, the grammar we obtain does not generalise enough and does not describe a good language model. In a second experiment, we ran the complete COMINO system. The grammar obtained from this experiment did not give competitive parsing results.

The first experiment shows that the merge decisions taken in the first phase do not hinder the possibility of finding a very good grammar for parsing. This means that the merge decisions taken by our system are good in general. Manual analysis on some of the merges taken confirms this. This experiment also shows that there exists a non-trivial PCFG in our restrictive class of grammars that is capable of achieving very good parsing results. This is a positive sign for the question of how adequate SC-PCFGs are for modelling natural languages. However, the real test remains that of finding SC-PCFGs that generate good bracketings *and* good language models. The second experiment shows that the second phase of our al-

Model	UP	UR	UF_1
State-of-the-art			
DMV+CCM	69.3	88.0	77.6
U-DOP	70.8	88.2	78.5
UML-DOP	-	-	82.9
Incremental	75.6	76.2	75.9
Upper bounds			
COMINO-UBOUND	75.8	96.9	85.1
CNF-UBOUND	78.8	100.0	88.1

Table 3: Parsing results on WSJ10. Note that *Incremental* is the only system listed as state-of-the-art which parses from plain text and can generate non-binary trees

gorithm is not giving good results. This means that the smallest possible grammar might not be the best grammar for parsing. Therefore, other criteria alongside the grammar size are needed when choosing a grammar consistent with the merges.

4.3 Discussion and Future Work

In order to improve our system, we think that our algorithm has to take a less conservative merging strategy in the first phase. Although the merges being taken are mostly correct, our analysis shows that not enough merging is being done. The problematic case is that of taking merge decisions on (the many) infrequent long phrases. Although many logically deduced merges involve infrequent phrases and also help in increasing the frequency of some long phrases, this proved to be not enough to mitigate this problem. As for future work, we think that clustering techniques can be used to help solve this problem.

A problem faced by the system is that, in certain cases, the statistical evidence on which merge decisions are taken does not point to the intuitively expected merges. As an example, consider the two POS sequences "DT NN" and "DT JJ NN" in the WSJ corpus. Any linguist would agree that these sequences are substitutable (in fact, they have lots of local contexts in common). However, statistical evidence points otherwise, since their context distributions are not close enough. This happens because, in certain positions of a sentence, "DT NN" is far more likely to occur than "DT JJ NN" (w.r.t. the ratio of their total frequencies) and in other positions, "DT JJ NN" occurs more than expected. The following table shows the frequencies of these two POS sequences over the whole WSJ corpus and their frequencies in contexts (#,VBD) and (IN,#) (the symbol # represents the end or beginning of a sentence):

	Totals	(#,VBD)	(IN,#)
"DT NN"	42,222	1,034	2,123
"DT JJ NN"	15,243	152	1,119
Ratios	3.16	6.80	1.90

It is clear that the ratios do not match, thus leading to context distributions which are not close enough. Thus, this shows that basic sequences such as "DT NN" and "DT JJ NN", which linguists would group into the same concept NP, are statistically derived from different sub-concepts of NP. Our algorithm is finding these sub-concepts, but it is being evaluated on concepts (such as NP) found in the treebank (created by linguists).

From the experiments we did on artificial natural language grammars, it resulted that the target grammar was always slightly bigger than the learned grammar. Although in these cases we still managed to identify the target language or have a good relative entropy result, the bracketing results were in general not good. This and our second experiment on the WSJ10 corpus show that the smallest possible grammar might not be the best grammar for bracketing. To not rely solely on finding the smallest grammar, a bias can be added in favour of congruence classes which, according to constituency tests (like the Mutual Information criterion in Clark (2001)), are more likely to contain substrings that are constituents. This can be done by giving different weights to the congruence class variables in the formula and finding the solution with the smallest sum of weights of its true variables.

The use of POS tags as input can also have its problems. Although we solve the lexical sparsity problem with POS tags, at the same time we lose a lot of information. In certain cases, one POS sequence can include raw phrases which ideally are not grouped into the same congruence class. To mitigate this problem, we can use POS tags only for rare words and subdivide or ignore POS tags for frequent words such as determinants and prepositions. This will reduce the number of raw phrases represented by POS sequences whilst keeping lexical sparsity low.

5 Conclusion

We defined a new class of PCFGs that adequately models natural language syntax. We described a learning algorithm for this class which scales well to large examples and is even capable of learning from small samples. The grammars induced by this algorithm are compact and perform well on unsupervised parsing and language modelling of typical CFLs and artificial natural language grammars.

Abstract

A common approach in text mining tasks such as text categorization, authorship identification or plagiarism detection is to rely on features like words, part-of-speech tags, stems, or some other high-level linguistic features. In this work, an approach that uses character n-grams as features is proposed for the task of native language identification. Instead of doing standard feature selection, the proposed approach combines several string kernels using multiple kernel learning. Kernel Ridge Regression and Kernel Discriminant Analysis are independently used in the learning stage. The empirical results obtained in all the experiments conducted in this work indicate that the proposed approach achieves state of the art performance in native language identification, reaching an accuracy that is 1.7% above the top scoring system of the 2013 NLI Shared Task. Furthermore, the proposed approach has an important advantage in that it is language independent and linguistic theory neutral. In the cross-corpus experiment, the proposed approach shows that it can also be topic independent, improving the state of the art system by 32.3%.

1 Introduction

Using words as basic units is natural in textual analysis tasks such as text categorization, authorship identification or plagiarism detection. Perhaps surprisingly, recent results indicate that methods handling the text at the character level can also be very effective (Lodhi et al., 2002; Sanderson and Guenter, 2006; Popescu and Dinu, 2007; Grozea et al., 2009; Popescu, 2011; Popescu and Grozea, 2012). By disregarding features of natural language such as words, phrases, or meaning, an approach that works at the character level has an important advantage in that it is language independent and linguistic theory neutral. This paper presents a state of the art machine learning system for native language identification that works at the character level. The proposed system is inspired by the system of Popescu and Ionescu (2013), but includes some variations and improvements. A major improvement is that several string kernels are combined via multiple kernel learning (Shawe-Taylor and Cristianini, 2004). Despite the fact that the (histogram) intersection kernel is very popular in computer vision (Maji et al., 2008; Vedaldi and Zisserman, 2010), it has never been used before in text mining. In this work, the intersection kernel is used for the first time in a text categorization task, alone and in combination with other kernels. The intersection kernel lies somewhere in the middle between the kernel that takes into account only the presence of n-grams and the kernel based on the frequency of n-grams (p-spectrum string kernel).

Two kernel classifiers are proposed for the learning task, namely Kernel Ridge Regression (KRR) and Kernel Discriminant Analysis (KDA). The KDA classifier is able to avoid the class-masking problem (Hastie and Tibshirani, 2003), which may often arise in the context of native language identification. Several experiments are conducted to evaluate the performance of the approach proposed in this work. While multiple kernel learning seems to produce a more robust system, the two kernel classifiers obtained mixed results in the experiments. Overall, the empirical results indicate that the approach proposed in this paper achieves state of the art performance in native language identification, while being both lan-

guage independent and linguistic theory neutral. Furthermore, the approach based on string kernels does not need any expert knowledge of words or phrases in the language.

The paper is organized as follows. Related work is presented in Section 2. Section 3 presents several similarity measures for strings, including string kernels and Local Rank Distance. The learning methods used in the experiments are described in Section 4. Section 5 presents details about the experiments. Finally, the conclusions are drawn in Section 6.

2 Related Work

2.1 Native Language Identification

The goal of automatic native language identification (NLI) is to determine the native language of a language learner, based on a piece of writing in a foreign language. This can provide useful information in forensic linguistic tasks (Estival et al., 2007) or could be used in an educational setting to provide contrastive feedback to language learners. Most research has focused on identifying the native language of English language learners, though there have been some efforts recently to identify the native language of writing in other languages (Malmasi and Dras, 2014).

In general most approaches to NLI have used multi-way classification with SVMs or similar models along with a range of linguistic features. The seminal paper by Koppel et al. (2005) introduced some of the best-performing features: character, word and part-of-speech n-grams along with features inspired by the work in the area of second-language acquisition such as spelling and grammatical errors. In 2013, Tetreault et al. (2013) organized the first shared task in the field. This allowed researchers to compare approaches for the first time on a specifically designed NLI corpus that was much larger than previously available data sets. In the shared task, 29 teams submitted results for the test set, and one of the most successful aspects of the competition was that it drew submissions from teams working in a variety of research fields. The submitted systems utilized a wide range of machine learning approaches, combined with several innovative feature contributions. The best performing system achieved an overall accuracy of 83.6% on the 11-way classification of the test set, although there was no significant difference between the top teams.

2.2 Methods that Work at the Character Level

In recent years, methods of handling text at the character level have demonstrated impressive performance levels in various text analysis tasks (Lodhi et al., 2002; Sanderson and Guenter, 2006; Popescu and Dinu, 2007; Grozea et al., 2009; Popescu, 2011; Popescu and Grozea, 2012). Lodhi et al. (2002) used string kernels for document categorization with very good results. String kernels were also successfully used in authorship identification (Sanderson and Guenter, 2006; Popescu and Dinu, 2007; Popescu and Grozea, 2012). For example, the system described in (Popescu and Grozea, 2012) ranked first in most problems and overall in the PAN 2012 Traditional Authorship Attribution tasks.

Using string kernels makes the corresponding learning method completely language independent, because the texts will be treated as sequences of symbols (strings). Methods working at the word level or above very often restrict their feature space according to theoretical or empirical principles. For instance, they select only features that reflect various types of spelling errors or only some type of words, such as function words. These features prove to be very effective for specific tasks, but it is possible that other good features also exist. String kernels embed the texts in a very large feature space, given by all the substrings of length p, and leave it to the learning algorithm to select important features for the specific task, by highly weighting these features. It is important to note that this approach is also linguistic theory neutral, since it disregards any features of natural language such as words, phrases, or meaning. On the other hand, a method that considers words as features cannot be completely language independent, since the definition of a word is necessarily language-specific. For example, a method that uses only function words as features is not completely language independent because it needs a list of function words which is specific to a language. When features such as part-of-speech tags are used, as in the work of Jarvis et al. (2013), the method relies on a part-of-speech tagger which might not be available (yet) for some languages. Furthermore, a way to segment a text into words is not an easy task for some languages, such as Chinese.

Character n-grams are used by some of the systems developed for native language identification.

In work where feature ablation results have been reported, the performance with only character n-gram features was modest compared to other types of features (Tetreault et al., 2012). Initially, most work limited the character features to unigrams, bigrams and trigrams, perhaps because longer n-grams were considered too expensive to compute or unlikely to improve performance. However, some of the top systems in the 2013 NLI Shared Task were based on longer character n-grams, up to 9-grams (Jarvis et al., 2013; Popescu and Ionescu, 2013). The results presented in this work are obtained using a range of 5–8 n-grams. Combining all 5–8 n-grams would generate millions of features, which are indeed expensive to compute and represent. The key to avoiding the computation of such a large number of features lies in using the dual representation provided by the string kernel. String kernel similarity matrices can be computed much faster and are extremely useful when the number of samples is much lower than the number of features.

3 Similarity Measures for Strings

3.1 String Kernels

The kernel function gives kernel methods the power to naturally handle input data that is not in the form of numerical vectors, e.g. strings. The kernel function captures the intuitive notion of similarity between objects in a specific domain and can be any function defined on the respective domain that is symmetric and positive definite. For strings, many such kernel functions exist with various applications in computational biology and computational linguistics (Shawe-Taylor and Cristianini, 2004).

Perhaps one of the most natural ways to measure the similarity of two strings is to count how many substrings of length p the two strings have in common. This gives rise to the p-spectrum kernel. Formally, for two strings over an alphabet Σ, $s, t \in \Sigma^*$, the p-spectrum kernel is defined as:

$$k_p(s,t) = \sum_{v \in \Sigma^p} \text{num}_v(s) \cdot \text{num}_v(t),$$

where $\text{num}_v(s)$ is the number of occurrences of string v as a substring in s.[1] The feature map defined by this kernel associates a vector of dimension $|\Sigma|^p$ containing the histogram of frequencies of all its substrings of length p (p-grams) with each string.

A variant of this kernel can be obtained if the embedding feature map is modified to associate a vector of dimension $|\Sigma|^p$ containing the presence bits (instead of frequencies) of all its substrings of length p with each string. Thus, the character p-grams presence bits kernel is obtained:

$$k_p^{0/1}(s,t) = \sum_{v \in \Sigma^p} \text{in}_v(s) \cdot \text{in}_v(t),$$

where $\text{in}_v(s)$ is 1 if string v occurs as a substring in s, and 0 otherwise.

In computer vision, the (histogram) intersection kernel has successfully been used for object class recognition from images (Maji et al., 2008; Vedaldi and Zisserman, 2010). In this paper, the intersection kernel is used for the first time as a kernel for strings. The intersection string kernel is defined as follows:

$$k_p^{\cap}(s,t) = \sum_{v \in \Sigma^p} \min\{\text{num}_v(s), \text{num}_v(t)\},$$

where $\text{num}_v(s)$ is the number of occurrences of string v as a substring in s.

For the p-spectrum kernel, the frequency of a p-gram has a very significant contribution to the kernel, since it considers the product of such frequencies. On the other hand, the frequency of a p-gram is completely disregarded in the p-grams presence bits kernel. The intersection kernel lies somewhere in the middle between the p-grams presence bits kernel and p-spectrum kernel, in the sense that the frequency of a p-gram has a moderate contribution to the intersection kernel. More precisely, the following inequality that describes the relation between the three kernels holds:

$$k_p^{0/1}(s,t) \leq k_p^{\cap}(s,t) \leq k_p(s,t).$$

What is actually more interesting is that the intersection kernel assigns a high score to a p-gram if it has a high frequency in both strings, since it considers the minimum of the two frequencies. The p-spectrum kernel assigns a high score even when the p-gram has a high frequency in only one of the two strings. Thus, the intersection kernel captures something about the correlation between the p-gram frequencies in the two strings, which may lead to a more sensitive similarity between strings.

[1] Note that the notion of substring requires contiguity. Shawe-Taylor and Cristianini (2004) discuss the ambiguity between the terms *substring* and *subsequence* across different domains: biology, computer science.

Normalized versions of these kernels ensure a fair comparison of strings of different lengths:

$$\hat{k}_p(s,t) = \frac{k_p(s,t)}{\sqrt{k_p(s,s) \cdot k_p(t,t)}},$$

$$\hat{k}_p^{0/1}(s,t) = \frac{k_p^{0/1}(s,t)}{\sqrt{k_p^{0/1}(s,s) \cdot k_p^{0/1}(t,t)}},$$

$$\hat{k}_p^{\cap}(s,t) = \frac{k_p^{\cap}(s,t)}{\sqrt{k_p^{\cap}(s,s) \cdot k_p^{\cap}(t,t)}}.$$

Taking into account p-grams of different length and summing up the corresponding kernels, new kernels, termed *blended spectrum kernels*, can be obtained.

The string kernel implicitly embeds the texts in a high dimensional feature space. Then, a kernel-based learning algorithm implicitly assigns a weight to each feature, thus selecting the features that are important for the discrimination task. For example, in the case of text categorization the learning algorithm enhances the features representing stems of content words (Lodhi et al., 2002), while in the case of authorship identification the same learning algorithm enhances the features representing function words (Popescu and Dinu, 2007).

3.2 Local Rank Distance

A recently introduced distance measure, termed Local Rank Distance (Ionescu, 2013), comes from the idea of better adapting rank distance (Dinu, 2003) to string data, in order to capture a better similarity between strings, such as DNA sequences or text. Local Rank Distance (LRD) has already shown promising results in computational biology (Ionescu, 2013) and native language identification (Popescu and Ionescu, 2013).

In order to describe LRD, the following notations are defined. Given a string x over an alphabet Σ, and a character $a \in \Sigma$, the length of x is denoted by $|x|$. Strings are considered to be indexed starting from position 1, that is $x = x[1]x[2]\cdots x[|x|]$. Moreover, $x[i:j]$ denotes its substring $x[i]x[i+1]\cdots x[j-1]$.

Local Rank Distance is inspired by rank distance (Dinu, 2003), the main differences being that it uses p-grams instead of single characters, and that it matches each p-gram in the first string with the nearest equal p-gram in the second string. Given a fixed integer $p \geq 1$, a threshold $m \geq 1$, and two strings x and y over Σ, the *Local Rank Distance* between x and y, denoted by $\Delta_{LRD}(x,y)$, is defined through the following algorithmic process. For each position i in x ($1 \leq i \leq |x|-p+1$), the algorithm searches for that position j in y ($1 \leq j \leq |y|-p+1$) such that $x[i:i+p] = y[j:j+p]$ and $|i-j|$ is minimized. If j exists and $|i-j| < m$, then the offset $|i-j|$ is added to the Local Rank Distance. Otherwise, the maximal offset m is added to the Local Rank Distance. An important remark is that LRD does not impose any mathematically developed global constraints, such as matching the i-th occurrence of a p-gram in x with the i-th occurrence of that same p-gram in y. Instead, it is focused on the local phenomenon, and tries to pair equal p-grams at a minimum offset. To ensure that LRD is a (symmetric) distance function, the algorithm also has to sum up the offsets obtained from the above process by exchanging x and y. LRD can be formally defined as follows.

Definition 1 *Let $x, y \in \Sigma^*$ be two strings, and let $p \geq 1$ and $m \geq 1$ be two fixed integer values. The Local Rank Distance between x and y is defined as:*

$$\Delta_{LRD}(x,y) = \Delta_{left}(x,y) + \Delta_{right}(x,y),$$

where $\Delta_{left}(x,y)$ and $\Delta_{right}(x,y)$ are defined as follows:

$$\Delta_{left}(x,y) = \sum_{i=1}^{|x|-p+1} \min\{|i-j| \text{ such that } 1 \leq j \leq |y|-p+1 \text{ and } x[i:i+p] = y[j:j+p]\} \cup \{m\},$$

$$\Delta_{right}(x,y) = \sum_{j=1}^{|y|-p+1} \min\{|j-i| \text{ such that } 1 \leq i \leq |x|-p+1 \text{ and } y[j:j+p] = x[i:i+p]\} \cup \{m\}.$$

Interestingly, the search for matching p-grams is limited within a window of fixed size. The size of this window is determined by the maximum offset parameter m. This parameter must be set a priori and should be proportional to the size of the alphabet, the p-grams, and to the lengths of the strings.

The following example offers a better understanding of how LRD actually works. LRD is computed between two strings using 2-grams.

Example 1 *Given two strings $x = abcaa$ and $y = cabca$, a fixed maximal offset $m = 3$, and*

a fixed size of p-grams $p = 2$, Δ_{left} and Δ_{right} are computed as follows:

$$\begin{aligned}\Delta_{left}(x, y) &= |1 - 2| + |2 - 3| \\ &\quad + |3 - 4| + 3 = 6, \\ \Delta_{right}(x, y) &= |1 - 3| + |2 - 1| \\ &\quad + |3 - 2| + |4 - 3| = 5.\end{aligned}$$

By summing up the two partial sums, Local Rank Distance is obtained

$$\Delta_{LRD}(x, y) = \Delta_{left}(x, y) + \Delta_{right}(x, y) = 11.$$

The maximum LRD value between two strings can be computed as the product between the maximum offset m and the number of pairs of compared p-grams. Thus, LRD can be normalized to a value in the $[0, 1]$ interval. By normalizing, LRD becomes a dissimilarity measure. LRD can be also used as a kernel, since kernel methods are based on similarity. The classical way to transform a distance or dissimilarity measure into a similarity measure is by using the Gaussian-like kernel (Shawe-Taylor and Cristianini, 2004):

$$\hat{k}_p^{LRD}(s, t) = e^{-\frac{\Delta_{LRD}(s,t)}{2\sigma^2}},$$

where s and t are two strings and p is the p-grams length. The parameter σ is usually chosen so that values of $\hat{k}(s, t)$ are well scaled. In the above equation, Δ_{LRD} is already normalized to a value in the $[0, 1]$ interval to ensure a fair comparison of strings of different length.

4 Learning Methods

Kernel-based learning algorithms work by embedding the data into a Hilbert feature space, and searching for linear relations in that space. The embedding is performed implicitly, that is by specifying the inner product between each pair of points rather than by giving their coordinates explicitly. More precisely, a kernel matrix that contains the pairwise similarities between every pair of training samples is used in the learning stage to assign a vector of weights to the training samples. Let α denote this weight vector. In the test stage, the pairwise similarities between a test sample x and all the training samples are computed. Then, the following binary classification function assigns a positive or a negative label to the test sample:

$$g(x) = \sum_{i=1}^{n} \alpha_i \cdot k(x, x_i),$$

where x is the test sample, n is the number of training samples, $X = \{x_1, x_2, ..., x_n\}$ is the set of training samples, k is a kernel function, and α_i is the weight assigned to the training sample x_i. In the primal form, the same binary classification function can be expressed as:

$$g(x) = \langle w, x \rangle,$$

where $\langle \cdot, \cdot \rangle$ denotes the scalar product, $x \in \mathbb{R}^m$ is the test sample represented as a vector of features, and $w \in \mathbb{R}^m$ is a vector of feature weights that can be computed as follows:

$$w = \sum_{i=1}^{n} \alpha_i \cdot x_i,$$

given that the kernel function k can be expressed as a scalar product between samples.

The advantage of using the dual representation induced by the kernel function becomes clear if the dimension of the feature space m is taken into consideration. Since string kernels are based on character n-grams, the feature space is indeed very high. For instance, using 5-grams based only on the 26 letters of the English alphabet will result in a feature space of $26^5 = 11,881,376$ features. However, in the experiments presented in this work the feature space includes 5-grams along with 6-grams, 7-grams and 8-grams. As long as the number of samples n is not greater than the number of features m, it is more efficient to use the dual representation given by the kernel matrix. This fact is also known as the *kernel trick* (Shawe-Taylor and Cristianini, 2004).

Various kernel methods differ in the way they learn to separate the samples. In the case of binary classification problems, kernel-based learning algorithms look for a discriminant function, a function that assigns $+1$ to examples belonging to one class and -1 to examples belonging to the other class. For the NLI experiments, two binary kernel classifiers are used, namely the SVM (Cortes and Vapnik, 1995), and the KRR. Support Vector Machines try to find the vector of weights that defines the hyperplane that maximally separates the images in the Hilbert space of the training examples

belonging to the two classes. Kernel Ridge Regression selects the vector of weights that simultaneously has small empirical error and small norm in the Reproducing Kernel Hilbert Space generated by the kernel function. More details about SVM and KRR can be found in (Shawe-Taylor and Cristianini, 2004). The important fact is that the above optimization problems are solved in such a way that the coordinates of the embedded points are not needed, only their pairwise inner products which in turn are given by the kernel function.

SVM and KRR produce binary classifiers, but native language identification is usually a multi-class classification problem. There are many approaches for combining binary classifiers to solve multi-class problems. Typically, the multi-class problem is broken down into multiple binary classification problems using common decomposing schemes such as: one-versus-all and one-versus-one. There are also kernel methods that take the multi-class nature of the problem directly into account, e.g. Kernel Discriminant Analysis. The KDA classifier is able to improve accuracy by avoiding the masking problem (Hastie and Tibshirani, 2003). In the case of multi-class native language identification, the masking problem may appear when non-native English speakers have acquired, as the second language, a different language to English. For example, an essay written in English produced by a French native speaker that is also proficient in German, could be identified as either French or German.

5 Experiments

5.1 Data Sets Description

In this paper, experiments are carried out on three datasets: a modified version of the ICLEv2 corpus (Granger et al., 2009), the ETS Corpus of Non-Native Written English, or TOEFL11 (Blanchard et al., 2013), and the TOEFL11-Big corpus as used by Tetreault et al. (2012). A summary of the corpora is given in Table 1.

Corpus	Languages	Documents
ICLE	7	770
TOEFL11	11	12,100
TOEFL11-Big	11	87,502

Table 1: Summary of corpora used in the experiments.

The ICLEv2 is a corpus of essays written by highly-proficient non-native college-level students of English. For many years this was the standard corpus used in the task of native language identification. However, the corpus was originally collected for the purpose of corpus linguistic investigations, and because of this contains some idiosyncrasies that make it problematic for the task of NLI (Brooke and Hirst, 2012). Therefore, a modified version of the corpus that has been normalized as much as possible for topic and character encoding (Tetreault et al., 2012) is used. This version of the corpus contains 110 essays each for 7 native languages: Bulgarian, Chinese, Czech, French, Japanese, Russian and Spanish.

The ETS Corpus of Non-Native Written English (TOEFL11) was first introduced by Tetreault et al. (2012) and extended for the 2013 Native Language Identification Shared Task (Tetreault et al., 2013). It was designed to overcome many of the shortcomings identified with using the ICLEv2 corpus for this task. The TOEFL11 corpus contains a balanced distribution of essays per prompt (topic) per native language. It also contains information about the language proficiency of each writer. The corpus contains essays written by speakers of the following 11 languages: Arabic, Chinese, French, German, Hindi, Italian, Japanese, Korean, Spanish, Telugu and Turkish. For the shared task, the 12,100 essays were split into 9,900 for training, 1,100 for development and 1,100 for testing.

Tetreault et al. (2012) present a corpus, TOEFL11-Big, to investigate the performance of their NLI system on a very large data set. This data set contains the same languages as TOEFL11, but with no overlap in content. It contains a total of over 87 thousand essays written to a total of 76 different prompts. The distribution of L1 per prompt is not as even as for TOEFL11, though all topics are represented for all L1s.

5.2 Parameter Tuning and Implementation Choices

In the string kernels approach proposed in this work, documents or essays from this corpus are treated as strings. Therefore, the notions of *string* or *document* is used interchangeably throughout this work. Because the approach works at the character level, there is no need to split the texts into words, or to do any NLP-specific preprocessing. The only editing done to the texts was the replacing of sequences of consecutive space characters

(space, tab, new line, and so on) with a single space character. This normalization was needed in order to prevent the artificial increase or decrease of the similarity between texts, as a result of different spacing. All uppercase letters were converted to the corresponding lowercase ones.

A series of preliminary experiments were conducted in order to select the best-performing learning method. In these experiments the string kernel was fixed to the p-spectrum normalized kernel of length 5 ($\hat{k}_5$), because the goal was to select the best learning method, and not to find the best kernel. The following learning methods were evaluated: one-versus-one SVM, one-versus-all SVM, one-versus-one KRR, one-versus-all KRR, and KDA. A 10-fold cross-validation procedure was carried out on the TOEFL11 training set to evaluate the classifiers. The preliminary results indicate that the one-versus-all KRR and the KDA classifiers produce the best results. Therefore, they are selected for the remaining experiments.

Another set of preliminary experiments were performed to determine the range of n-grams that gives the most accurate results on a 10-fold cross-validation procedure carried out on the TOEFL11 training set. All the n-grams in the range 2-10 were evaluated. Furthermore, experiments with different blended kernels were conducted to see whether combining n-grams of different lengths could improve the accuracy. The best results were obtained when all the n-grams with the length in the range 5-8 were used. Other authors (Bykh and Meurers, 2012; Popescu and Ionescu, 2013) also report better results by using n-grams with the length in a range, rather than using n-grams of fixed length. Consequently, the results reported in this work are based on blended string kernels based on 5-8 n-grams.

Some preliminary experiments were also performed to establish the type of kernel to be used, namely the blended p-spectrum kernel ($\hat{k}_{5-8}$), the blended p-grams presence bits kernel ($\hat{k}^{0/1}_{5-8}$), the blended p-grams intersection kernel ($\hat{k}^{\cap}_{5-8}$), or the kernel based on LRD ($\hat{k}^{LRD}_{5-8}$.). These different kernel representations are obtained from the same data. The idea of combining all these kernels is natural when one wants to improve the performance of a classifier. When multiple kernels are combined, the features are actually embedded in a higher-dimensional space. As a consequence, the search space of linear patterns grows, which helps the classifier to select a better discriminant function. The most natural way of combining two kernels is to sum them up. Summing up kernels or kernel matrices is equivalent to feature vector concatenation. Another option is to combine kernels by kernel alignment (Cristianini et al., 2001). Instead of simply summing kernels, kernel alignment assigns weights for each of the two kernels based on how well they are aligned with the ideal kernel YY' obtained from training labels. The kernels were evaluated alone and in various combinations. The best kernels are the blended p-grams presence bits kernel and the blended p-grams intersection kernel. The best kernel combinations include the blended p-grams presence bits kernel, the blended p-grams intersection kernel and the kernel based on LRD. Since the kernel based on LRD is slightly slower than the other string kernels, the kernel combinations that include it were only evaluated on the TOEFL11 corpus and on the ICLE corpus.

5.3 Experiment on TOEFL11 Corpus

This section describes the results on the TOEFL11 corpus. Thus, results for the 2013 *Closed* NLI Shared Task are also included. In the closed shared task the goal is to predict the native language of testing examples, restricted to learning only from the training and the development data. The additional information from *prompts* or the English language proficiency level were not used in the proposed approach.

The regularization parameters were tuned on the development set. In this case, the systems were trained on the entire training set. A 10-fold cross-validation (CV) procedure was done on the training and the development sets. The folds were provided along with the TOEFL11 corpus. Finally, the results of the proposed systems are also reported on the NLI Shared Task test set. For testing, the systems were trained on both the training set and the development set. The results are summarized in Table 2.

The results presented in Table 2 show that string kernels can reach state of the art accuracy levels for this task. Overall, it seems that KDA is able to obtain better results than KRR. The intersection kernel alone is able to obtain slightly better results than the presence bits kernel. The kernel based on LRD gives significantly lower accuracy rates, but it is able to improve the performance when it is

Method	Development	10-fold CV	Test
Ensemble model (Tetreault et al., 2012)	-	80.9%	-
KRR and string kernels (Popescu and Ionescu, 2013)	-	82.6%	82.7%
SVM and word features (Jarvis et al., 2013)	-	**84.5%**	83.6%
KRR and $\hat{k}^{0/1}_{5-8}$	85.4%	82.5%	82.0%
KRR and $\hat{k}^{\cap}_{5-8}$	84.9%	82.2%	82.6%
KRR and $\hat{k}^{LRD}_{5-8}$	78.7%	77.1%	77.5%
KRR and $\hat{k}^{0/1}_{5-8} + \hat{k}^{LRD}_{5-8}$	85.7%	82.6%	82.7%
KRR and $\hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	84.9%	82.2%	82.0%
KRR and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8}$	85.5%	82.6%	82.5%
KRR and $a_1\hat{k}^{0/1}_{5-8} + a_2\hat{k}^{\cap}_{5-8}$	85.5%	82.6%	82.5%
KDA and $\hat{k}^{0/1}_{5-8}$	86.2%	83.6%	83.6%
KDA and $\hat{k}^{\cap}_{5-8}$	85.2%	83.5%	84.6%
KDA and $\hat{k}^{LRD}_{5-8}$	79.7%	78.5%	79.2%
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{LRD}_{5-8}$	**87.1%**	84.0%	84.7%
KDA and $\hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	85.8%	83.4%	83.9%
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8}$	86.4%	84.1%	85.0%
KDA and $a_1\hat{k}^{0/1}_{5-8} + a_2\hat{k}^{\cap}_{5-8}$	86.5%	84.1%	**85.3%**
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	87.0%	84.1%	84.8%

Table 2: Accuracy rates on TOEFL11 corpus of various classification systems based on string kernels compared with other state of the art approaches. The best accuracy rates on each set of experiments are highlighted in bold. The weights a_1 and a_2 from the weighted sums of kernels are computed by kernel alignment.

combined with the blended p-grams presence bits kernel. In fact, most of the kernel combinations give better results than each of their components. The best kernel combination is that of the presence bits kernel and the intersection kernel. Results are quite similar when they are combined either by summing them up or by kernel alignment. The best performance on the test set (85.3%) is obtained by the system that combines these two kernels via kernel alignment and learns using KDA. This system is 1.7% better than the state of the art system of Jarvis et al. (2013) based on SVM and word features, this being the top scoring system in the NLI 2013 Shared Task. It is also 2.6% better than the state of the art system based on string kernels of Popescu and Ionescu (2013). On the cross validation procedure, there are three systems that reach the accuracy rate of 84.1%. All of them are based on KDA and various kernel combinations. The greatest accuracy rate of 84.1% reported for the cross validation procedure is 3.2% above the state of the art system of Tetreault et al. (2012) and 0.4% below the top scoring system of Jarvis et al. (2013). The empirical results obtained in this experiment demonstrate that the approach proposed in this paper can reach state of the art accuracy levels. It is worth mentioning that a significance test performed by the organizers of the NLI 2013 Shared Task showed that the top systems that participated in the competition are not essentially different. Further experiments on the ICLE corpus and on the TOEFL11-Big corpus are conducted to determine whether the approach proposed in this paper is significantly better than other state of the art approaches.

5.4 Experiment on ICLE Corpus

The results on the ICLE corpus using a 5-fold cross validation procedure are summarized in Table 3. To adequately compare the results with a state of the art system, the same 5-fold cross validation procedure used by Tetreault et al. (2012) was also used in this experiment. Table 3 shows that the results obtained by the presence bits kernel and by the intersection kernel are systematically better than the state of the art system of Tetreault et al. (2012). While both KRR and KDA produce accuracy rates that are better than the state of the art accuracy rate, it seems that KRR is slightly better in this experiment. Again, the idea of combining kernels seems to produce more robust systems. The best systems are based on combining the presence bits kernel either with the kernel based on LRD or the intersection kernel. Overall, the reported accuracy rates are higher than the state of the art accuracy rate. The best performance (91.3%) is achieved by the KRR classifier based on combining the presence bits kernel with

Method	5-fold CV
Ensemble model (Tetreault et al., 2012)	90.1%
KRR and $\hat{k}^{0/1}_{5-8}$	91.2%
KRR and $\hat{k}^{\cap}_{5-8}$	90.5%
KRR and $\hat{k}^{LRD}_{5-8}$	81.8%
KRR and $\hat{k}^{0/1}_{5-8} + \hat{k}^{LRD}_{5-8}$	**91.3%**
KRR and $\hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	90.1%
KRR and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8}$	90.9%
KRR and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	90.6%
KDA and $\hat{k}^{0/1}_{5-8}$	90.5%
KDA and $\hat{k}^{\cap}_{5-8}$	90.5%
KDA and $\hat{k}^{LRD}_{5-8}$	82.3%
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{LRD}_{5-8}$	90.8%
KDA and $\hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	90.4%
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8}$	91.0%
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8} + \hat{k}^{LRD}_{5-8}$	90.8%

Table 3: Accuracy rates on ICLE corpus of various classification systems based on string kernels compared with a state of the art approach. The accuracy rates are reported for the same 5-fold CV procedure as in (Tetreault et al., 2012). The best accuracy rate is highlighted in bold.

the kernel based on LRD. This represents an 1.2% improvement over the state of the art accuracy rate of Tetreault et al. (2012). Two more systems are able to obtain accuracy rates greater than 91.0%. These are the KRR classifier based on the presence bits kernel (91.2%) and the KDA classifier based on the sum of the presence bits kernel and the intersection kernel (91.0%). The overall results on the ICLE corpus show that the string kernels approach can reach state of the art accuracy levels. It is worth mentioning the purpose of this experiment was to use the same approach determined to work well in the TOEFL11 corpus. To serve this purpose, the range of n-grams was not tuned on this data set. Furthermore, other classifiers were not tested in this experiment. Nevertheless, better results can probably be obtained by adding these aspects into the equation.

5.5 Cross-corpus Experiment

In this experiment, various systems based on KRR or KDA are trained on the TOEFL11 corpus and tested on the TOEFL11-Big corpus. The kernel based on LRD was not included in this experiment since it is more computationally expensive. Therefore, only the presence bits kernel and the intersection kernel were evaluated on the TOEFL11-Big corpus. The results are summarized in Table 4. The same regularization parameters determined to work well on the TOEFL11 development set were used.

Method	Test
Ensemble model (Tetreault et al., 2012)	35.4%
KRR and $\hat{k}^{0/1}_{5-8}$	66.7%
KRR and $\hat{k}^{\cap}_{5-8}$	67.2%
KRR and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8}$	**67.7%**
KRR and $a_1\hat{k}^{0/1}_{5-8} + a_2\hat{k}^{\cap}_{5-8}$	**67.7%**
KDA and $\hat{k}^{0/1}_{5-8}$	65.6%
KDA and $\hat{k}^{\cap}_{5-8}$	65.7%
KDA and $\hat{k}^{0/1}_{5-8} + \hat{k}^{\cap}_{5-8}$	66.2%
KDA and $a_1\hat{k}^{0/1}_{5-8} + a_2\hat{k}^{\cap}_{5-8}$	66.2%

Table 4: Accuracy rates on TOEFL11-Big corpus of various classification systems based on string kernels compared with a state of the art approach. The systems are trained on the TOEFL11 corpus and tested on the TOEFL11-Big corpus. The best accuracy rate is highlighted in bold. The weights a_1 and a_2 from the weighted sums of kernels are computed by kernel alignment.

The most interesting fact is that all the proposed systems are at least 30% better than the state of the art system. Considering that the TOEFL11-Big corpus contains 87 thousand samples, the 30% improvement is significant without any doubt. Diving into details, it can be observed that the results obtained by KRR are higher than those obtained by KDA. However, both methods perform very well compared to the state of the art. Again, kernel combinations are better than each of their individual kernels alone.

It is important to mention that the significant performance increase is not due to the learning method (KRR or KDA), but rather due to the string kernels that work at the character level. It is not only the case that string kernels are language independent, but for the same reasons they can also be topic independent. Since the topics (prompts) from TOEFL11 are different from the topics from TOEFL11-Big, it becomes clear that a method that uses words as features is strongly affected, since the distribution of words per topic can be completely different. But mistakes that reveal the native language can be captured by character n-grams that can appear more often even in different topics. The results indicate that this is also the case of the approach based on string kernels, which seems to be more robust to such topic variations of the data set. The best system has an accuracy rate that is 32.3% better than the state of

the art system of Tetreault et al. (2012). Overall, the empirical results indicate that the string kernels approach can achieve significantly better results than other state of the art approaches.

6 Conclusions

A language-independent approach to native language identification was presented in this paper. The system works at the character level, making the approach completely language independent and linguistic theory neutral. The results obtained in all the three experiments were very good. The best system presented in this work is based on combining the intersection and the presence string kernels by kernel alignment and on deciding the class label either with KDA or KRR. The best system is 1.7% above the top scoring system of the 2013 NLI Shared Task. Furthermore, it has an impressive generalization capacity, achieving results that are 30% higher than the state of the art method in the cross-corpus experiment.

Despite the fact that the approach based on string kernels performed so well, it remains to be further investigated why this is the case and why such a simple approach can compete with far more complex approaches that take words, lemmas, syntactic information, or even semantics into account. It seems that there are generalizations to the kinds of mistakes that certain non-native English speakers make that can be captured by n-grams of different lengths. Interestingly, using a range of n-grams generates a large number of features including (but not limited to) stop words, stems of content words, word suffixes, entire words, and even n-grams of short words. Rather than doing feature selection before the training step, which is the usual NLP approach, the kernel classifier selects the most relevant features during training. With enough training samples, the kernel classifier does a better job of selecting the right features from a very high feature space. This may be one reason for why the string kernel approach works so well. To gain additional insights into why this technique is working well, the features selected by the classifier as being more discriminating can be analyzed in future work. This analysis would also offer some information about localized language transfer effects, since the features used by the proposed model are n-grams of lengths 5 to 8. As mentioned before, the features captured by the model typically include stems, function words, word prefixes and suffixes, which have the potential to generalize over purely word-based features. These features would offer insights into two kinds of language transfer effects, namely word choice (lexical transfer) and morphological differences.

Acknowledgments

The authors would like to thank Beata Beigman Klebanov, Nitin Madnani and Xinhao Wang from ETS for their helpful comments and suggestions. The author also thank the anonymous reviewers for their valuable insights which lead to improvements in the presentation of this work.

Abstract

Predicting vocabulary of second language learners is essential to support their language learning; however, because of the large size of language vocabularies, we cannot collect information on the entire vocabulary. For practical measurements, we need to sample a small portion of words from the entire vocabulary and predict the rest of the words. In this study, we propose a novel framework for this sampling method. Current methods rely on simple heuristic techniques involving inflexible manual tuning by educational experts. We formalize these heuristic techniques as a graph-based non-interactive active learning method as applied to a special graph. We show that by extending the graph, we can support additional functionality such as incorporating domain specificity and sampling from multiple corpora. In our experiments, we show that our extended methods outperform other methods in terms of vocabulary prediction accuracy when the number of samples is small.

1 Introduction

Predicting the vocabulary of second language learners is essential to support them when they are reading. Educational experts have been continuously studying methods for measuring the size of a learner's vocabulary, i.e., the number of words the learner knows, over the decades (Meara and Buxton, 1987; Laufer and Nation, 1999). Ehara et al. (2012) formalized a more fine-grained measurement task called *vocabulary prediction*. The goal of this task is to predict whether a learner knows a given word based on only a relatively small portion of his/her vocabulary. This vocabulary prediction task can be further used for predicting the readability of texts. By predicting vocabulary unknown to readers and showing the meaning of those specific words to readers, Ehara et al. (2013) showed that the number of documents that learners can read increases.

Word sampling is essential for vocabulary prediction. Because of the large size of language vocabularies, we usually cannot collect information on the entire vocabulary. For practical measurements, we inevitably need to sample a small portion of words from the entire vocabulary and then predict the rest. We refer to this sampling technique as word sampling.

Word sampling can greatly affect the performance of vocabulary prediction. For example, if we consider only short everyday general domain words such as "cat" and "dog" as samples, the rest of the vocabulary is difficult to predict since learners likely know most of these words. To more accurately measure a learner's vocabulary, we ideally must sample words that are representative of the entire set of words. More specifically, we wish to sample words such that if a learner knows these words, he/she is likely to know the rest of the words in the given vocabulary, and vice versa.

To our knowledge, however, all current studies have relied on a simple heuristic method. In this heuristic method, educational experts first somehow create groups of words with the aim that the words in a group are of similar difficulty for learn-

*The main body of this work was done when the first author was a Ph.D. candidate in the University of Tokyo and the paper was later greatly revised when the first author was a JSPS (Japan Society for the Promotion of Science) research fellow (PD) at National Institute of Informatics. ers. To create groups of words, the experts typically make use of word frequencies and sometimes manually reclassify words based on experience. Next, a fixed number of words are randomly sampled from each group via a uniform distribution. We call this approach *heuristic word sampling*.

In this study, we propose a novel framework that formalizes word sampling as *non-interactive* graph-based active learning based on weighted graphs. In our approach, nodes of a graph correspond to words, whereas the edge weights show how similar the difficulty levels of a word pair are. Unlike *interactive* active learning algorithms used in the NLP community, which use expert annotators' human labels for sampling nodes, non-interactive active learning algorithms exclude expert annotators' human labels from the protocol (Ji and Han, 2012; Gu and Han, 2012). Given a weighted graph and using only its structure, without human labels, these algorithms sample nodes that are important for classification with algorithms called *label propagation*. Excluding annotators' human labels from the protocol is beneficial for educational purposes since learners can share the same set of sampled words via, for example, printed handouts.

Formalizing the current methods as non-interactive graph-based active learning enables us to extend the sampling methods with additional functionality that current methods cannot handle without applying burdensome manual heuristics because we can flexibly design the weighted graphs fed to the active learning algorithms. In our framework, this extension is achieved by extending the graph, namely, our framework can handle *domain specificity* and *multiple corpora*.

Domains are important when one wants to measure the vocabulary of learners. For example, consider measuring non-native English speakers taking computer science graduate courses. We may want to measure their English vocabulary with an emphasis on computer science rather than their general English vocabulary. However, such an extension is impossible via current methods, and thus it is desirable to sample algorithms to be able to handle domain specificity. Our framework can incorporate domain specificity between words in the form of edges between such words.

Handling multiple corpora is important when we cannot single out which corpus we should rely on. The current technique used by educational experts to handle multiple corpora is to heuristically integrate multiple frequency lists from multiple corpora into a single list of words; however, such manual integration is burdensome. Thus, automatic integration is desirable. Our framework converts multiple corpora into graphs, merges these graphs together, and then samples from the merged graph.

Our contributions as presented in this paper are summarized as follows:

1. We formalize word sampling for vocabulary prediction as graph-based active learning.

2. Based on this formalization, we can perform more flexible word sampling that can handle domain specificity and multiple corpora.

The remaining parts of this paper are organized as follows. In §2, we explain the problem setting in detail. We first explain how existing heuristic word sampling works and how it relies on the *cluster assumption* from the viewpoint of graphs. Then, we introduce existing graph-based non-interactive active learning methods. In §3, we show that the existing heuristic word sampling is merely a special case of a non-interactive active learning method (Gu and Han, 2012). Precisely, the existing sampling is identical to the case where a special graph called a "multi-complete graph" is fed to a non-interactive active learning method. Since this method can take any weighted graphs other than this special graph, this immediately leads to a way of devising new sampling methods by modifying graphs. §4 explains exactly how we can modify graphs for improving active learning. §5 evaluates the proposed method both quantitatively and qualitatively, and §6 concludes our paper.

2 Problem Setting

2.1 Heuristic Word Sampling

A simple vocabulary estimation technique introduced by educational experts is to use the frequency rank of words in a corpus based on the assumption that learners using words with similar frequency ranks have a similar vocabulary (Laufer and Nation, 1999). In accordance with this assumption, they first group words by frequency ranks in a corpus and then assume that words in each group have a similar vocabulary status. For example, they sampled words as follows:

1. Rank words by frequency in a corpus.

2. Group words with frequency ranks from 1 to $1,000$ as Level 1000, words with frequency ranks from $1,001$ to $2,000$ as Level 2000, and so on.

3. Take 18 samples from Level 1000, another 18 samples from Level 2000, and so on.

The rationale behind this method is to treat high-ranked and low-ranked words separately rather than sample words from the entire vocabulary. After sampling words, this sampling method can be used for various measurements; for example, Laufer and Nation (1999) used this method to estimate the size of the learners' vocabulary by simply adding $1,000 * \frac{\text{Correctly answered words}}{18}$ for each level.

2.2 Cluster Assumption

In the previous subsection, we noted that existing word sampling methods rely on the assumption that *words with similar frequency ranks are known to learners whose familiar words are similar each other*. This assumption is known as the cluster assumption in the field of graph studies (Zhou et al., 2004).

To further describe the cluster assumption, we first define graphs. A graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ consists of a set of nodes (vertices) $\mathcal{V}$ and a set of edges $\mathcal{E}$. Here, each node has a *label*, and each edge has a *weight*. A label denotes the category of its corresponding node. For example, in binary classification, a label is taken from $\{+1, -1\}$. A weight is a real value; when the weight of an edge is large, we describe the edge as being heavy.

The cluster assumption is an assumption that *heavily connected nodes in a graph should have similar labels*. In other words, the cluster assumption states that weights of edges and labels of nodes should be consistent.

We explain how the cluster assumption relates to our task. In our application, each node corresponds to a word. Labels of the nodes in a graph denote the vocabulary of a learner. If he/she knows a word, the label of the node corresponding to the word is $+1$; if not, the label is -1. The cluster assumption in our application is that the heavier the edge, the higher the similarity between users familiar with the two words.

In this manner, existing word sampling methods implicitly assume cluster assumption. This is therefore the underlying approach for reducing the word sampling problem into graph-based active learning. Since graphs allow for more flexible modeling by changing the weights of edges, we expect that more flexible word sampling will be enabled by graph-based active learning.

2.3 Label Propagation

Since the graph-based active learning algorithms are based on *label propagation* algorithms, we will explain them first. Basically, given a weighted graph, label propagation algorithms classify their nodes in a weakly supervised manner. While the graph-based active learning algorithm that we are trying to use (Gu and Han, 2012) does not use label propagation algorithms' outputs directly, it is tuned to be used with a state-of-the-art label propagation method called Learning with Local and Global Consistency (LLGC) (Zhou et al., 2004).

Label propagation algorithms predict the labels of nodes from a few manually supervised labels and graph weights. To this end, label propagation algorithms follow the following steps. First, humans label a small subset of the nodes in the graph. This subset of nodes is called the set of *labeled nodes*, and the remaining nodes are called *unlabeled nodes*. Second, label propagation algorithms propagate labels to the unlabeled nodes based on edge weights. The rationale behind label propagation algorithms lies in cluster assumption; as label propagation algorithms assume that two nodes connected by a heavily weighted edge should have similar labels, more heavily weighted edges should propagate more labels.

We formalize Learning with Local and Global Consistency (LLGC) (Zhou et al., 2004), one of the state-of-the-art label propagation methods. Here, for simplicity, suppose that we want to perform binary classification of nodes. Let N be the total number of nodes in a graph. Then, we denote labels of each node by $\mathbf{y} \stackrel{\text{def}}{=} (y_1, \ldots, y_N)^\top$. For unlabeled nodes, y_i is set to 0. For labeled nodes, y_i is set to $+1$ if the learner knows a word, -1 if not. We also introduce a label propagation (LP) *score vector* $\mathbf{f} = (f_1, \ldots, f_N)^\top$. This LP score vector is the output of label propagation and is real-valued. To obtain the classification result from this real-valued LP score vector for an unlabeled node (word) i, the learner is predicted to know the word i if $f_i > 0$, and he/she is predicted to be unfamiliar with the word if $f_i \leq 0$.

Next, we formally define a normalized graph-Laplacian matrix, which is used for penalization based on the cluster assumption. Let an $N \times N$ -sized square matrix $\mathbf{W}$ be a *weighted adjacency matrix* of $\mathcal{G}$. $\mathbf{W}$ is symmetric and non-negative definite; its diagonal elements $\mathbf{W}_{i,i} = 0$ and all other elements are non-negative[1]. The graph Laplacian of a normalized graph, known as a *normalized graph Laplacian* matrix, is defined as $\mathbf{L}^{\text{norm}}_{\mathbf{W}} \stackrel{\text{def}}{=} \mathbf{I} - \mathbf{D}_{\mathbf{W}}^{-\frac{1}{2}} \mathbf{W} \mathbf{D}_{\mathbf{W}}^{-\frac{1}{2}}$. Here, $\mathbf{D}_{\mathbf{W}}$ is defined as a diagonal matrix whose diagonal element is $(\mathbf{D}_{\mathbf{W}})_{i,i} \stackrel{\text{def}}{=} \sum_{j=1}^{|\mathcal{V}|} \mathbf{W}_{i,j}$, and $\mathbf{I}$ denotes the identity matrix of the appropriate size. Note that a normalized graph Laplacian $\mathbf{L}^{\text{norm}}_{\mathbf{W}}$ depends on the weighted adjacency matrix $\mathbf{W}$.

Then, LLGC can be formalized as a simple optimization problem as shown in Equation 1.

$$\min_{\mathbf{f}} \|\mathbf{f} - \mathbf{y}\|_2^2 + \mu \mathbf{f}^\top \mathbf{L}^{\text{norm}}_{\mathbf{W}} \mathbf{f} \qquad (1)$$

Equation 1 consists of two terms. Intuitively, the first term tries to make the LP score vector, the final output $\mathbf{f}$, as close as possible to the given labels $\mathbf{y}$. The second term is designed to meet the cluster assumption: it penalizes the case where two nodes with heavy edges have very different LP scores. $\mu > 0$ is the only hyper-parameter of LLGC: it determines how strong the penalization based on the cluster assumption should be. Thus, in total, Equation 1 outputs an LP score vector $\mathbf{f}$ considering both the labeled input $\mathbf{y}$ and the cluster assumption of the given graph $\mathbf{W}$: the heavier an edge, the closer the scores of the two nodes connected by the edge becomes.

2.4 Graph-based active learning algorithms

An important categorization of graph-based active learning for applications is whether it is *interactive* or *non-interactive*. Here, interactive approaches use human labels during the learning process; they present a node for humans to label, and based on this label, the algorithms compute the next node to be presented to the humans. Thus, in interactive algorithms, human labeling and computations of the next node must run concurrently.

Non-interactive algorithms do not use human labels during the learning process. Given the entire graph, these algorithms sample important nodes for label propagation algorithms. Here, important nodes are the ones that minimize estimated classification error of label propagation when the nodes are labeled. Note that, unlike active learning used in the NLP community, non-interactive active learning algorithms exclude expert annotators' human labels from the protocol. While they exclude expert annotators, they are still regarded as active learning methods in the machine learning community since they try to choose such nodes that are beneficial for classification (Ji and Han, 2012; Gu and Han, 2012).

For educational purposes, *non-interactive* algorithms are preferred over *interactive* algorithms. The main drawback of interactive algorithms is that they must run concurrently with the human labeling. For our applications, this means that the vocabulary tests for vocabulary prediction must always be computerized. In contrast, non-interactive algorithms allow us to have vocabulary tests printed in the form of handouts, so we focus on non-interactive algorithms throughout this paper.

Compared with interactive algorithm studies, such as Zhu et al. (2003), graph-based non-interactive active learning algorithms have been introduced in recent years. There has been a seminal paper on non-interactive algorithms (Ji and Han, 2012). We used Gu and Han's algorithm because it reports higher accuracy for many tasks with competitive computation times over Ji and Han's algorithm (Gu and Han, 2012).

These active learning methods share two basic rules although their objective functions are different. First, these methods tend to select globally important nodes, also known as *hubs*. A notable example of global importance is the number of edges. Second, these methods tend to avoid sampling nodes that are heavily connected to previously sampled nodes. This is due to *cluster assumption*, the assumption that similar nodes should have similar labels, which suggests that it is redundant to select nodes close to previously sampled nodes; the labels of such nodes should be reliably predicted from the previously sampled nodes.

Gu and Han's algorithm, which is the algorithm we used, also follows these rules. In this algorithm, when considering the k-th sample, for every node i in the current set of not-yet-chosen nodes, a score $score(k, i)$ is calculated, and the node with the highest score is chosen. First, the score is de-

[1]While all elements of a non-negative definite matrix are not necessarily non-negative, we define all elements of $\mathbf{W}$ as non-negative here, following the definition of Zhou et al. (2004).

signed to be large if the i-th node is globally important. In the algorithm, the global importance of a node is measured by an eigenvalue decomposition of the normalized graph-Laplacian, $\mathbf{L}^{\text{norm}}$. Transformed from the graph's adjacency matrix, this matrix stores the graph's global information. Second, the score is designed to be smaller if the i-th node is close to one of the previously sampled nodes.

Score $score\,(k,i)$ is defined as follows. We perform eigenvalue decomposition beforehand. $\mathbf{L}^{\text{norm}}_{\mathbf{W}} = \mathbf{U}\Lambda\mathbf{U}^{\top}$, $\mathbf{u}_i$ is the transpose of the i-th row of $\mathbf{U}$, and λ_i is its corresponding eigenvalue.

$$score\,(k,i) \stackrel{\text{def}}{=} \frac{\left(\mathbf{H}_k^{-1}\mathbf{u}_i\right)^{\top}\mathbf{\Lambda}^{-1}\left(\mathbf{H}_k^{-1}\mathbf{u}_i\right)}{1+\mathbf{u}_i^{\top}\mathbf{H}_k^{-1}\mathbf{u}_i} \quad (2)$$

In Equation 2, $\mathbf{H}_k$ preserves information of the previous $k-1$ samples. First, $\mathbf{H}_0$ is a diagonal matrix whose i-th diagonal element is defined as $\frac{1}{(\mu\lambda_i+1)^2-1}$ where μ is a hyper-parameter. $\mathbf{H}_0$ weighs the score of globally important nodes through the eigenvalue decomposition. Second, $\mathbf{H}_k$ is updated such that the scores of the nodes distant from the previously taken samples are higher. The precise update formula of $\mathbf{H}_k$ follows. i_{k+1} is the index of the node sampled at $k+1$-th round. For the derivation of this formula, see Gu and Han (2012).

$$\mathbf{H}_{k+1}^{-1} = \mathbf{H}_k^{-1} - \frac{\left(\mathbf{H}_k^{-1}\mathbf{u}_{i_{k+1}}\right)\left(\mathbf{H}_k^{-1}\mathbf{u}_{i_{k+1}}\right)^{\top}}{1+\mathbf{u}_{i_{k+1}}^{\top}\mathbf{H}_k^{-1}\mathbf{u}_{i_{k+1}}} \quad (3)$$

Hyper-parameter μ determines how strong the cluster assumption should be; the larger the value, the more strongly the algorithm avoids selecting nodes near previously selected samples over the graph. Note that μ is inherited from the LLGC[2] algorithm (Zhou et al., 2004), i.e., the label propagation algorithm that Gu and Han's algorithm is based on. From the optimization viewpoint, μ determines the degree of penalization.

Remember that the $score$ has nothing to do with the LP scores described in §2.3. $score$ is used to choose nodes used for training in the graph-based non-interactive active learning. LP scores are later used for classification by label propagation algorithms that use the chosen training nodes. Throughout this paper, when we mean LP scores, we explicitly write "LP scores". All the other scores mean $score$.

[2]Learning with Local and Global Consistency.

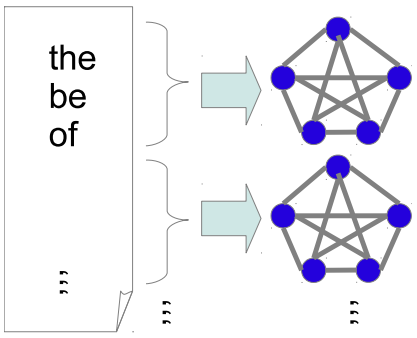

Figure 1: Converting frequency list into multiple-complete graph.

3 Formalizing heuristic word sampling as graph-based active learning

Figure 1 shows how to formalize a word frequency list into a multiple complete graph. The word frequency list is split into clusters, and each cluster forms a complete graph. Each node in a graph corresponds to a word. By gathering all the complete graphs, a multiple complete graph can be formed.

Multiple complete graph $\mathcal{G}_{T,n}$ is defined as a graph of T complete graphs, each of which consists of n nodes fully connected within the n nodes. An example of a multiple complete graph can be seen in Figure 2. We can define the $Tn \times Tn$ adjacency matrix for multiple complete graphs. $\mathbf{W}^{\text{complete}}_{\text{all}}$ is defined as follows:

$$\mathbf{W}^{\text{complete}}_{\text{all}} \stackrel{\text{def}}{=} \begin{pmatrix} \mathbf{W}^{\text{complete}} & 0 & \cdots & 0 \\ 0 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & \mathbf{W}^{\text{complete}} \end{pmatrix} \quad (4)$$

$$\mathbf{W}^{\text{complete}} \stackrel{\text{def}}{=} \begin{pmatrix} 0 & 1 & \cdots & 1 & 1 \\ 1 & 0 & 1 & \cdots & 1 \\ \vdots & 1 & \ddots & & \vdots \\ 1 & \vdots & & \ddots & 1 \\ 1 & 1 & \cdots & 1 & 0 \end{pmatrix} \quad (5)$$

We can see that $\mathbf{W}^{\text{complete}}_{\text{all}}$ is a block-diagonal matrix where each block is a $n \times n$ matrix, $\mathbf{W}^{\text{complete}}$.

Heuristic word sampling can be rewritten into non-interactive active learning on graphs. Suppose there are T groups, each of which has n words, and we want to sample n_0 words from each. In

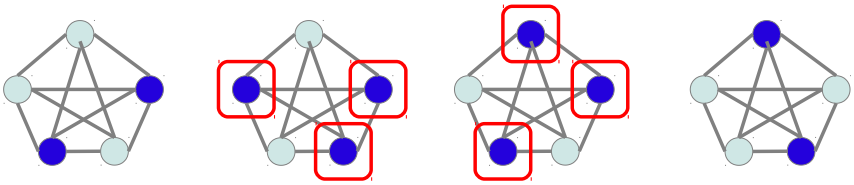

Figure 2: Example of multi-complete graph, where Theorem 3.1 holds true. Here, $T = 4$, $n = 5$, and $k = 10$; 10 light blue (light) nodes have already been sampled, and 10 blue (dark) nodes remain; the 11-th node is sampled uniformly randomly from the nodes within the red rectangles.

heuristic word sampling, for each group from T groups, n_0 words are sampled from the n words in the group uniformly randomly. Thus, there are Tn_0 words in total.

Since heuristic word sampling takes a node from each of the T groups, T concurrent sampling processes are involved. For simplicity, we further express the same sampling using only one sampling process from the entire graph as follows:

- For every round, we sample words uniformly randomly from the remaining words of the groups where the number of samples selected in previous rounds is least.

Figure 2 shows an example of this sampling process. Here, the second and third groups from the left are the groups in which the number of previously selected nodes is the least. This is because they have only two previously selected nodes, while the others have three. Thus, in the figure, the remaining words of the groups are the nodes with red rectangles. Randomly sampling one node from the nodes with red rectangles means sampling a node from the second or third group. We call the set of nodes in a graph from which samples will be taken in the next round a *seed pool*. Thus, in Figure 2, the set of nodes with red rectangles is the seed pool. Nodes that have already been sampled are taken out of the current seed pool.

Next, we more formally explain the seed pool concept. We start sampling nodes from a multiple complete graph via the algorithm presented by Gu and Han. The initial seed pool is set to all nodes in the graph, i.e., $\mathcal{V}$. We sample one node in each round; thus, $k \leq |\mathcal{V}|$ nodes are selected by the k-th round. Let $t \leq T$ be the index of the complete graph in the multiple complete graph. Then, the following theorem holds with ϵ being a small positive value that substitutes the 0 eigenvalues in the eigen decomposition.

Theorem 3.1 *Let* $0 < \epsilon < 1$ *and* $n \in \{2, 3, 4, \ldots\}$. *Then, among* T *complete graphs,* $k \mod T$ *complete graphs have* $\lfloor \frac{k}{T} \rfloor + 1$ *samples, and the remaining graphs have* $\lfloor \frac{k}{T} \rfloor$ *samples*[3]. *Moreover, the* $(k+1)$*-th sample is taken uniformly randomly from the remaining complete graphs.*

In Theorem 3.1, $\epsilon > 0$ is a substitute for the 0 eigenvalue of $\mathbf{L_W}$ [4]. Since ϵ is a substitute for the 0 eigenvalue, it is rational to assume $1 > \epsilon$. Also, remember that n is the number of nodes in one complete graph. The algorithm stops when $k = Tn_0 + 1$, i.e., at the $Tn_0 + 1$-th round when there are no remaining nodes to sample. Figure 2 shows an example of Theorem 3.1.

A proof of this theorem is presented in the supplementary material. Briefly, in a multiple complete graph, the score of a node depends only on the complete graph or the cluster that the node belongs to. Thus, we only have to consider one complete graph in which k is the number of nodes that have been already chosen. Then, mathematical induction proves that, within one complete graph, all the not-yet-chosen nodes have the same $score(k, i)$. Second, we have to show that the score always decreases by taking a sample, i.e., $score(k, i) > score(k+1, i)$. By a long but straightforward calculation, we can express $score(k, i)$ by using only μ, ϵ, n, and k. Then, by substituting the formula to $score(k, i)$, we obtain $score(k, i) - score(k+1, i) > 0$.

4 Extending Graphs

In the previous section, we explained how to formalize heuristic word sampling as active learning on multiple complete graphs. This formaliza-

[3] Here, both k and T are non-negative integers. Thus, $k\%T$ denotes the remainder of the division of k by T, and $\lfloor \frac{k}{T} \rfloor$ is the quotient of the division.

[4] In Gu and Han's algorithm, they substitute the 0 eigenvalue with a small positive value ϵ, and they set $\epsilon = 10^{-6}$.

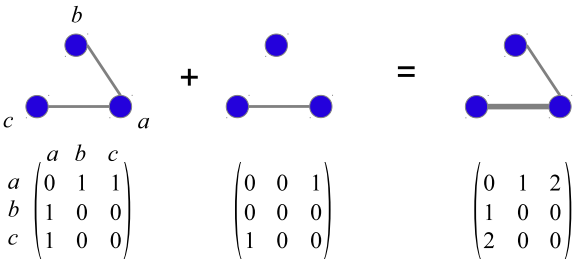

Figure 3: Example of merging two graphs.

tion can lead to better active learning by extending these graphs. In this section, we describe such graph extensions.

We extend graphs by *merging* graphs. Figure 3 shows how to merge graphs. We define "merging" two weighted graphs as creating a weighted graph whose adjacency matrix is the sum of the two adjacency matrices of the two weighted graphs. This suggests that an edge of the merged graph is simply the sum of the corresponding edges of the two weighted graphs.

The merged graph is expected to inherit the characteristics of its original graphs. Thus, applying graph-based active learning to the merged graph is expected to sample nodes in accordance with the characteristics of its original graphs. For example, if we merge a graph representing domain-specific relations and a multiple complete graph representing difficulty grouping of words, active learning from the resulting merged graph is expected to sample words considering both domain specificity and difficulty grouping of words.

For another example, suppose we merge two multiple complete graphs created from frequency lists from two different corpora. Then, active learning from the resulting merged graph is expected to sample words taking into account frequency lists from both corpora.

5 Evaluation

We evaluate our proposed method both quantitatively and qualitatively. In the quantitative evaluation, we measure the prediction accuracy of graphs. Note that the heuristic word sampling method is identical to using Gu and Han's algorithm with a multiple complete graph; however, our proposed graphs have enriched relations between words. In the qualitative evaluation, we explain in detail what words are appropriate as training examples for vocabulary prediction by presenting sampled examples.

5.1 Quantitative evaluation

To evaluate the accuracy of vocabulary prediction, we used the dataset that Ehara et al. (2010) and Ehara et al. (2012) used. This dataset was gleaned from questionnaires answered by 15 English as a second language (ESL) learners. Every learner was asked to answer how well he/she knew 11,999 English words. The data was collected in January 2009. One learner was unpaid, whereas the other 15 learners were paid. We used the data from the 15 paid learners since the data from the unpaid learner was noisy. Most of the learners were native Japanese speakers and graduate students. Because most of the learners in this dataset were native Japanese speakers, words from SVL 12,000 (SPACE ALC Inc., 1998) were used for the learners in this dataset. Note that SVL 12,000 is a collection of 12,000 words that are deemed important for Japanese learners of English, as judged by native English teachers.

Next, we required frequency lists for the words that appeared in the dataset. To create frequency lists, lemmatization is important because the number of word types depends on the method used to lemmatize the words. Note that in the field of vocabulary measurement, lemmatization is mainly performed by ignoring conjugation (Nation and Beglar, 2007). Lemmatizing the dataset resulted in a word list of 8,463 words. We adjusted the size of the word list to a round 8,000 by removing 463 randomly chosen words. Note that all constituent words were labeled by the 15 ESL learners.

We created the following four graphs by spanning edges among the $8,000$ words.

BNC multi-complete This graph corresponds to heuristic word sampling and served as our baseline. It is a multiple complete graph comprising eight complete graphs, each of which consisted of 1,000 words based on the sorted frequency list from the British National Corpus (BNC). We chose the BNC because the method presented by Nation and Beglar was based on it (Nation and Beglar, 2007). Note that all edge weights are set to 1.

BNC+domain To form this graph, edges representing domain specificity are added to the "BNC multi-complete" graph. For domain specificity, we used domain information

from WordNet 3.0.[5] First, we extracted 102 domain-specific words under the "computer" domain among the 8,000 words and created a complete graph consisting of these domain-specific words. The edge weights of the complete graph were set to 1. Next, we simply *merged*[6] the complete graph consisting of the domain-specific words with the "BNC multi-complete" graph.

BNC+COCA In addition to the "BNC multi-complete" graph, edges based on another corpus, the Corpus of Contemporary American English (COCA), were introduced. We first created the COCA multi-complete graph, a multiple complete graph consisting of eight complete graphs, each of which consisted of 1,000 words based on the sorted frequency list using COCA. The edge weights of the COCA multi-complete graph were set to 1. Next, we merged the BNC multi-complete and COCA multi-complete graphs to form the "BNC + COCA graph".

BNC+domain+COCA This graph is the graph produced by merging the "BNC + domain" and "BNC + COCA" graphs.

Note that our experiment setting differed from the usual label propagation setting used for semi-supervised learning because the purpose of our task differed. In the usual label propagation setting, the "test" nodes (data) are prepared separately from the training nodes to determine how accurately the algorithm can classify *forthcoming* or *unseen* nodes. However, in our setting, there were no such forthcoming words. Of course, there will always be words that do not emerge, even in a large corpus; however, such rare words are too difficult for language learners to identify, and many are proper nouns, which are not helpful for measuring the vocabulary of second language learners.

Therefore, our focus here is to measure how well the learners know a fixed set of words, that is, the given 8,000 words. Even if an algorithm can achieve high accuracy for words outside this fixed set, we have no way of evaluating it using the pooled annotations. Here, we want to measure, from a fixed number of samples (e.g., 50), how accurately an algorithm can predict a learner's vocabulary for the entire 8,000 words. Thus, we define accuracy to be the number of words that each algorithm finds correctly divided by the vocabulary size. We set hyper-parameter μ to 0.01 as Gu and Han (2012) did. Note that this hyper-parameter is reportedly not sensitive to accuracy (Zhou et al., 2011).

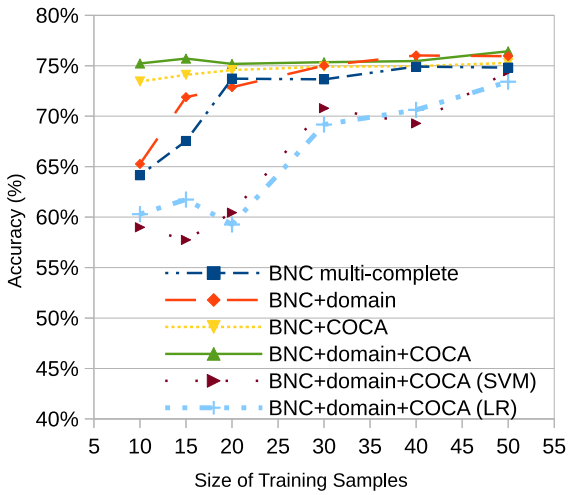

Figure 4: Results of our quantitative experiments. Vertical axis denotes accuracy, and horizontal axis shows number of samples, i.e., training words.

Figure 4 and Table 1 show the results of the experiment over the different datasets. The vertical axis in the figure denotes accuracy, whereas the horizontal axis denotes the number of samples, i.e., training words. Note that the accuracy is averaged over 15 learners and that LLGC is used for classification unless otherwise specified. For example, "BNC multi-complete" indicates that samples taken from the BNC multi-complete graph are used for training, and LLGC is used for classification. Note that "BNC + domain + COCA (SVM)" uses a support vector machine (SVM) for classification, and "BNC + domain + COCA (LR)" uses logistic regression (LR) for classification. Among many supervised machine learning methods, we chose SVM and LR because SVM is widely used in the NLP community, and LR was used for theoretical reasons (Ehara et al., 2012; Ehara et al., 2013).

SVM and LR require features of a word for classification while LLGC requires a weighted graph of words. Since the graph "BNC+domain+COCA" is made from three features, namely the word frequencies of BNC

[5]We used the NLTK toolkit http://nltk.org/ to extract the domain information.

[6]Definition of how to *merge* two graphs is in §4.

Table 1: Results of our quantitative experiments. LLGC is used for classification unless otherwise specified. Bold letters indicate top accuracy. Asterisks (*) indicate that values are statistically significant against baseline, heuristic sampling, i.e., "BNC multi-complete" (using sign test $p < 0.01$).

	10	15	20	30	40	50
BNC multi-complete	64.15 (%)	67.54	73.73	73.66	74.92	74.82
BNC+domain	65.27	71.88	72.88	75.02	**76.03** *	75.95
BNC+COCA	73.45	74.10	74.57	74.90	74.96	75.29
BNC+domain+COCA	**75.23** *	**75.71** *	**75.18** *	**75.35** *	75.47	**76.44** *
BNC+domain+COCA (SVM)	58.99	57.74	60.44	70.79	69.29	74.46
BNC+domain+COCA (LR)	60.29	61.74	59.27	69.17	70.63	73.42

and COCA corpora and whether a word is in the computer domain, we used these features for the features of SVM and LR in this experiment for a fair comparison. When using word frequencies for features, we used the logarithm of raw frequencies since it is reported to work well (Ehara et al., 2013). SVM and LR are also known to heavily depend on a hyper-parameter called C, which determines the strength of regularization. We tried $C = 0.1, 0.5, 1.0, 2.0, 5.0, 10.0, 20.0, 50.0,$ and 100.0 for each of SVM and LR where the size of training data is 50 and chose the C value that performs best. As a result, we set $C = 5.0$ for SVM and $C = 50.0$ for LR. Note that this setting is advantageous for SVM and LR compared to LLGC because the hyper-parameters of SVM and LR are tuned while LLGC's hyper-parameter remains untuned. For the implementation of SVM and LR, we used the "scikit-learn" package in Python [7].

We first observed that our proposed methods constantly outperform the baseline, heuristic word sampling, i.e., "BNC multi-complete" in Table 1. This indicates that we successfully obtained better accuracy by formalizing heuristic word sampling as active learning and extending graphs. In Table 1, the accuracy of the top-ranked methods (shown using **bold** letters) is statistically significantly better than the accuracy of "BNC multi-complete" (using the sign test $p < 0.01$).

We then observed that "BNC multi-complete" and "BNC + domain" show competitive accuracy with sample sizes from 10 to 20; furthermore, "BNC + domain" is slightly better than "BNC multi-complete" with sample sizes ranging from 30 to 50 (statistically significant $p < 0.01$ using sign test). Next, we note that there is a trade-off between domain and word frequency when choosing samples. More specifically, if we select too many words from the domain, the measurement of the general English ability of learners can be inaccurate; conversely, if we select too many words from the corpus-based word frequency list, while the general English ability of learners is accurately measured, we may obtain no information on the learner's vocabulary for the targeted domain. The competitive or slightly better accuracy of "BNC + domain" over "BNC multi-complete" shows that "BNC + domain" could successfully integrate domain information into the frequency-based groups without deteriorating measurements of general English ability.

We also observe that "BNC + COCA" greatly outperforms "BNC multi-complete" when the number of samples is 10. This shows that the integration of the two corpora, BNC and COCA (i.e., "BNC + COCA"), successfully increases the accuracy when there are only a small number of samples.

"BNC + domain + COCA" achieves the best accuracy of all the graphs except when the number of samples is 40. This indicates that the domain information and the information from the COCA corpus helped one another to improve the accuracy because "BNC + domain" and "BNC + COCA" introduce different types of domain information into "BNC multi-complete."

Finally, we observe that "BNC + domain + COCA (SVM)" and "BNC + domain + COCA (LR)" perform worse than LLGC over the same dataset for all sample sizes, particularly when the size of the training data is small. Since LLGC is a semi-supervised classifier while SVM and LR are not, SVM and LR perform poorly for small amounts of training data. This result shows that LLGC is appropriate for this task compared to SVM because, in this task, an increase in the size

[7] http://scikit-learn.org/stable/

Table 2: Computer-related samples in top 30 samples.

Name	Num. of Samples	Examples
BNC multi-complete	0	-
BNC+domain	5	input, client, field, background, register
BNC+COCA	0	-
BNC+domain +COCA	3	drive, client, command

of training data directly leads to an increased burden on the human learners.

5.2 Qualitative evaluation

In this subsection, we qualitatively evaluate our results to determine the types of nodes that are sampled when domain specificity is introduced. Specifically, we evaluate what words are selected as samples in the "BNC + domain" graph.

As noted above, in the "BNC + domain" graph, the computer science domain is introduced into "BNC multi-complete" to measure learners' vocabulary with a specific emphasis on the computer science domain. Thus, it is desirable that some words in the computer science domain are sampled from the "BNC + domain" graph; otherwise, we need to predict the learners' vocabulary for the computer science domain from general words rather than those in the computer science domain, which is extremely difficult.

Table 2 shows the number of words in the computer science domain sampled in the first 30 samples. Note that only "BNC + domain" and "BNC + domain + COCA" select samples from the computer science domain. This indicates that in the other two methods, to measure vocabulary with an emphasis on the computer science domain, we need to predict learners' vocabulary from the general words, which is almost impossible with only 30 samples. Furthermore, it is interesting to note that "BNC + domain" and "BNC + domain + COCA" select different samples from the computer science domain, except for the word "client," although originally the same computer science domain wordlist was introduced to both graphs.

Since "BNC + domain" achieves competitive or slightly better accuracy than "BNC multi-complete" in the quantitative analysis and the qualitative analysis, we conclude that our method can successfully introduce domain specificity into the sampling methodology without reducing accuracy.

6 Conclusion

In this study, we propose a novel sampling framework that measures the vocabulary of second language learners. We call existing sampling methods heuristic sampling. This approach to sampling ranks words from a single corpus by frequency and creates groups of 1,000 words. Next, tens of words are sampled from each group. This method assumes that the relative difficulty of all 1,000 words is the same.

In this paper, we introduce a novel sampling method by showing that the existing heuristic sampling approach is simply a special case of a graph-based active learning algorithm by Gu and Han (2012) applied to a special graph. We also propose a method to extend this graph to enable us to handle domain specificity of words and multiple corpora, which are difficult or impossible to handle using current methods.

We evaluate our method both quantitatively and qualitatively. In our quantitative evaluation, the proposed method achieves higher prediction accuracy compared with the current approach to vocabulary prediction. This suggests that our proposed method can successfully make use of domain specificity and multiple corpora for predicting vocabulary. In our qualitative evaluation, we examine the words sampled by our proposed method and observe that targeted domain-specific words are successfully sampled.

For our future work, because the graph used in this paper was constructed manually, we plan to automatically create a graph suitable for active learning and classification. There are several algorithms that create graphs from feature-based representations of words, but these have never been used for active learning of this task.

Abstract

Language transfer, the characteristic second language usage patterns caused by native language interference, is investigated by Second Language Acquisition (SLA) researchers seeking to find overused and underused linguistic features. In this paper we develop and present a methodology for deriving ranked lists of such features. Using very large learner data, we show our method's ability to find relevant candidates using sophisticated linguistic features. To illustrate its applicability to SLA research, we formulate plausible language transfer hypotheses supported by current evidence. This is the first work to extend Native Language Identification to a broader linguistic interpretation of learner data and address the automatic extraction of underused features on a per-native language basis.

1 Introduction

It has been noted in the linguistics literature since the 1950s that speakers of particular languages have characteristic production patterns when writing in a second language. This language transfer phenomenon has been investigated independently in a number of fields from different perspectives, including qualitative research in Second Language Acquisition (SLA) and more recently though predictive computational models in NLP.

Motivated by the aim of improving foreign language teaching and learning, such analyses are often done manually in SLA, and are difficult to perform for large corpora. Smaller studies yield poor results due to the sample size, leading to extreme variability (Ellis, 2008). Recently, researchers have noted that NLP has the tools to use large amounts of data to automate this analysis, using complex feature types. This has motivated studies in Native Language Identification (NLI), a subtype of text classification where the goal is to determine the native language (L1) of an author using texts they have written in a second language (L2) (Tetreault et al., 2013).

Despite the good results in predicting L1s, few attempts have been made to interpret the features that distinguish L1s. This is partly because no methods for an SLA-oriented feature analysis have been proposed; most work focuses on testing feature types using standard machine learning tools.

The overarching contribution of this work is to develop a methodology that enables the transformation of the NLI paradigm into SLA applications that can be used to link these features to their underlying linguistic causes and explanations. These candidates can then be applied in other areas such as remedial SLA strategies or error detection.

2 Related Work

SLA research aims to find distributional differences in language use between L1s, often referred to as **overuse**, the extensive use of some linguistic structures, and **underuse**, the underutilization of particular structures, also known as *avoidance* (Gass and Selinker, 2008). While there have been some attempts in SLA to use computational approaches on small-scale data,[1] these still use fairly elementary techniques and have several shortcomings, including in the manual approaches to annotation and the computational artefacts derived from these.

Conversely, NLI work has focused on automatic learner L1 classification using Machine Learning with large-scale data and sophisticated linguistic features (Tetreault et al., 2012). Here, feature ranking could be performed with relevancy methods such as the F-score:

[1] E.g. Chen (2013), Lozanó and Mendikoetxea (2010) and Diéz-Bedmar and Papp (2008).

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1385–1390,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

$$F(j) \equiv \frac{\left(\bar{x}_j^{(+)} - \bar{x}_j\right)^2 + \left(\bar{x}_j^{(-)} - \bar{x}_j\right)^2}{\frac{1}{n_+-1}\sum_{i=1}^{n_+}\left(x_{i,j}^{(+)} - \bar{x}_j^{(+)}\right)^2 + \frac{1}{n_--1}\sum_{i=1}^{n_-}\left(x_{i,j}^{(-)} - \bar{x}_j^{(-)}\right)^2} \quad (1)$$

The F-score (Fisher score) measures the ratio between the intraclass and interclass variance in the values of feature j, where x represents the feature values in the negative and positive examples.[2] More discriminative features have higher scores.

Another alternative method is Information Gain (Yang and Pedersen, 1997). As defined in equation (2), it measures the entropy gain associated with feature t in assigning the class label c.

$$\begin{aligned} G(t) \;=\; & -\; \textstyle\sum_{i=1}^{m} \Pr(c_i) \log \Pr(c_i) \\ & +\; \Pr(t) \textstyle\sum_{i=1}^{m} \Pr(c_i|t) \log \Pr(c_i|t) \\ & +\; \Pr(\bar{t}) \textstyle\sum_{i=1}^{m} \Pr(c_i|\bar{t}) \log \Pr(c_i|\bar{t}) \end{aligned} \quad (2)$$

However, these methods are limited: they do not provide ranked lists per-L1 class, and more importantly, they do not explicitly capture underuse.

Among the efflorescence of NLI work, a new trend explored by Swanson and Charniak (2014) aims to extract lists of candidate language transfer features by comparing L2 data against the writer's L1 to find features where the L1 use is mirrored in L2 use. This allows the detection of obvious effects, but Jarvis and Crossley (2012) note (p. 183) that many transfer effects are "too complex" to observe in this manner. Moreover, this method is unable to detect underuse, is only suitable for syntactic features, and has only been applied to very small data (4,000 sentences) over three L1s. Addressing these issues is the focus of the present work.

3 Experimental Setup

3.1 Corpus

We use TOEFL11, the largest publicly available corpus of English L2 texts (Blanchard et al., 2013), containing 11 L1s with 1,100 texts each.[3]

3.2 Features

Adaptor grammar collocations Per Wong et al. (2012), we utilize an adaptor grammar to discover arbitrary length n-gram collocations. We explore both the pure part-of-speech (POS) n-grams as well as the more promising mixtures of POS and function words. We derive two adaptor grammars where each is associated with a different set of vocabulary: either pure POS or the mixture of POS and function words. We use the grammar proposed by Johnson (2010) for capturing topical collocations:

$Sentence \rightarrow Doc_j$	$j \in 1, \ldots, m$
$Doc_j \rightarrow \_j$	$j \in 1, \ldots, m$
$Doc_j \rightarrow Doc_j\ Topic_i$	$i \in 1, \ldots, t;$
	$j \in 1, \ldots, m$
$\underline{Topic_i} \rightarrow Words$	$i \in 1, \ldots, t$
$\overline{Words} \rightarrow Word$	
$Words \rightarrow Words\ Word$	
$Word \rightarrow w$	$w \in V_{pos};$
	$w \in V_{pos+fw}$

V_{pos} contains 119 distinct POS tags based on the Brown tagset and V_{pos+fw} is extended with 398 function words. The number of topics t is set to 50. The inference algorithm for the adaptor grammars are based on the Markov Chain Monte Carlo technique made available by Johnson (2010).[4]

Stanford dependencies We use Stanford dependencies as a syntactic feature: for each text we extract all the basic dependencies returned by the Stanford Parser (de Marneffe et al., 2006). We then generate all the variations for each of the dependencies (grammatical relations) by substituting each lemma with its corresponding POS tag. For instance, a grammatical relation of `det(knowledge, the)` yields the following variations: `det(NN, the)`, `det(knowledge, DT)`, and `det(NN, DT)`.

Lexical features Content and function words are also considered as two feature types related to learner's vocabulary and spelling.

3.3 Extracting Linear SVM Feature Weights

Using the extracted features, we train linear Support Vector Machine (SVM) models for each L1. We use a one-vs-rest approach to find features most relevant to each native language. L2-regularization is applied to remove noisy features and reduce the size of the candidate feature list. More specifically, we employ the LIBLINEAR SVM package (Fan et al., 2008)[5] as it is well-suited to text classification tasks with large numbers of features and texts as is the case here.

[2] See Chang and Lin (2008) for more details.

[3] Over 4 million tokens in 12,100 texts.

[4] http://web.science.mq.edu.au/%7Emjohnson/Software.htm

[5] http://www.csie.ntu.edu.tw/%7Ecjlin/liblinear/

In training the models for each feature, the SVM weight vector[6] is calculated according to (3):

$$\mathbf{w} = \sum_i \alpha_i y_i \mathbf{x}_i \quad (3)$$

After training, the positive and negative weights are split into two lists and ranked by weight. The positive weights represent overused features, while features whose absence (i.e. underuse) is indicative of an L1 class will have large negative weights. This yields two candidate language transfer feature lists per L1.

4 Results

We now turn to an analysis of the output from our system to illustrate its applicability for SLA research. Table 1 lists some elements from the underuse and overuse lists for various L1s. The lists are of different feature types. They have been chosen to demonstrate all feature types and also a variety of different languages. For reasons of space, only several of the top features are analysed here.

Hindi L1 writers are distinguished by certain function words including *hence*, *thus*, and *etc*, and a much higher usage rate of male pronouns. It has been observed in the literature (Sanyal, 2007, for example) that the English spoken in India still retains characteristics of the English that was spoken during the time of the Raj and the East India Company that have disappeared from other English varieties, so it sounds more formal to other speakers, or retains traces of an archaic business correspondence style; the features noted fit that pattern.

The second list includes content words overused by Arabic L1 learners. Analysis of content words here, and for other L1s in our data, reveals very frequent misspellings which are believed to be due to orthographic or phonetic influences (Tsur and Rappoport, 2007; Odlin, 1989). Since Arabic does not share orthography with English, we believe most of these are due to phonetics. Looking at items 1, 3 and 5 we can see a common pattern: the English letter *u* which has various phonetic realizations is being replaced by a vowel that more often represents that sound. Items 2 and 5 are also phonetically similar to the intended words.

For Spanish L1 authors we provide both underuse and overuse lists of syntactic dependencies. The top 3 overuse rules show the word *that* is very often used as the subject of verbs. This is almost certainly a consequence of the prominent syntactic role played by the Spanish word *que* which, depending on the context, is equivalent to the English words *whom*, *who*, *which*, and most commonly, *that*. The fourth rule shows they often use *this* as a determiner for plural nouns. A survey of the corpus reveals many such errors in texts of Spanish learners, e.g. *this actions* or *this emissions*. The fifth rule shows that the adjectival modifier of a plural noun is often being incorrectly pluralised to match the noun in number as would be required in Spanish, for example, *differents subjects*.

Turning to the underused features in Spanish L1 texts, we see that four related features rank highly, showing that *these* is not commonly used as a determiner for plural nouns and *which* is rarely used as a subject. The final feature shows that *no* is avoided as a determiner. This may be because while *no* mostly has the same role in Spanish as it does in English, it cannot be used as a determiner; *ningún* must be used instead. We hypothesize that this construction is being avoided as placing *no* before a noun in Spanish is ungrammatical. This example demonstrates that our two list methodology can not only help identify overused structures, but also uncovers the related constructs that are being underutilized at their expense.

The final list in Table 1 is of underused Adaptor Grammar patterns by Chinese learners. The first three features show that these writers significantly underuse determiners, here *an*, *other* and *these* before nouns. This is not unexpected since Chinese learners' difficulties with English articles are well known (Robertson, 2000). More interestingly, we find underuse of features like *even if* and *might*, along with others not listed here such as *could* VB[7] plus many other variants related to the subjunctive mood. One explanation is that linguistic differences between Chinese and English in expressing counterfactuals could cause them to avoid such constructions in L2 English. Previous research in this area has linked the absence of subjunctive linguistic structures in Chinese to different cognitive representations of the world and consequences for thinking counterfactually (Bloom, 2014), although this has been disputed (Au, 1983; Garbern Liu, 1985).

Adaptor Grammars also reveal frequent use of the "existential there"[8] in German L1 data while

[6] See Burges (1998) for a detailed explanation.

[7] e.g. *could be*, *could have*, *could go* and other variants

[8] e.g. *There is/are ...*, as opposed to the locative *there*.

Overuse			Underuse	
Hindi	Arabic	Spanish	Spanish	Chinese
#2: thus	#2: anderstand	#1: nsubj(VBP,that)	#2: det(NNS,these)	#12: *an* NN
#4: hence	#4: mony	#2: nsubj(VBZ,that)	#3: nsubj(VBZ,which)	#16: *other* NN
#22: his	#6: besy	#3: nsubj(VB,that)	#6: nsubj(VB,which)	#18: *these* NNS
#30: etc	#15: diffrent	#4: det(NNS,this)	#7: nsubj(VBP,which)	#19: *even if*
#33:rather	#38: seccessful	#25: amod(NNS,differents)	#10: det(NN,no)	#68: *might*

Table 1: Example transfer candidates and rankings from the overuse/underuse lists for various L1s and features types, in order: Hindi function words, Arabic content words, Spanish dependencies (2) and Chinese Adaptor Grammars.

English	**Spanish**	**English**	**Spanish**
diferent	diferente	conclution	conclusión
consecuence	consecuencia	desagree	Neg. affix *des-*
responsability	responsabilidad	especific	específico
oportunity	oportunidad	necesary	necesario

Table 2: Highly ranked English misspellings of Spanish learners and their Spanish cognates.

they are highly underused in French L1 data. The literature supports our data: The German equivalent *es gibt* is common while French use is far more constrained (Cappelle and Loock, 2013).

Lexical analysis also revealed Spanish–English orthographic transfer, listed in Table 2. This list includes many cognates, in contrast with the Arabic L1 data where most misspellings were phonetic in nature.

We also observe other patterns which remain unexplained. For instance, Chinese, Japanese and Korean speakers make excessive use of phrases such as *however*, *first* and *second*. One possibility is that this relates to argumentation styles that are possibly influenced by cultural norms. More broadly, this effect could also be teaching rather than transfer related. For example, it may be case that a widely-used text book for learning English in Korea happens to overuse this construction.

Some recent findings from the 2013 NLI Shared Task found that L1 Hindi and Telugu learners of English had similar transfer effects and their writings were difficult to distinguish. It has been posited that this is likely due to shared culture and teaching environments (Malmasi et al., 2013).

Despite some clearcut instances of overuse,[9] more research is required to determine the causal factors. We hope to expand on this in future work using more data.

[9]More than half of the Korean scripts contained a sentence-initial *however*.

5 Discussion and Conclusion

Using the proposed methodology, we generated lists of linguistic features overused and underused by English learners of various L1 backgrounds. Through an analysis of the top items in these ranked lists, we demonstrated the high applicability of the output by formulating plausible language transfer hypotheses supported by current evidence. We also showcased the method's generalizability to numerous linguistic feature types.

Our method's output consists of two ranked lists of linguistic features: one for overuse and the other for underuse, something which had not been addressed by research to date. We also found Adaptor Grammar collocations to be highly informative for this task.

This work, an intersection of NLP, Machine Learning and SLA, illustrates how the various disciplines can complement each other by bringing together theoretical, experimental and computational issues. NLP provides accurate and automated tagging of large corpora with sophisticated features not available in corpus linguistics, e.g. with state-of-the-art dependency parsing. Sophisticated machine learning techniques then enable the processing of large quantities of data (thousands of times the size of manual studies) in a way that will let SLA researchers explore a variety of assumptions and theoretical analyses. And conversely, NLP can benefit from the long-term study and language acquisition insights from SLA.

In terms of NLI, this work is the first attempt to expand NLI to a broad linguistic interpretation of the data, including feature underuse. NLI systems achieve classification accuracies of over 80% on this 11-class task, leading to theoretical questions about the features that make them so effective. This work also has a backwards link in this regard by providing qualitative evidence about the underpinning linguistic theories that make NLI work.

The work presented here has a number of applications; chief among them is the development of tools for SLA researchers. This would enable them to not just provide new evidence for previous findings, but to also perform semi-automated data-driven generation of new and viable hypotheses. This, in turn, can help reduce expert effort and involvement in the process, particularly as such studies expand to more corpora and emerging language like Chinese (Malmasi and Dras, 2014b) and Arabic (Malmasi and Dras, 2014a).

The brief analysis included here represents only a tiny portion of what can be achieved with this methodology. We included but a few of the thousands of features revealed by this method; practical SLA tools based on this would have a great impact on current research.

In addition to language transfer hypotheses, such systems could also be applied to aid development of pedagogical material within a needs-based and data-driven approach. Once language use patterns are uncovered, they can be assessed for teachability and used to create tailored, L1-specific exercises and teaching material.

From the examples discussed in Section 4 these could include highly specific and targeted student exercises to improve spelling, expand vocabulary and enrich syntactic knowledge — all relative to their mother tongue. Such exercises can not only help beginners improve their fundamental skills and redress their errors but also assist advanced learners in moving closer to near-nativeness.

The extracted features and their weights could also be used to build statistical models for grammatical error detection (Leacock et al., 2014). Contrary to the norm of developing error checkers for native writers, such models could be specifically targeted towards learners or even particular L1–L2 pairs which could be useful in Computer-Assisted Language Learning (CALL) systems.

One limitation here is that our features may be corpus-dependent as they are all exam essays. This can be addressed by augmenting the data with new learner corpora, as they become available. While a strength here is that we compared each L1 against others, a paired comparison only against native texts can be insightful too.

There are several directions for future work. The first relates to clustering the data within the lists. Our intuition is that there might be coherent clusters of related features, with these clusters characterising typical errors or idiosyncrasies, that are predictive of a particular L1. As shown in our results, some features are highly related and may be caused by the same underlying transfer phenomena. For example, our list of overused syntactic constructs by Spanish learners includes three high ranking features related to the same transfer effect. The use of unsupervised learning methods such as Bayesian mixture models may be appropriate here. For parse features, tree kernels could help measure similarity between the trees and fragments (Collins and Duffy, 2001).

Another avenue is to implement weight-based ranking methods to further refine and re-rank the lists, potentially by incorporating the measures mentioned in Section 2 to assign weights to features. As the corpus we used includes learner proficiency metadata, it may also be possible to create proficiency-segregated models to find the features that characterise errors at each language proficiency level. Finally, the use of other linguistic features such as Context-free Grammar phrase structure rules or Tree Substitution Grammars could provide additional insights.

In addition to these further technical investigations, we see as a particularly useful direction the development of an SLA research tool to conduct a large SLA study with a wide range of experts. We believe that this study makes a contribution to this area and hope that it will motivate future work.

Abstract

Languages spoken by immigrants change due to contact with the local languages. Capturing these changes is problematic for current language technologies, which are typically developed for speakers of the standard dialect only. Even when dialectal variants are available for such technologies, we still need to predict which dialect is being used. In this study, we distinguish between the immigrant and the standard dialect of Turkish by focusing on Light Verb Constructions. We experiment with a number of grammatical and contextual features, achieving over 84% accuracy (56% baseline).

1 Introduction

Human languages are in constant evolution, driven in part by contact with other languages (Uriel, 1953; Thomason, 2008). In immigrant contexts, bilingual and multilingual speakers act as agents of change by transmitting borrowed words and expressions across languages (Grosjean, 2014). Depending on social factors such as duration and intensity of contact with the local languages, large-scale spread of borrowed elements could lead to differences between the contact and non-contact dialects of the same language (Winford, 2005). For example, Spanish spoken by immigrants in USA sounds different in comparison to Spanish spoken in South America (Corvalán, 2003).

In this study, we focus on the immigrant dialect of Turkish as spoken in the Netherlands (NL-Turkish), which differs from Turkish spoken in Turkey (TR-Turkish). In contact situations, it is common for verbs to be borrowed across languages and integrated as nominal complements of Light Verb Constructions (LVCs) (Edwards and Gardner-Chloros, 2007; Butt, 2010). NL-Turkish LVCs are changing due to Dutch influence (Doğruöz and Backus, 2007; Doğruöz and Backus, 2009; Doğruöz and Gries, 2012). However, assessing Dutch influence is not always easy since NL-Turkish LVCs still co-exist with the TR-Turkish LVCs. This study aims to automatically identify the features that can distinguish between NL-Turkish and TR-Turkish LVCs.

Our study would benefit Machine Translation systems targeting dialectal variation. It differs from studies concerning the well-established dialectal variations of Arabic, e.g., Levantine, Gulf, Egyptian, Maghrebi (Salloum and Habash, 2012), EU vs. Brazilian Portuguese (Marujo et al., 2011) or Turkish vs. Tatar (Altintas and Cicekli, 2002). In contrast, we are interested in developing language technologies for *immigrant* dialects, which are often understudied and lack written resources due to their unofficial status. When immigrant speakers face communication difficulties (e.g., bureaucratic affairs with the local officials, teacher-parent meetings, doctor-patient conversations) in the local languages (e.g., Dutch) of the host country, they are often provided with translation equivalents in the standard dialect (e.g., TR-Turkish) of their native languages. However, these translations ignore the evolution of the immigrant dialect.[1] By identifying the differences between two dialects of the same variety, we aim to improve Machine Translation systems targeting immigrant speakers. Our contributions are the following:

- We are the first to predict on-going dialect variation in immigrant contexts as opposed to studying established dialect variations.
- We are also the first to compare bilingual LVCs with the monolingual ones across two dialects of the same language.

[1] One of the authors failed the driving test in the Netherlands due to the dialect variation in the Turkish translation.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1391–1395,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

- Our comparison of grammatical versus contextual features reveals context to be much more important.
- We experiment with LVCs extracted from natural spoken data rather than relying on isolated occurences, out of context.

2 Method

We follow Baldwin and Kim (2010) and Butt (2010) in their definitions of LVCs, which state that there is a unity between the nominal and the verbal complements, but the meaning of the verb is somewhat bleached. In this study, we focus on Turkish LVCs with the verbal complements of *yapmak*/*etmek*, which both can be translated as "make/do". LVCs with these verbal complements are undergoing change in NL-Turkish (Doğruöz and Backus, 2009).

We experiment with the following features to predict NL-Turkish vs. TR-Turkish LVCs.

2.1 Nominal Features

In addition to traditional LVCs (e.g. [*ütü yapmak*] "iron do" (to iron) with both complements of Turkish origins), there is also foreign influence on Turkish LVCs. Section 2.1.1 describes the foreign influence on both NL-Turkish and TR-Turkish nominal complements based on their etymological origins.

2.1.1 Influence on Nominal Complements

Dutch Influence In example (1), the Dutch verb *overplaats* is nominalized through the infinitive marker (*-en*) and precedes the Turkish verb *yapmak* to form a Turkish-Dutch bilingual LVC.

Example 1:
O arkadaş [**overplaats-en yap-ıl-acak-tı**.]
That friend [replace-inf[2] do-pass-fut-past].
That friend would have been replaced.

In addition to borrowing nominalized Dutch verbs to form bilingual LVCs, Dutch LVCs are also translated as a chunk into NL-Turkish. These translated LVCs sound unconventional to TR-Turkish speakers (Doğruöz and Gries, 2012). In example (2), the LVC [*sınav yapmak*] "exam do" is a literal translation of the Dutch [*examen doen*] "exam-pl do", which is used to describe how students take high school exams to graduate.

[2]acc: accusative, fut:future, inf:infinitive, past:past tense, part: participle, pres: present tense, pl: plural, poss: possesive, prog:progressive tense, sg: singular

In a similar context, TR-Turkish speakers would have used [*sınav-a girmek*] "exam enter" instead. These LVCs are also classified as having their origins in another language.

Example 2:
Üç gündür [**sınav yap-ıyor-uz**].
Three day [exam do-prog-1pl].
We are having exams for the last three days.

Other Foreign Influences Although Dutch influence is clearly present in NL-Turkish LVCs, TR-Turkish LVCs are also not free of foreign influence. We have come across Arabic, Persian, French and English influences on Turkish LVCs with nominalized foreign verbs or literally translated LVCs as chunks. Example (3) illustrates how a borrowed Arabic verb (*hitap*, "address") is integrated as a nominal complement into a Turkish LVC [*hitap etmek*] "address do".

Example 3:
Hoca-m diye [**hitap edi-yo-z**] biz.
Teacher-poss.1sg like [address do-prog-1pl] we.
We address (him) as the teacher.

Example (4) illustrates how an English LVC [*do sports*] is borrowed into Turkish as a chunk [*spor yapmak*] "sports do".

Example 4:
Yazın [**spor yap-ıyo-z**].
summer spor do-prog-1pl
We do sports in summer.

We have identified the etymological origins of LVCs in both corpora using an online etymological dictionary.[3] Although LVCs of Dutch origin only occur in NL-Turkish, LVCs borrowed from other languages (e.g., Arabic, English, French) occur both in NL-Turkish and in TR-Turkish.

2.1.2 Case Marking

We also came across Turkish [N V] constructions with "*yapmak*" and "*etmek*" where the nominal complement acts as the object of the verb.

Turkish marks the direct objects with accusative case marking if they are definite (Enç, 1991). In example (5), the nominal element is the object of the verb, and thus it has the accusative marker.

Example 5:
Ben kendi [**iş-im-i yap-ıyor-um.**]
I own [work-poss.1sg-acc do-prog-1sg].
I do my own work.

[3]http://www.nisanyansozluk.com/

However, indefinite objects of the verb are left unmarked for case. In example (6), *yapmak* takes an indefinite object (*food*) as the complement. The boundary between [N V] constructions with indefinite nominal objects and LVCs are somewhat blurry. In both cases, the meaning of the verbal complement is bleached out and the nominal complement weighs heavier than the verbal one. We will not dwell further on this subtle distinction, but we plan future work on this topic following Cook et al. (2007) and Vincze et al. (2013).

Example 6:
Bazen [**yemek yap-ar-dı-m**]
Sometimes [food do-pres-past-1sg]
I used to sometimes prepare food.

Since Dutch does not mark objects of the verb morphologically, NL-Turkish speakers have difficulty (e.g., unnecessary addition or omission of case markers) in determining the definiteness of the nominal complements in [N V] constructions (Doğruöz and Backus, 2009). Therefore, we expect this feature to differentiate well between NL-Turkish and TR-Turkish [N V] constructions and LVCs with *yapmak/etmek* as verbal complements.

2.2 Verbal Complements

2.2.1 Finiteness

The verbs in LVCs are assumed to be flexible for inflection (Baldwin and Kim, 2010). However, we know little about how fineteness contributes to the formation of LVCs. To the best of our knowledge, finiteness has not been tested as a feature for identifying LVCs earlier. Therefore, we encoded the finiteness on *yapmak/etmek* as a binary (yes/no) feature in both data sets. Example (7) illustrates a non-finite LVC where the verb stem (*et*) is accompanied with an infinitive marker (*-mek*).

Example 7:
Misafir-ler-e [**ikram et-mek**] için al-dı-k
Guest-pl-dat [serve do-inf.] for buy-past-1pl
We bought (it) to serve the guests.

2.2.2 Type

NL-Turkish speakers could use other light verbs than TR-Turkish speakers for the same LVC construction. In example (8), the NL-Turkish speaker uses [*doğum etmek*] "birth do" instead of [*doğum yapmak*] "birth do", which is commonly preferred by TR-Turkish speakers. To capture this difference between the two dialects, we include the verb type as a feature as well.

Example 8:
Orda kadın [**doğum et-ti**].
There lady [birth do-past].
The lady gave birth there.

2.3 Word Order in LVCs

To the best of our knowledge, the influence of word order in LVCs has not been investigated as a feature. Although Turkish has a relatively flexible constituent order, object-verb (OV) is the most frequent word order for both NL-Turkish and TR-Turkish (Doğruöz and Backus, 2007). NL-Turkish speakers have adopted Dutch word order verb-object (VO) for some syntactic constructions, but we know little about the word order variation for LVCs. Encoding the word order of LVCs as a binary feature (OV vs. VO) could give us clues about differences or similarities of LVC use in NL-Turkish and in TR-Turkish. In example (9), the nominal complement (*one thing*) follows the verbal complement instead of preceding it as seen in earlier examples.

Example 9:
[**Yap-acak bir şey**] yok.
[Do-part. one thing] exist.not
There is nothing to do.

2.4 Context

So far, most studies were carried out ignoring the context of LVCs but focusing on their inherent grammatical features (e.g., lexical, syntactic, semantic or morphological). However, the context of an utterance could potentially provide additional useful cues. Since our data comes from natural conversations, we also experimented with the contextual information (words surrounding LVCs) as a feature for both data sets.

3 Data

Our data comes from spoken NL-Turkish (46 speakers from the Netherlands, 74,461 words) and TR-Turkish (22 speakers from Turkey, 28,731 words) corpora collected by one of the authors. LVC's are automatically extracted from the data using their stem forms ("yap-", "et-" without the infinitive -mEk). Table 1 illustrates the frequency of [N V] constructions with *etmek* and *yapmak* in both data sets.

	# etmek	# yapmak	# Total
NL-Turkish	449	543	992
TR-Turkish	527	755	1282
Total	976	1298	

Table 1: Distribution of *etmek* and *yapmak*.

4 Experiments

Our aim is to build a classifier that can determine whether a particular utterance containing an LVC (with the verbs *yapmak* or *etmek*) is uttered by an NL-Turkish or a TR-Turkish speaker.

We make use the following features in our classifier: (1) words from the context of the LVCs, (2) type of the light verb (*yapmak* or *etmek*), (3) the nominal complements, (4) finiteness of the verb (finite/non-finite), (5) case marking on the nominal complement (yes/no), (6) word order (VO/OV), and (7) etymological origins of the nominal complement (Arabic/Dutch/French/English/Persian/Turkish/mixed).

For the contextual features, we experiment with two models: (a) we distinguish between a word extracted from the context to the left or to the right of the verb (*yapmak* or *etmek*) in the feature space, and (b) we do not make a distinction in terms of context. The reason to experiment with option (a) is due to the potential importance of the word order. While the word order variation is already modeled through feature (6), we also include the context as an additional feature to test its effect. On the down side, adding context doubles the feature space size and could lead to data sparseness issues. For the context words, we did not filter out stopwords since they are part of natural speech.

For our experiments, we used an SVM classifier as implemented in LibSVM. We used a linear kernel; more complex kernels did not help. We report results for a 5-fold cross-validation.

5 Results

Table 2 illustrates the results of our experiments. All models outperform the majority class baseline of always predicting TR-Turkish (which is 56.38% accuracy) by a sizable margin. Furthermore, splitting the context into left/right yields approximately 1.5% absolute drop in accuracy.

	Split the Context?	
Features	**Left vs. Right**	**No Split**
Baseline	56.38	
Full model	**82.81**	**84.30**
no context	70.67	
no nominal complements	82.19	83.64
no info about etymol. origin	82.10	83.99
no finiteness	83.03	84.35
no case marking info	82.76	84.43
no word order info	82.89	84.43
no verb type	82.94	84.39

Table 2: Cross-validation accuracy (5 folds).

The lower part of the table shows the results when turning off each of the feature types. The context seems to be the most important feature since its exclusion leads to a drop from low-to-mid eighties to about 70% accuracy. Except the nominal complements and the information about etymological origins, most other features seem to have marginal impact on accuracy. Excluding the two features (nominal complements and etymological origins) lead to approximately 0.5% absolute drop in accuracy. The impact of the last four features in the table is tiny; excluding some of them even leads to a tiny improvement.

Overall, we can conclude that by far the most important features are the context features (without the left/right context split). The other useful features are the nominal complements and the information about the etymological origin of the borrowed LVCs. The remaining four linguistic features seem to be largely irrelevant.

6 Conclusion and Future Work

Language technologies are usually developed for standard dialects, ignoring the linguistic differences in other dialects such as those in immigrant contexts. One of the reasons for this is the difficulty of assessing and predicting linguistic differences across dialects. This is similar to efforts to translate well-established Arabic dialects (Bakr et al., 2008; Sawaf, 2010), or to adapt between Brazilian and European Portuguese (Marujo et al., 2011), Czech–Slovak (Hajič et al., 2000), Spanish–Portuguese (Nakov and Ng, 2009; Nakov and Ng, 2012), Turkish–Crimean Tatar (Altintas and Cicekli, 2002), Irish–Scottish Gaelic (Scannell, 2006), Bulgarian–Macedonian (Nakov and Tiedemann, 2012), Malay–Indonesian (Wang et al., 2012) or Mandarin–Cantonese (Zhang, 1998).

In this work, we have built a classifier that uses LVCs to differentiate between two different Turkish dialects: standard and immigrant. The results indicate that contextual features are most useful for this task. Although this requires further investigation, we can explain it by the thousands of features context generates: each contextual word is a feature. Thus, it is very hard for our grammatical features to compete against contextual features but they do have an impact.

We are planning to extend our study to dialects in other immigrant settings (e.g., Turkish in Germany) and to other types of multiword expressions (e.g., [N N] compounds).

Device-Dependent Readability for Improved Text Understanding

Abstract

Readability is used to provide users with high-quality service in text recommendation or text visualization. With the increasing use of hand-held devices, reading device is regarded as an important factor for readability. Therefore, this paper investigates the relationship between readability and reading devices such as a smart phone, a tablet, and paper. We suggest readability factors that are strongly related with the readability of a specific device by showing the correlations between various factors in each device and human-rated readability. Our experimental results show that each device has its own readability characteristics, and thus different weights should be imposed on readability factors according to the device type. In order to prove the usefulness of the results, we apply the device-dependent readability to news article recommendation.

1 Introduction

Readability is a function that maps a given text into a readability score by considering "how easily the text is read and understood" (Richards et al., 1992; Zamanian and Heydari, 2012). Normally, the readability score is formulated as a combination of various factors. These factors reflect the easiness and understanding of the text and include text presentation format, font size, average ratio of annotated images, and sentence length (Hasegawa et al., 2008; Kitson, 1927; Ma et al., 2012; Öquist, 2006). Therefore, readability can be used to provide satisfiable services in text recommendation or text visualization.

The study on readability has begun in the education field to measure the level of a text. With the success of using readability in education (François and Fairon, 2012; Heilman et al., 2008; Ma et al., 2012), readability has been used in a range of domains recently. For example, in document retrieval, readability is used to provide documents to non-expert users so that they can read the retrieved documents easily (Jameel et al., 2012; Yan et al., 2006). In text mining, readability has been employed to analyze the characteristics of text. Especially, Hillbom showed the differences in readability between broadsheet newspapers and tabloids that share a similar political stance (Hillbom, 2009).

There is one important issue of readability that has not been studied in natural language processing. It is a reading device. That is, previous studies focused only on text printed on paper. However, with the increasing use of hand-held devices, people in these days use various reading devices such as a tablet and a smart phone as well as a paper. Readability score can be different according to the device type, because each device has its own idiosyncrasy. For example, assume that a system recommends the same news article to both user A who reads it in her smart phone and user B who reads it on paper. Although both users read the same article, user A might believe that her article is more difficult to read than user B because of the screen size of her smart phone.

This paper explores the relationship between reading devices and readability. For this purpose, we first investigate whether readability changes according to device type or not. Then, we analyze which readability factors are affected by reading devices. To see the relationship between readability factors and devices, various well-known readability factors are computed for news articles collected from an Internet portal. At the same time, the readability of each article is also manually rated. When the readability is rated manually, it is done three times for different reading devices of a smart phone, a tablet, and paper. The factors that affect the readability actually in each device are found out through the correlations between the factors and the manually-labeled readability. Some factors are important to the readability of smart phone, but insignificant to that of paper. Therefore, we discover the importance of each readability factor for each device by analyzing the correlations.

The usefulness of the device-dependent readability is proven by applying it to news article recommendation. That is, different importance weights for readability factors are considered according to device type when recommending news articles. Our experimental results show that the performance of news article recommendation gets best when the device used for reading news articles is identical to the device used for measuring readability. Therefore, it is essential to consider different importance weights according to device type

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1396–1404,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

in news article recommendation. It also proves that the proposed device-dependent readability reflects the characteristics of reading devices well.

The rest of this paper is organized as follows. We first review related studies on readability. Next, we introduce various readability factors and propose the device-dependent readability. Then, the news article recommendation using the device-dependent readability is explained. This recommendation is prepared to prove the usefulness of the device-dependent readability. In the experiments, we present the experimental results on the relationship between reading devices and readability. We also describe the experiments on news recommendation using the device-dependent readability and present their results. Finally, we summarize our research.

2 Related work

The history of readability studies began in the 1800s. Early studies focused on the frequency of easy words, sentence length, and word length (Huldén, 2004). Flesch designed a formula to calculate "reading ease" using only the average word length and sentence length (Flesch, 1948). He adjusted the relative importance between word length and sentence length using 100 words selected randomly from a corpus. This formula is called the Flesch-Kincaid formula, and is generally used in measuring the readability of a textbook (Kincaid et al., 1975). Dale and Chall (1949) defined a list of 3,000 easy words. Then, they used the average sentence length and the percentage of words not included in the list. These studies simply used superficial factors, and thus do not reflect syntactic factors.

Recent studies on readability use various factors including syntactic ones, and combine them to produce a highly predictive model of readability. François and Faircon (2012) proposed a readability formula with 46 textual factors for French as a foreign language. The factors represent lexical, syntactic, and semantic characteristics of sentences, and the specificities of French. They are extracted from 28 French Foreign Language (FFL) textbooks written for adults learning FFL. On the other hand, Pitler and Nenkova (2008) showed the relation between readability factors and readability. They used human ratings from the Wall Street Journal corpus, and computed the correlations between the readability factors and the average human ratings. According to their results, the average number of verb phrases in a sentence, the number of words in an article, the likelihood of the vocabulary, and the likelihood of the discourse relations are highly correlated with human ratings. However, these studies did not consider the reading devices, but focused on how well a text is written. Since the readability can be differentiated according to reading device, a reading device should be considered when computing the readability of a given text.

To the best of our knowledge, there are few studies on the readability on mobile devices that do not consider language-related aspects. Most studies on mobile devices focused on the development of new text format and layout to help users read documents easily. Öquist (2006) proposed a new text presentation format called the dynamic Rapid Serial Visual Presentation. According to his experimental results, this format helps to reduce eye movements. On the other hand, Hasegawa et al. (2008) evaluated the readability of documents on mobile devices with regard to screen and font size. They reported that the readability is improved when the characters are vertically enlarged. Readability on mobile devices is not reflected only by the visualization factors, but also by textual factors. Therefore, this paper explores the readability factors that reflect the lexical and grammatical complexity of text and are affected by reading devices.

3 Readability Factors

Table 1 lists the readability factors used in this paper. Basically, they are based on the factors proposed by Pitler and Nenkova (2008). However, some factors are excluded and some new factors are added. This is because some of their factors are computationally infeasible and language-dependent. As a result, we have thirteen readability factors. These readability factors are divided into four types: superficial, lexical, syntactic factors, and lexical cohesion.

3.1 Superficial Factors

Superficial factors were used in most early readability studies (Dale and Chall, 1949; Flesch, 1948; Kincaid et al., 1975), and reflect the construction of a text. We investigate four factors: text length (`TL`), sentence length (`SL`), average number of words per sentence (`WS`), and average number of characters per word (`CW`). Since longer text is perceived as "harder-to-read" than short one, these factors are all reciprocally related with readability.

The first two factors are related to length. `TL` counts the number of characters in a text, whereas `SL` computes the number of sentences. When a writer attempts to write many topics in a text, she tends to use many kinds of words simultaneously. As a result, the text becomes longer and more complex. Such long length of text disturbs a reader's comprehension of the text, and then it is more difficult for the reader to read the text (Heilman et al., 2008).

`WS` counts the average number of words per sentence, and `CW` reflects the average number of characters per word. When they are large, the sentence is difficult to read, which leads to difficulties in understanding the text. Especially, `CW` reflects compound nouns and technical words. For instance, compound nouns in Korean are usually long, because there is no spacing between words in a compound noun. For example, let us consider a compound noun, "*Daehanmingukjungboo*," which means the Korean government. Actually this compound noun consists of two independent nouns.

Type of Factors	Abbr.	Description
Superficial factors	TL	The number of characters in a text
	SL	The number of sentences in a text
	WS	Average number of words per sentence
	CW	Average number of characters per word
Lexical factor	LL	Article likelihood estimated by language model
Syntactic factors	PTD	Average parse tree depths per sentence
	NP	Average number of noun phrases per sentence
	VP	Average number of verb phrases per sentence
	SBAR	Average number of subordinate clauses per sentence
Lexical cohesion	COS	Average cosine similarity between pairs of adjacent sentences
	WO	Average word overlap between pairs of adjacent sentences
	NPO	Average word overlap over noun and pronoun only
	PRP	Average number of pronouns per sentence

Table 1: Description of readability factors

One is "*Daehanminguk*" meaning Korea and the other is "*Jungboo*" meaning a government. The two are concatenated to form a compound noun and become a long single word. In addition, many difficult words such as domain-specific terms tend to be long. Such lengthy words make it difficult to read a text.

3.2 Lexical Factor

Lexical factor determines whether a given text consists of frequent words. Texts that express a new trend in various fields often use many newly coined words. Such neologisms make it difficult to read and understand a text. Therefore, an easily-understandable text is composed of widely-used words rather than unusual words.

In order to compute the use of frequent words in a text, a unigram language model is used as in the work of Pitler and Nenkova (2008). In this model, the log likelihood of text t is computed by

$$\sum_{w \in t} C(w) \cdot \log P(w|B). \quad (1)$$

where $P(w|B)$ is the probability of a word w according to a background corpus B, and $C(w)$ is the number of times that w appears in t.

This factor examines the familiarity of the words used in the text. The more frequently a word appears in the background corpus, the more familiar it is regarded. The frequency of a word w is then reflected into $P(w|B)$ computed from the independent background corpus B. Therefore, the factor LL is positively related with readability.

3.3 Syntactic Factors

Syntactic factors reflect sentence complexity directly that affects human processing of a sentence. We consider the average parse tree depth per sentence (PTD), the average number of noun phrases per sentence (NP), the average number of verb phrases per sentence (VP), and the average number of subordinate clauses per sentence (SBAR) as syntactic factors. These four factors were defined by Schwarm and Ostendorf (2005).

A reader regards a text as difficult when the sentences in the text have large parse tree depths or many subordinate clauses. Thus, PTD and SBAR are related negatively with readability. On the other hand, the relationship of NP and VP to readability are not one way. The large number of noun phrases in a text requires a reader to remember more items (Barzilay and Lapata, 2008; Pitler and Nenkova, 2008). However, it also makes the text more interesting. The texts written for adults actually contain more entities than those written for children (Barzilay and Lapata, 2008). The same is true for VP. The large number of verb phrases in a sentence makes the sentence more complex. However, people feel that a text is more easier to comprehend when related clauses are grouped together (Bailin and Grafstein, 2001).

3.4 Lexical Cohesion

Lexical cohesion denotes how the sentences in a text are semantically connected. People usually bring continuous sentences into their mind at the same time, and interpret them as a single unit (Okazaki et al., 2005). In other words, a reader prefers text whose sentences are smoothly connected to text whose sentences are independent of one another. Therefore, sentence continuity plays a primary role in understanding an entire text.

In the classic study of cohesion, various uses of cohesive elements such as pronouns, definite articles, and topic continuity have been discussed (Halliday and Hasan, 1976). This paper uses the average cosine similarity (COS), word overlap (WO), word overlap over just nouns and pronouns (NPO) between pairs of adjacent sentences, and the average number of pronouns per sentence (PRP). COS, WO, and NPO are superficial measures of topic continuity, whereas PRP is an indicative feature of sentence continuity. High values for these factors imply that the sentences in the text are related somehow. Therefore, these factors are believed to be related positively with readability.

3.5 Measurement of Readability

When a reading device d is given, the readability of text t, represented as $R(t|d)$, is formulated as a combination of readability factors with their corresponding weight in the device. We assume that $w_{i|d}$, the weight of a readability factor f_i, is dependent on the reading device d. Following the previous work of Pitler and Nenkova (2008), we also assume that each readability factor affects readability independently. Therefore, readability is calculated as a weighted linear sum of all readability factors. That is, $R(t|d)$ is computed by

$$R(t|d) = \sum_{i \in \{1,2,...,M\}} w_{i|d} \cdot f_i(t) \quad (2)$$

where M is the number of readability factors.

Each weight $w_{i|d}$ is determined from a set of news articles T. We collected a large number of news articles from an Internet news portal. The readability of each article was manually labeled. This is done three times, since we have three different devices of a smart phone, a tablet, and paper. Since human rating of each article $t \in T$ is available for each device, $w_{i|d}$'s can be estimated by linear regression. These weights are different according to the devices.

4 News Article Recommendation by Device-Dependent Readability

The fact that the weights $w_{i|d}$ in Equation (2) are different for each device d implies that the readability measurement should be different depending on the device type. In order to see the usefulness of this device-dependent readability, we apply it to news article recommendation. News article recommendation aims to provide a user with news articles that interest the user. Thus, it selects a few articles that meet user preference from a gigantic amount of news events. Various methods have reported notable results in news article recommendation (Das et al., 2007; Li et al., 2010; Liu et al., 2010). In addition, with the recent interest in hand-held devices, the demand for news recommendation on hand-held devices is increasing. However, there has been, at least as far as we know, no study on the readability of hand-held devices.

Device-dependent readability is reflected into news article recommendation through a re-ranking framework. Figure 1 depicts the overall process of suggesting news articles for a specific device with the device-dependent readability. The point of this figure is to measure how appropriate a news article is for a specific reading device. For this, a news recommendation system first chooses a set of news articles from a news repository based on its own criterion. Then, we re-rank them by the device-dependent readability to obtain the final set of ranked news articles for the device.

Formally, a news article recommendation ranks a set of articles, $\mathbf{A} = \{a_1, a_2, ..., a_m\}$, where a_i represents the i-th article. The order between ranks $a_1 \succ a_2 \succ ... \succ a_m$ should be satisfied by the criterion of the recommendation system. That is, assuming that the system has a score function $score(a_i)$, $score(a_i) > score(a_j)$ has to be met if $a_i \succ a_j$. Then, the top $k(k \leq m)$ articles of $\mathbf{A}$ by the score function are suggested as appropriate news articles. After that, the selected articles are re-ranked by another criterion, the device-dependent readability. That is, the final rank of an article within the selected set is determined by another function, $rerank$. Since this function has to reflect the device-dependent readability, it takes two parameters. One is an article, and the other is a device type. The re-rank function is modeled as

$$\begin{aligned} rerank(a, d) &= R(a|d) \\ &= \sum_{i \in \{1,2,...,M\}} w_{i|d} \cdot f_i(a). \end{aligned} \quad (3)$$

As a result, the readability-based re-ranking module suggests the news articles based on how easily the articles are read on a specific reading device. Note that even the same article would be ranked differently according to the device type because the article is re-ranked by the device-dependent readability. At last, the top $k^*(k^* \leq k)$ re-ranked articles among them are suggested as final news articles.

	Min	Max	Average
Article length	68	610	346.5
# of sentences	1	14	6.24
# of words per sentence	8	33	16.93
# of words per article	17	178	99.34

Table 2: Statistics of the news article data

5 Experiments

5.1 Experiments on Readability Factors

5.1.1 Experiment Settings

For the experiments of analyzing relationship between readability factors and readability, we collected a Korean news corpus from Naver News[1]. This corpus contains news articles from June 10, 2013 to June 25, 2013. We selected 74 articles randomly from the corpus which were used for readability formula and showing the relationships between readability factors. All selected articles belong to one of three categories: 'Politics', 'Entertainment', and 'Sports'. A set of these 74 news articles becomes T, and is used to compute the weights in Equation (2). Table 2 describes a simple statistics of the selected news articles. The shortest article consists of 68 characters, whereas the longest one has 610 characters. The average length of article is 346.5. The shortest article is written in one sentence, and the longest has 14 sentences. One article has approximately 6.24 sentences on average. In addition, the

[1] A Korean news portal of which web address is `http://news.naver.com`.

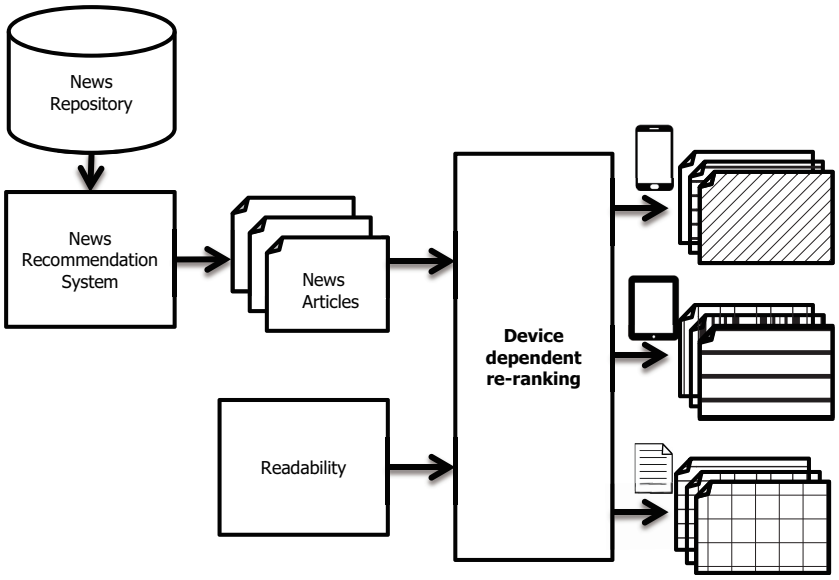

Figure 1: Overall process of re-ranking news articles based on device-dependent readability

number of words per sentence ranges from 8 to 33, and the average is 16.93. The minimum number of words in an article is 17, and the maximum number of words is 178. An article is composed of 99.34 words on average.

In order to compute the lexical factor LL by Equation (1), a background corpus B is required. Since this corpus should be independent from the news articles explained above, the Naver News is adopted again to generate B. For the background corpus B, we collected news articles from January 1, 2013 to September 6, 2013, but excluded the articles from June 10 to June 25, because they are already used. This corpus consists of 298,729 articles with 3,264,104 distinct words.

The readability score for each article was manually labeled by three undergraduate students. To investigate the relationship between reading devices and readability, each article was read using three different reading devices. The Galaxy Note 1 with a 5-inch screen is used as the smart phone, Galaxy Tab 10.1 with a 10.1-inch screen is used as the tablet, and A4-size paper is used for the paper. That is, the human annotators read and rated 74 articles per device. The order of the devices where the annotators evaluated readability is smart phone, tablet, and paper. This order was maintained for all the experiments. All aspects but content texts were under control. For instance, font = "Gothic, 12 pt" (this is most commonly used font and size that most Korean web pages and textbooks use), font color = "black", alignment = "both" were used for all three devices. In addition, the non-content aspects were exactly same for devices because the annotators of readability and the recommended articles shared the reading devices. Although these aspects affect readability and many previous studies already proved it, it is not our concern. We only attempt to capture how readability is affected by the content in different types of devices.

Reading device	Min	Max	Average
Smart phone	1.67	5	3.423 ± 0.741
Tablet	1.33	5	3.531 ± 0.837
Paper	2	5	3.360 ± 0.594

Table 3: Readability scores given by human annotators

Human annotators can remember the content of news articles when they read articles with three devices. The human annotators were asked to read and evaluate many articles within a relatively short period. Therefore, before the main experiments, we performed a pilot experiment on the memory effects of previously read articles and verified it empirically. We hired three undergraduate students who were not involved in our main experiments. The students read the same 250 articles four times, and these also come from Naver News corpus which are not included the previous 74 articles. After their first reading, they read the articles again in 3, 7, and 14 days later. After 3 days, two students remembered the articles somewhat, but one student remembered them vaguely. Since they almost forgot the articles after 7 days, we placed 7 days interval between devices.

The readability score of an article was rated by the annotators using the questions in the work of Pitler and Nenkova (2008). We use only two of the questions, while they used four questions for the annotators. Their questions are intended to measure the extent of how well a text is written, how it fits together, how easy it is to understand, and how interesting it is. We can consider "well-written" and "fit-together" as a syntactic perspective, whereas "easy to understand" and "interesting" belong to a content perspective. For such a

Smart phone		Tablet		Paper	
Factor	Value	Factor	Value	Factor	Value
SL	-0.394	SL	-0.370	NP	0.298
TL	-0.293	WS	0.321	WS	0.278
WS	0.288	LL	0.253	LL	0.268
LL	0.249	NP	0.240	VP	0.244

Table 4: Pearson correlation coefficients of important readability factors

reason, four questions can be summarized in two questions. The two questions used are

- How well-written is this article?
- How interesting is this article?

For these two questions, each annotator assigns a score between 1 and 5 to each article. Here, 1 point means that the article is worst and 5 point implies that it is best. A readability score of one human annotator is composed with the average of two questions (well-written, interesting). We used the average of three human annotators' readability scores in our experiments. Table 3 shows the readability scores of the articles for each device. According to this table, the readability score ranges from 1.67 to 5 for the smart phone, 1.33 to 5 for the tablet, and ranges from 2 to 5 for the paper. The average readability is 3.423 for the smart phone, 3.531 for the tablet, and 3.360 for the paper. To see the inter-judge agreement among annotators, the Kappa coefficient (Fleiss, 1971) is used. The Kappa values for the 'smart phone', 'tablet', and 'paper' are 0.342, 0.333, and 0.361, respectively. All these values correspond to *fair agreement*.

5.1.2 Experimental Results

In order to see the importance of each factor in a specific device, we adopt the Pearson correlation coefficients between readability factors and reading devices. Table 4 lists the four most important factors in each device and their Pearson correlation coefficients. Especially, p-value is smaller than 0.05 for all factors in this table.

For the smart phone, SL, the number of sentences in a text, is the most important readability factor. Its correlation with the smart phone is -0.394. TL, the number of characters, is the second important factor and has a negative correlation of -0.293. These results imply that readers are negatively sensitive to the length of an article because of the small display size of a smart phone. That is, in the smart phone, longer articles are recognized as difficult to read compared to shorter ones. The number of words per sentence, WS, is the third important factor with correlation of 0.288. The log-likelihood of an article, LL, is also positively related with the readability, which proves that widely-used words make it easy to understand an article. The top three factors are superficial with regard to text length. Therefore, the superficial factors are more important than other types of factors for the smart phone.

SL is the most critical readability factor even for the tablet. It affects readability with high correlation of -0.370. The second important factor is WS with correlation of 0.321. Both of these factors are superfical. The third important factor, LL, is positively related with readability as expected. The fourth factor that affects readability is the number of noun phrases, NP. It is natural for NP to be positively related with the readability.

Finally, for the paper, NP is most strongly related to readability with correlation of 0.298. The second important factor is WS, whose correlation is 0.278. LL is the third important factor and shows a positive relationship. Note that WS and LL are important readability factors for all devices. The next important readability factor for the paper is the average number of verb phrases (VP). The articles with many noun phrases and verb phrases are perceived as easier-to-read for the paper. Note that the importance of superficial factors is limited for the paper. We expected that WS is negatively related, but, it is positively related with readability for all three devices. The reason for this could be that the annotators thought the articles with higher WS are more interesting.

The important factors for the smart phone are different from those for the paper. On the other hand, the tablet shares many factors with both the smart phone and the paper. Because the screen size of a tablet is similar to the size of an A4 paper, the tablet and the paper share readability factors. However, length-related factors play a more important role than syntactic factors in the smart phone because a smart phone has a smaller screen.

5.2 Experiments on News Recommendation

5.2.1 Experiment Settings

Experiments for news article recommendation were performed to see the effectiveness of device-dependent readability. The process of news recommendation with device-dependent readability is as follows. For a specific device,

1. Select top-k news articles from a news repository by the criterion of the recommendation system.
2. Re-rank the k articles by the readability of the device using Equation (3).
3. Select top-k^* news articles by the new rank.
4. Human annotators read and rate the k^* articles with the device.
5. Compare the ranks of k^* articles by device-dependent readability with those by human ratings.

Since we have three types of devices, this process is performed three times with a different device.

The news articles from September 10, 2013 to September 12, 2013 collected from Naver News were

	Min	Max	Average
Article length	277	6,077	990.68
# of sentences	4	199	22.85
# of words per sentence	4	100	15.73
# of words per article	71	2,034	301.61

Table 5: Statistics of news data for recommendation

Reading device	Min	Max	Average
Smart phone	1	5	3.513 ± 0.962
Tablet	1	5	3.344 ± 0.852
Paper	1	5	3.250 ± 0.907

Table 6: Scores of news articles by human annotators in news recommendation

used as the news repository. The number of times that a news article was actually read by its anonymous readers at the portal site is used as the criterion for the recommendation system. Since this criterion is provided on a daily basis and news articles were collected for three days, the process explained above is performed three times. The top twenty articles were selected by the criterion every day. That is, $k = 20$. Table 5 shows the statistics of the total 60 articles. The shortest article consists of 277 characters, and the longest article has 6,077 characters. On average, an article is written with 990.68 characters. The minimum number of sentences in an article is 4, and the maximum number of sentences is 199. An article is composed of 22.85 sentences on average. The average number of words in a sentence is 15.73, whereas a sentence length ranges from 4 to 100 words. The shortest article has 71 words, and the longest article has 2,034 words. One article has approximately 301.61 words on average.

Three human annotators labeled the scores of the news articles manually. The annotators were the same persons who labeled the readability scores. Similar to the previous experiments, 7 days intervals was placed among devices to reduce the memory effect. The same two questions used in the previous section were used again for this experiment. The annotators assigned a score between 1 and 5 to every article for each question. The final score of an article was obtained by averaging six scores (two questions from three annotators). Table 6 summarizes the scores of the articles by the human annotators. As shown in this table, the article scores vary for all reading devices. The average scores for smart phone, tablet, and paper are 3.513, 3.344, and 3.250 respectively. The Kappa value for the 'smart phone' is 0.402, and that for both the 'tablet' and the 'paper' is 0.393. Thus, the value of 'smart phone' falls into *moderate agreement*, whereas those of the 'tablet' and 'paper' correspond to *fair agreement*. The performance of the news article recommendation is evaluated with the Normalized Discounted Cumulative Gain at top P (NDCG@P) (Järvelin and Kekäläinen, 2002).

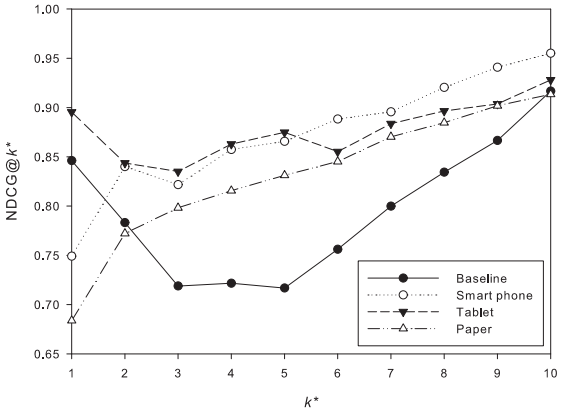

Figure 2: NDCG@k^* scores with various k^* for the *smart phone*.

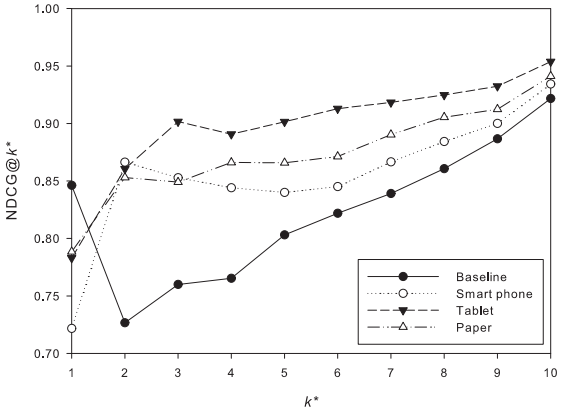

Figure 3: NDCG@k^* scores with various k^* for the *tablet*.

5.2.2 Experimental Results

For the a baseline criterion, we use the news article recommendation system in Naver, which recommends news article by the number of article hits. Figures 2 to 4 show the NDCG@k^* scores with $1 \leq k^* \leq 10$ for the three devices. Each graph in these figures compares the performance of various devices when the readability for a specific device is used. That is, Figure 2 depicts the NDCG@k^* scores for the recommended news articles when the articles are shown in the smart phone, the tablet, and the paper respectively. In computing their NDCG@k^* scores, the news articles are re-ranked by readability for the smart phone. Therefore, in this figure we expect that the NDCG@k^* score for using the smart phone is higher than those for using the tablet and paper. In the same way, Figure 3 and Figure 4 compare the NDCG@k^* scores when the readabilities for the tablet and paper are used.

In all three graphs, the best news recommendation performance is achieved when the device used to read

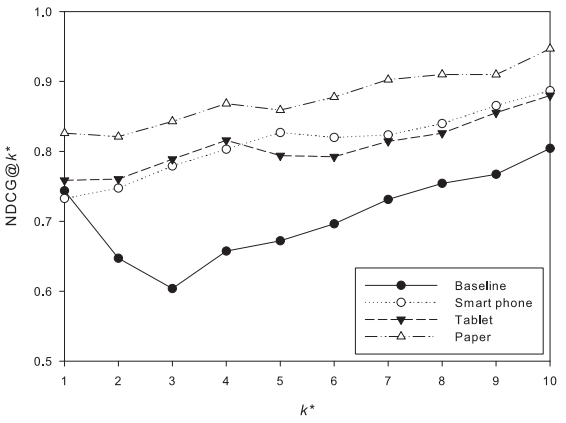

Figure 4: NDCG@k^* scores with various k^* for the *paper*.

news articles is the same as the device used for readability. In Figure 2, the use of the smart phone outperforms those of other devices when $k^* \geq 6$. This proves that the quality of highly ranked news articles is much better for the smart phone than for other devices, when the readability for smart phone is used.

Figure 3 shows the NDCG@k^* scores for using various devices when the news articles are re-ranked by readability for the tablet. In this figure, the use of the tablet as a reading device is better than using the smart phone or the paper. The performance difference is largest at $k^* = 3$. The difference becomes smaller as k^* increases up to 10, but the performance of tablet is still higher than those of others. In Figure 2 and 3, when $k^* = 1$, the baseline outperforms other devices. We believe this happens because the baseline chooses news articles by user-hit. Therefore, many articles recommended by the baseline are interesting because people tend to click more often when an article is interesting. As noted, readability reflects users' interests, which leads to high performance of the baseline. The performance of paper is best in Figure 4, since the articles are re-ranked by the readability for paper. Paper outperforms all other devices for all k^*s. Note that the performances of the baseline are always lowest regardless of reading device.

From all results above, we can infer that the use of device-dependent readability is helpful to news article recommendation. This is because the readability factors that affect the readers of news articles are different according to the reading device. Therefore, it is important to reflect the characteristics of a reading device when recommending news articles.

6 Conclusion

In this paper, we have proposed a device-dependent readability. Since a reading device is one of the most important features of readability, different weights have been assigned to the readability factors according to device type. We have shown that the important readability factors are distinct according to the reading device by investigating the correlation between the readability factors and the reading device. Through the correlation, we found that tablet shares many important factors with both smart phone and paper.

The experiments on the news articles collected from an Internet portal proved that readability is actually affected by the reading device. In addition, the validity of the device-dependent readability was shown by applying it to the news article recommendation. The news articles were first ranked by the criterion of the recommendation system. Then, they were re-ranked by the device-dependent readability. Our experiments showed that the recommendation performance of the re-ranked articles gets best when the device used for readability is the same as the reading device. These two types of experiments proved the importance and effectiveness of the device-dependent readability.

Abstract

We propose a new Chinese abbreviation prediction method which can incorporate rich local information while generating the abbreviation globally. Different to previous character tagging methods, we introduce the minimum semantic unit, which is more fine-grained than character but more coarse-grained than word, to capture word level information in the sequence labeling framework. To solve the "character duplication" problem in Chinese abbreviation prediction, we also use a substring tagging strategy to generate local substring tagging candidates. We use an integer linear programming (ILP) formulation with various constraints to globally decode the final abbreviation from the generated candidates. Experiments show that our method outperforms the state-of-the-art systems, without using any extra resource.

1 Introduction

Abbreviation is defined as a shortened description of the original fully expanded form. For example, "NLP" is the abbreviation for the corresponding full form "Natural Language Processing". The existence of abbreviations makes it difficult to identify the terms conveying the same concept in the information retrieval (IR) systems and machine translation (MT) systems. Therefore, it is important to maintain a dictionary of the prevalent original full forms and the corresponding abbreviations.

Previous works on Chinese abbreviation generation focus on the sequence labeling method, which give each character in the full form an extra label to indicate whether it is kept in the abbreviation. One drawback of the character tagging strategy is that Chinese characters only contain limited amount of information. Using character-based method alone is not enough for Chinese abbreviation generation. Intuitively we can think of a word as the basic tagging unit to incorporate more information. However, if the basic tagging unit is word, we need to design lots of tags to represent which characters are kept for each unit. For a word with n characters, we should design at least 2^n labels to cover all possible situations. This reduces the generalization ability of the proposed model. Besides, the Chinese word segmentation errors may also hurt the performance. Therefore we propose the idea of "Minimum Semantic Unit" (MSU) which is the minimum semantic unit in Chinese language. Some of the MSUs are words, while others are more fine-grained than words. The task of selecting representative characters in the full form can be further broken down into selecting representative characters in the MSUs. We model this using the MSU-based tagging method, which can both utilize semantic information while keeping the tag set small.

Meanwhile, the sequence labeling method performs badly when the "character duplication" phenomenon exists. Many Chinese long phrases contain duplicated characters, which we refer to as the "character duplication" phenomenon. There is no sound criterion for the character tagging models to decide which of the duplicated character should be kept in the abbreviation and which one to be skipped. An example is "北京航空航天大学"(Beijing University of Aeronautics and Astronautics) whose abbreviation is "北航". The character "航" appears twice in the full form and only one is kept in the abbreviation. In these cases, we can break the long phase into local substrings. We can find the representative characters in the substrings instead of the long full form and let the decoding phase to integrate useful information globally. We utilize this sub-string based approach and obtain this local tagging information by labeling

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1405–1414,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

on the sub-string of the full character sequence.

Given the MSU-based and substring-based methods mentioned above, we can get a list of potential abbreviation candidates. Some of these candidates may not agree on keeping or skipping of some specific characters. To integrate their advantages while considering the consistency, we further propose a global decoding strategy using Integer Linear Programming(ILP). The constraints in ILP can naturally incorporate 'non-local' information in contrast to probabilistic constraints that are estimated from training examples. We can also use linguistic constraints like "adjacent identical characters is not allowed" to decode the correct abbreviation in examples like the previous "北航" example.

Experiments show that our Chinese abbreviation prediction system outperforms the state-of-the-art systems. In order to reduce the size of the search space, we further propose pruning constraints that are learnt from the training corpus. Experiment shows that the average number of constraints is reduced by about 30%, while the top-1 accuracy is not affected.

The paper is structured as follows. Section 1 gives the introduction. In section 2 we describe our method, including the MSUs, the substring-based tagging strategy and the ILP decoding process. Experiments are described in section 3. We also give a detailed analysis of the results in section 3. In section 4 related works are introduced, and the paper is concluded in the last section.

2 System Architecture

2.1 Chinese Abbreviation Prediction

Chinese abbreviations are generated by selecting representative characters from the full forms. For example, the abbreviation of "北京大学" (Peking University) is "北大" which is generated by selecting the first and third characters, see TABLE 1. This can be tackled from the sequence labeling point of view.

Full form	北	京	大	学
Status	Keep	Skip	Keep	Skip
Result	北		大	

Table 1: The abbreviation "北大" of the full form "北京大学" (Peking University)

From TABLE 1 we can see that Chinese abbreviation prediction is a problem of selecting representative characters from the original full form[1]. Based on this assumption, previous works mainly focus on this character tagging schema. In these methods, the basic tagging unit is the Chinese character. Each character in the full form is labeled as 'K' or 'S', where 'K' means the current character should be kept in abbreviation and 'S' means the current character should be skipped.

However, a Chinese character can only contain limited amount of information. Using character-based method alone is not enough for Chinese abbreviation generation. We introduce an MSU-based method, which models the process of selecting representative characters given local MSU information.

2.2 MSU Based Tagging

2.2.1 Minimum Semantic Unit

Because using the character-based method is not enough for Chinese abbreviation generation, we may think of word as the basic tagging unit to incorporate more information intuitively. In English, the abbreviations (similar to acronyms) are usually formed by concatenating initial letters or parts of a series of words. In other words, English abbreviation generation is based on words in the full form. However, in Chinese, word is not the most suitable abbreviating unit. Firstly, there is no natural boundary between Chinese words. Errors from the Chinese word segmentation tools will accumulate to harm the performance of abbreviation prediction. Second, it is hard to design a reasonable tag set when the length of a possible Chinese word is very long. The second column of TABLE 2 shows different ways of selecting representative characters of Chinese words with length 3. For a Chinese compound word with 3 characters, there are 6 possible ways to select characters. In this case we should have at least 6 kinds of tags to cover all possible situations. The case is even worse for words with more complicated structures. A suitable abbreviating unit should be smaller than word.

We propose the "Minimum Semantic Unit (MSU)" as the basic tagging unit. We define MSU as follows:

1. A word whose length is less or equal to 2 is an MSU.

[1] A small portion of Chinese abbreviations are not generated from the full form. For example, the abbreviation of "山东"(Shan Dong Province) is "鲁". However, we can use a look-up table to get this kind of abbreviations.

Full form	SK Label	MSUs
幼儿园(nursery)	幼/K 儿/S 园/S	幼儿+园
补贴费(allowance)	补/S 贴/K 费/S	补贴+费
信用卡(Credit card)	信/S 用/S 卡/K	信用+卡
水电站(Hydropower Station)	水/K 电/K 站/S	水+电+站
参议院(Senate)	参/K 议/S 院/K	参+议+院
音乐团(Music group)	音/S 乐/K 团/K	音乐+团

Table 2: Representing characters of Chinese words with length 3 (K for keep and S for skip) and the corresponding MSUs

2. A word whose length is larger than 2, but does not contain any MSUs with length equal to 2. For example, "火车站"(Railway Station) is not an MSU because the first two characters "火车"(Train) can form an MSU.

By this definition, all 6 strings in TABLE 2 are often thought as a word, but they are not MSUs in our view. Their corresponding MSU forms are shown in TABLE 2.

We collect all the MSUs from the benchmark datasets provided by the second International Chinese Word Segmentation Bakeoff[2]. We choose the Peking University (PKU) data because it is more fine-grained than all other corpora. Suppose we represent the segmented data as L (In our case L is the PKU word segmentation data), the MSU selecting algorithm is shown in TABLE 3.

For a given full form, we first segment it using a standard word segmenter to get a coarse-grained segmentation result. Here we use the Stanford Chinese Word Segmenter [3]. Then we use the MSU set to segment each word using the strategy of "Maximum Forward Matching"[4] to get the fine-grained MSU segmentation result.

2.2.2 Labeling strategy

For MSU-based tagging, we use a labeling method which uses four tags, "KSFL". "K" stands for "Keep the whole unit", "S" stands for "Skip the whole unit", "F" stands for "keep the First character of the unit", and Label "L" stands for "keep the Last character of the unit". An example is shown in TABLE 4.

The "KSFL" tag set is also applicable for MSUs whose length is greater than 2 (an example is "巧克力/chocolate"). By examining the corpus we find that such MSUs are either kept of skipped in the final abbreviations. Therefore, the labels of these long MSUs are either 'K' or 'S'. Empirically, this assumption holds for MSUs, but does not hold for words[5].

"国家语言文字工作委员会" (The abbreviation is "国家语委")	
KSFL	国家/K 语言/F 文字/S 工作/S 委员/F 会/S

Table 4: The abbreviation "国家语委" of "国家语言文字工作会" (National Linguistics Work Committee) based on MSU tagging.

2.2.3 Feature templates

The feature templates we use are as follows. See TABLE 5.

1. Word X_i $(-2 \leq i \leq 2)$
2. POS tag of word X_i $(-2 \leq i \leq 2)$
3. Word Bigrams (X_i, X_{i+1}) $(-2 \leq i \leq 1)$
4. Type of word X_i $(-2 \leq i \leq 2)$
5. Length of word X_i $(-2 \leq i \leq 2)$

Table 5: Feature templates for unit tagging. X represents the MSU sequence of the full form. X_i represents the ith MSU in the sequence.

Templates 1, 2 and 3 express word uni-grams and bi-grams. In MSU-based tagging, we can utilize the POS information, which we get from the Stanford Chinese POS Tagger[6]. In template 4, the type of word refers to whether it is a number, an English word or a Chinese word. Because the basic tagging unit is MSU, which carries word information, we can use many features that are infeasible in character-based tagging.

For each word w in L:
  If $Length(w) \leq 2$
    Add w to $MSUSet$
  End if
End for
For each word w in L:
  If $Length(w) > 2$ and no word x in $MSUSet$ is a substring of w
    Add w to $MSUSet$
  End if
End for
Return $MSUSet$

Table 3: Algorithm for collecting MSUs from the PKU corpus

2.2.4 Sequence Labeling Model

The MSU-based method gives each MSU an extra indicative label. Therefore any sequence labeling model is appropriate for the method. Previous works showed that Conditional Random Fields (CRFs) can outperform other sequence labeling models like MEMMs in abbreviation generation tasks (Sun et al., 2009; Tsuruoka et al., 2005). For this reason we choose CRFs model in our system.

For a given full form's MSU list, many candidate abbreviations are generated by choosing the k-best results of the CRFs. We can use the forward-backward algorithm to calculate the probability of a specified tagging result. To reduce the searching complexity in the ILP decoding process, we delete those candidate tagged sequences with low probability.

2.3 Substring Based Tagging

As mentioned in the introduction, the sequence labeling method, no matter character-based or MSU-based, perform badly when the "character duplication" phenomenon exists. When the full form contains duplicated characters, there is no sound criterion for the sequence tagging strategy to decide which of the duplicated character should be kept in the abbreviation and which one to be skipped. On the other hand, we can tag the substrings of the full form to find the local representative characters in the substrings of the long full form. Therefore, we propose the sub-string based approach to given labeling results on sub-strings. These results can be integrated into a more accurate result using ILP constraints, which we will describe in the next section.

Another reason for using the sub-string based methods is that long full forms contain more characters and are much easier to make mistakes during the sequence labeling phase. Zhang et al. (2012) shows that if the full form contains less than 5 characters, a simple tagger can reach an accuracy of 70%. Zhang et al. (2012) also shows that if the full form is longer than 10 characters, the average accuracy is less than 30%. The numerous potential candidates make it hard for the tagger to choose the correct one. For the long full forms, although the whole sequence is not correctly labeled, we find that if we only consider its short substrings, we may find the correct representative characters. This information can be integrated into the decoding model to adjust the final result.

We use the MSU-based tagging method in the sub-string tagging. The labeling strategy and feature templates are the same to the MSU-based tagging method. In practice, enumerating all subsequences of a given full form is infeasible if the full form is very long. For a given full form, we use the boundary MSUs to reduce the possible sub-sequence set. For example, "中国科学院"(Chinese Academy of Science) has 5 subsequences: "中国", "中国科学", "科学", "科学院" and "院".

2.4 ILP Formulation of Decoding

Given the MSU-based and sub-sequence-based methods mentioned above as well as the prevalent character-based methods, we can get a list of potential abbreviation candidates and abbreviated substrings. We should integrate their advantages while keeping the consistency between each

candidate. Therefore we further propose a global decoding strategy using Integer Linear Programming(ILP). The constraints in ILP can naturally incorporate 'non-local' information in contrast to probabilistic constraints that are estimated from training examples. We can also use linguistic constraints like "adjacent identical characters is not allowed" to decode the correct abbreviation in examples like the "北航" example in section 1.

Formally, given the character sequence of the full form $c = c_1...c_l$, we keep Q top-ranked MSU-based tagging results T=($T_1, ..., T_Q$) and M tagged substrings S=($S_1, ..., S_M$) using the methods described in previous sections. We also use N top-ranked character-based tagging results R=($R_1, ..., R_N$) based on the previous character-based works. We also define the set $U = S \cup R \cup T$ as the union of all candidate sequences. Our goal is to find an optimal binary variable vector solution $\vec{v} = \vec{x}\vec{y}\vec{z} = (x_1, ..., x_M, y_1, ..., y_N, z_1, ..., z_Q)$ that maximizes the object function:

$$\lambda_1 \sum_{i=1}^{M} score(S_i) \cdot x_i + \lambda_2 \sum_{i=1}^{N} score(R_i) \cdot y_i$$

$$+\lambda_3 \sum_{i=1}^{Q} score(T_i) \cdot z_i$$

subject to constrains in TABLE 6. The parameters λ_1, λ_2, λ_3 controls the preference of the three parts, and can be decided using cross-validation.

Constraint 1 indicates that x_i, y_i, z_i are all boolean variables. They are used as indicator variables to show whether the corresponding tagged sequence is in accordance with the final result.

Constraint 2 is used to guarantee that at most one candidate from the character-based tagging is preserved. We relax the constraint to allow the sum to be zero in case that none of the top-ranked candidate is suitable to be the final result. If the sum equals zero, then the sub-sequence based tagging method will generate a more suitable result. Constrain 3 has the same utility for the MSU-based tagging.

Constraint 4, 5, 6 are inter-method constraints. We use them to guarantee that the labels of the preserved sequences of different tagging methods do not conflict with each other. Constraint 7 is used to guarantee that the labels of the preserved sub-strings do not conflict with each other.

Constraint 8 is used to solve the "character duplicate" problem. When two identical characters are kept adjacently, only one of them will be kept. Which one will be kept depends on the global decoding score. This is the advantage of ILP against traditional sequence labeling methods.

2.5 Pruning Constraints

The efficiency of solving the ILP decoding problem depends on the number of candidate tagging sequences N and Q, as well as the number of subsequences M. Usually, N and Q is less than 10 in our experiment. Therefore, M influences the time complexity the most. Because we use the boundary of MSUs instead of enumerating all possible subsequences, the value of M can be largely reduced.

Some characters are always labeled as "S" or "K" once the context is given. We can use this phenomenon to reduce the search space of decoding. Let c_i denote the i_{th} character relative to the current character c_0 and t_i denote the tag of c_i. The context templates we use are listed in TABLE 7.

Uni-gram Contexts	c_0, c_{-1}, c_1
Bi-gram Contexts	$c_{-1}c0$, $c_{-1}c_1$, c_0c_1

Table 7: Context templates used in pruning

With respect to a training corpus, if a context C relative to c_0 always assigns a certain tag t to c_0, then we can use this constraint in pruning. We judge the degree of "always" by checking whether $\frac{count(C \wedge t_0 = t)}{count(C)} > threshold$. The threshold is a non-negative real number under 1.0.

3 Experiments

3.1 Data and Evaluation Metric

We use the abbreviation corpus provided by Institute of Computational Linguistics (ICL) of Peking University in our experiments. The corpus is similar to the corpus used in Sun et al. (2008, 2009); Zhang et al. (2012). It contains $8,015$ Chinese abbreviations, including noun phrases, organization names and some other types. Some examples are presented in TABLE 8. We use 80% abbreviations as training data and the rest as testing data. In some cases, a long phrase may contain more than one abbreviation. For these cases, the corpus just keeps their most commonly used abbreviation for each full form.

The evaluation metric used in our experiment is the top-K accuracy, which is also used by Tsuruoka et al. (2005), Sun et al. (2009) and

1. $x_i \in \{0,1\}$, $y_i \in \{0,1\}$, $z_i \in \{0,1\}$
2. $\sum_{i=1}^{N} y_i \leq 1$
3. $\sum_{i=1}^{Q} z_i \leq 1$
4. $\forall R_i \in R$, $S_j \in S$, if R_i and S_j have a same position but the position gets different labels, then $y_i + x_j \leq 1$
5. $\forall T_i \in T$, $S_j \in S$, if T_i and S_j have a same position but the position gets different labels, then $z_i + x_j \leq 1$
6. $\forall R_i \in R$, $T_j \in T$, if R_i and T_j have a same position but the position gets different labels, then $x_i + z_j \leq 1$
7. $\forall S_i, S_j \in S$ if S_i and S_j have a same position but the position gets different labels, then $z_i + z_j \leq 1$
8. $\forall S_i, S_j \in S$ if the last character S_i keeps is the same as the first character S_j keeps, then $z_i + z_j \leq 1$

Table 6: Constraints for ILP

Type	Full form	Abbreviation
Noun Phrase	优秀稿件(Excellent articles)	优稿
Organization	作家协会(Writers' Association)	作协
Coordinate phrase	受伤死亡(Injuries and deaths)	伤亡
Proper noun	传播媒介(Media)	传媒

Table 8: Examples of the corpus (Noun Phrase, Organization, Coordinate Phrase, Proper Noun)

Zhang et al. (2012). The top-K accuracy measures what percentage of the reference abbreviations are found if we take the top N candidate abbreviations from all the results. In our experiment, top-10 candidates are considered in re-ranking phrase and the measurement used is top-1 accuracy (which is the accuracy we usually refer to) because the final aim of the algorithm is to detect the exact abbreviation.

CRF++[7] , an open source linear chain CRF tool, is used in the sequence labeling part. For ILP part, we use lpsolve[8], which is also an open source tool. The parameters of these tools are tuned through cross-validation on the training data.

3.2 Results

TABLE 9 shows the top-K accuracy of the character-based and MSU-based method. We can see that the MSU-based tagging method can utilize word information, which can get better performance than the character-based method. We can also figure out that the top-5 candidates include the reference abbreviation for most full forms. Therefore reasonable decoding by considering all possible labeling of sequences may improve the performance. Although the MSU-based methods only outperforms character-based methods by 0.75% for top-1 accuracy, it is much better when considering top-2 to top-5 accuracy (+2.5%). We further select the top-ranked candidates for ILP decoding. Therefore the MSU-based method can further improve the performance in the global decoding phase.

K	char-based	MSU-based
1	0.5714	0.5789
2	0.6879	0.7155
3	0.7681	0.7819
4	0.8070	0.8283
5	0.8333	**0.8583**

Table 9: Top-K ($K \leq 5$) results of character-based tagging and MSU-based tagging

We then use the top-5 candidates of character-based method and MSU-based method, as well as the top-2 results of sub-sequence labeling in the ILP decoding phase. Then we select the top-ranked candidate as the final abbreviation of each instance. TABLE 10 shows the results. We can see that the accuracy of our method is 61.0%, which improved by +3.89% compared to the character-based method, and +3.14% compared to the MSU-based method.

We find that the ILP decoding phase do play an important role in generating the right an-

swer. Some reference abbreviations which are not picked out by either tagging method can be found out after decoding. TABLE 11 shows the example of the organization name "高等学校统一招生办公室" (Higher Education Admissions Office). Neither the character-based method nor the MSU-based method finds the correct answer "高招办", while after ILP decoding, "高招办" becomes the final result. TABLE 12 and TABLE 13 give two more examples.

Char-based	声光效
MSU-based	声效果
ILP Decoding	声光视效

Table 13: Top-1 result of "声音灯光视觉效果" (Visual effects of sound and lights)

3.3 Improvements Considering Length

Full forms that are longer than five characters are long terms. Long terms contain more characters, which is much easier to make mistakes. Figure 1 shows the top-1 accuracy respect to the term length using different tagging methods and using ILP decoding. The x-axis represents the length of the full form. The y-axis represents top-1 accuracy. We find that our method works especially better than pure character-based or MSU-based approach when the full form is long. By decoding using ILP, both local and global information are incorporated. Therefore many of these errors can be eliminated.

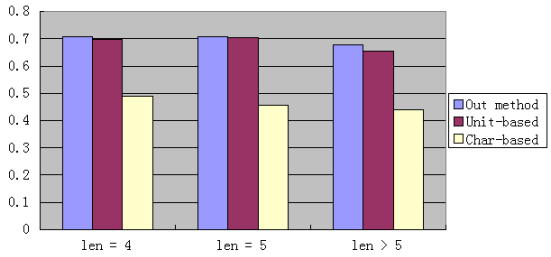

Figure 1: Top-1 accuracy of different methods considering length

3.4 Effect of pruning

As discussed in previous sections, if we are able to pre-determine that some characters in a certain context should be kept or skipped, then the number of possible boolean variable x can be reduced. TABLE 14 shows the differences. To guarantee a high accuracy, we set the threshold to be 0.99. When the original full form is partially tagged by the pruning constraints, the number of boolean variables per full form is reduced from 34.4 to 25.5. By doing this, we can improve the prediction speed over taking the raw input.

From TABLE 14 we can also see that the top-1 accuracy is not affected by these pruning constraints. This is obvious, because CRF itself has a strong modeling ability. The pruning constraints cannot improve the model accuracy. But they can help eliminate those false candidates to make the ILP decoding faster.

	Accuracy	Average length	Time(s)
raw	0.6103	34.4	12.5
pruned	0.6103	25.5	7.1

Table 14: Comparison of testing time of raw input and pruned input

3.5 Compare with the State-of-the-art Systems

We also compare our method with previous methods, including Sun et al. (2009) and Zhang et al. (2012). Because we use a different corpus, we re-implement the system Sun et al. (2009), Zhang

et al. (2012) and Sun et al. (2013), and experiment on our corpus. The first two are CRF+GI and DPLVM+GI in Sun et al. (2009), which are reported to outperform the methods in Tsuruoka et al. (2005) and Sun et al. (2008). For DPLVM we use the same model in Sun et al. (2009) and experiment on our own data. We also compare our approach with the method in Zhang et al. (2012). However, Zhang et al. (2012) uses different sources of search engine result information to re-rank the original candidates. We do not use any extra web resources. Because Zhang et al. (2012) uses web information only in its second stage, we use "BIEP"(the tag set used by Zhang et al. (2012)) to denote the first stage of Zhang et al. (2012), which also uses no web information. TABLE 15 shows the results of the comparisons. We can see that our method outperforms all other methods which use no extra resource. Because Zhang et al. (2012) uses extra web resource, the top-1 accuracy of Zhang et al. (2012) is slightly better than ours.

Method	Top-1 Accuracy
CRF+GI	0.5850
DPLVM+GI	0.5990
BIEP	0.5812
Zhang et al. (2012)	**0.6205**
Our Result	**0.6103**

Table 15: Comparison with the state-of-the-art systems

4 Related Work

Previous research mainly focuses on "abbreviation disambiguation", and machine learning approaches are commonly used (Park and Byrd, 2001; HaCohen-Kerner et al., 2008; Yu et al., 2006; Ao and Takagi, 2005). These ways of linking abbreviation pairs are effective, however, they cannot solve our problem directly. In many cases the full form is definite while we don't know the corresponding abbreviation.

To solve this problem, some approaches maintain a database of abbreviations and their corresponding "full form" pairs. The major problem of pure database-building approach is obvious. It is impossible to cover all abbreviations, and the building process is quit laborious. To find these pairs automatically, a powerful approach is to find the reference for a full form given the context, which is referred to as "abbreviation generation".

There is research on heuristic rules for generating abbreviations Barrett and Grems (1960); Bourne and Ford (1961); Taghva and Gilbreth (1999); Park and Byrd (2001); Wren et al. (2002); Hearst (2003). Most of them achieved high performance. However, hand-crafted rules are time consuming to create, and it is not easy to transfer the knowledge of rules from one language to another.

Recent studies of abbreviation generation have focused on the use of machine learning techniques. Sun et al. (2008) proposed a supervised learning approach by using SVM model. Tsuruoka et al. (2005); Sun et al. (2009) formalized the process of abbreviation generation as a sequence labeling problem. In Tsuruoka et al. (2005) each character in the full form is associated with a binary value label y, which takes the value S (Skip) if the character is not in the abbreviation, and value P (Preserve) if the character is in the abbreviation. Then a MEMM model is used to model the generating process. Sun et al. (2009) followed this schema but used DPLVM model to incorporate both local and global information, which yields better results. Sun et al. (2013) also uses machine learning based methods, but focuses on the negative full form problem, which is a little different from our work.

Besides these pure statistical approaches, there are also many approaches using Web as a corpus in machine learning approaches for generating abbreviations.Adar (2004) proposed methods to detect such pairs from biomedical documents. Jain et al. (2007) used web search results as well as search logs to find and rank abbreviates full pairs, which show good result. The disadvantage is that search log data is only available in a search engine backend. The ordinary approaches do not have access to search engine internals. Zhang et al. (2012) used web search engine information to rerank the candidate abbreviations generated by statistical approaches. Compared to their approaches, our method uses no extra resource, but reaches comparable results.

ILP shows good results in many NLP tasks. Punyakanok et al. (2004); Roth and Yih (2005) used it in semantic role labeling (SRL). Martins et al. (2009) used it in dependency parsing. (Zhao and Marcus, 2012) used it in Chinese word segmentation. (Riedel and Clarke, 2006) used ILP

in dependency parsing. However, previous works mainly focus on the constraints of avoiding boundary confliction. For example, in SRL, two argument of cannot overlap. In CWS, two Chinese words cannot share a same character. Different to their methods, we investigate on the conflict of labels of character sub-sequences.

5 Conclusion and Future work

We propose a new Chinese abbreviation prediction method which can incorporate rich local information while generating the abbreviation globally. We propose the MSU, which is more coarse-grained than character but more fine-grained than word, to capture word information in the sequence labeling framework. Besides the MSU-based method, we use a substring tagging strategy to generate local substring tagging candidates. We use an ILP formulation with various constraints to globally decode the final abbreviation from the generated candidates. Experiments show that our method outperforms the state-of-the-art systems, without using any extra resource. This method is not limited to Chinese abbreviation generation, it can also be applied to similar languages like Japanese.

The results are promising and outperform the baseline methods. The accuracy can still be improved. Potential future works may include using semi-supervised methods to incorporate unlabeled data and design reasonable features from large corpora. We are going to study on these issues in the future.

Abstract

It has been shown that news events influence the trends of stock price movements. However, previous work on news-driven stock market prediction rely on shallow features (such as bags-of-words, named entities and noun phrases), which do not capture structured entity-relation information, and hence cannot represent complete and exact events. Recent advances in Open Information Extraction (Open IE) techniques enable the extraction of structured events from web-scale data. We propose to adapt Open IE technology for event-based stock price movement prediction, extracting structured events from large-scale public news without manual efforts. Both linear and nonlinear models are employed to empirically investigate the hidden and complex relationships between events and the stock market. Large-scale experiments show that the accuracy of S&P 500 index prediction is 60%, and that of individual stock prediction can be over 70%. Our event-based system outperforms bags-of-words-based baselines, and previously reported systems trained on S&P 500 stock historical data.

1 Introduction

Predicting stock price movements is of clear interest to investors, public companies and governments. There has been a debate on whether the market can be predicted. The Random Walk Theory (Malkiel, 1973) hypothesizes that prices are determined randomly and hence it is impossible to outperform the market. However, with advances of AI, it has been shown empirically that stock price movement is predictable (Bondt and Thaler, 1985; Jegadeesh, 1990; Lo and MacKinlay, 1990; Jegadeesh and Titman, 1993). Recent work (Das and Chen, 2007; Tetlock, 2007; Tetlock et al., 2008; Si et al., 2013; Xie et al., 2013; Wang and Hua, 2014) has applied Natural Language Processing (NLP) techniques to help analyze the effect of web texts on stock market prediction, finding that events reported in financial news are important evidence to stock price movement prediction.

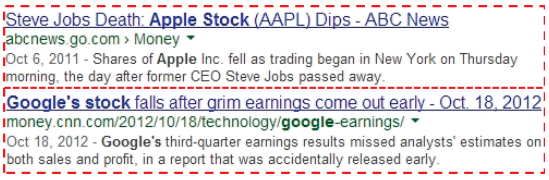

Figure 1: Example news for *Apple Inc.* and *Google Inc.*

As news events affect human decisions and the volatility of stock prices is influenced by human trading, it is reasonable to say that events can influence the stock market. Figure 1 shows two pieces of financial news about *Apple Inc.* and *Google Inc.*, respectively. Shares of *Apple Inc.* fell as trading began in New York on Thursday morning, the day after its former CEO Steve Jobs passed away. Google's stock fell after grim earnings came out. Accurate extraction of events from financial news may play an important role in stock market prediction. However, previous work represents news documents mainly using simple features, such as bags-of-words, noun phrases, and named entities (Lavrenko et al., 2000; Kogan et al., 2009; Luss and d'Aspremont, 2012; Schumaker and Chen, 2009). With these unstructured features, it is difficult to capture key events embedded in financial news, and even more difficult to model the impact of events on stock market prediction. For example, representing the event "Apple has sued Samsung Electronics for copying 'the look and feel'

*This work was done while the first author was visiting Singapore University of Technology and Design

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1415–1425,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

of its iPad tablet and iPhone smartphone." using term-level features {"Apple", "sued", "Samsung", "Electronics", "copying", ...} alone, it can be difficult to accurately predict the stock price movements of *Apple Inc.* and *Samsung Inc.*, respectively, as the unstructured terms cannot indicate the actor and object of the event.

In this paper, we propose using structured information to represent events, and develop a prediction model to analyze the relationship between events and the stock market. The problem is important because it provides insights into understanding the underlying mechanisms of the influence of events on the stock market. There are two main challenges to this method. On the one hand, how to obtain structured event information from large-scale news streams is a challenging problem. We propose to apply Open Information Extraction techniques (Open IE; Banko et al. (2007); Etzioni et al. (2011); Fader et al. (2011)), which do not require predefined event types or manually labeled corpora. Subsequently, two ontologies (i.e. VerbNet and WordNet) are used to generalize structured event features in order to reduce their sparseness. On the other hand, the problem of accurately predicting stock price movement using structured events is challenging, since events and the stock market can have complex relations, which can be influenced by hidden factors. In addition to the commonly used linear models, we build a deep neural network model, which takes structured events as input and learn the potential relationships between events and the stock market.

Experiments on large-scale financial news datasets from Reuters[1] (106,521 documents) and Bloomberg[2] (447,145 documents) show that events are better features for stock market prediction than bags-of-words. In addition, deep neural networks achieve better performance than linear models. The accuracy of S&P 500 index prediction by our approach outperforms previous systems, and the accuracy of individual stock prediction can be over 70% on the large-scale data.

Our system can be regarded as one step towards building an expert system that exploits rich knowledge for stock market prediction. Our results are helpful for automatically mining stock price related news events, and for improving the accuracy of algorithm trading systems.

2 Method

2.1 Event Representation

We follow the work of Kim (1993) and design a structured representation scheme that allows us to extract events and generalize them. Kim defines an event as a tuple (O_i, P, T), where $O_i \subseteq O$ is a set of *objects*, P is a *relation* over the objects and T is a time interval. We propose a representation that further structures the event to have *roles* in addition to relations. Each event is composed of an **action** P, an **actor** O_1 that conducted the action, and an **object** O_2 on which the action was performed. Formally, an event is represented as $E = (O_1,\ P,\ O_2,\ T)$, where P is the action, O_1 is the actor, O_2 is the object and T is the timestamp (T is mainly used for aligning stock data with news data). For example, the event "Sep 3, 2013 - Microsoft agrees to buy Nokia's mobile phone business for $7.2 billion." is modeled as: (Actor = *Microsoft*, Action = *buy*, Object = *Nokia's mobile phone business*, Time = *Sep 3, 2013*).

Previous work on stock market prediction represents events as a set of individual terms (Fung et al., 2002; Fung et al., 2003; Hayo and Kutan, 2004; Feldman et al., 2011). For example, "Microsoft agrees to buy Nokia's mobile phone business for $7.2 billion." can be represented by {"Microsoft", "agrees", "buy", "Nokia's", "mobile", ...} and "Oracle has filed suit against Google over its ever-more-popular mobile operating system, Android." can be represented by {"Oracle", "has", "filed", "suit", "against", "Google", ...}. However, terms alone might fail to accurately predict the stock price movement of *Microsoft*, *Nokia*, *Oracle* and *Google*, because they cannot indicate the actor and object of the event. To our knowledge, no effort has been reported in the literature to empirically investigate structured event representations for stock market prediction.

2.2 Event Extraction

A main contribution of our work is to extract and use structured events instead of bags-of-words in prediction models. However, structured event extraction can be a costly task, requiring predefined event types and manual event templates (Ji and Grishman, 2008; Li et al., 2013). Partly due to this, the bags-of-words-based document representation has been the mainstream method for a long time. To tackle this issue, we resort to Open IE, extracting event tuples from wide-coverage data with-

out requiring any human input (e.g. templates). Our system is based on the system of Fader et al. (2011) and the work of Ding et al. (2013); it does not require predefined target event types and labeled training examples. Given a natural language sentence obtained from news texts, the following procedure is used to extract structured events:

1. **Event Phrase Extraction.** We extract the predicate verb P of a sentence based on the dependency parser of Zhang and Clark (2011), and then find the longest sequence of words P_v, such that P_v starts at P and satisfies the syntactic and lexical constraints proposed by Fader et al. (2011). The content of these two constraints are as follows:
   - **Syntactic constraint:** every multi-word event phrase must begin with a verb, end with a preposition, and be a contiguous sequence of words in the sentence.
   - **Lexical constraint:** an event phrase should appear with at least a minimal number of distinct argument pairs in a large corpus.
2. **Argument Extraction.** For each event phrase P_v identified in the step above, we find the nearest noun phrase O_1 to the left of P_v in the sentence, and O_1 should contain the subject of the sentence (if it does not contain the subject of P_v, we find the second nearest noun phrase). Analogously, we find the nearest noun phrase O_2 to the right of P_v in the sentence, and O_2 should contain the object of the sentence (if it does not contain the object of P_v, we find the second nearest noun phrase).

An example of the extraction algorithm is as follows. Consider the sentence,

Instant view: Private sector adds 114,000 jobs in July: ADP.

The predicate verb is identified as "adds", and its subject and object "sector" and "jobs", respectively. The structured event is extracted as (*Private sector*, *adds*, *114,000 jobs*).

2.3 Event Generalization

Our goal is to train a model that is able to make predictions based on various expressions of the same event. For example, "Microsoft swallows Nokia's phone business for $7.2 billion" and "Microsoft purchases Nokia's phone business" report the same event. To improve the accuracy of our prediction model, we should endow the event extraction algorithm with generalization capacity. To this end, we leverage knowledge from two well-known ontologies, WordNet (Miller, 1995) and VerbNet (Kipper et al., 2006). The process of event generalization consists of two steps. First, we construct a morphological analysis tool based on the WordNet stemmer to extract lemma forms of inflected words. For example, in "Instant view: Private sector adds 114,000 jobs in July.", the words "adds" and "jobs" are transformed to "add" and "job", respectively. Second, we generalize each verb to its class name in VerbNet. For example, "add" belongs to the *multiply* class. After generalization, the event (*Private sector*, *adds*, *114,000 jobs*) becomes (*private sector*, *multiply_class*, *114,000 job*). Similar methods on event generalization have been investigated in Open IE based event causal prediction (Radinsky and Horvitz, 2013).

2.4 Prediction Models

1. Linear model. Most previous work uses linear models to predict the stock market (Fung et al., 2002; Luss and d'Aspremont, 2012; Schumaker and Chen, 2009; Kogan et al., 2009; Das and Chen, 2007; Xie et al., 2013). To make direct comparisons, this paper constructs a linear prediction model by using Support Vector Machines (SVMs), a state-of-the-art classification model. Given a training set $(d_1,\ y_1)$, $(d_2,\ y_2)$, ..., $(d_N,\ y_N)$, where $n \in [1,\ N]$, d_n is a news document and $y_i \in \{+1,\ -1\}$ is the output class. d_n can be news titles, news contents or both. The output Class +1 represents that the stock price will increase the next day/week/month, and the output Class -1 represents that the stock price will decrease the next day/week/month. The features can be bag-of-words features or structured event features. By SVMs, $y = \arg\max\{Class + 1,\ Class - 1\}$ is determined by the linear function $\boldsymbol{w} \cdot \boldsymbol{\Phi}(d_n, y_n)$, where $\boldsymbol{w}$ is the feature weight vector, and $\boldsymbol{\Phi}(d_n, y_n)$ is a function that maps d_n into a *M*-dimensional feature space. Feature templates will be discussed in the next subsection.

2. Nonlinear model. Intuitively, the relationship between events and the stock market may be more complex than linear, due to hidden and indirect

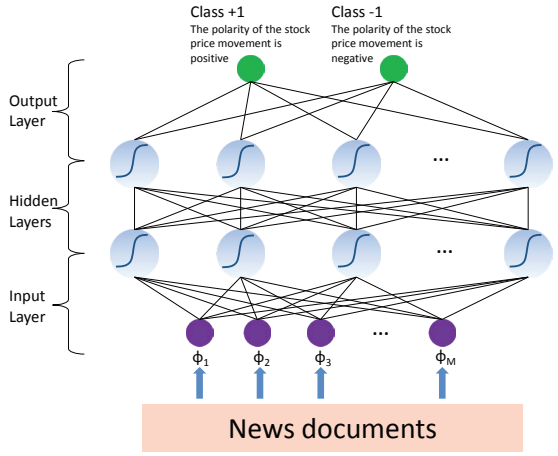

Figure 2: Structure of the deep neural network model

relationships. We exploit a deep neural network model, the hidden layers of which is useful for learning such hidden relationships. The structure of the model with two hidden layers is illustrated in Figure 2. In all layers, the sigmoid activation function σ is used.

Let the values of the neurons of the output layer be y_{cls} ($cls \in \{+1, -1\}$), its input be net_{cls}, and $\mathbf{y_2}$ be the value vector of the neurons of the last hidden layer; then:

$$y_{cls} = f(net_{cls}) = \sigma(\boldsymbol{w_{cls}} \cdot \mathbf{y_2}) \quad (1)$$

where $\boldsymbol{w_{cls}}$ is the weight vector between the neuron *cls* of the output layer and the neurons of the last hidden layer. In addition,

$$\begin{aligned} y_{2k} &= \sigma(\boldsymbol{w_{2k}} \cdot \mathbf{y_1}) \quad (k \in [1, |y_2|]) \\ y_{1j} &= \sigma(\boldsymbol{w_{1j}} \cdot \mathbf{\Phi}(d_n)) \quad (j \in [1, |y_1|]) \end{aligned} \quad (2)$$

Here $\mathbf{y_1}$ is the value vector of the neurons of the first hidden layer, $\boldsymbol{w_{2k}} = (w_{2k1}, w_{2k2}, ..., w_{2k|y_1|})$, $k \in [1, |y_2|]$ and $\boldsymbol{w_{1j}} = (w_{1j1}, w_{1j2}, ..., w_{1jM})$, $j \in [1, |y_1|]$. w_{2kj} is the weight between the *k*th neuron of the last hidden layer and the *j*th neuron of the first hidden layer; w_{1jm} is the weight between the *j*th neuron of the first hidden layer and the *m*th neuron of the input layer $m \in [1, M]$; d_n is a news document and $\mathbf{\Phi}(d_n)$ maps d_n into a *M*-dimensional features space. News documents and features used in the nonlinear model are the same as those in the linear model, which will be introduced in details in the next subsection. The standard back-propagation algorithm (Rumelhart et al., 1985) is used for supervised training of the neural network.

	train	dev	test

number of events	54776	6457	6593
time interval	02/10/2006 - 18/16/2012	19/06/2012 - 21/02/2013	22/02/2013 - 21/11/2013

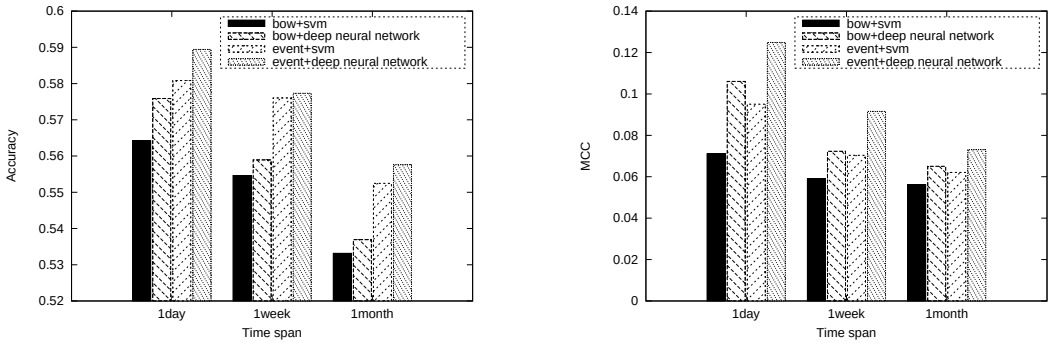
Table 1: Dataset splitting

2.5 Feature Representation

In this paper, we use the same features (i.e. document representations) in the linear and nonlinear prediction models, including bags-of-words and structured events.

(1) Bag-of-words features. We use the classic "TFIDF" score for bag-of-words features. Let L be the vocabulary size derived from the training data (introduced in the next section), and $freq(t_l)$ denote the number of occurrences of the *l*th word in the vocabulary in document d. $\mathbf{TF_l} = \frac{1}{|d|} freq(t_l)$, $\forall l \in [1, L]$, where $|d|$ is the number of words in the document d (stop words are removed). $\mathbf{TFIDF_l} = \frac{1}{|d|} freq(t_l) \times log(\frac{N}{|\{d: freq(t_l) > 0\}|})$, where N is the number of documents in the training set. The feature vector $\mathbf{\Phi}$ can be represented as $\mathbf{\Phi} = (\phi_1, \phi_2, ..., \phi_M) = (TFIDF_1, TFIDF_2, ..., TFIDF_M)$. The TFIDF feature representation has been used by most previous studies on stock market prediction (Kogan et al., 2009; Luss and d'Aspremont, 2012).

(2) Event features. We represent an event tuple (O_1, P, O_2, T) by the combination of elements (except for T) $(O_1, P, O_2, O_1 + P, P + O_2, O_1 + P + O_2)$. For example, the event tuple (Microsoft, buy, Nokia's mobile phone business) can be represented as (*#arg1*=Microsoft, *#action*=get_class, *#arg2*=Nokia's mobile phone business, *#arg1_action*=Microsoft get_class, *#action_arg2*=get_class Nokia's mobile phone business, *#arg1_action_arg2*=Microsoft get_class Nokia's mobile phone business). Structured events are more sparse than words, and we reduce sparseness by two means. First, verb classes (Section 2.3) are used instead of verbs for *P*. For example, "get_class" is used instead of the verb "buy". Second, we use back-off features, such as $O_1 + P$ ("Microsoft get_class") and $P + O_2$ ("get_class Nokia's mobile phone business"), to address the sparseness of O_1 and O_2. Note that the order of O_1 and O_2 is important for our task since they indicate the actor and object, respectively.



(a) Accuarcy (b) MCC

Figure 3: Overall development experiment results

3 Experiments

Our experiments are carried out on three different time intervals: short term (1 day), medium term (1 week) and long term (1 month). We test the influence of events on predicting the polarity of stock change for each time interval, comparing the event-based news representation with bag-of-words-based news representations, and the deep neural network model with the SVM model.

3.1 Data Description

We use publicly available financial news from Reuters and Bloomberg over the period from October 2006 to November 2013. This time span witnesses a severe economic downturn in 2007-2010, followed by a modest recovery in 2011-2013. There are 106,521 documents in total from Reuters News and 447,145 from Bloomberg News. News titles and contents are extracted from HTML. The timestamps of the news are also extracted, for alignment with stock price information. The data size is larger than most previous work in the literature.

We mainly focus on predicting the change of the Standard & Poor's 500 stock (S&P 500) index[3], obtaining indices and stock price data from Yahoo Finance. To justify the effectiveness of our prediction model, we also predict price movements of fifteen individual shares from different sectors in S&P 500. We automatically align 1,782 instances of daily trading data with news titles and contents from the previous day/the day a week before the stock price data/the day a month before the stock price data, 4/5 of which are used as the training data, 1/10 for development testing and 1/10 for testing. As shown in Table 1, the training, development and test set are split temporally, with the data from 02/10/2006 to 18/16/2012 for training, the data from 19/06/2012 to 21/02/2013 for development testing, and the data from 22/02/2013 to 21/11/2013 for testing. There are about 54,776 events in the training set, 6,457 events in the development set and 6,593 events in the test set.

[3]Standard & Poor's 500 is a stock market index based on the market capitalizations of 500 large companies having common stock listed on the NYSE or NASDAQ.

3.2 Evaluation Metrics

We use two assessment metrics. First, a standard and intuitive approach to measuring the performance of classifiers is accuracy. However, this measure is very sensitive to data skew: when a class has an overwhelmingly high frequency, the accuracy can be high using a classifier that makes prediction on the majority class. Previous work (Xie et al., 2013) uses an additional evaluation metric, which relies on the Matthews Correlation Cofficient (MCC) to avoid bias due to data skew (our data are rather large and not severely skewed, but we also use MCC for comparison with previous work). MCC is a single summary value that incorporates all 4 cells of a 2*2 confusion matrix (True Positive, False Positive, True Negative and False Negative, respectively). Given TP, TN, FP and FN:

$$MCC = \frac{TP \cdot TN - FP \cdot FN}{\sqrt{(TP+FP)(TP+FN)(TN+FP)(TN+FN)}} \quad (3)$$

3.3 Overall Development Results

We evaluate our four prediction methods (i.e. SVM with bag-of-word features (bow), deep neural network with bag-of-word features (bow),

		1 day	1 week	1 month
1 layer	Accuracy	58.94%	57.73%	55.76%
	MCC	0.1249	0.0916	0.0731
2 layers	Accuracy	59.60%	57.73%	56.19%
	MCC	0.1683	0.1215	0.0875

Table 4: Individual stock prediction results

SVM with event features and deep neural network with event features) on three time intervals (i.e. 1 day, 1 week and 1 month, respectively) on the development dataset, and show the results in Figure 3. We find that:

(1) Structured event is a better choice for representing news documents. Given the same prediction model (SVM or deep neural network), the event-based method achieves consistently better performance than the bag-of-words-based method over all three time intervals. This is likely due to the following two reasons. First, being an extraction of predicate-argument structures, events carry the most essential information of the document. In contrast, bag-of-words can contain more irrelevant information. Second, structured events can directly give the actor and object of the action, which is important for predicting stock market.

(2) The deep neural network model achieves better performance than the SVM model, partly by learning hidden relationships between structured events and stock prices. We give analysis to these relationships in the next section.

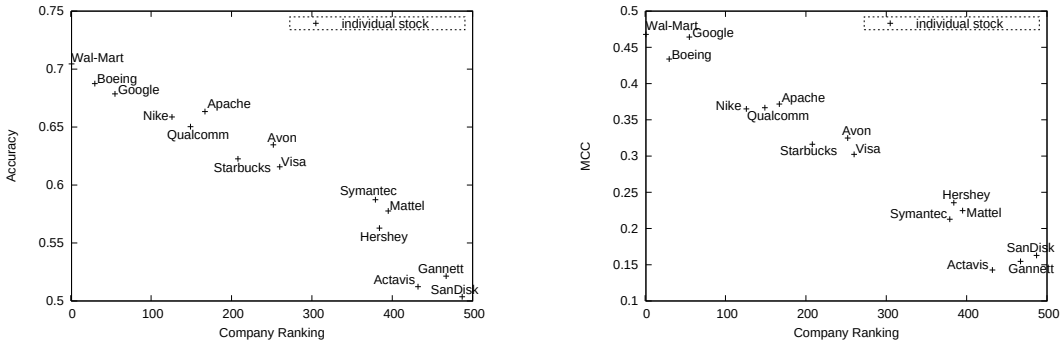
(3) Event information is a good indicator for short-term volatility of stock prices. As shown in Figure 3, the performance of daily prediction is better than weekly and monthly prediction. Our experimental results confirm the conclusion of Tetlock, Saar-Tsechansky, and Macskassy (2008) that there is a one-day delay between the price response and the information embedded in the news. In addition, we find that some events may cause immediate changes of stock prices. For example, former Microsoft CEO Steve Ballmer announced he would step down within 12 months on 23/08/2013. Within an hour, Microsoft shares jumped as much as 9 percent. This fact indicates that it may be possible to predict stock price movement on a shorter time interval than one day. However, we cannot access fine-grained stock price historical data, and this investigation will be left as future work.

3.4 Experiments with Different Numbers of Hidden Layers of the Deep Neural Network Model

Cybenko (1989) states that when every processing element utilizes the sigmoid activation function, one hidden layer is enough to solve any discriminant classification problem, and two hidden layers are capable to parse arbitrary output functions of input pattern. Here we conduct a development experiment by different number of hidden layers for the deep neural network model. As shown in Table 2, the performance of two hidden layers is better than one hidden layer, which is consistent with the experimental results of Sharda and Delen (2006) on the task of movie box-office prediction. It indicates that more hidden layers can explain more complex relations (Bengio, 2009). Intuitively, three or more hidden layers may achieve better performance. However, three hidden layers mean that we construct a five-layer deep neural network, which is difficult to train (Bengio et al., 1994). We did not obtain improved accuracies using three hidden layers, due to diminishing gradients. A deep investigation of this problem is out of the scope of this paper.

3.5 Experiments with Different Amounts of Data

We conduct a development experiment by extracting news titles and contents from Reuters and Bloomberg, respectively. While titles can give the central information about the news, contents may provide some background knowledge or details. Radinsky et al. (2012) argued that news titles are more helpful for prediction compared to news con-



(a) Accuarcy (b) MCC

Figure 4: Individual stock prediction experiment results

tents, and this paper mainly uses titles. Here we design a comparative experiment to analyze the effectiveness of news titles and contents. First, we use Reuters news to compare the effectiveness of news titles and contents, and then add Bloomberg news titles to investigate whether the amounts of data matters. Table 3 shows that using only news titles achieves the best performance. A likely reason is that we may extract some irrelevant events from news contents.

With the additional Bloomberg data, the results are not dramatically improved. This is intuitively because most events are reported by both Reuters news and Bloomberg news. We randomly select about 9,000 pieces of news documents from Reuters and Bloomberg and check the daily overlap manually, finding that about 60% of the news are reported by both Reuters and Bloomberg. The overlap of important news (news related to S&P 500 companies) is 80% and the overlap of unimportant news is 40%.

3.6 Individual Stock Prediction

In addition to predicting the S&P 500 index, we also investigate the effectiveness of our approach on the problem of individual stock prediction using the development dataset. We select three well-known companies, *Google Inc.*, *Boeing Company* and *Wal-Mart Stores* from three different sectors (i.e. Information Technology, Industrials and Consumer Staples, respectively) classified by the Global Industry Classification Standard (GICS). We use company news, sector news and all news to predict individual stock price movement, respectively. The experimental results are listed in Table 4.

The result of individual stock prediction by using only company news dramatically outperforms the result of S&P 500 index prediction. The main reason is that company-related events can directly affect the volatility of company shares. There is a strong correlation between company events and company shares. Table 4 also shows that the result of individual stock prediction by using sector news or all news does not achieve a good performance, probably because there are many irrelevant events in all news, which would reduce the performance of our prediction model.

The fact that the accuracy of these well-known stocks are higher than the index may be because there is relatively more news events dedicated to the relevant companies. To gain a better understanding of the behavior of the model on more individual stocks, we randomly select 15 companies (i.e. *Google Inc.*, *Boeing Company*, *Wal-Mart Stores*, *Nike Inc.*, *QUALCOMM Inc.*, *Apache Corporation*, *Starbucks Corp.*, *Avon Products*, *Visa Inc.*, *Symantec Corp.*, *The Hershey Company*, *Mattel Inc.*, *Actavis plc*, *Gannett Co.* and *SanDisk Corporation*) from S&P 500 companies. More specifically, according to the Fortune ranking of S&P 500 companies[4], we divide the ranked list into five parts, and randomly select three companies from each part. The experimental results are shown in Figure 4. We find that:

(1) All 15 individual stocks can be predicted with accuracies above 50%, while 60% of the stocks can be predicted with accuracies above 60%. It shows that the amount of company-related events has strong relationship with the volatility of

[4]http://money.cnn.com/magazines/fortune/fortune500/. The amount of company-related news is correlated to the fortune ranking of companies. However, we find that the trade volume does not have such a correlation with the ranking.

	S&P 500 Index Prediction		Individual Stock Prediction					
			Google Inc.		Boeing Company		Wal-Mart Stores	
	Accuracy	MCC	Accuracy	MCC	Accuracy	MCC	Accuracy	MCC
dev	59.60%	0.1683	67.86%	0.4642	68.75%	0.4339	70.45%	0.4679
test	58.94%	0.1649	66.97%	0.4435	68.03%	0.4018	69.87%	0.4456

Table 5: Final experimental results on the test dataset

company shares.

(2) With decreasing company fortune rankings, the accuracy and MCC decrease. This is mainly because there is not as much daily news about low-ranking companies, and hence one cannot extract enough structured events to predict the volatility of these individual stocks.

3.7 Final Results

The final experimental results on the test dataset are shown in Table 5 (as space is limited, we show the results on the time interval of one day only). The experimental results on the development and test datasets are consistent, which indicate that our approach has good robustness. The following conclusions obtained from development experiments also hold on the test dataset:

(1) Structured events are more useful representations compared to bags-of-words for the task of stock market prediction.

(2) A deep neural network model can be more accurate on predicting the stock market compared to the linear model.

(3) Our approach can achieve stable experiment results on S&P 500 index prediction and individual stock prediction over a large amount of data (eight years of stock prices and more than 550,000 pieces of news).

(4) The quality of information is more important than the quantity of information on the task of stock market prediction. That is to say that the most relevant information (i.e. news title *vs* news content, individual company news *vs* all news) is better than more, but less relevant information.

3.8 Analysis and Discussion

We use Figure 5 to demonstrate our analysis to the development experimental result of *Google Inc.* stock prediction, which directly shows the relationship between structured events and the stock market. The links between each layer show the magnitudes of feature weights in the model learned using the training set.

Three events, (Google, says bought stake in, China's XunLei), (Google, reveals stake in, Chinese social website) and (Capgemini, partners, Google apps software), have the highest link weights to the first hidden node (from the left). These three events indicate that Google constantly makes new partners and expands its business area. The first hidden node has high-weight links to Class +1, showing that Google's positive cooperation can lead to the rise of its stock price.

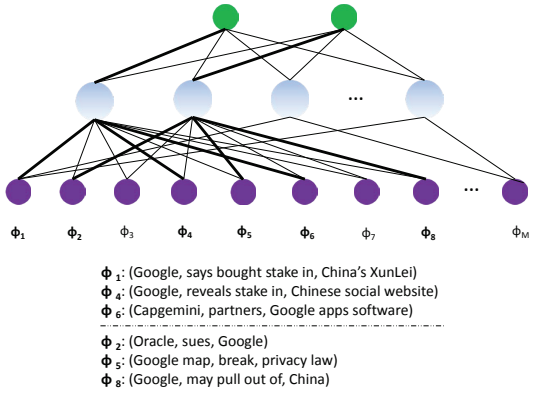


Figure 5: Prediction of *Google Inc.* (we only show structured event features since backoff features are less informative)

Three other events, (Oracle, sues, Google), (Google map, break, privacy law) and (Google, may pull out of, China), have high-weight links to the second hidden node. These three events show that Google was suffering questions and challenges, which could affect its reputation and further pull down its earnings. Correspondingly, the second hidden node has high-weight links to Class -1. These suggest that our method can automatically and directly reveal complex relationships between structured events and the stock market, which is very useful for investors, and can facilitate the research of stock market prediction.

Note that the event features used in our prediction model are generalized based on the algorithm introduced in Section 2.5. Therefore, though a specific event in the development test set might have never happened, its generalized form can be found in the training set. For example, "Google acquired social marketing company Wildfire In-

teractive" is not in the training data, but "Google get_class" ("get" is the class name of "acquire" and "buy" in VerbNet) can indeed be found in the training set, such as "Google bought stake in XunLei" on 04/01/2007. Hence although the full specific event feature does not fire, its back-offs fire for a correct prediction. For simplicity of showing the event, we did not include back-off features in Figure 5.

4 Related Work

Stock market prediction has attracted a great deal of attention across the fields of finance, computer science and other research communities in the past. The literature of stock market prediction was initiated by economists (Keynes, 1937). Subsequently, the influential theory of Efficient Market Hypothesis (EMH) (Fama, 1965) was established, which states that the price of a security reflects all of the information available and that everyone has a certain degree of access to the information. EMH had a significant impact on security investment, and can serve as the theoretical basis of event-based stock price movement prediction.

Various studies have found that financial news can dramatically affect the share price of a security (Chan, 2003; Tetlock et al., 2008). Culter et al. (1998) was one of the first to investigate the relationship between news coverage and stock prices, since which empirical text analysis technology has been widely used across numerous disciplines (Lavrenko et al., 2000; Kogan et al., 2009; Luss and d'Aspremont, 2012). These studies primarily use bags-of-words to represent financial news documents. However, as Schumaker and Chen (2009) and Xie et al. (2013) point out, bag-of-words features are not the best choice for predicting stock prices. Schumaker and Chen (2009) extract noun phrases and named entities to augment bags-of-words. Xie et al. (2013) explore a rich feature space that relies on frame semantic parsing. Wang et al. (2014) use the same features as Xie et al. (2013), but they perform non-parametric kernel density estimation to smooth out the distribution of features. These can be regarded as extensions to the bag-of-word method. The drawback of these approaches, as discussed in the introduction, is that they do not directly model events, which have structured information.

There has been efforts to model events more directly (Fung et al., 2002; Hayo and Kutan, 2005; Feldman et al., 2011). Fung, Yu, and Lam (2002) use a normalized word vector-space to model event. Feldman et al. (2011) extract 9 predefined categories of events based on heuristic rules. There are two main problems with these efforts. First, they cannot extract structured event (e.g. the actor of the event and the object of the event). Second, Feldman et al. (2011) can obtain only limited categories of events, and hence the scalability of their work is not strong. In contrast, we extract structured events by leveraging Open Information Extraction technology (Open IE; Yates et al. (2007); Etzioni et al. (2011); Faber et al. (2011)) without predefined event types, which can effectively solve the two problems above.

Apart from events, sentiment analysis is another perspective to the problem of stock prediction (Das and Chen, 2007; Tetlock, 2007; Tetlock et al., 2008; Bollen et al., 2011; Si et al., 2013). Tetlock (2007) examines how qualitative information (i.e. the fraction of negative words in a particular news column) is incorporated in aggregate market valuations. Tetlock, Saar-Tsechansky, and Macskassy (2008) extend that analysis to address the impact of negative words in all Wall Street Joural (WSJ) and Dow Jones News Services (DJNS) stories about individual S&P500 firms from 1980 to 2004. Bollen and Zeng (2011) study whether the large-scale collective emotion on Twitter is correlated with the volatility of Dow Jones Industrial Average (DJIA). From the experimental results, they find that changes of the public mood match shifts in the DJIA values that occur 3 to 4 days later. Sentiment-analysis-based stock market prediction focuses on investigating the influence of subjective emotion. However, this paper puts emphasis on the relationship between objective events and the stock price movement, and is orthogonal to the study of subjectivity. As a result, our model can be combined with the sentiment-analysis-based method.

5 Conclusion

In this paper, we have presented a framework for event-based stock price movement prediction. We extracted structured events from large-scale news based on Open IE technology and employed both linear and nonlinear models to empirically investigate the complex relationships between events and the stock market. Experimental results showed that events-based document representations are

better than bags-of-words-based methods, and deep neural networks can model the hidden and indirected relationship between events and the stock market. For further comparisons, we freely release our data at http://ir.hit.edu.cn/∼xding/data.
