Extracting Clusters of Specialist Terms from Unstructured Text

Aaron Gerow

gerow@uchicago.edu

Abstract

Automatically identifying related specialist terms is a difficult and important task required to understand the lexical structure of language. This paper develops a corpus-based method of extracting coherent clusters of satellite terminology — terms on the edge of the lexicon — using co-occurrence networks of unstructured text. Term clusters are identified by extracting communities in the co-occurrence graph, after which the largest is discarded and the remaining words are ranked by centrality within a community. The method is tractable on large corpora, requires no document structure and minimal normalization. The results suggest that the model is able to extract coherent groups of satellite terms in corpora with varying size, content and structure. The findings also confirm that language consists of a densely connected core (observed in dictionaries) and systematic, semantically coherent groups of terms at the edges of the lexicon.

1 Introduction

Natural language consists of a number of relational structures, many of which can be obscured by lexical idiosyncrasies, regional variation and domain-specific conventions. Despite this, patterns of word use exhibit loose semantic structure, namely that proximate words tend to be related. This distributional hypothesis has been operationalized in a variety of ways, providing insights and solutions into practical and theoretical questions about meaning, intention and the use of language. Distributional analyses rely primarily on observing natural language to build statistical representations of words, phrases and documents (Turney and Pantel, 2010). By studying dictionaries and thesauri, lexicographic and terminological research has proposed that a core lexicon is used to define the remaining portions of vocabulary (Itô and Mester, 1995; Massé et al., 2008). Though many words that comprise general language use reside in this core lexicon, even the most general language contains specialist or so-called "satellite" words. This paper introduces a method of extracting this peripheral structure, with co-occurrence networks of unstructured text.

The core-periphery structure has been observed in dictionaries where definitions tend to use a restricted vocabulary, repetitively employing a core set of words to define others (Sinclair, 1996; Picard et al., 2013). In the farther regions of the lexicon, it is more difficult to find systematic semantic definition with corpus-based techniques due to the overwhelming number of infrequent words. Unfortunately, the fringe of the lexicon can be more important than the core because this is where domain-specific terminology resides — features that may be more important than frequent.

Examining dictionaries, (Picard et al., 2013) propose that the lexicon consists of four main parts: a *core* set of ubiquitous words used to define other words, a *kernel* that makes up most of the lexicon, a *minimal grounding set* that includes most of the core and some of the kernel, leaving a set of *satellites* in the periphery. This topography, reproduced in Figure 1, has been found in the way dictionary entries use words to define one another. In networks of dictionary definitions, the core component tends to form a strongly connected component (SCC) leaving satellites in smaller SCCs with relatively weak links to the core. This paper explores whether these these satellites form systematic, cohesive groups and whether they are observable in natural language.

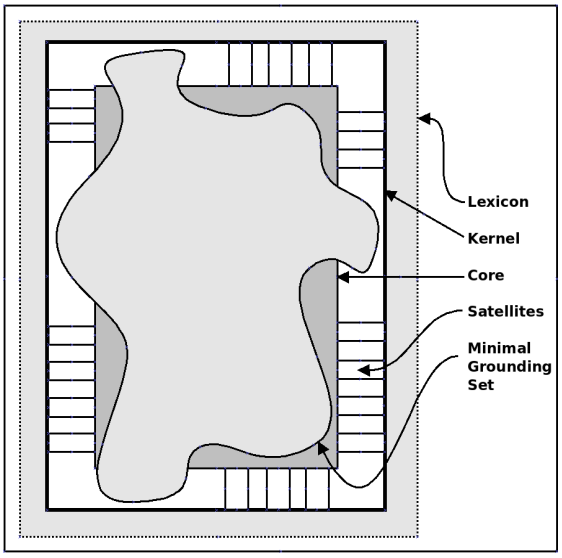

Figure 1: Dictionary studies have proposed that the lexicon consists of a strongly connected core, around which there is a kernel, an asymmetric grounding set and satellites. Adapted from (Picard et al., 2013).

Words with relatively specific definitions within subjects, referred to as *terms* in lexicographic research, are apparent in nearly all domains of discourse. Here, the goal is to explore structure among these peripheral terms without a dictionary. To do this, a method based on community detection in textual co-occurrence networks is developed. Such graph-based methods have become increasingly popular in a range of language-related tasks such as word clustering, document clustering, semantic memory, anaphora resolution and dependency parsing (see Mihalcea and Radev, 2011 for a review).

This paper seeks to address two important questions about the observed landscape of the lexicon in natural language: to investigate whether satellite clusters found in dictionaries can be observed in text, and more importantly, to explore whether statistical information in co-occurrence networks can elucidate this peripheral structure in the lexicon. We frame these questions as the task of extracting clusters of related terms. If satellites are systematically organized, then we can expect to find cohesive clusters in this region. Moreover, if the networked structure of dictionary entries supports the landscape in Figure 1, a similar structure may be present in co-occurrence patterns in natural text.

2 Method

Word clustering, as a means to explore underlying lexical structure, should accommodate fuzzy and potentially contradictory notions of similarity. For example, *red* and *green* are at once similar, being colors, but as colors, they are very different. Alternatively, the words *car*, *fast*, *wheel*, *export* and *motorists* share a thematic similarity in their relation to automobiles. One conception of word clustering is to construct a thesaurus of synonyms (Calvo et al., 2005), but clustering could allow other lexical semantic relationships. One such database, WordNet, defines specific semantic relationships and has been used to group words according to explicit measures of relatedness and similarity (Miller, 1995; Pedersen et al., 2004). Distributional, corpus-based techniques that define words as feature vectors (eg. word-document co-occurrences), can address many limitations of manually created lexicons (see Turney et al., 2010 for a review). Clustering nouns by argument structure can uncover naturally related objects (Hindle, 1990) and spectral methods can relate distinct classes of nouns with certain kinds of verbs to induce selectional preferences (Resnik, 1997; Sun and Korhonen, 2009; Wilks, 1975) and assist metaphor processing (Shutova et al., 2013).

A pervasive weakness of many existing approaches to word-clustering, is an underlying prioritization of frequent words. To help address this sparsity, many models collapse words into stems, preclude uncommon words, or underestimate the relevance of infrequent words (Dagan et al., 1999). Probabilistic topic models have emerged as a uniquely flexible kind of word-clustering used in content analysis (Steyvers and Griffiths, 2007), text classification (Wei and Croft, 2006) and provide an extensible framework to address other tasks (Blei, 2012). Because the structure of satellite terms is not likely to rely on specific (much less consistent) lexical semantic relationships, we adopt a measure of *semantic coherence*, commonly used to qualify the results of topic models, as an indirect measure of what people tend to view as a cohesive set of words. This measure, which is defined in the next section, is particularly attractive because it is corpus-based, does not assume any specific semantic relationship and correlates with expert evaluations (Mimno et al., 2011; Newman et al., 2010). Using semantic coherence provides a way of measuring the qual-

ity of word-associations without appeal to a dictionary or assuming rigid relationships among the clustered words.

The first step is to construct a co-occurrence graph from which communities are extracted. Then the centrality of each word is computed within a community to generate cluster-specific rankings. The goal is not to categorize words into classes, nor to provide partitions that separate associated words across a corpus. Instead, the method is designed to extract qualifiable sets of specialist terms found in arbitrary text. Crucially, the method is designed to require no document structure and minimal pre-processing: stop-words and non-words are not removed and no phrasal, sentence or document structure is required. Although stemming or lemmatization could provide more stream-lined interpretations, the minimal pre-processing allows the method to operate efficiently on large amounts of unstructured text of any language.

Co-occurrence networks have been used in a variety of NLP applications, the basic idea being to construct a graph where proximate words are connected. Typically, words are connected if they are observed in an n-word window. We set this window to a symmetric 7 words on either side of the target and did not use any weighting[1]. In the resulting network, edge frequencies are set to the number of times the given co-occurrence is observed. The resulting networks are typically quite dense and exhibit small-world structure where most word-pairs are only a few edges apart (Baronchelli et al., 2013; Ferror i Cancho and Solé, 2001). To explore the effect of this density, different minimum node- and edge-frequencies were tested (analogous to the word- and co-occurrence frequencies in text). It was found that not setting any thresholds provided the best results (see Figure 2), supporting our minimal pre-processing approach.

To extract clusters from the co-occurrence matrix, the Infomap community detection algorithm was used. Infomap is an information-theoretic method that optimizes a compression dictionary using it to describe flow through connected nodes (Rosvall and Bergstrom, 2008). By minimizing a description of this flow, the algorithm can also extract nested communities (Rosvall and Bergstrom, 2011). In our experiments, we used the co-occurrence frequencies as edge-weights and ran 50 trials for each run of the algorithm. Co-occurrence networks tended to form one monolithic community, corresponding to the lexicon's core SCC, surrounded by a number of smaller communities. The monolithic community is discarded out-right, as it represents the core of the lexicon where few specialist terms reside. As we will see, the community detection algorithm naturally identifies this SCC, distinguishing satellite clusters of terminology. Though we do not explore its effect, the sensitivity of Infomap can be tuned to vary the relative size of the core SCC compared to the satellites, effectively allowing less modular communities to be considered satellites.

[1]7 was found to be the optimal window-size in terms of coherence. These preliminary results are available at knowledgelab.org/docs/coherent_clusters-data.xls.

Corpus	Docs	Tokens	Nodes	Edges
TASA	38,972	10.7M	58,357	1,319,534
NIPS	3,742	5.2M	28,936	1,612,659
enTenTen	92,327	72.2M	69,745	7,721,413

Table 1: Co-occurrence networks of each corpus.

To compare and interpret the resulting clusters, various measures of centrality were tested for ranking words within their communities. The goal of this ranking is to find words that typify or define their community without assuming its underlying semantics. The results in the next section show that a number of common centrality measures work comparably well for this task. The final output of the system is a set of communities, in which words are ranked by their centrality.

3 Results & Analysis

Three corpora were used for evaluation: the TASA, NIPS and enTenTen collections. TASA consists of paragraph-length excerpts from high-school level, American English texts (Landauer and Dumais, 1997). The NIPS collection contains 17 volumes of annual proceedings from the conference of the same name. The enTenTen corpus is a web-based collection of text-heavy, English web-sites. Table 1 summarizes the collections and their co-occurrence networks.

The extracted communities, which consist of word-centrality pairs, are similarly structured to the output of topic models. Because appeals to human judgement are expensive and can introduce issues of consistency (Chang et al., 2009; Hu et al., 2011), a corpus-based measure of semantic coherence has been proposed (Mimno et al., 2011). Co-

herence is used as a proxy for human judgments. A general form of semantic coherence can be defined as the mean pair-wise similarity over the top n words in a topic or cluster t

$$C(t) = \frac{1}{n} \sum_{\substack{(w_i,w_j)\in t \\ i<j}}^{n} S(w_i, w_j)$$

where S is a symmetric measure of similarity. Newman, et al. (2010) surveyed a number of similarity metrics and found that mean point-wise mutual information (PMI) correlated best to human judgements. PMI is a commonly used measure of how much more information co-occurring words convey together compared to their independent contributions (Church and Hanks, 1990; Bouma, 2009). Using PMI as S, we can define a version of coherence, known as *UCI Coherence*:

$$C_{UCI}(t) = \frac{1}{n} \sum_{\substack{(w_i,w_j)\in t \\ i<j}}^{n} \log \frac{p(w_i, w_j)}{p(w_i)p(w_j)}$$

where $p(w)$ is estimated as relative frequency in a corpus: $\frac{f(w)}{\sum_i f(w_i)}$. Using coherence to optimize topic models, Mimno et al. (2011) found that a simplified measure, termed *UMass Coherence*, is more strongly correlated to human judgments than C_{UCI}. For topic t, C_{UMass} is defined as follows:

$$C_{UMass}(t) = \frac{1}{n} \sum_{\substack{(w_i,w_j)\in t \\ i<j}}^{n} \log \frac{D(w_i, w_j) + 1}{D(w_j)}$$

where $D(w)$ is the number of documents containing w, and $D(w, w')$ is the number of documents containing both w and w'. Note that D relies crucially on document segmentation in the reference corpus, which is not encoded in the co-occurrence networks derived by the method described above. Thus, though the networks being analyzed and the coherence scores are both based on co-occurrence information, they are distinct from one another. Following convention, we compute coherence for the top 10 words in a given community. C_{UMass} was used as the measure of semantic coherence. and D was computed over the TASA corpus, which means the resulting scores are not directly comparable to (Mimno et al., 2011), though comparisons to other published results are provided below.

3.1 Ranking Functions & Frequency Thresholds

After communities are extracted from the co-occurrence graph, words are ranked by their centrality in a community. Six centrality measures were tested as ranking functions: degree centrality, closeness centrality, eigenvector centrality, Pagerank, hub-score and authority-score (Friedl et al., 2010). Degree centrality uses a node's degree as its centrality under the assumption that highly connected nodes are central. Closeness centrality measures the average distance between a node and all other nodes, promoting nodes that are "close" to the rest of the network. Eigenvector centrality favors well-connected nodes that are themselves connected to well-connected nodes. Pagerank is similar to eigenvector centrality, but also promotes nodes that mediate connections between strongly connected nodes. Hub and authority scores measure interconnectedness (hubs) and connectedness to interconnected nodes (authorities). Figure 2 shows the average coherence, across all communities extracted from the TASA corpus, for each centrality measure. The average coherence scores are highest using hub-score, though not significantly better than auth-score, eigenvector centrality or closeness centrality. In the results that follow, hub-scores were used to rank nodes within communities.

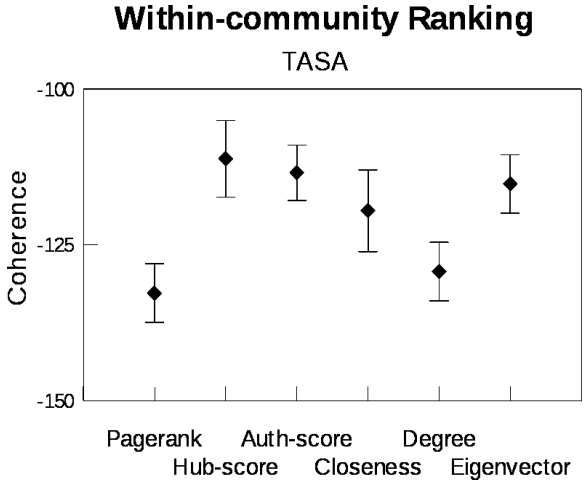

Figure 2: Mean coherence for six centrality measures. Error-bars are ±2 SE of the mean.

Imposing minimum node and edge frequencies in the co-occurrence graph was also tested. However, applying no thresholds provided the highest average coherence. Figure 3 shows the average coherence for eight threshold configurations. Though we used the TASA corpus for these tests, we have no reason to believe the results would differ significantly for the other corpora.

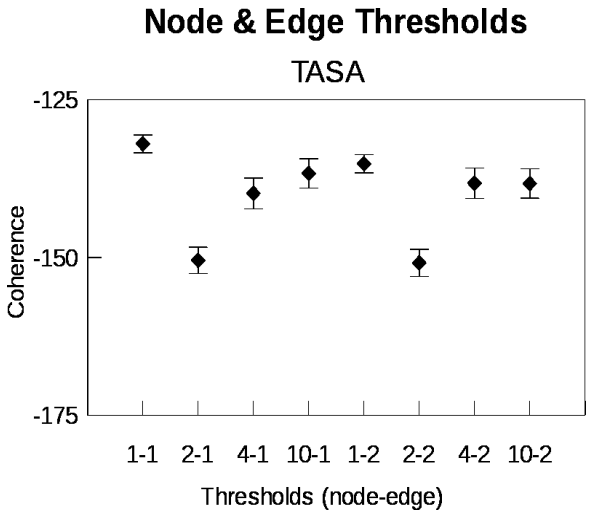

Figure 3: Mean coherence for different minimum node and edge frequencies, corresponding to thresholds for word and co-occurrence counts. Error-bars are ± 2 SE of the mean.

3.2 Community Coherence

Table 2 shows three communities of specialist terms extracted from each text collection, with their normalized hub-scores. Normalizing the scores preserves their rank-ordering and provides an indication of relative centrality within the community itself. For example, compare the first and last words from the top TASA and NIPS clusters: the difference between *thou* and *craven* (TASA) is considerably more than *model* and *network* (NIPS). In general, higher ranked words appear to typify their communities, with words like *model*, *university* and *nuclear* in the NIPS examples. These clusters are typical of those produced by the method, though in some cases, the communities contain less than 10 terms and were not included in the coherence analysis. Note that these clusters are not systematic in any lexical semantic sense, though in almost every case there are discernible thematic relations (middle-English words, Latin America and seafood in TASA).

TASA		**NIPS**		**enTenTen**

Table 2: Sample clusters from the TASA, NIPS and enTenTen collections. Shown are the clusters' top ten words, ranked by their normalized hub-score within the community. Note the differences in hub-score distributions between clusters.

Figure 4 shows the average coherence for our method, compared to that of a 20-topic latent Dirichlet allocation (LDA) model fit to the same corpora. Results from an LDA model fit to our corpora, as well as from a sample of published topics, are provided as a baseline to calibrate readers' intuitions about coherence[2]. Although topics from LDA do not necessarily consist of specialist terms those in the current model, the expectation of coherence remains: probable or central words should comprise a cohesive group. In every case, coherence is calculated over the top 10 words ranked using within-community hub-scores, for every community of 10 or more words. The results show that LDA provides relatively consistent coherence across collections, though with generally more variance than the communities of specialist terms. The term clusters are more coherent for the enTenTen collection than the others, which may

[2]Coherence was computed for the published results with C_{UMass} using TASA as the reference corpus.

be due to its larger size. This up-tick on the largest corpus may have to do with the proportional size of the monolithic community for the less structured documents in enTenTen. Figure 5 depicts how the proportional size of the core would effect the number and size of satellite clusters. It was found that the largest community (the core SCC) comprised 95% of TASA, 90% of NIPS and 97% of enTenTen. It may be that specialized language will have a proportionally smaller core and more satellite communities, whereas more general language will have a larger core and fewer satellites.

A critical question remains as to whether the method is actually observing the core-periphery structure of the lexicon or if it is an artifact. To test this, the frequencies of words in satellite communities were compared to those in the monolithic cases. If the monolithic community does indeed correspond to the core proposed in Figure 1, words in the satellites should have significantly lower frequencies. Indeed, the monolithic community in every corpus contained words that were significantly more frequent than those in the communities (Wilcoxon rank-sum test; Table 3). Taken with the coherence scores, these results show that there is coherent structure in the periphery of the lexicon, that can be extracted from unstructured text.

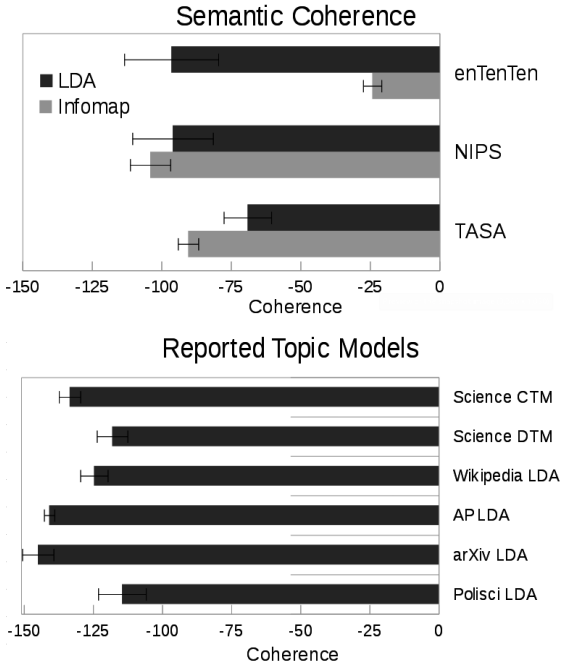

Figure 4: Mean coherence (C_{UMass}) for satellite clusters and topics from LDA on the TASA, NIPS and enTenTen collections (top). Also shown are the mean coherence of topics found in published models (LDA, a dynamic topic model, *DTM* and a correlated topic model, *CTM*; bottom). Error-bars are ± 2 SE of the mean.

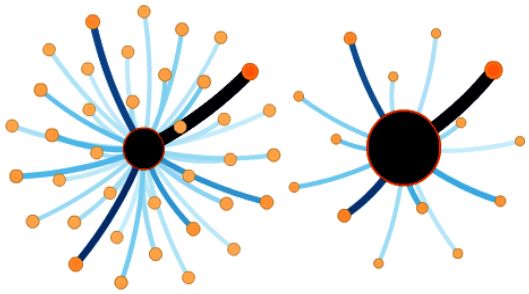

Figure 5: A proportionally larger core SCC (right) would force satellite communities to be smaller, less numerous and more isolated. Alternatively, with a small core (left), satellite communities would be more numerous and prominent.

Corpus	mean f_c	mean f_s	W	df
TASA	112.3	7.3	39985454	40895
NIPS	211.5	10.7	28342663	25077
enTenTen	365.1	15.9	246095083	72695

Table 3: Comparison of frequency for core words, f_c, found in the monolithic community and specialist terms, f_s, found in the satellite communities (Wilcoxon rank-sum test). All differences were significant at $p < 0.001$.

4 Discussion

The results of our method show that outlying structure in the lexicon can be extracted directly from large collections of unstructured text. The lexicon's topography, previously explored in dictionary studies, contains modular groups of satellite terms that are observable without appeal to external resources or document structure and with minimal normalization. The contribution of this method is two-fold: it confirms the structure of the *observed* lexicon is similar to that apparent in the organization of dictionaries (Picard et al., 2013). Second, it offers a tractable, reliable means of extracting and summarizing structure in the fringes of the lexicon.

The output of the model developed here is similar to topic models, but with some important differences. Topic models produce a probability distribution over words to define a topic, which can be summarized by the top 10 to 20 most likely words. Instead of probabilities, the within-

community hub-scores were used to rank words in each cluster. This means that the actual structure of the community (to which topics have no analogue) is responsible for producing the scores that rate words' internal relevance. Another crucial difference is that topic size from a single sampling iteration tends to correlate with coherence (Mimno et al., 2011), but in the current method, there is no correlation between cluster size and coherence ($p = 0.98$). The other important difference is that whereas topic models produce a topic-document mixture that can be used for posterior inference, to perform such inference with our method, the output would have to be used indirectly.

One understated strength of the community detection method is the minimal required preprocessing. Whereas many solutions in NLP (including topic models) require document segmentation, lexical normalization and statistical normalizations on the co-occurrence matrix itself, the only variable in our method is the co-occurrence window size. However, lemmatization (or stemming) could help collapse morpho-syntactic variation among terms in the results, but stop-word removal, sentence segmentation and TF-IDF weighting appear unnecessary. What might be most surprising given the examples in Table 2 is that word-document occurrence information is not used at all. This makes the the method particularly useful for large collections with little to no structure.

One question overlooked in our analysis concerns the effect the core has on the satellites. It could be that the proportional size of a collection's core is indicative of the degree of specialist terminology contained in the collection. Also, the raw number of satellite communities might indicate the level of diversity in a corpus. Addressing these questions could yield measures of previously vague and latent variables like specialty or topical diversity, without employing a direct semantic analysis. By measuring a collection's core size, relative to its satellites, one could also use measure changes in specialization. The Infomap algorithm could accommodate such an experiment: by varying the threshold of density that constitutes a community, the core could be made smaller, yielding more satellites, the coherence of which could be compared to those reported here. One could examine the position of individual words in the satellite(s) to explore what features signal important, emerging and dying terms or to track diachronic movement of terms like *computer* or *gene* from the specialized periphery to core of the lexicon.

At the level of inter-related term clusters, there are likely important or central groups that influence other satellites. There is no agreed upon measure of "community centrality" in a network sense (Eaton and Mansbach, 2012). One way to measure the importance of a community would be to use significance testing on the internal link mass compared to the external (Csardi and Nepusz, 2006). However, this approach discards some factors for which one might want to account, such as centrality in the network of communities and their composition. Future work could seek to combine graph-theoretic notions of centrality and intuitions about the defining features of term clusters. Another avenue for future research would be to use mixed membership community detection (Gopalan and Blei, 2013). Allowing terms to be represented in more than one community would accommodate words like *nuclear*, that might be found relating to weaponry, energy production and physics research at the same time. Using co-occurrence networks to extract clusters of specialist terms, though an important task, is perhaps only a starting point for exploring the observed lexicon. Network-based analysis of language offers a general and powerful potential to address a range of questions about the lexicon, other NLP tasks and language more generally.

Abstract

Given the large amounts of online textual documents available these days, e.g., news articles, weblogs, and scientific papers, *effective* methods for extracting keyphrases, which provide a high-level topic description of a document, are greatly needed. In this paper, we propose a supervised model for keyphrase extraction from research papers, which are embedded in citation networks. To this end, we design novel features based on citation network information and use them in conjunction with traditional features for keyphrase extraction to obtain remarkable improvements in performance over strong baselines.

1 Introduction

Keyphrase extraction is the problem of automatically extracting important phrases or concepts (i.e., the *essence*) of a document. Keyphrases provide a high-level topic description of a document and are shown to be rich sources of information for many applications such as document classification, clustering, recommendation, indexing, searching, and summarization (Jones and Staveley, 1999; Zha, 2002; Hammouda et al., 2005; Pudota et al., 2010; Turney, 2003). Despite the fact that keyphrase extraction has been widely researched in the natural language processing community, its performance is still far from being satisfactory (Hasan and Ng, 2014).

Many previous approaches to keyphrase extraction generally used only the textual content of a target document to extract keyphrases (Hulth, 2003; Mihalcea and Tarau, 2004; Liu et al., 2010). Recently, Wan and Xiao (2008) proposed a model that incorporates a local neighborhood of a document. However, their neighborhood is limited to textually-similar documents, where the cosine similarity between the *tf-idf* vectors of documents is used to compute their similarity. We posit that, in addition to a document's textual content and textually-similar neighbors, other informative neighborhoods exist that have the potential to improve keyphrase extraction. For example, in a scholarly domain, research papers are not isolated. Rather, they are highly inter-connected in giant *citation networks*, in which papers *cite* or *are cited* by other papers. In a citation network, information flows from one paper to another via the citation relation (Shi et al., 2010). This information flow and the influence of one paper on another are specifically captured by means of *citation contexts*, i.e., short text segments surrounding a citation's mention. These contexts are not arbitrary, but they serve as brief summaries of a cited paper. Figure 1 illustrates this idea using a small citation network of a paper by Rendle et al. (2010) that cites (Zimdars et al., 2001), (Hu et al., 2008), (Pan and Scholz, 2009) and (Shani et al., 2005) and is cited by (Cheng et al., 2013). The citation mentions and citation contexts are shown with a dashed line. Note the high overlap between the words in contexts and those in the title and abstract (shown in bold) and the author-annotated keywords.

One question that can be raised is the following: *Can we effectively exploit information available in large inter-linked document networks in order to improve the performance of keyphrase extraction?* The research that we describe in this paper addresses specifically this question using *citation networks of research papers* as a case study. Extracting keyphrases that can accurately "represent" research papers is crucial to dealing with the large numbers of research papers published during these "big data" times. The importance of keyphrase extraction from research papers is also emphasized by the recent SemEval 2010 Shared Task on this topic (Kim et al., 2010; Kim et al., 2013).

Our contributions. We present a supervised

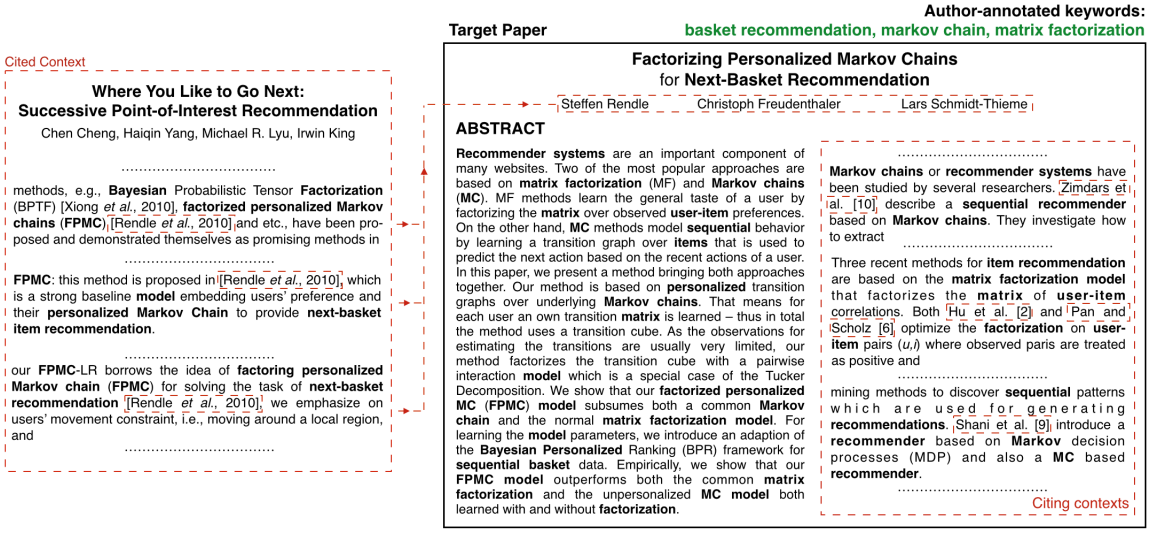

Figure 1: A small citation network corresponding to a paper by Rendle et al. (2010).

approach to keyphrase extraction from research papers that, in addition to the information contained in a paper itself, effectively incorporates, in the learned models, information from the paper's local neighborhood available in citation networks. To this end, we design novel features for keyphrase extraction based on citation context information and use them in conjunction with traditional features in a supervised probabilistic framework. We show empirically that the proposed models substantially outperform strong baselines on two datasets of research papers compiled from two machine learning conferences: the World Wide Web and Knowledge Discovery from Data.

The rest of the paper is organized as follows: We summarize closely related work in Section 2. The supervised classification for keyphrase extraction is discussed in Section 3. Experiments and results are presented in Section 4, followed by conclusions and future directions of our work.

2 Related Work

Many approaches to keyphrase extraction have been proposed in the literature along two lines of research: supervised and unsupervised, using different types of documents including scientific abstracts, newswire documents, meeting transcripts, and webpages (Frank et al., 1999; Hulth, 2003; Nguyen and Kan, 2007; Liu et al., 2009; Marujo et al., 2013; Mihalcea and Tarau, 2004).

In the supervised line of research, keyphrase extraction is formulated as a binary classification problem, where candidate phrases are classified as either positive (i.e., keyphrases) or negative (i.e., non-keyphrases) (Frank et al., 1999; Turney, 2000; Hulth, 2003). Different feature sets and classification algorithms gave rise to different models. For example, Hulth (2003) used four different features in conjunction with a *bagging* technique. These features are: term frequency, collection frequency, the relative position of the first occurrence and the part-of-speech tag of a term. Frank et al. (1999) developed a system called KEA that used only two features: *tf-idf* (term frequency-inverse document frequency) of a phrase and the *distance* of a phrase from the beginning of a document (i.e., its relative position) and used them as input to Naïve Bayes. Nguyen and Kan (2007) extended KEA to include features such as the distribution of keyphrases among different sections of a research paper, and the acronym status of a term. In contrast to these works, we propose novel features extracted from the local neighborhoods of documents available in interlinked document networks. Medelyan et al. (2009) extended KEA as well to integrate information from Wikipedia. In contrast, we used only information intrinsic to our data. Enhancing our models with Wikipedia information would be an interesting future direction to pursue.

In the unsupervised line of research, keyphrase extraction is formulated as a ranking problem, where keyphrases are ranked using their *tf* (Barker and Cornacchia, 2000), *tf-idf* (Zhang et al., 2007; Lee and Kim, 2008; Liu et al., 2009; Tonella et al., 2003), and *term informativeness* (Wu and Giles, 2013; Rennie and Jaakkola, 2005; Kireyev, 2009) (among others). The ranking based on *tf-idf* has

been shown to work well in practice (Liu et al., 2009; Hasan and Ng, 2010) despite its simplicity. Frantzi et al. (1998) combined linguistics and statistical information to extract technical terms from documents in digital libraries. Graph-based algorithms and centrality measures are also widely used in unsupervised models. A word graph is built for each document such that nodes correspond to words and edges correspond to word association patterns. Nodes are then ranked using graph centrality measures such as PageRank and its variants (Mihalcea and Tarau, 2004; Wan and Xiao, 2008; Liu et al., 2010; Zhao et al., 2011), HITS scores (Litvak and Last, 2008), as well as node degree and betweenness (Boudin, 2013; Xie, 2005). Wan and Xiao (2008) were the first to consider modeling a local neighborhood of a target document in addition to the document itself, and applied this approach to news articles on the Web. Their local neighborhood consists of textually similar documents, and did not capture information contained in document networks.

Using terms from citation contexts of scientific papers is not a new idea. It was used before in various applications. For example, Ritchie et al. (2006) used a combination of terms from citation contexts and existing index terms of a paper to improve indexing of cited papers. Citation contexts were also used to improve the performance of citation recommendation systems (Kataria et al., 2010; He et al., 2010) and to study author influence (Kataria et al., 2011). This idea of using terms from citation contexts resembles the analysis of hyperlinks and the graph structure of the Web, which are instrumental in Web search (Manning et al., 2008). Many current Web search engines build on the intuition that the anchor text pointing to a page is a good descriptor of its content, and thus use anchor text terms as additional index terms for a target webpage. The use of links and anchor text was thoroughly researched for IR tasks (Koolen and Kamps, 2010), broadening a user's search (Chakrabarti et al., 1998), query refinement (Kraft and Zien, 2004), and enriching document representations (Metzler et al., 2009).

Moreover, citation contexts were used for scientific paper summarization (Abu-Jbara and Radev, 2011; Qazvinian et al., 2010; Qazvinian and Radev, 2008; Mei and Zhai, 2008; Lehnert et al., 1990; Nakov et al., 2004). Among these, probably the most similar to our work is the work by Qazvinian et al. (2010), where a set of important keyphrases is extracted first from the citation contexts in which the paper to be summarized is cited by other papers and then the "best" subset of sentences that contain such keyphrases is returned as the summary. However, keyphrases in (Qazvinian et al., 2010) are extracted using frequent n-grams in a language model framework, whereas in our work, we propose a supervised approach to a different task: keyphrase extraction. Mei and Zhai (2008) used information from citation contexts to determine what sentences of a paper are of high impact (as measured by the influence of a target paper on further studies of similar or related topics). These sentences constitute the impact-based summary of the paper.

Despite the use of citation contexts and anchor text in many IR and NLP tasks, to our knowledge, we are the first to propose the incorporation of information available in citation networks for keyphrase extraction. In our recent work (Gollapalli and Caragea, 2014), we designed a fully unsupervised graph-based algorithm that incorporates evidence from multiple sources (citation contexts as well as document content) in a flexible manner to score keywords. In the current work, we present a supervised approach to keyphrase extraction from research papers that are embedded in large citation networks, and propose novel features that show improvement over strong supervised and unsupervised baselines. To our knowledge, features extracted from citation contexts have not been used before for keyphrase extraction in a supervised learning framework.

3 Problem Characterization

In citation networks, in addition to the information contained in a paper itself, *citing* and *cited* papers capture different aspects (e.g., topicality, domain of study, algorithms used) about the target paper (Teufel et al., 2006), with *citation contexts* playing an instrumental role. A citation context is defined as a window of n words surrounding a citation mention. We conjecture that citation contexts, which act as brief summaries about a cited paper, provide additional clues in extracting keyphrases for a target paper. These clues give rise to the unique design of our model, called citation-enhanced keyphrase extraction (CeKE).

3.1 Citation-enhanced Keyphrase Extraction

Our proposed citation-enhanced keyphrase extraction (CeKE) model is a supervised binary classifi-

Feature Name	Description
Existing features for keyphrase extraction	
tf-idf	term frequency * inverse document frequency, computed from a target paper; used in KEA
relativePos	the position of the first occurrence of a phrase divided by the total number of tokens; used in KEA and Hulth's methods
POS	the part-of-speech tag of the phrase; used in Hulth's methods
Novel features - Citation Network Based	
inCited	if the phrase occurs in cited contexts
inCiting	if the phrase occurs in citing contexts
citation tf-idf	the *tf-idf* value of the phrase, computed from the aggregated citation contexts
Novel features - Extensions of Existing Features	
first position	the distance of the first occurrence of a phrase from the beginning of a paper
tf-idf-Over	*tf-idf* larger than a threshold θ
firstPosUnder	the distance of the first occurrence of a phrase from the beginning of a paper is below some value β

Table 1: The list of features used in our model.

cation model, built on a combination of *novel* features that capture information from citation contexts and existing features from previous works. The features are described in §3.1.1. CeKE classifies candidate phrases as keyphrases (i.e., positive) or non-keyphrases (i.e., negative) using Naïve Bayes classifiers. Positive examples for training correspond to manually annotated keyphrases from the training research papers, whereas negative examples correspond to the remaining candidate phrases from these papers. The generation of candidate phrases is explained in §3.2.

Note that Naïve Bayes classifies a phrase as a keyphrase if the probability of the phrase belonging to the positive class is greater than 0.5. However, the default threshold of 0.5 can be varied to allow only high-confidence (e.g., 0.9 confidence) phrases to be classified as keyphrases.

3.1.1 Features

We consider the following features in our model, which are shown in Table 1. They are divided into three categories: (1) *Existing features for keyphrase extraction* include: *tf-idf*, i.e., the term frequency - inverse document frequency of a candidate phrase, computed for each target paper; This feature was used in KEA (Frank et al., 1999); *relative position*, i.e., the position of the first occurrence of a phrase normalized by the length (in the number of tokens) of the target paper; *POS*, i.e., a phrase's part-of-speech tag. If a phrase is composed by more than one term, then the POS will contain the tags of all terms. The relative position was used in both KEA and Hulth (2003), and POS was used in Hulth; (2) *Novel features - Citation Network Based* include: *inCited* and *inCiting*, i.e., boolean features that are true if the candidate phrase occurs in cited and citing contexts, respectively. We differentiate between cited and citing contexts for a paper: let d be a target paper and $\mathcal{C}$ be a citation network such that $d \in \mathcal{C}$. A cited context for d is a context in which d is cited by some paper d_i in $\mathcal{C}$. A citing context for d is a context in which d is citing some paper d_j in $\mathcal{C}$. If a paper is cited in multiple contexts by another paper, the contexts are aggregated into a single one; *citation tf-idf*, i.e., the tf-idf score of each phrase computed from the citation contexts; (3) *Novel features - Extend Other Existing Features* include: *first position* of a candidate phrase, i.e., the distance of the first occurrence of a phrase from the beginning of a paper; this is similar to relative position except that it does not consider the length of a paper; *tf-idf-Over*, i.e., a boolean feature, which is true if the *tf-idf* of a candidate phrase is greater than a threshold θ, and *firstPosUnder*, also a boolean feature, which is true if the distance of the first occurrence of a phrase from the beginning of a target paper is below some value β. This feature is similar to the feature *is-in-title*, used previously in the literature (Litvak and Last, 2008; Jiang et al., 2009). Both *tf-idf* and *citation tf-idf* features showed better results when each *tf* was divided by the maximum *tf* values from the target paper or citation contexts.

The *tf-idf* features have high values for phrases that are frequent in a paper or citation contexts, but are less frequent in collection and have low values for phrases with high collection frequency. We computed the *idf* component from each collection used in experiments. Phrases that occur in cited and citing contexts as well as early in a paper are likely to be keyphrases since: (1) they capture some aspect about the target paper and (2) authors start to describe their problem upfront.

3.2 Generating Candidate Phrases

We generate candidate phrases from the textual content of a target paper by applying parts-of-

Dataset	Num. (#) Papers	Average Cited Ctx.	Average Citing Ctx.	Average Keyphrases	#uni-grams	#bi-grams	#tri-grams
WWW	425	15.45	18.78	4.87	680	1036	247
KDD	365	12.69	19.74	4.03	363	853	189

Table 2: A summary of our datasets.

speech filters. Consistent with previous works (Hulth, 2003; Mihalcea and Tarau, 2004; Liu et al., 2010; Wan and Xiao, 2008), only nouns and adjectives are retained to form candidate phrases. The generation process consists of two steps. First, using the NLP Stanford part of speech tagger, we preprocess each document and keep only the nouns and adjectives corresponding to $\{NN, NNS, NNP, NNPS, JJ\}$. We apply the Porter stemmer on every word. The position of each word is kept consistent with the initial state of the document before any word removal is made.

Second, words extracted in the first step that have contiguous positions in a document are concatenated into n-grams. We used unigrams, bigrams, and trigrams ($n = 1, 2, 3$) as candidate phrases for classification. Similar to Wan and Xiao (2008), we eliminated phrases that end with an adjective and the unigrams that are adjectives.

4 Experiments and Results

In this section, we first describe our datasets and then present experimental design and results.

4.1 Datasets

In order to test the performance of our proposed approach, we built our own datasets since *citation-enhanced* evaluation benchmarks are not available for keyphrase extraction tasks. In particular, we compiled two datasets consisting of research papers from two top-tier machine learning conferences: World Wide Web (WWW) and Knowledge Discovery and Data Mining (KDD). Our choice for WWW and KDD was motivated by the availability of *author-input* keywords for each paper, which we used as gold-standard for evaluation.

Using the CiteSeer^x digital library[1], we retrieved the papers published in WWW and KDD (available in CiteSeer^x), and their citation network information, i.e., their cited and citing contexts. Since our goal is to study the impact of citation network information on extracting keyphrases, a paper was considered for analysis if it had at least one cited and one citing context. For each paper, we used: the title and abstract (referred to as the target paper) and its citation contexts. The reason for not considering the entire text of a paper is that scientific papers contain details, e.g., discussion of results, experimental design, notation, that do not provide additional benefits for extracting keyphrases. Hence, similar to (Hulth, 2003; Mihalcea and Tarau, 2004; Liu et al., 2009), we did not use the entire text of a paper. However, extracting keyphrases from sections such as "introduction" or "conclusion" needs further attention.

From the pdf of each paper, we extracted the author-input keyphrases. An analysis of these keyphrases revealed that generally authors describe their work using, almost half of the time, bigrams, followed by unigrams and only rarely using trigrams (or higher n-grams). A summary of our datasets that contains the number of papers, the average number of cited and citing contexts per paper, the average number of keyphrases per paper, and the number of unigrams, bigrams and trigrams, in each collection, is shown in Table 2.

Consistent with previous works (Frank et al., 1999; Hulth, 2003), the positive and negative examples in our datasets correspond to candidate phrases that consist of up to three tokens. The positive examples are candidate phrases that have a match in the author-input keyphrases, whereas negative examples correspond to the remaining candidate phrases.

Context lengths. In CiteSeer^x, citation contexts have about 50 words on each side of a citation mention. A previous study by Ritchie et al. (2008) shows that a fixed window length of about 100 words around a citation mention is generally effective for information retrieval tasks. For this reason, we used the contexts provided by CiteSeer^x directly. However, in future, it would be interesting to incorporate in our models more sophisticated approaches to identifying the text that is relevant to a target citation (Abu-Jbara and Radev, 2012; Teufel, 1999) and study the influence of context lengths on the quality of extracted keyphrase.

KEA	0.210	0.146	0.168	0.178	0.124	0.145

Table 3: The comparison of CeKE with supervised approaches on WWW and KDD collections.

4.2 Experimental Design

Our experiments are designed around the following research questions:

1. *How does the performance of citation-enhanced keyphrase extraction (CeKE) compare with the performance of existing supervised models that use only information intrinsic to the data and what are the most informative features for classification?* We compared CeKE's performance with that of classifiers trained on KEA features only and Hulth's features only and present a ranking of features based on information gain.
2. *How do supervised models that integrate citation network information compare with recent unsupervised models?* Since recent unsupervised approaches are becoming competitive with supervised approaches (Hasan and Ng, 2014), we also compared CeKE with unsupervised ranking of candidate phrases by TF-IDF, TextRank (Mihalcea and Tarau, 2004) and ExpandRank (Wan and Xiao, 2008). For unsupervised, we considered top 5 and top 10 ranked phrases when computing "@5" and "@10" measures.
3. *How well does our proposed model perform in the absence of either cited or citing contexts?* Since newly published scientific papers are not cited by many other papers, e.g., due to their recency, no cited contexts are available. We studied the quality of predicted keyphrases when either cited or citing contexts are missing. For this, we compared the performance of models trained using both cited and citing contexts with that of models that use either cited or citing contexts.

Evaluation metrics. To evaluate the performance of CeKE, we used the following metrics: precision, recall and F1-score for the positive class since correct identification of keyphrases is of most interest. These metrics were widely used in previous works (Hulth, 2003; Mihalcea and Tarau, 2004; Wan and Xiao, 2008; Hasan and Ng, 2010). The reported values are averaged in 10-fold cross-validation experiments, where folds were created at document level and candidate phrases were extracted from the documents in each fold to form the training and test sets. In all experiments, we used Naïve Bayes and their Weka implementation[2]. However, any probabilistic classifier that returns a posterior probability of the class given an example, can be used with our features.

The θ parameter was set to the (title and abstract) *tf-idf averaged* over the entire collection, while β was set to 20. These values were estimated on a validation set sampled from training.

4.3 Results and Discussion

The impact of citation network information on the keyphrase extraction task. Table 3 shows the results of the comparison of CeKE with two supervised approaches, KEA and Hulth's approach. The features used in KEA are the *tf-idf* and the *relative position* of a candidate phrase, whereas those used in Hulth's approach are *tf*, *cf* (i.e., collection frequency), *relative position* and *POS tags*. CeKE is trained using all features from Table 1. Among the three methods for candidate phrase formation proposed in Hulth (2003), i.e., n-grams, NP-chunks, and POS Tag Patterns, our Hulth's implementation is based on n-grams since this gives the best results among all methods (see (Hulth, 2003) for more details). In addition, the n-grams method is the most similar to our candidate phrase generation and that used in Frank et al. (1999).

As can be seen from Table 3, CeKE outperforms KEA and Hulth's approach in terms of all performance measures on both WWW and KDD, with a substantial improvement in recall over both approaches. For example, on WWW, CeKE achieves a recall of 0.386 compared to 0.146 and 0.107 recall achieved by KEA and Hulth's, respectively.

Table 5: The comparison of CeKE with unsupervised approaches on WWW and KDD collections.

Rank	*Feature*	IG Score
1	*abstract tf-idf*	0.0234
2	*first position*	0.0188
3	*citation tf-idf*	0.0177
4	*relativePos*	0.0154
5	*firstPosUnder*	0.0148
6	*inCiting*	0.0129
7	*inCited*	0.0098
8	*POS*	0.0085
9	*tf-idf-Over*	0.0078

Table 4: Feature ranking by Info Gain on WWW.

Although there are only small variations from KEA to Hulth's approach, KEA performs better on WWW, but worse on KDD compared with Hulth's approach. In contrast, CeKE shows consistent improvement over the two approaches on both datasets, hence, effectively making use of the information available in the citation network.

In order to understand the importance of our features, we ranked them based on Information Gain (IG), which determines how informative a feature is with respect to the class variable. Table 4 shows the features ranked in decreasing order of their IG scores for WWW. As can be seen from the table, *tf-idf* and *citation tf-idf* are both highly ranked, first and third, respectively, illustrating that they contain significant information in predicting keyphrases. The *first position* of a phrase is also of great impact. This is consistent with the fact that almost half of the identified keywords and about 20% of the annotated keyphrases appear in title. Similar ranking is obtained on KDD.

The comparison of CeKE with unsupervised state-of-the-art models. Table 5 shows the results of the comparison of CeKE with three unsupervised ranking approaches: TF-IDF (Tonella et al., 2003), TextRank (Mihalcea and Tarau, 2004), and ExpandRank (Wan and Xiao, 2008). TF-IDF and TextRank use information only from the target paper, whereas ExpandRank uses a small textual neighborhood in addition to the target paper. Note that, for all unsupervised methods, we used Porter stemmer and the same candidate phrase generation as in CeKE, as explained in §3.2.

For TF-IDF, we first tokenized the target paper and computed the score for each word, and then formed phrases and summed up the score of every word within a phrase. For TextRank, we built an undirected graph for each paper, where the nodes correspond to words in the target paper and edges are drawn between two words that occur next to each other in the text, i.e., the window size is 2. For ExpandRank, we built an undirected graph for each paper and its local textual neighborhood. Again, nodes correspond to words in the target paper and its textually similar papers and edges are drawn between two words that occur within a window of 10 words from each other in the text, i.e., the window size is 10. We performed experiments with 1, 5, and 10 textually-similar neighbors. For TextRank and ExpandRank, we summed up the scores of words within a phrase as in TF-IDF.

	WWW			KDD		
Method	Precision	Recall	F1-score	Precision	Recall	F1-score
CeKE - Both contexts	**0.227**	**0.386**	**0.284**	**0.213**	**0.413**	**0.280**
CeKE - Only cited contexts	0.222	0.286	0.247	0.192	0.300	0.233
CeKE - Only citing contexts	0.203	0.342	0.253	0.195	0.351	0.250

Table 6: Results of CeKE using both contexts and using with only cited or citing contexts.

For each unsupervised method, we computed results for top 5 and top 10 ranked phrases. As can be seen from Table 5, CeKE substantially outperforms all the other methods for our domain of study, i.e., papers from WWW and KDD, illustrating again that the citation network of a paper contains important information that can show remarkable benefits for keyphrase extraction. Among all unsupervised methods, ExpandRank with fewer textual similar neighbor (one or five) performs the best. This is generally consistent with the results shown in (Wan and Xiao, 2008) for news articles.

The effect of cited and citing contexts information on models' performance. Table 6 shows the precision, recall and F-score values for some variations of our method when: (1) all the citation contexts for a paper are used, (2) only cited contexts are used, (3) only citing contexts are used. The motivation behind this experiment was to determine how well the proposed model would perform on newly published research papers that have not accumulated citations yet. As shown in the table, there is no substantial difference in terms of precision between CeKE models that use only cited or only citing contexts, although the recall is substantially higher for the case when only citing contexts are used, for both WWW and KDD. The CeKE that uses both citing and cited contexts achieves a substantially higher recall and only a slightly higher precision compared with the cases when only one context type is available. The fact that the citing context information provides a slight improvement in performance over cited contexts is consistent with the intuition that when citing a paper y, an author generally summarizes the main ideas from y using important words from a target paper x, making the citing contexts to have higher overlap with words from x. In turn, a paper z that cites x may use paraphrasing to summarize ideas from x with words more similar to those from z.

Note that the results of all above experiments are statistically significant at p-values ≥ 0.05, using a paired t-test on F1-scores.

4.4 Anecdotal Evidence

In order to check the transferability of our proposed approach to other research fields, e.g., natural language processing, it would be interesting to use our trained classifiers on WWW and KDD collections and evaluate them on new collections such as NLP related collections. Since NLP collections annotated with keyphrases are not available, we show anecdotal evidence for only one paper. We selected for this task an award winning paper published in the EMNLP conference. The paper's title is "Unsupervised semantic parsing" and has won the Best Paper Award in the year 2009 (Poon and Domingos, 2009). In order for our algorithm to work, we gathered from the Web (using Google Scholar) all the cited and citing contexts that were available (49 cited contexts and 30 citing contexts). We manually annotated the target paper with keyphrases. The title, abstract and all the contexts were POS tagged using the NLP Stanford tool. We then trained a classifier on the features shown in Table 1, on both WWW and KDD datasets combined. The trained classifier was used to make predictions, which were compared against the manually annotated keyphrases. The results are shown in Figure 2, which displays the title and abstract of the paper and the predicted keyphrases. Candidate phrases that are predicted as keyphrases are marked in red bold, those predicted as non-keyphrases are shown in black, while the filtered out words are shown in light gray.

We tuned our classifier trained on WWW and KDD to return as keyphrases only those that had an extremely high probability to be keyphrases. Specifically, we used a threshold of 0.985. The probability of each returned keyphrase (which is above 0.985) is shown in the upper right corner of a keyphrase. Human annotated keyphrases are marked in italic, under the figure. There is a clear match between the predictions and the human annotations. It is also possible to extract more or less keyphrases simply by adjusting the threshold

Unsupervised Semantic Parsing$^{0.997}$

We present the first unsupervised approach to the problem of learning a **semantic parser**$^{1.000}$, using **Markov logic**$^{0.991}$. Our **USP system**$^{0.985}$ transforms dependency trees into quasi-logical forms, recursively induces lambda forms from these, and clusters them to abstract away syntactic variations of the same meaning. The MAP **semantic parse**$^{1.000}$ of a sentence is obtained by recursively assigning its parts to lambda-form clusters and composing them. We evaluate our approach by using it to extract a knowledge base from biomedical abstracts and answer questions. **USP**$^{1.000}$ substantially outperforms TextRunner, DIRT and an informed baseline on both precision and recall on this task.

Human annotated labels: *unsupervised semantic parsing, Markov logic, USP system*

Figure 2: The title and abstract of an EMNLP paper by Poon and Domingos (2009) and human annotated keyphrases for the paper. Black words represent candidate phrases. Red bold words represent predicted keyphrases. The numbers above predicted keyphrases are probabilities for the positive class assignment.

on the probability output by Naïve Bayes. For example, if we decrease the threshold to 0.920 the following phrases would be added to the returned set of keyphrases: *dependency trees, quasi-logical forms* and *unsupervised approach*.

Another interesting aspect is the frequency of occurrence of the predicted keyphrases in the cited and citing contexts. Table 7 shows the term-frequency of every predicted keyphrase within the citation network. For example, the phrase *semantic parser* appears in 29 cited contexts and 26 citing contexts. The reason for the higher cited context frequency is not necessarily due to importance, but could be due to the larger number of cited vs. citing contexts for this paper (49 vs. 30). The high rate of keyphrases within the citation network validates our assumption of the importance of citation networks for keyphrase extraction.

Finally, we performed the same experiment with Hulth's and KEA methods. While the classifier trained on Hulth's features did not identify any keyphrases, KEA managed to identify several good ones (e.g., *USP*, *semantic parser*), but left out some important ones (e.g., *Markov logic, unsupervised*). Moreover, the keyphrases predicted by KEA have a lower confidence. For this reason, lowering the probability threshold would result in selecting other bad keyphrases.

4.5 Error analysis

We performed an error analysis and found that candidate phrases are predicted as keyphrases (FPs), although they do not appear in gold standard, i.e., the set of author-input keyphrases, in cases when: 1) a more general terms is used to describe an important concept of a document, e.g., *co-authorship prediction* represented as *link prediction* or *Twitter platform* represented as *social media*; 2) an important concept is omitted (either intentionally or forgetfully) from the set of author-input keyphrases.

Keyphrase	#cited c.	#citing c.
semantic parser	29	26
USP	31	10
Markov logic	15	10
unsupervised semantic parsing	12	1
USP system	3	2

Table 7: Frequency of the predicted keyphrases in cited / citing contexts.

Hence, while we believe that authors are the best keyphrase annotators for their own work, there are cases when important keyphrases are overlooked or expressed in different ways, possibly due to the human subjective nature in choosing important keyphrases that describe a document. To this end, a limitation of our model is the use of a single gold standard keyphrase annotation. In future, we plan to acquire several human keyphrase annotation sets for our datasets and test the performance of the proposed approach on these annotation sets, independently and in combination.

Keyphrases that appear in gold standard are predicted as non-keyphrases (FNs) when: 1) a keyphrase is infrequent in abstract; 2) its distance from the beginning of a document is large; 3) does not occur or occurs only rarely in a document's citation contexts, either citing or cited contexts. Examples of FNs are model/algorithm/approach names, e.g., *random walks*, that appear in sentences such as: "In this paper, we model the problem [· · ·] by using *random walks*." Although such

a sentence may appear further away from the beginning of an abstract, it contains significant information from the point of view of keyphrase extraction. The design of patters such as $< by\ using\ \$model >$ or $< uses\ \$model >$ could lead to improved classification performance.

Further investigation of FPs and FNs will be considered in future work. We believe that a better understanding of errors has the potential to advance *state-of-the-art* for keyphrase extraction.

5 Conclusion and Future Directions

In this paper, we presented a supervised classification model for keyphrase extraction from scientific research papers that are embedded in citation networks. More precisely, we designed novel features that take into account citation network information for building supervised models for the classification of candidate phrases as keyphrases or non-keyphrases. The results of our experiments show that the proposed supervised model trained on a combination of citation-based features and existing features for keyphrase extraction performs substantially better compared with state-of-the-art supervised and unsupervised models.

Although we illustrated the benefits of leveraging inter-linked document networks for keyphrase extraction from scientific documents, the proposed model can be extended to other types of documents such as webpages, emails, and weblogs. For example, the anchor text on hyperlinks in weblogs can be seen as the "citation context".

Another aspect of future work would be the use of external sources to better identify candidate phrases. For example, the use of Wikipedia was studied before to check if the concept behind a phrase has its own Wikipedia page (Medelyan et al., 2009). Furthermore, since citations occur in all sciences, extensions of the proposed model to other domains, e.g., Biology and Chemistry, and other applications, e.g., document summarization, similar to Mihalcea and Tarau (2004) and Qazvinian et al. (2010), are of particular interest.

Acknowledgments

We are grateful to Dr. C. Lee Giles for the CiteSeerX data, which allowed the generation of citation graphs. We also thank Kishore Neppalli and Juan Fernández-Ramízer for their help with various dataset construction tasks. We very much appreciate the constructive feedback from our anonymous reviewers. This research was supported in part by NSF awards #1353418 and #1423337 to Cornelia Caragea. Using Mined Coreference Chains as a Resource for a Semantic Task

Heike Adel and Hinrich Schütze
Center for Information and Language Processing
University of Munich
Germany
heike.adel@cis.lmu.de

Abstract

We propose to use coreference chains extracted from a large corpus as a resource for semantic tasks. We extract three million coreference chains and train word embeddings on them. Then, we compare these embeddings to word vectors derived from raw text data and show that coreference-based word embeddings improve F_1 on the task of antonym classification by up to .09.

1 Introduction

After more than a decade of work on coreference resolution, coreference resolution systems have reached a certain level of maturity (e.g., Recasens et al. (2010)). While accuracy is far from perfect and many phenomena such as bridging still pose difficult research problems, the quality of the output of these systems is high enough to be useful for many applications.

In this paper, we propose to run coreference resolution systems on large corpora, to collect the coreference chains found and to use them as a resource for solving semantic tasks. This amounts to using mined coreference chains as an automatically compiled resource similar to the way cooccurrence statistics, dependency pairs and aligned parallel corpora are used in many applications in NLP. Coreference chains have interesting complementary properties compared to these other resources. For example, it is difficult to distinguish true semantic similarity (e.g., "cows" – "cattle") from mere associational relatedness (e.g., "cows" – "milk") based on cooccurrence statistics. In contrast, coreference chains should be able to make that distinction since only "cows" and "cattle" can occur in the same coreference chain, not "cows" and "milk".

As a proof of concept we compile a resource of mined coreference chains from the Gigaword corpus and apply it to the task of identifying antonyms. We induce distributed representations for words based on (i) cooccurrence statistics and (ii) mined coreference chains and show that a combination of both outperforms cooccurrence statistics on antonym identification.

In summary, we make two contributions. First, we propose to use coreference chains mined from large corpora as a resource in NLP and publish the first such resource. Second, in a proof of concept study, we show that they can be used to solve a semantic task – antonym identification – better than is possible with existing resources.

We focus on the task of finding antonyms in this paper since antonyms usually are distributionally similar but semantically dissimilar words. Hence, it is often not possible to distinguish them from synonyms with distributional models only. In contrast, we expect that the coreference-based representations can provide useful complementary information to this task. In general, coreference-based similarity can however be used as an additional feature for any task that distributional similarity is useful for. Thus, our coreference resource can be applied to a variety of NLP tasks, e.g. finding alternative names for entities (in a way similar to Wikipedia anchors) for tasks in the context of knowledge base population.

The remainder of the paper is organized as follows. In Section 2, we describe how we create word embeddings and how our antonym classifier works. The word embeddings are then evaluated qualitatively, quantitatively and for the task of antonym detection (Section 3). Section 4 discusses related work and Section 5 concludes.

2 System description

2.1 Coreference-based embeddings

Standard word embeddings derived from text data may not be able to distinguish between semantic

association and true synonymy. As a result, synonyms and antonyms may be mapped to similar word vectors (Yih et al., 2012). For many NLP tasks, however, information about true synonymy or antonymy may be important.

In this paper, we develop two different word embeddings: embeddings calculated on raw text data and embeddings derived from automatically extracted coreference chains. For the calculation of the vector representations, the word2vec toolkit[1] by Mikolov et al. (2013) is applied. We use the skip-gram model for our experiments because its results for semantic similarity are better according to Mikolov et al. (2013). We train a first model on a subset of English Gigaword data.[2] In the following sections, we call the resulting embeddings *text-based*. To improve the semantic similarities of the vectors, we prepare another training text consisting of coreference chains. We use CoreNLP (Lee et al., 2011) to extract coreference chains from the Gigaword corpus. Then we build a skip-gram model on these coreference chains. The extracted coreference chains are provided as an additional resource to this paper[3]. Although they have been developed using only a publicly available toolkit, we expect this resource to be helpful for other researchers since the process to extract the coreference chains of such a large text corpus takes several weeks on multi-core machines. In total, we extracted 3.1M coreference chains. 2.7M of them consist of at least two different markables. The median (mean) length of the chains is 3 (4.0) and the median (mean) length of a markable is 1 (2.7). To train word embeddings, the markables of each coreference chain are concatenated to one text line. These lines are used as input sentences for word2vec. We refer to the resulting embeddings as *coreference-based*.

2.2 Antonym detection

In the following experiments, we use word embeddings to discriminate antonyms from non-antonyms. We formalize this as a supervised classification task and apply SVMs (Chang and Lin, 2011).

The following features are used to represent a pair of two words w and v:

1. cosine similarity of the text-based embeddings of w and v;
2. inverse rank of v in the nearest text-based neighbors of w;
3. cosine similarity of the coreference-based embeddings of w and v;
4. inverse rank of v in the nearest coreference-based neighbors of w;
5. difference of (1) and (3);
6. difference of (2) and (4).

We experiment with three different subsets of these features: text-based (1 and 2), coreference-based (3 and 4) and all features.

3 Experiments and results

3.1 Qualitative analysis of word vectors

Table 1 lists the five nearest neighbors based on cosine similarity of text-based and coreference-based word vectors for "his" and "woman".

We see that the two types of embeddings capture different notions of similarity. Unlike the text-based neighbors, the coreference-based neighbors have the same gender. The text-based neighbors are mutually substitutable words, but substitution seems to change the meaning more than for the coreference-based neighbors.

In Figure 1, we illustrate the vectors for some antonyms (connected by lines).

For reducing the dimensionality of the vector space to 2D, we applied the t-SNE toolkit[4]. It uses stochastic neighbor embedding with a Student's t-distribution to map high dimensional vectors into a lower dimensional space (Van der Maaten and Hinton, 2008). The Figure shows that the coreference-based word embeddings are able to

enlarge the distance between antonyms (especially for *guilt* vs. *innocence* and *toughness* vs. *frailty*) compared to text-based word vectors.

3.2 Quantitative analysis of word vectors

To verify that coreference-based embeddings better represent semantic components relevant to coreference, we split our coreference resource into two parts (about 85% and 15% of the data), trained embeddings on the first part and computed the cosine similarity – both text-based and coreference-based – for each pair of words occurring in the same coreference chain in the second part. The statistics in Table 2 confirm that coreference-based vectors have higher similarity within chains than text-based vectors.

3.3 Experimental setup

We formalize antonym detection as a binary classification task. Given a target word w and one of its nearest neighbors v, the classifier decides whether v is an antonym of w. Our data set is a set of pairs, each consisting of a target word w and a candidate v. For all word types of our vocabulary, we search for antonyms using the online dictionary Merriam Webster.[5] The resulting list is provided as an additional resource[6]. It contains 6225 words with antonyms. Positive training examples are collected by checking if the 500 nearest text-based neighbors of w contain one of the antonyms listed by Webster. Negative training examples are created by replacing the antonym with a random word from the 500 nearest neighbors that is not listed as an antonym. By selecting both the positive and the negative examples from the nearest neighbors of the word vectors, we intend to develop a task which is hard to solve: The classifier has to find the small portion of semantically dissimilar words (i.e., antonyms) among distributionally very similar words. The total number of positive and negative examples is 2337 each. The data are split into training (80%), development (10%) and test (10%) sets.

In initial experiments, we found only a small difference in antonym classification performance between text-based and coreference-based features. When analyzing the errors, we realized that our rationale for using coreference-based embeddings only applies to nouns, not to other parts of speech. This will be discussed in detail below. We therefore run our experiments in two modes: *all word classification* (all pairs are considered) and *noun classification* (only pairs are considered for which the target word is a noun). We use the Stanford part-of-speech tagger (Toutanova et al., 2003) to determine whether a word is a noun or not.

Our classifier is a radial basis function (rbf) support vector machine (SVM). The rbf kernel performed better than a linear kernel in initial experiments. The SVM parameters C and γ are optimized on the development set. The representation of target-candidate pairs consists of the features described in Section 2.

3.4 Experimental results and discussion

We perform the experiments with the three different feature sets described in Section 2: text-based, coreference-based and all features. Table 3 shows

coref.-based vectors	-0.318	0.999	0.161

Table 2: Cosine similarity of words in the same coreference chain

results for development and test sets.

For all word classification, coreference-based features do not improve performance on the development set (e.g., F_1 is .74 for text-based vs .72 for text+coref). On the test set, however, the combination of all features (text+coref) has better performance than text-based alone: .66 vs .63.

For noun classification, using coreference-based features in addition to text-based features improves results on development set (F_1 is .78 vs .73) and test set (.69 vs .60).

These results show that mined coreference chains are a useful resource and provide information that is complementary to other methods. Even though adding coreference-based embeddings improves performance on antonym classification, the experiments also show that using only coreference-based embeddings is almost always worse than using only text-based embeddings. This is not surprising given that the amount of training data for the word embeddings is different in the two cases. Coreference chains provide only a small subset of the word-word relations that are given to the word2vec skip-gram model when applied to raw text. If the sizes of the training data sets were similar in the two cases, we would expect performance to be comparable.

In the beginning, our hypothesis was that coreference information should be helpful for antonym classification in general. When we performed an error analysis for our initial results, we realized that this hypothesis only holds for nouns. Other types of words cooccurring in coreference chains are not more likely to be synonyms than words cooccurring in text windows. Two contexts that illustrate this point are "*bright sides*, but also *difficult and dark ones*" and "a series of *black and white shots*" (elements of coreference chains in italics). Thus, adjectives with opposite meanings can cooccur in coreference chains just as they can cooccur in window-based contexts. For nouns, it is much less likely that the same coreference chain will contain both a noun and its antonym since – by definition – markables in a coreference chain refer to the same identical entity.

4 Related work

Traditionally, words have been represented by vectors of the size of the vocabulary with a one at the word index and zeros otherwise (one-hot vectors). However, this approach cannot handle unknown words (Turian et al., 2010) and similarities among words cannot be represented (Mikolov et al., 2013). Therefore, distributed word representations (embeddings) become more and more popular. They are low-dimensional, real-valued vectors. Mikolov et al. (2013) have published word2vec, a toolkit that provides different possibilities to estimate word embeddings (cbow model and skip-gram model). They show that the resulting word vectors capture semantic and syntactic relationships of words. Baroni et al. (2014) show that word embeddings are able to outperform count based word vectors on a variety of NLP tasks. Recently, Levy and Goldberg (2014) have generalized the skip-gram model to include not only linear but arbitrary contexts like contexts derived from dependency parse trees. Andreas and Klein (2014) investigate the amount of additional information continuous word embeddings could add to a constituency parser and find that most of their information is redundant to what can be learned from labeled parse trees. In (Yih et al., 2012), the vector space representation of words is modified so that high positive similarities are assigned to synonyms and high negative similarities to antonyms. For this, latent semantic analysis is applied to a matrix of thesaurus entries. The val-

ues representing antonyms are negated.

There has been a great deal of work on applying the vector space model and cosine similarity to find synonyms or antonyms. Hagiwara et al. (2006) represent each word as a vector with cooccurrence frequencies of words and contexts as elements, normalized by the inverse document frequency. The authors investigate three types of contextual information (dependency, sentence cooccurrence and proximity) and find that a combination of them leads to the most stable results. Schulte im Walde and Köper (2013) build a vector space model on lexico-syntactic patterns and apply a Rocchio classifier to distinguish synonyms from antonyms, among other tasks. Van der Plas and Tiedemann (2006) use automatically aligned translations of the same text in different languages to build context vectors. Based on these vectors, they detect synonyms.

In contrast, there are also studies using linguistic knowledge from external resources: Senellart and Blondel (2008) propose a method for synonym detection based on graph similarity in a graph generated using the definitions of a monolingual dictionary. Harabagiu et al. (2006) recognize antonymy by generating antonymy chains based on WordNet relations. Mohammad et al. (2008) look for the word with the highest degree of antonymy to a given target word among five candidates. For this task, they use thesaurus information and the similarity of the contexts of two contrasting words. Lin et al. (2003) use Hearst patterns to distiguish synonyms from antonyms. Work by Turney (2008) is similar except that the patterns are learned.

Except for the publicly available coreference resolution system, our approach does not need external resources such as dictionaries or bilingual corpora and no human labor is required. Thus, it can be easily applied to any corpus in any language as long as there exists a coreference resolution system in this language. The pattern-based approach (Lin et al., 2003; Turney, 2008) discussed above also needs few resources. In contrast to our work, it relies on patterns and might therefore restrict the number of recognizable synonyms and antonyms to those appearing in the context of the pre-defined patterns. On the other hand, patterns could explicitely distinguish contexts typical for synonyms from contexts for antonyms. Hence, we plan to combine our coreference-based method with pattern-based methods in the future.

5 Conclusion

In this paper, we showed that mined coreference chains can be used for creating word embeddings that capture a type of semantic similarity that is different from the one captured by standard text-based embeddings. We showed that coreference-based embeddings improve performance of antonym classification by .09 F_1 compared to using only text-based embeddings. We achieved precision values of up to .79, recall values of up to .61 and F_1 scores of up to .69.

Abstract

This paper proposes to apply the continuous vector representations of words for discovering keywords from a financial sentiment lexicon. In order to capture more keywords, we also incorporate syntactic information into the Continuous Bag-of-Words (CBOW) model. Experimental results on a task of financial risk prediction using the discovered keywords demonstrate that the proposed approach is good at predicting financial risk.

1 Introduction

In the present environment with a great deal of information, how to discover useful insights for decision making is becoming increasingly important. In finance, there are typically two kinds of information (Petersen, 2004): *soft information* usually refers to text, including opinions, ideas, and market commentary, whereas *hard information* is recorded as numbers, such as financial measures and historical prices. Most financial studies related to risk analysis are based on hard information, especially on time series modeling (Christoffersen and Diebold, 2000; Lee and Tong, 2011; Wu et al., 2014; Yümlü et al., 2005). Despite of using only hard information, some literature incorporates soft textual information to predict financial risk (Kogan et al., 2009; Leidner and Schilder, 2010; Tsai and Wang, 2013). Moreover, sentiment analysis, a technique to make an assessment of the sentiments expressed in various information, has also been applied to analyze the soft textual information in financial news, reports, and social media data (Devitt and Ahmad, 2007; Loughran and McDonald, 2011; Wang et al., 2013).

Continuous vector space models (Bengio et al., 2003; Schwenk, 2007; Mikolov et al., 2010) are neural network language models, in which words are represented as high dimensional real valued vectors. These representations have recently demonstrated promising results across variety of tasks (Schwenk, 2007; Collobert and Weston, 2008; Glorot et al., 2011; Socher et al., 2011; Weston et al., 2011), because of their superiority of capturing syntactic and semantic regularities in language. In this paper, we apply the Continuous Bag-of-Words (CBOW) model (Mikolov et al., 2013) on the soft textual information in financial reports for discovering keywords via financial sentiments. In specific, we use the continuous vector representations of words to find out similar terms based on their contexts. Additionally, we propose a straightforward approach to incorporate syntactic information into the CBOW model for better locating similarly meaningful or highly correlated words. To the best of our knowledge, this is the first work to incorporate more syntactic information by adding Part-Of-Speech (POS) tags to the words before training the CBOW model.

In our experiments, the corpora are the annual SEC[1]-mandated financial reports, and there are 3,911 financial sentiment keywords for expansion. In order to verify the effectiveness of the expanded keywords, we then conduct two prediction tasks, including regression and ranking. Observed from our experimental results, for the regression and ranking tasks, the models trained on the expanded keywords are consistently better than those trained the original sentiment keywords only. In addition, for comparison, we conduct experiments with random keyword expansion as baselines. According to the experimental results, the expansion either with or without syntactic information outperforms the baselines. The results suggest that the CBOW model is effective at expanding keywords for financial risk prediction.

2 Keyword Expansion via Financial Sentiment Lexicon

2.1 Financial Sentiment Lexicon

A sentiment lexicon is the most important resource for sentiment analysis. Loughran and McDonald (2011) states that a general purpose sentiment lexicon (e.g., the Harvard Psychosociological Dictionary) might misclassify common words in financial texts. Therefore, in this paper, we use a finance-specific lexicon that consists of the 6 word lists provided by (Loughran and McDonald, 2011) as seeds to expand keywords. The six lists are negative (Fin-Neg), positive (Fin-Pos), uncertainty (Fin-Unc), litigious (Fin-Lit), strong modal words (MW-Strong), and weak modal words (MW-Weak).[2]

2.2 Simple Keyword Expansion

With the financial sentiment lexicon, we first use a collection of financial reports as the training texts to learn continuous vector representations of words. Then, each word in the sentiment lexicon is used as a seed to obtain the words with the highest n cosine distances (called the top-n words for the word) via the learned word vector representations. Finally, we construct an expanded keyword list from the top-n words for each word.

2.3 Keyword Expansion with Syntactic Information

For the expansion considering syntactic information, we attach the POS tag to each word in the training texts first. Then, the words in the sentiment lexicon with 4 major POS tags (i.e., `JJ`, `NN`, `VB`, `RB`) are used as seeds to expand. The rest of steps is similar to that in Section 2.2.

The reason of considering POS tags for expansion is that, in general, a word with different POS tags may result in different lists of top-n words. Table 1 shows the top-5 words for the word "default" with different POS tags (noun and adjective). Note that none of the words in the two lists overlaps.

default (`NN`)		default (`JJ`)	
Word	Cosine Distance	Word	Cosine Distance
default (v.)	0.63665	nonconform (v.)	0.63462
unwaiv (v.)	0.63466	subprim (v.)	0.62404
uncur (v.)	0.62285	chattel (n.)	0.61510
trigger (n.)	0.60080	foreclos (adj.)	0.61397
unmatur (v.)	0.58208	unguarante (v.)	0.60559

Table 1: Top-5 Words for the word "default."

3 Financial Risk Prediction

3.1 The Risk Measure: Volatility

Volatility is a measure for variation of prices of a stock over a period of time. Let S_t be the price of a stock at time t. Holding the stock from time $t-1$ to time t would lead to a simple return: $R_t = S_t/S_{t-1} - 1$ (Tsay, 2005). The volatility of returns for a stock from time $t-n$ to t can thus be defined as follows:

$$v_{[t-n,t]} = \sqrt{\frac{\sum_{i=t-n}^{t} (R_i - \bar{R})^2}{n}}, \qquad (1)$$

where $\bar{R} = \sum_{i=t-n}^{t} R_i/(n+1)$.

3.2 Regression Task

Given a collection of financial reports $D = \{\mathbf{d_1}, \mathbf{d_2}, \ldots, \mathbf{d_n}\}$, in which each $\mathbf{d_i} \in \mathbb{R}^p$ and is associated with a company c_i, we aim to predict the future risk of each company c_i (which is characterized by its volatility v_i). This prediction problem can be defined as follows:

$$\hat{v}_i = f(\mathbf{d_i}; \mathbf{w}). \qquad (2)$$

The goal is to learn a p-dimensional vector $\mathbf{w}$ from the training data $T = \{(\mathbf{d}_i, v_i) | \mathbf{d}_i \in \mathbb{R}^p, v_i \in \mathbb{R}\}$. In this paper, we adopt the Support Vector Regression (SVR) (Drucker et al., 1997) for training such a regression model. More details about SVR can be found in (Schölkopf and Smola, 2001).

3.3 Ranking Task

Instead of predicting the volatility of each company in the regression task, the ranking task aims to rank companies according to their risk via the textual information in their financial reports. We first split the volatilities of company stock returns within a year into different risk levels by the mechanism provided in (Tsai and Wang, 2013). The risk levels can be considered as the relative difference of risk among the companies.

After obtaining the relative risk levels of the companies, the ranking task can be defined as follows: Given a collection of financial reports D, we aim to rank the companies via a ranking model $f : \mathbb{R}^p \rightarrow \mathbb{R}$ such that the rank order of the set of companies is specified by the real value that the

[2] `http://www.nd.edu/~mcdonald/Word_Lists.html`.

model f takes. Specifically, $f(\mathbf{d_i}) > f(\mathbf{d_j})$ means that the model asserts that $c_i \succ c_j$, where $c_i \succ c_j$ means that c_i is ranked higher than c_j; that is, the company c_i is more risky than c_j. For this task, this paper adopts Ranking SVM (Joachims, 2006).

4 Experiments

4.1 Dataset and Preprocessings

In the experiments, we use the 10-K corpus (Kogan et al., 2009) to conduct our financial risk prediction tasks. All documents and the 6 financial sentiment word lists are stemmed by the Porter stemmer (Porter, 1980), and some stop words are also removed.

For financial risk prediction, the ground truth, the twelve months after the report volatility for each company, $v^{+(12)}$, (which measures the future risk for each company) can be calculated by Equation (1), where the stock prices can be obtained from the Center for Research in Security Prices (CRSP) US Stocks Database. In addition, to obtain the relative risks among companies used in the ranking task, we follow (Tsai and Wang, 2013) to split the companies of each year into 5 risk levels.

4.2 Keyword Expansion

In our experiments, Section 7 (Management Discussion and Analysis) in 10-K corpus is used as training texts for the tool (word2vec[3]) to learn the continuous vector representations of words.

For the simple expansion (denoted as EXP−SIM hereafter), we use the total 1,667 stemmed sentiment words as seeds to obtain the expanded keywords via the learned word vector representations. For the expansion considering syntactic information (denoted as EXP−SYN), NLTK[4] is applied to attach the POS tag[5] to each word in the training texts; we attach the POS tag to a word with an underscore notation (e.g., default_VB). For simplicity, we combine some POS tags to one tag via the tag replacement; for example, the tags JJR (adjective, comparative) and JJS (adjective, superlative) are replaced to JJ (adjective). The detailed replacement rules are tabulated in Table 2. Words from the sentiment lexicon with the four types of POS tags (i.e., JJ, NN, VB, RB) are consider as the seeds to expand the keywords. For both EXP−SIM and EXP−SYN, we use the top-20 expanded words for each word (e.g., Table 3) to construct expanded keyword lists. In total, for EXP−SIM, the expanded list contains 9,282 unique words and for EXP−SYN, the list has 13,534 unique words.

Table 3: Top-20 (Stemmed) Words for the Word "default."

4.3 Word Features

In the experiments, the bag-of-words model is adopted and three word features are used to represent the 10-K reports in the experiments. Given a document $\mathbf{d}$, three word features (i.e., TF, TFIDF and LOG1P) are calculated as follows:

- $\texttt{TF}(t, \mathbf{d}) = \texttt{TC}(t, \mathbf{d})/|\mathbf{d}|$,
- $\texttt{TFIDF}(t, \mathbf{d}) = \texttt{TF}(t, \mathbf{d}) \times \texttt{IDF}(t, \mathbf{d}) = \texttt{TC}(t, \mathbf{d})/|\mathbf{d}| \times \log(|D|/|\mathbf{d} \in D : t \in \mathbf{d}|)$,
- $\texttt{LOG1P} = \log(1 + \texttt{TC}(t, \mathbf{d}))$,

where $\texttt{TC}(t, \mathbf{d})$ denotes the term count of t in $\mathbf{d}$, $|\mathbf{d}|$ is the length of document $\mathbf{d}$, and D denotes the set of all documents in each year.

4.4 Experimental Results

Tables 4 and 5 tabulate the experimental results of regression and ranking, respectively, in which the training data is composed of the financial reports in a five-year period, and the following year is the test data. For example, the reports from year 1996 to 2000 constitute a training data, and the learned model is tested on the reports of year 2001.

[TFIDF] Year	SEN	(Baseline) EXP−RAN	EXP−SIM	EXP−SYN	SEN	(Baseline) EXP−RAN	EXP−SIM	EXP−SYN

2005	0.2241	0.2014	0.1754	**0.1682**
2006	0.2256	0.2072	0.1889	**0.1825**

Table 4: Performance of Regression

In the tables, SEN denotes the experiments trained on the words from the original financial sentiment lexicon. Despite of the experiments trained on EXP−SIM and EXP−SYN, we also conduct experiments with random keyword expansion (called EXP−RAN); for the comparison purpose, we keep the number of words in the randomly expanded word list the same as that in EXP−SYN. Note that the randomly expanded list contains all sentiment words and the rest of words are randomly chosen from the vocabulary of the dataset. The columns with label EXP−RAN denote the results averaged from 20 randomly expanded word lists. The bold face numbers denote the best performance among the four word lists.

As shown in Tables 4 and 5, for both regression and ranking tasks, the models trained on expanded keywords (i.e., EXP−$\star$) are consistently better than those trained on the original sentiment keywords only.[6] Additionally, we treat the experiments with randomly expanded word list (EXP−RAN) as the baselines.[7] From the two tables, we observe that the expansion either with or without syntactic information outperforms the baselines. Note that, for the EXP−SIM, the number of words used for training the regression and ranking models is even less than that of EXP−RAN. The results suggest that the CBOW model is effective at expanding keywords for financial risk prediction. Furthermore, incorporating syntactic information into the CBOW model can even enhance the performance for the tasks of financial risk prediction.

[6]Due to the page limits, only the results trained on features LOGP for regression and TFIDF for ranking are reported, but the performance for models trained on features TF, TFIFG, and LOGP is very consistent.

[7]The results for EXP−SYN are all significant better than the baseline with $p < 0.05$.

4.5 Discussions

Below we provide the original texts from 10-K reports that contain the top 1 expanded word, "uncur" (stemmed), for "default" in Table 3. Two pieces of sentences are listed as follows (the company Investment Technology Group, 1997):

> $\cdots$ terminate the agreement upon certain events of bankruptcy or insolvency or upon an **uncured** breach by the Company of certain covenants $\cdots$

> $\cdots$ any termination of the license agreement resulting from an **uncured** default would have a material adverse effect on the Company's results of operations.

From the above examples, the expanded word "uncur" has similar meaning to "default," which confirms the capability of our method of capturing similarly meaningful or highly correlated words.

5 Conclusions

This paper applies the continuous bag-of-words model on the textual information in financial reports for expanding keywords from a financial sentiment lexicon. Additionally, we propose a simple but novel approach to incorporate syntactic information into the continuous bag-of-words model for capturing more similarly meaningful or highly correlated keywords. The experimental results for the risk prediction problem show that the expansion either with or without syntactic information outperforms the baselines. As a direction for further

research, it is interesting and important to provide more analysis on the expanded words via the continuous vector representations of words.

Abstract

When it is not possible to compare the suspicious document to the source document(s) plagiarism has been committed from, the evidence of plagiarism has to be looked for intrinsically in the document itself. In this paper, we introduce a novel language-independent intrinsic plagiarism detection method which is based on a new text representation that we called n-gram classes. The proposed method was evaluated on three publicly available standard corpora. The obtained results are comparable to the ones obtained by the best state-of-the-art methods.

1 Introduction and Related Works

Intrinsic plagiarism detection is an essential alternative in situations where the plagiarism source does not have a digital version, e.g. an old book, or the plagiarized text was directly written by another author without copying from any source, e.g. the case of a student who asked someone else to write for him parts of his essay or thesis. Hence, the task of detecting plagiarism intrinsically is to identify, in the given suspicious document, the fragments that are not consistent with the rest of the text in terms of writing style.

The automatic analysis of the writing style is an important component of many NLP applications. For some of them, when analyzing the style, a document is considered as a whole, which is the case of the authorship identification (Stamatatos, 2009a) and the authorship verification (Koppel and Seidman, 2013). For other applications, a document is perceived as a set of fragments, for each of them the writing style needs to be analyzed individually. Examples of such applications include: paragraph authorship clustering (Brooke and Hirst, 2012), authorial segmentation of multi-author documents (Akiva and Koppel, 2013), detection of stylistic inconsistencies between consecutive paragraphs (Graham et al., 2005) and plagiarism direction identification (Grozea and Popescu, 2010).

For intrinsic plagiarism detection, it is crucial to analyze the writing style at fragments level. However, the majority of methods tend to analyze the whole document writing style as well. Indeed, intrinsic plagiarism detection puts together, in one research problem, many difficulties that are not present, or present separately, in the aforementioned related problems. Its main difficulties are listed below.

In contrast to multi-author documents related problems, the number of authors in the suspicious documents is unknown, i.e., it might be one author if the document is plagiarism-free or many unknown authors if it contains plagiarism.

Unlike the authorship attribution and verification, where the examined text and the potential author text are separate (and hence their writing styles could be readily characterized and compared), these two parts are both merged in the same document with unknown boundaries. Furthermore, the plagiarized fragments in a suspicious document might stem from different authors, which renders the computational characterization of plagiarism difficult.

As opposed to the problem of authorship clustering, where the task is merely to attribute already defined fragments of a given document to different authors, the segmentation is a crucial and inevitable task in a real scenario of intrinsic plagiarism detection. Indeed, a granular segmentation may lead to an undependable style analysis, and a coarse segmentation may prevent the identification of the short plagiarized texts.

Due to the aforementioned difficulties, intrinsic plagiarism detection is still a challenging

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1459–1464,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

problem. This is evidenced by the still low performance scores of the majority of methods[1]. To the best of our knowledge, just two methods, namely Stamatatos (2009b) and Oberreuter et al. (2011), reached an f-measure greater than 0.30 on a standardized corpus. Other methods, for instance (Stein et al., 2011) and (Tschuggnall and Specht, 2013), obtained better performance scores. Nonetheless, they have been evaluated on only selected documents from the whole standardized evaluation corpus which makes their results not comparable to the others.

Although the writing style analysis is an old research area and has been applied successfully to solve many problems, notably authorship attribution, it is obvious that its application to identify the plagiarized fragments still needs to be investigated further. In this paper, we address this research problem by proposing a novel way of quantifying the writing style that we called n-gram classes. We show that our method, which is supervised classification-based, is able to discriminate between the plagiarized and the original text fragments with a performance comparable to the best state-of-the-art methods despite it uses a small number of features when building the classification model.

The remainder of the paper is organized as follows. Section 2 presents our motivation. Sections 3 and 4 present the new features and the proposed method. Section 5 provides the evaluation results. Finally, Section 6 draws our conclusions.

2 Motivation

The idea of our method is inspired by the work of Grozea and Popescu (2010), in the context of plagiarism direction identification. They reported that the character 8-grams of a plagiarized text fragment are more frequent in the source document (because the author is the same) than in the plagiarized document. Thus, we believe that, it is possible to distinguish the plagiarized fragments from the original ones on the basis of the frequency of their character n-grams in the suspicious document. That is, if many of the character n-grams of a fragment are infrequent in the document, it would be probably a plagiarized fragment. However, if many of them are frequent, then the fragment is likely to be original.

On the other hand, according to the authorship attribution researches, character n-grams are a powerful tool for characterizing the writing style (Stamatatos, 2009a). Moreover, they have been used in one of the best intrinsic plagiarism detection methods (Stamatatos, 2009b).

Generally, in n-gram based methods the text is represented by a vector of n-grams with their frequencies. The shortcoming of this text representation is the increase of its size with the increase of the text or the n-gram length.

Our method proposes a novel way of using character n-grams[2] for text representation. The idea is to represent the fragments of the suspicious document in a reduced vector where each feature value is the frequency of a class of n-grams instead of a particular n-gram. Therefore, the dimension of any fragment vector is always equal to the number of classes rather than the number of n-grams. The class of an n-gram is determined according to its frequency level in the given document as we will show in the next section.

3 N-gram Classes

Formally, we define an n-gram class as a number from 0 to $m-1$ such that the class labeled 0 involves the *least frequent* n-grams and the class labeled $m-1$ contains the *most frequent* n-grams in a document. If $m > 2$, classes between 0 and $m-1$ will contain n-grams with *intermediate frequency levels*.

Concretely, to assign the n-grams of a given document to m classes, first, the document is represented by a $2 \times l$ matrix (l is the total number of n-grams), where the first row contains the n-grams ng_i (i =1..l) and the second one contains their number of occurrences $freq_i$ (raw frequency).

Let *max_freq* denotes the maximum frequency, so:

$$max\_freq = \text{argmax} \quad freq_i ; \quad i=1..l \qquad (1)$$

Then, the class of a n-gram ng_i is computed as follows:

$$\text{Class } ng_i = \text{Log}_{\text{base}} (freq_i); \qquad (2)$$

Given that:

$$\text{base} = \sqrt[m-1]{max\_freq} \quad . \qquad (3)$$

By computing the base of the logarithm as shown in the equation (3), the most frequent n-grams (i.e. the n-grams with the maximum number of occurrences) will be in the class $m-1$, and

[1] See for instance PAN workshop (http://pan.webis.de) series, from 2007 to 2012, where several papers on intrinsic plagiarism detection have been published.

[2] In the rest of the paper, when not said differently, the term n-gram is always used to denote character n-gram.

the least frequent n-grams (e.g. the ones that appear only once) will be in the class 0, and the n-grams with intermediate levels of frequency will be in the classes between 0 and $m-1$. Figure 1 illustrates an example of computing the n-gram classes of a document. The chosen number of classes m in this example is 3.

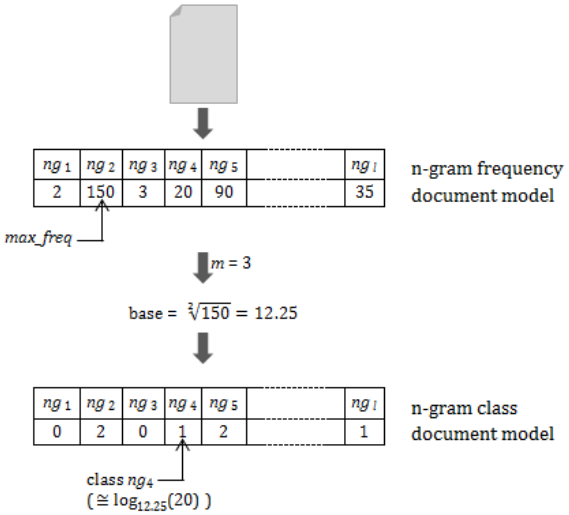

Figure 1. Steps for computing the n-gram classes of a document. The number of classes in this example is 3 (class labels are from 0 to 2).

Note that, what we explained above is solely how to compute the class of each n-gram of a document. However, our purpose is to represent the document fragments using these classes. To this end, for each fragment, first, its n-grams are extracted. Then, each n-gram is replaced by its class obtained from the document model built previously. Finally, the proportion of each class in the fragment is computed. So, the fragment can be represented by a vector of m values, where the first value is the proportion of the class 0, the second value is the proportion of the class 1 and so on. Figure 2 illustrates these steps. For the sake of simplicity, we suppose that the fragment contains only 5 n-grams.

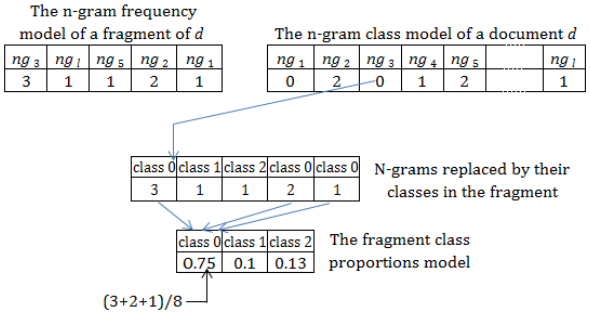

Figure 2. Steps for representing a document fragment by the proportion of 3 n-gram classes.

4 The Proposed Method

Once the suspicious document has been segmented to fragments and these latter have been represented by a set of features, an important phase in the process of the intrinsic plagiarism detection is to decide whether a fragment is plagiarized or original. This phase has been implemented in the literature methods using different techniques, notably clustering (Akiva, 2011), supervised classification (Meyer zu Eissen et al., 2007), distance functions with thresholds (Stamatatos, 2009b; Oberreuter et al., 2011) and density-based methods (Stein et al., 2011).

In our supervised method, the classification model is trained with a small number of features which are the proportions of the n-gram classes described in the previous section.

In detail, our method is composed of the following steps:

1. Segment each document d into fragments s_i by using the sliding window technique. Let S denotes the set of these fragments.
2. Build the n-gram class document model (see Figure 1) without considering numerals. We choose to consider the frequency of a n-gram ng_i as the number of its occurrence in d such that it is counted once per fragment. Therefore, the minimum value that could take a frequency is 1 if ng_i appears only in one fragment, and its maximum value is $|S|$ (the number of fragments in d) if ng_i occurs in each fragment $s_i \in S$.
3. Represent each fragment s_i by a vector of m features f_j , $j \in \{0,\ldots, m-1\}$. So that, each f_j is the proportion of the n-grams that belong to the class labeled j to the total number of n-grams in s_i.
4. Combine into one dataset the fragment vectors obtained from all the training corpus documents. Then, label each vector with its authenticity state, i.e. plagiarized, if the fragment plagiarism percentage exceeds 50% and original otherwise.
5. Build a classifier using the training set produced in the previous step. For this purpose, we trained and tested several classification algorithms implemented on WEKA software (Hall et al., 2009). The best results were obtained with the Naïve Bayes algorithm[3].

The aforementioned steps represent the training phase of our method, which aims to construct the classifier. In practice, in order to detect the plagiarism in a given document, this classifier is

[3] Consult the arff file from the archive file associated to this paper which contains the fragments class proportion model and the plagiarism prediction for each fragment.

directly applied to the document fragments after the step 3.

5 Evaluation

5.1 Datasets

We evaluated our method on 3 corpora: PAN-PC-09[4] and PAN-PC-11[5] which are the corpora used in the international competition of plagiarism detection in 2009 and 2011 respectively[6], as well as InAra corpus[7], which is a publicly available collection of artificial suspicious documents in Arabic (Bensalem et al., 2013). The three document collections include XML annotations indicating the plagiarized segments positions.

For the evaluation on English and Spanish documents, the classifier has been trained on PAN-PC-11 test corpus and evaluated on this same corpus using 10-fold cross validation as well as PAN-PC-09 test corpus. For the evaluation on Arabic documents, the classifier has been trained and tested on InAra corpus using 10-fold cross validation.

5.2 Results

As evaluation measures we used macro-averaged precision, recall, f-measure, granularity and plagdet as they were defined in (Potthast et al., 2010).

In order to choose the parameters of our method, we trained the classifier using various training sets generated by using the different combinations of the n-gram length *n* (from 1 to 10) and the number of classes *m* (from 2 to 10). We adopted the parameters that yielded the higher f-measure, namely $n = 6$ and $m = 4$.

With regard the sliding window parameters, we used three different options for the window size, which are 100, 200 and 400 words, with a step equal to the quarter of the window size. Only one option is applied to a given document depending on its length.

We deliberately use similar sliding window parameters as the method of Oberreuter et al. (2011)[8] in order to compare the two methods without being much affected by the segmentation strategy.

Table 1 compares the results of our method to the one of Oberreuter et al. (2011) being the winner in PAN 2011 competition and considered one of the best intrinsic plagiarism detection methods.

		Our method	Oberreuter et al.[9]
PAN-PC-09	Precision	0.31	**0.39**
	Recall	**0.49**	0.31
	F-measure	**0.38**	0.35
	Granularity	1.21	**1.00**
PAN-PC-11	Precision	0.22	**0.34**
	Recall	**0.50**	0.31
	F-measure	0.30	**0.33**
	Granularity	1.13	**1.00**
InAra	Precision	0.24	**0.29**
	Recall	**0.69**	0.25
	F-measure	**0.35**	0.27
	Granularity	**1.27**	1.44

Table 1. Performance of the n-gram frequency class method on 3 corpora.

From Table 1 it can be appreciated that our method in terms of recall noticeably outperforms Oberreuter et al. (2011), although precision and granularity still needs to be further improved. Nonetheless, in comparison with other methods such as the one of Stamatatos (2009b), that obtained the best results in PAN 2009 competition on plagiarism detection, precision is still very much competitive: 0.31 vs. 0.23 (PAN-PC-09) and 0.22 vs. 0.14 (PAN-PC-11). In terms of f-measure, Oberreuter et al. (2011) method is significantly higher than our method on PAN-PC-11 corpus, but both methods have statistically similar results on InAra[10].

Considering plagdet, which is a score that represents the overall performance of a plagiar-

[4] http://www.uni-weimar.de/en/media/chairs/webis/research/corpora/corpus-pan-pc-09/

[5] http://www.uni-weimar.de/en/media/chairs/webis/research/corpora/corpus-pan-pc-11/

[6] We used only the corpora parts that are dedicated to the evaluation of the intrinsic approach.

[7] http://sourceforge.net/projects/inaracorpus/

[8] Oberreuter et al. (2011) used mainly 400 words as the window size that may change according to the document length.

[9] The results of Oberreuter et al. method (2011) on PAN-PC-09 and PAN-PC-11 are taken from his paper. However, we re-implemented this method in order to evaluate it on InAra. Note that our re-implementation maybe not perfectly similar to the original one since the authors did not provide details on the parameters tuning.

[10] The Kolomogorov Smirnov test with a significance level of 5% has been used to compare the two methods f-measures on PAN-PC-11 and InAra. Unfortunately, on the PAN-PC-09 corpora we were unable to carry out this test since we do not have the results of Oberreuter et al. per each document.

ism detection method, our method could be ranked the 2nd, after Oberreuter et al. (2011) and before Stamatatos (2009b) as it is shown in Table 2.

	Oberreuter et al.	Our method	Stamatatos
PAN-PC-09	0.35	0.33	0.25
PAN-PC-11	0.33	0.28	0.19

Table 2. Plagdet of our method in comparison with the two best methods on PAN competition corpora.

6 Conclusion

In this paper we have shown that representing the text fragments of a given suspicious document by the proportion of character n-gram classes (the most frequent, the least frequent and intermediate levels) is a promising way for detecting plagiarism intrinsically.

The experiments described in this paper were performed on three corpora comprising documents in English, Spanish and for the first time Arabic. We obtained comparable results to the best performing systems.

Our method best configuration is 6 as the n-grams length and only 4 as the number of classes (i.e. 4 features). As future work, it would be interesting to combine the most precise classes of different n-gram lengths in order to improve the precision. It would be important as well to try other segmentation strategies and post-processing techniques in order to improve the granularity. Another interesting experiment we plan to carry out in the future is to use the n-gram classes along with the traditional stylistic features such as the vocabulary richness, average sentence length, etc.

Acknowledgments

The first author would like to thank Parth Gupta for his helpful feedback and Gabriel Oberreuter for providing some implementation details of his method.

Verifiably Effective Arabic Dialect Identification

Kareem Darwish, Hassan Sajjad, Hamdy Mubarak

Qatar Foundation
{kdarwish,hsajjad,hmubarak}@qf.org.qa

Abstract

Several recent papers on Arabic dialect identification have hinted that using a word unigram model is sufficient and effective for the task. However, most previous work was done on a standard fairly homogeneous dataset of dialectal user comments. In this paper, we show that training on the standard dataset does not generalize, because a unigram model may be tuned to topics in the comments and does not capture the distinguishing features of dialects. We show that effective dialect identification requires that we account for the distinguishing lexical, morphological, and phonological phenomena of dialects. We show that accounting for such can improve dialect detection accuracy by nearly 10% absolute.

1 Introduction

Modern Standard Arabic (MSA) is the lingua franca of the so-called Arab world, which includes northern Africa, the Arabian Peninsula, and Mesopotamia. However, Arabic speakers generally use dramatically different languages (or dialects) in daily interactions and in social media. These dialects may differ in vocabulary, morphology, and spelling from MSA and most do not have standard spellings. There is often large lexical overlap between dialects and MSA. Performing proper Arabic dialect identification may positively impact many Natural Language Processing (NLP) application. For example, transcribing dialectal speech or automatically translating into a particular dialect would be aided by the use of targeted language models that are trained on texts in that dialect.

This has led to recent interest in automatic identification of different Arabic dialects (Elfardy et al., 2013; Cotterell et al., 2014; Zaidan et al., 2014). Though previous work (Cotterell et al., 2014) have reported high accuracies for dialect identification using word unigram model, which implies that this is a solved problem, we argue that the problem is far from being solved. The reason for this assertion stems from the fact that the available dialectal data is drawn from singular sources, namely online news sites, for each dialect. This is problematic because comments on singular news site are likely to have some homogeneity in topics and jargon. Such homogeneity has caused fairly simple classification techniques that use word unigrams and character n-grams to yield very high identification accuracies. Perhaps, this can be attributed to topical similarity and not just differences between dialects. To showcase this, we trained a classifier using the best reported methods, and we tested the classifier on a new test set of 700 tweets, with dialectal Egyptian (ARZ) and MSA tweets, which led to a low accuracy of 83.3%. We also sorted words in the ARZ part from our training dataset by how much they discriminate between ARZ and MSA (using mutual information) and indeed many of the top words were in fact MSA words.

There seems to be a necessity to identify lexical and linguistic features that discriminate between MSA and different dialects. In this paper, we highlight some such features that help in separating between MSA and ARZ. We identify common ARZ words that do not overlap with MSA and identify specific linguistic phenomena that exist in ARZ, and not MSA, such as morphological patterns, word concatenations, and verb negation constructs (Section 3). We also devise methods for capturing the linguistic phenomena, and we use the appearance of such phenomena as features (Section 4). Further, we show the positive impact of using the new features in identifying ARZ (Section 5).

2 Previous Work

Previous work on Arabic dialect identification uses n-gram based features at both word-level and character-level to identify dialectal sentences (Elfardy et al., 2013; Cotterell et al., 2014; Zaidan et al., 2011; Zaidan et al., 2014). Zaidan et al. (2011) created a dataset of dialectal Arabic. They performed cross-validation experiments for dialect identification using word n-gram based features. Elfardy et al. (2013) built a system to distinguish between ARZ and MSA. They used word n-gram features combined with core (token-based and perplexity-based features) and meta features for training. Their system showed a 5% improvement over the system of Zaidan et al. (2011). Later, Zaidan et al. (2014) used several word n-gram based and character n-gram based features for dialect identification. The system trained on word unigram-based feature performed the best with character five-gram-based feature being second best. A similar result is shown by Cotterell et al. (2014) where word unigram model performs

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1465–1468,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

the best.

All of the previous work except Cotterell et al. (2014)[1] evaluate their systems using cross-validation. These models heavily rely on the coverage of training data to achieve better identification. This limits the robustness of identification to genres inline with the training data.

Language identification is a related area to dialect identification. It has raised some of the issues which we discussed in this paper in the context of dialect identification. Lui et al. (2011) showed that in-domain language identification performs better than cross domain language identification. Tiedemann et al. (2012) argued that the linguistic understanding of the differences between languages can lead to a better language identification system. kilgarriff (2001) discussed the differences between datasets as a poor representation of differences between dialects of English.

In this paper, we exploit the linguistic phenomena that are specific to Arabic dialects to show that they produce significant improvements in accuracy. We show that this also helps in achieving high quality cross-domain dialect identification system.

3 Dialectal Egyptian Phenomena

There are several phenomena in ARZ that set it apart from MSA. Some of them are as follows:

Dialectal words: ARZ uses unique words that do not overlap with MSA and may not overlap with other dialects. Some of the common ARZ words are: "zy" (like), "kdh" (like this), and "Azyk" (how are you) [2]. These dialectal terms stem from the following:

• Using proper Arabic words that are rarely used in MSA such as "$nTp" (bag) and "n$wf" (we see).

• Fusing multiple words together by concatenating and dropping letters such as the word "mEl$" (no worry), which is a fusion of "mA Elyh $y' ".

• Using non-standard spelling of words such as "SAbE" (finger) instead of "<sbE" in MSA. Consequently, broken plurals may also be non-standard.

• using non-Arabic words such as "<y$Arb" (scarf), which is transliterated from the French écharpe.

• altering the forms of some pronouns such as the feminine second person pronoun from "k" to "ky", the second person plural pronoun "tm" to "tw", and the object pronoun "km" to "kw".

Morphological differences: ARZ makes use of particular morphological patterns that do not exist in MSA and often alters some morphological constructs. Some examples include:

• Adding the letter "b" in front of verb in present tense. Ex. MSA: "ylEb" (he plays) → EG: "bylEb".

• Using the letters "H" or "h", instead of "s", to indicate future tense. Ex. MSA: "sylEb" (he will play) → EG: "hylEb" or "HylEb".

• Adding the letters "At" to passive past tense verbs. Ex. MSA: "luEiba" (was played) → "AtlaEab".

• Adding the letters "m" or "mA" before the verb and "$" or "$y" after the verb to express negation. Ex. MSA: "lm ylEb" (he did not play) → "mlEb$".

• the merging of verbs and prepositional phrases of the form (to-pronoun) that follow it. Ex. MSA: "ylEb lh" (he plays for/to him) → "bylEblh".

• Replacing a short vowel with a long vowel in imperative verbs that are derived from hollow roots. Ex. MSA: "qul" (say) → "qwl".

Letter substitution: in ARZ the following letter substitutions are common:

• "v" → "t". Ex. MSA: "kvyr" (a lot) → EG: "ktyr".

• "}" → "y". Ex. MSA: "b}r" (well) → "byr".

• Trailing "y" → "Y". Ex. MSA: "Hqy" (my right) → "HqY".

• "*" → "d". Ex. MSA: "xu*" (take) → "xud".

• middle or trailing ">" → "A". Ex. MSA: "f>r" (mouse) → "fAr".

• "D" → "Z". Ex. MSA: "DAbT" (officer) → "ZAbT".

• "Z" → "D". Ex. MSA: "Zhr" (back) → "Dhr".

• Middle "|" → "yA". Ex. MSA: "ml|n" (full) → "mlyAn".

• Removal of trailing " ' ". Ex. MSA: "AlsmA' " (the sky) → "AlsmA".

Syntactic differences: some of the following phenomena are generally observed:

• Common use of masculine plural or singular noun forms instead dual and feminine plural. Ex. MSA "jnyhyn" (two pounds) → EG: "Atnyn jnyh".

• Dropping some articles and preposition in some syntactic constructs. For example, the preposition "<lY" (to) in ">nA rAyH <lY Al$gl" (I am going to work) is typically dropped. Also, the particle ">n" (to) is dropped in the sentence ">nA mHtAj >n >nAm" (I need to sleep).

• Using only one form of noun and verb suffixes such as "yn" instead of "wn" and "wA" instead of "wn" respectively. Also, so-called "five nouns", are used in only one form (ex. ">bw" (father of) instead of ">bA" or ">by").

4 Detecting Dialectal Peculiarities

ARZ is different from MSA lexically, morphologically, phonetically, and syntactically. Here, we present methods to handle such peculiarities. We chose not to handle syntactic differences, because they may be captured using word n-gram models.

To capture lexical variations, we extracted and sorted by frequency all the unigrams from the Egyptian side of the LDC2012T09 corpus (Zbib et al., 2012), which has ≈ 38k Egyptian-English parallel sentences. A linguist was tasked with manually reviewing the words from the top until 1,300 dialectal words were found. Some of the words on the list included dialectal words, commonly used foreign words, words that exhibit morphological variations, and others with letter substitution.

[1] Zaidan et al. (2014) applied their classifier to a different genre but did not evaluate it's performance.

[2] Buckwalter encoding is used throughout the paper.

For morphological phenomenon, we employed three methods, namely:

• **Unsupervised Morphology Induction:** We employed the unsupervised morpheme segmentation tool, Morfessor (Virpioja et al., 2013). It is a data driven tool that automatically learns morphemes from data in an unsupervised fashion. We used the trained model to segment the training and test sets.

• **Morphological Rules:** In contrast to Morfessor, we developed only 15 morphological rules (based on the analysis proposed in Section 3) to segment ARZ text. These rules would separate prefixes and suffixes like a light stemmer. Example rules would segment a leading "b" and segment a combination of a leading "m" and trailing "$".

• **Morphological Generator:** For morphological generation, we enumerated a list of ≈ 200 morphological patterns that derive dialectal verbs from Arabic roots. One such pattern is ytCCC that would generate the dialectal verb-form ytktb (to be written) from the root "ktb". We used the root list that is distributed with Sebawai (Darwish, 2002). We also expanded the list by attaching negation affixes and pronouns. We retained generated word forms that: a) exist in a large corpus of 63 million Arabic tweets from 2012 with more than 1 billion tokens; and b) don't appear in a large MSA corpus of 10 years worth of Aljazeera articles containing 114 million tokens [3]. The resulting list included 94k verb surface forms such as "mbyEmlhA$" (he does not do it).

For phonological differences, we used a morphological generator that makes use of the aforementioned root list and an inventory of ≈ 605 morphological patterns (with diacritization) to generate possible Arabic stems. The generated stems with their diacritics were checked against a large diacritized Arabic corpus containing more than 200 million diacritized words [4]. If generated words contained the letters "v", "}", "*", and "D", we used the aforementioned letter substitutions. We retained words that exist in the large tweet corpus but not in the Aljazeera corpus. The list contained 8k surface forms.

5 Evaluation Setup

Dataset: We performed dialect identification experiment for ARZ and MSA. For ARZ, we used the Egyptian side of the LDC2012T09 corpus (Zbib et al., 2012) [5]. For MSA, we used the Arabic side of the English/Arabic parallel corpus from the International Workshop on Arabic Language Translation[6] which consists of ≈ 150k sentences. For testing, we constructed an evaluation set that is markedly different from the training set. We crawled Arabic tweets from Twitter during March 2014 and selected those where user location was set to Egypt or a geographic location within Egypt, leading to 880k tweets. We randomly selected 2k tweets, and we manually annotated them as ARZ, MSA, or neither until we obtained 350 ARZ and 350 MSA tweets. We used these tweets for testing. We plan to release the tweet ID's and our annotations. We preprocessed the training and test sets using the method described by Darwish et al. (2012), which includes performing letter and word normalizations, and segmented all data using an open-source MSA word segmentor (Darwish et al., 2012). We also removed punctuations, hashtags, and name mentions from the test set. We used a Random Forest (RF) ensemble classifier that generates many decision trees, each of which is trained on a subset of the features.[7] We used the RF implementation in Weka (Breiman, 2001).

5.1 Classification Runs

Baseline *BL*: In our baseline experiments, we used word unigram, bigram, and trigram models and character unigram to 5-gram models as features. We first performed a cross-validation experiment using ARZ and MSA training sets. The classifier achieved fairly high results (+95%) which are much higher than the results mentioned in the literature. This could be due in part to the fact that we were doing ARZ-MSA classification instead of multi-dialect classification and MSA data is fairly different in genre from ARZ data. We did not further discuss these results. This experiment was a sanity check to see how does in-domain dialect identification perform.

Later, we trained the RF classifier on the complete training set using word n-gram features (WRD), character n-gram features (CHAR), or both (BOTH) and tested it on the tweets test set. We referred to this system as *BL* later on.

Dialectal Egyptian Lexicon S_{lex}: As mentioned earlier, we constructed three word lists containing 1,300 manually reviewed ARZ words (MAN), 94k dialectal verbs (VERB), and 8k words with letter substitutions (SUBT). Using the lists, we counted the number of words in a tweet that exist in the word lists and used it as a standalone feature for classifications. LEX refers to concatenation of all three lists.

Morphological Features: For S_{mrph}, we trained Morfessor separately on the MSA and Egyptian training data and applied to the same training data for segmentation. For S_{rule}, we segmented Egyptian part of the training data using the morphological rules mentioned in Section 4. For both, word and character n-gram features were calculated from the segmented data and the

[3] http://aljazeera.net

[4] http://www.sh.rewayat2.com

[5] We did not use the Arabic Online Commentary data (Zaidan et al., 2011) as annotations were often not reliable.

[6] https://wit3.fbk.eu/mt.php?release=2013-01

[7] We tried also the multi-class Bayesian classifier and SVM classifier. SVM classifier had comparable results with Random Forest classifier. However, it was very slow. So, we decided to go with Random Forest classifier for the rest of the experiments.

SYS	WRD	CHR	BOTH	BEST+LEX
BL	53.0	74.0	83.3	84.7
S_{mrph}	72.0	88.0	62.1	89.3
S_{rule}	53.9	85.9	85.9	90.1

Table 1: Dialect identification accuracy using various classification settings: only word-based (WRD), character-based (CHAR), and both features. BEST+LEX is built on the best feature of that system plus a feature built on the concatenation of all lists

SYS	MAN	+VERB	+SUBT
S_{lex}	93.6	94.6	94.4

Table 2: Accuracy of the dialect identification system with the addition of various types of lexicon

classifier was trained on them and tested on the tweet test set.

5.2 Results

Table 1 summarizes the results. Unlike results in the literature, character-based n-gram features outperformed word-based n-gram features, as they seemed to better generalize to the new test set, where lexical overlap between the training and test sets was low. Except for S_{mrph}, adding both character and word n-gram features led to improved results. We observed that Morfessor over-segmented the text, which in turns created small character segments and enabled the character-based language model to learn the phenomenon inherit in a word. The baseline system achieved an accuracy of 84.7% when combined with the S_{lex} feature. Combining S_{mrph} and S_{rule} features with the S_{lex} feature led to further improvement. However, as shown in Table 2, using the S_{lex} feature alone with the MAN and VERB lists led to the best results (94.6%), outperforming using all other features either alone or in combination. This suggests that having a clean list of dialectal words that cover common dialectal phenomena is more effective than using word and character n-grams. It also highlights the shortcomings of using a homogeneous training set where word unigrams could be capturing topical cues along with dialectal ones.

6 Conclusion

In this paper, we identified lexical, morphological, phonological, and syntactic features that help distinguish between dialectal Egyptian and MSA. Given the substantial lexical overlap between dialectal Egyptian and MSA, targeting words that exhibit distinguishing traits is essential to proper dialect identification. We used some of these features for dialect detection leading to nearly 10% (absolute) improvement in classification accuracy. We plan to extend our work to other dialects.

Keystroke Patterns as Prosody in Digital Writings: A Case Study with Deceptive Reviews and Essays

Abstract

In this paper, we explore the use of keyboard strokes as a means to access the real-time writing process of online authors, analogously to prosody in speech analysis, in the context of deception detection. We show that differences in keystroke patterns like editing maneuvers and duration of pauses can help distinguish between truthful and deceptive writing. Empirical results show that incorporating keystroke-based features lead to improved performance in deception detection in two different domains: online reviews and essays.

1 Introduction

Due to the practical importance of detecting deceit, interest in it is ancient, appearing in papyrus dated back to 900 B.C. (Trovillo, 1939). In more recent years, several studies have shown that the deceiver often exhibits behavior that belies the content of communication, thus providing cues of deception to an observer. These include linguistic (*e.g.,* Newman et al. (2003), Hancock et al. (2004)) as well as paralinguistic (*e.g.,* Ekman et al. (1991), DePaulo et al. (2003)) cues. Recognizing deception, however, remains a hard task for humans, who perform only marginally better than chance (Bond and DePaulo, 2006; Ott et al., 2011).

Recent studies suggest that computers can be surprisingly effective in this task, albeit in limited domains such as product reviews. Prior research has employed lexico-syntactic patterns (Ott et al., 2011; Feng et al., 2012) as well as online user behavior (Fei et al., 2013; Mukherjee et al., 2013). In this paper, we study the effect of keystroke patterns for deception detection in digital communications, which might be helpful in understanding the psychology of deception and help toward trustful online communities. This allows us to investigate differences in the writing and revisional processes of truthful and fake writers. Our work thus shares intuition with HCI research linking keystroke analysis to cognitive processes (Vizer et al., 2009; Epp et al., 2011) and psychology research connecting cognitive differences to deception (Ekman, 2003; Vrij et al., 2006).

Recent research has shown that lying generally imposes a cognitive burden (*e.g.,* McCornack (1997), Vrij et al. (2006)) which increases in real-time scenarios (Ekman, 2003). Cognitive burden has been known to produce differences in keytroke features (Vizer et al., 2009; Epp et al., 2011). Previous research has not, however, directly investigated any quantitative connection between keystroke patterns and deceptive writing.

In this paper, we posit that cognitive burdens in deception may lead to measurable characteristics in keystroke patterns. Our contributions are as follows: (1) introducing keystroke logs as an extended linguistic signal capturing the real-time writing process (analogous to prosody in speech analysis) by measuring the *writing rate*, *pauses* and *revision rate*. (2) showing their empirical value in deception detection, (3) providing novel domain-specific insights into deceptive writing, and (4) releasing a new corpus of deception writings in new domains.[1]

2 Related Work

Prior research has focused mainly on using keystroke traits as a behvioral biometric. Forsen et al. (1977) first demonstrated that users can be distinguished by the way they type their names. Subsequent work showed that typing patterns are *unique to individuals* (Leggett and Williams, 1988), and can be used for authentication (Cho et al., 2000; Bergadano et al., 2002) and intrusion detection (Killourhy and Maxion, 2009).

Keystroke pauses have been linked to linguistic patterns in discourse (e.g. Matsuhashi (1981), van Hell et al. (2008)) and regarded as indications of cognitive burden (*e.g.,* Johansson (2009), Zulkifli (2013)). In this paper, we present the *first* empirical study that quantitatively measures the deception cues in real-time writing process as manifested in keystroke logs.

3 Data Collection

As discussed by Gokhman et al. (2012), the crowdsourcing approach to soliciting deceptive content simulates the real world of online deceptive content creators. We collected the data via Amazon Mechanical Turk.[2] Turkers were led to a separate website where keylogging was enabled, and asked to write truthful and deceptive texts ($\geq$ 100 words) on one of three top-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1469–1473,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

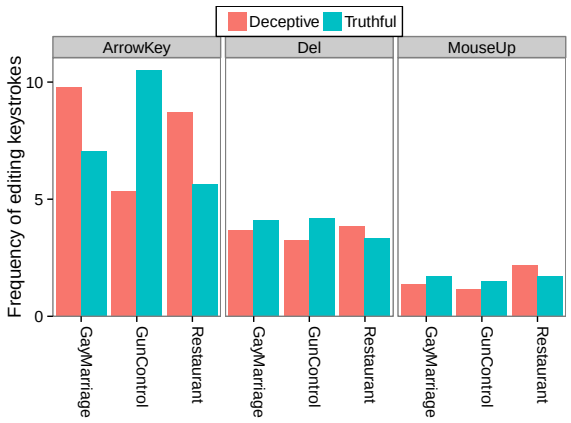

Figure 1: Number of keystrokes corresponding to the three types of edit patterns ($\mathcal{E}_3$): (a) use of arrow keys, (b) deletion (Delete and Backspace) and (c) text selection with mouse.

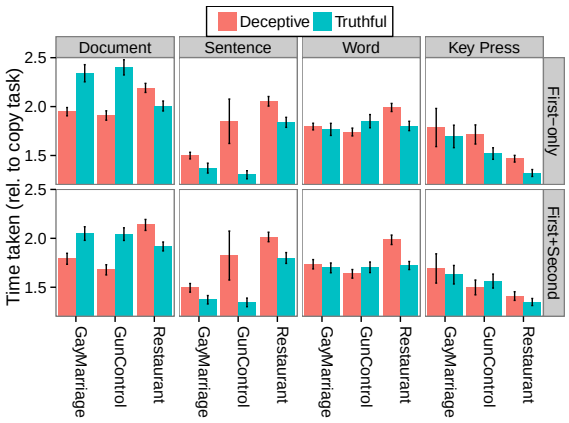

Figure 2: Average normalized timespan $\widehat{\delta}(e)$ for documents, sentences, words and key presses. The top row considers only the first text, while the bottom row considers both flows.

ics: *restaurant review*, *gay marriage* and *gun control*. Each Turker was required to agree to their typing being logged. Since copy/paste operations defeat our purpose of studying keystrokes in the typing process, they were disabled. This restriction also acts as a hindrance to plagiarism. All texts were reviewed manually, and those not meeting the requirements (due to the being too short, plagiarized content, etc.) were disregarded.

Writing task design: The task was designed such that each Turker wrote a pair of texts, one truthful and one deceptive, on the same topic. For restaurant reviews, they were asked to write a truthful review of a restaurant they liked, and a deceptive review of a restaurant they have never been to or did not like. For the other two topics – 'gun control' and 'gay marriage' – we asked their opinion: *support*, *neutral*, or *against*. Then, they were asked to write a truthful and a deceptive essay articulating, respectively, their actual opinion and its opposite.[3] The tasks further were divided into two 'flows': writing the truthful text before the deceptive one, and vice versa. Each Turker was assigned only one flow, and was not allowed to participate in the other. After completing this, each Turker was asked to *copy* their own typing, *i.e.,* re-type the two texts.

Finally, in order to get an idea of the cognitive burden associated with truthful and deceptive writing, we asked the Turkers which task was easier for them. Of the 196 participants, 152 answered "truthful", 40 answered "deceptive" and only 4 opted for "not sure".

What are logged: We deployed a keylogger to capture the mouse and keyboard events in the "text area". The events *KeyUp*, *KeyDown* and *MouseUp*, along with the keycode and timestamp were logged.[4] For the three topics *restaurant review*, *gay marriage* and *gun control* we obtained 1000, 800 and 800 texts, respectively.

In the remainder of this paper, k^{dn} and k^{up} denote the KeyDown and KeyUp events for a key k. For any event e, its *timespan*, *i.e.,* the time interval between the beginning and end of e, is denoted by $\delta(e)$.

[3]To prevent a change in opinion depending on task availability, Turkers were redirected to other tasks if their opinion was neutral, or if we had enough essays of their opinion.

[4]Printable (*e.g.,* alphanumeric characters) as well as non-printable keystrokes like (*e.g.,* 'Backspace'), are logged.

4 Feature Design

Keystroke logging enables the study of two types of information that go beyond conventional linguistic analysis. First, it captures editing processes (*e.g.,* deletions, insertions made by changing cursor position, etc.). Second, it reveals the temporal aspect of text generation (*e.g.,* duration, latency). Our exploration of these features and their application in deception detection is motivated by the similarities between text and speech generation. Editing patterns, for instance, can be viewed as attempts to veil *incoherence* in deceptive writing and temporal patterns like latency or pause can be treated as analogous to *disfluency*.

Different people, of course, have varying typing skills, and some may type faster than others. In order to control for this variation, we normalize all event timespans $\delta(e)$ with respect to the corresponding event timespan in the *copy* task: $\widehat{\delta}(e) = \delta(e)/\delta(e_{copy})$.

4.1 Editing Patterns

In this work, we treat keys that are used only for editing as different from others. Text editing is done by employing a small subset of available keys: deletion keys ('Backspace' and 'Delete'), arrow keys ($\leftarrow$, $\rightarrow$, $\uparrow$ and $\downarrow$) and by using the mouse for text selection (*i.e.,* the 'MouseUp' event). The three types of editing keystrokes are collectively denoted by

$$\mathcal{E}_3 = \langle |\text{DEL}|, |\text{MSELECT}|, |\text{ARROW}| \rangle$$

where

(i) $|\text{DEL}|$ = number of deletion keystrokes
(ii) $|\text{MSELECT}|$ = number of 'MouseUp' events, and
(iii) $|\text{ARROW}|$ = number of arrow keystrokes

The editing differences between truthful and deceptive writing across all three topics are shown in Fig. 1.

4.2 Temporal Aspects

Each event is logged with a keycode and a timestamp. In order to study the temporal aspects of digital writing, we calculate the timespan of different linguistic

Topic	Features	Flow	
		First + Second	First-only
Restaurants	BoW	73.9	78.8
	BoW + $\mathcal{T}_6$	74.3	79.1
	BoW + $\mathcal{T}_6 + \mathcal{E}_3$	74.6	**80.3***
Gun Control (Support)	BoW	86.5	80.0
	BoW + $\mathcal{T}_6$	86.8	82.5*
	BoW + $\mathcal{T}_6 + \mathcal{E}_3$	**88.0**§	83.5*
Gun Control (Oppose)	BoW	88.5	88.0
	BoW + $\mathcal{T}_6$	89.8	87.5
	BoW + $\mathcal{T}_6 + \mathcal{E}_3$	**90.8***	89.1
Gay Marriage (Support)	BoW	92.5	92.0
	BoW + $\mathcal{T}_6$	93.8	92.5
	BoW + $\mathcal{T}_6 + \mathcal{E}_3$	**94.3***	92.0
Gay Marriage (Oppose)	BoW	84.5	86.5
	BoW + $\mathcal{T}_6$	85.0	**87.0**
	BoW + $\mathcal{T}_6 + \mathcal{E}_3$	85.3	86.8

Table 1: SVM classifier performance for truthful vs. deceptive writing. Statistically significant improvements over the baseline are marked * ($p < 0.05$) and § ($p < 0.1$). $\mathcal{E}_3 = \langle |\text{DEL}|, |\text{MSELECT}|, |\text{ARROW}| \rangle$ denotes the editing keystrokes, and $\mathcal{T}_6$ is the set of normalized timespans of documents, words (plus preceding keystroke), all keystrokes, spaces, non-whitespace keystrokes and inter-word intervals: $\mathcal{T}_6 = \{\widehat{\delta}(\text{D}), \widehat{\delta}(k), \widehat{\delta}(\text{SP}), \widehat{\delta}(\neg\text{SP}), \widehat{\delta}(\neg\text{W}), \widehat{\delta}(k_{prv} + \text{W})\}$

units such as words, sentences and even entire documents. Further, we separately inspect the timespans of different parts of speech, function words and content words. In addition to event timespans, intervals between successive events (*e.g.,* inter-word and inter-sentence pauses) and pauses preceding or succeeding and event (*e.g.,* time interval before and after a function word) are measured as well.

5 Experimental Results

This section describes our experimental setup and presents insights based on the obtained results. All classification experiments use 5-fold cross validation with 80/20 division for training and testing. In addition to experimenting on the entire dataset, we also separately analyze the texts written first (of the two texts in each 'flow'). This additional step is taken in order to eliminate the possibility of a text being primed by its preceding text.

Deception cues in keystroke patterns: To empirically check whether keystroke features can help distinguish between truthful and deceptive writing, we design binary SVM classifiers.[5] Unigrams with `tf-idf` encoding is used as the baseline. The average baseline accuracy across all topics is 82.58% when considering both texts of a flow, and 83.62% when considering only the first text of each flow. The better performance in the latter possibly indicates that the second text of a flow exhibits some amount of lexical priming with the first.

The high accuracy of the baseline is not surprising. Previous work by Ott et al. (2011) reported similar performance of unigram models. The focus of our work is to explore the completely new feature space of typographic patterns in deception detection. We draw motivation from parallels between the text generation and speech generation processes. Prosodic concepts such as *speed*, *disfluency* and *coherence* can be realized in typographic behavior by analyzing timestamp of keystrokes, pauses and editing patterns, respectively.

[5]We use the LIBLINEAR (Fan et al., 2008) package.

Table 2: Top 20 words in **restaurant reviews** with greatest timespan difference between deceptive and truthful writing.

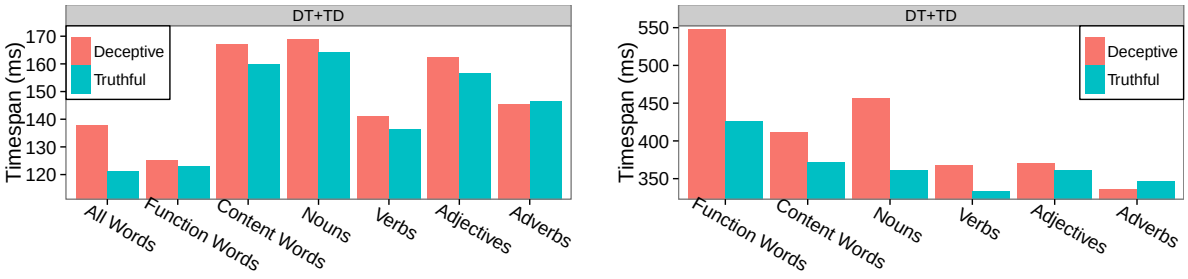
Based on the differences in the temporal aspects of keystrokes, we extract six timespan features to improve this baseline. This set, denoted by $\mathcal{T}_6$, comprises of

(i) $\widehat{\delta}(\text{D})$ = timespan of entire document
(ii) $\widehat{\delta}(k_{prv}+\text{W})$ = average timespan of word plus preceding keystroke
(iii) $\widehat{\delta}(k)$ = average keystroke timespan
(iv) $\widehat{\delta}(\text{SP})$ = average timespan of spaces
(v) $\widehat{\delta}(\neg\text{SP})$ = average timespan of non whitespace keystrokes
(vi) $\widehat{\delta}(\neg\text{W})$ = average interval between words.

The improvements attained by adding $\mathcal{T}_6$ to the baseline are shown in Table 1. Adding the edit patterns ($\mathcal{E}_3$) (cf. § 4.1) further improves the performance (with the exception of two cases) by 0.7–3.5%.

Writing speed, pauses and revisions: To study the temporal aspect of language units across all topics, we first consider all texts, and then restrict to only the first of each 'flow'. The timespan measurements are presented in Fig. 2, showing the average duration of typing documents, sentences, words and individual keystrokes. The timespans are measured as the interval between the first and the last keystrokes. The sentence timespan, for instance, does not include the gap between a sentence end and the first keystroke marking the beginning of the next.

The sentence timespans for "gay marriage" and "gun



(a) (b)

Figure 3: Event timespans in restaurant reviews: (a) language units, and (b) language units including their preceding k^{dn}.

control" are lower in truthful writing, even though the document timespans are higher. This difference implies that the writer is spending a longer period of time to think before commencing the next sentence, but once started, the actual typing proceeds rapidly.

Apart from restaurant reviews, truthful writers have typed slower. This may be due to exercising better care while expressing their honest opinion.

For restaurant reviews, the document, sentence and word timespans are significantly higher in deceptive writing. This, however, is not the case for documents and words in the other two topics. We conjecture that this is because deception is harder to write for product reviews, due to their dependence on factual details. Gun control and gay marriage, on the other hand, are topics well discussed in media, and it is possible that the writers are aware of the arguments that go against their personal belief. The frequency of revisional occurrences (*i.e.,* keys used for editing) shown in Fig. 1, too, supports the thought that writing fake reviews may be harder than adopting a fake stance on well-known issues. Deceptive reviews exhibit a higher number of revisions than truthful ones, but essays show the opposite trend. Our findings align with previous studies (Ott et al., 2011) which showed that deception cues are domain dependent.

Writing speed variations over word categories: Next, we investigate whether there is any quantitative difference in the writing rate over different words with respect to the deceptive and truthful intent of the author. In an attempt to understand this, we analyze words which show the highest timespan difference between deceptive and truthful writings.

Table 2 presents words in the restaurant review topic for which deceptive writers took a lot longer than truthful writers, and vice versa. Some word categories exhibit common trends across all three topics. Highly subjective words, for instance (*e.g.,* "love", "best", "great") are words over which truthful writers spent more time.

Deceptive and truthful texts differ in the typing rate of first- and second-person pronouns. Deceptive reviews reveal more time spent in using 2^{nd}-person pronouns, as shown by "you" and "your". This finding throws some light on how people perceive text cues. Toma and Hancock (2012) showed that readers perform poorly at deception detection because they rely on unrelated text cues such as 2^{nd}-person pronouns. Our analysis indicates that people associate the use of 2^{nd}-person pronouns more with deception not only while reading, but while writing as well.

Deceptive reviews also exhibit longer time spans for 1^{st}-person pronouns (*e.g.,* "we", "me"), which have been known to be useful in deception detection (Newman et al., 2003; Ott et al., 2011). Newman et al. (2003) attributed the less frequent usage of 1^{st}-person pronouns to *psychological distancing*. The longer time taken by deceptive writers in our data is a possible sign of increased cognitive burden when the writer is unable to maintain the psychological distance. Deceptive reviewers also paused a lot more around relative clauses, e.g., "if", "when", and "which".

In essays, however, the difference in timespans of 1^{st}-person and 2^{nd}-person pronouns as well as the timespan difference in relative clauses were insignificant ($< 50\,ms$).

A broader picture of the temporal difference in using different types of words is presented in Fig. 3, which shows deceptive reviewers spending less time on adverbs as compared to truthful writers, but more time on nouns, verbs, adjectives, function words and content words. They also exhibited significantly longer pauses before nouns, verbs and function words.

6 Conclusion

In this paper, we investigated the use of typographic style in deception detection and presented distinct temporal and revisional aspects of keystroke patterns that improve the characterization of deceptive writing. Our study provides novel empirically supported insights into the writing and editing processes of truthful and deceptive writers. It also presents the first application of keylogger data used to distinguish between true and fake texts, and opens up a new range of questions to better understand what affects these different keystroke patterns and what they exhibit. It also suggests new possibilities for making use of keystroke information as an extended linguistic signal to accompany writings.

Abstract

Statistical language modeling (LM) that purports to quantify the acceptability of a given piece of text has long been an interesting yet challenging research area. In particular, language modeling for information retrieval (IR) has enjoyed remarkable empirical success; one emerging stream of the LM approach for IR is to employ the pseudo-relevance feedback process to enhance the representation of an input query so as to improve retrieval effectiveness. This paper presents a continuation of such a general line of research and the main contribution is threefold. First, we propose a principled framework which can unify the relationships among several widely-used query modeling formulations. Second, on top of the successfully developed framework, we propose an extended query modeling formulation by incorporating critical query-specific information cues to guide the model estimation. Third, we further adopt and formalize such a framework to the speech recognition and summarization tasks. A series of empirical experiments reveal the feasibility of such an LM framework and the performance merits of the deduced models on these two tasks.

1 Introduction

Along with the rapidly growing popularity of the Internet and the ubiquity of social web communications, tremendous volumes of multimedia contents, such as broadcast radio and television programs, digital libraries and so on, are made available to the public. Research on multimedia content understanding and organization has witnessed a booming interest over the past decade. By virtue of the developed techniques, a variety of functionalities were created to help distill important content from multimedia collections, or provide locations of important speech segments in a video accompanied with their corresponding transcripts, for users to listen to or to digest. Statistical language modeling (LM) (Jelinek, 1999; Jurafsky and Martin, 2008; Zhai, 2008), which manages to quantify the acceptability of a given word sequence in a natural language or capture the statistical characteristics of a given piece of text, has been proved to offer both efficient and effective modeling abilities in many practical applications of natural language processing and speech recognition (Ponte and Croft, 1998; Jelinek, 1999; Huang, *et al.*, 2001; Zhai and Lafferty, 2001[a]; Jurafsky and Martin, 2008; Furui *et al.*, 2012; Liu and Hakkani-Tur, 2011).

The LM approach was first introduced for the information retrieval (IR) problems in the late 1990s, indicating very good potential, and was subsequently extended in a wide array of follow-up studies. One typical realization of the LM approach for IR is to access the degree of relevance between a query and a document by computing the likelihood of the query generated by the document (usually referred to as the query-likelihood approach) (Zhai, 2008; Baeza-Yates and Ribeiro-Neto, 2011). A document is deemed to be relevant to a given query if the corresponding document model is more likely to generate the query. On the other hand, the Kullback-Leibler divergence measure (denoted by KLM for short hereafter), which quantifies the degree of relevance between a document and a query from a more rigorous information-theoretic perspective, has been proposed (Lafferty and Zhai, 2001; Zhai and Lafferty, 2001[b]; Baeza-Yates and Ribeiro-Neto, 2011). KLM not only can be thought as a natural generalization of the query-likelihood approach, but also has the additional merit of being able to accommodate extra information cues to improve the performance of document ranking. For example, a main challenge facing such a measure is that since a given query usually consists of few words, the true information need is hard to be inferred from the surface statistics of a query. As such, one emerging stream of thought for KLM is to employ the

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1474–1480,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

pseudo-relevance feedback process to construct an enhanced query model (or representation) so as to achieve better retrieval effectiveness (Hiemstra *et al.*, 2004; Lv and Zhai, 2009; Carpineto and Romano, 2012; Lee and Croft, 2013).

Following this line of research, the major contribution of this paper is three-fold: 1) we analyze several widely-used query models and then propose a principled framework to unify the relationships among them; 2) on top of the successfully developed query models, we propose an extended modeling formulation by incorporating additional query-specific information cues to guide the model estimation; 3) we explore a novel use of these query models by adapting them to the speech recognition and summarization tasks. As we will see, a series of experiments indeed demonstrate the effectiveness of the proposed models on these two tasks.

2 Language Modeling Framework

2.1 Kullback-Leibler Divergence Measure

A promising realization of the LM approach to IR is the Kullback-Leibler divergence measure (KLM), which determines the degree of relevance between a document and a query from a rigorous information-theoretic perspective. Two different language models are involved in KLM: one for the document and the other for the query. The divergence of the document model with respect to the query model is defined by

$$\mathrm{KL}(Q \| D) = \Sigma_{w \in V} P(w|Q) \log \frac{P(w|Q)}{P(w|D)}. \quad (1)$$

KLM not only can be thought as a natural generalization of the traditional query-likelihood approach (Yi and Allan, 2009; Baeza-Yates and Ribeiro-Neto, 2011), but also has the additional merit of being able to accommodate extra information cues to improve the estimation of its component models in a systematic way for better document ranking (Zhai, 2008).

Due to that a query usually consists of only a few words, the true query model $P(w|Q)$ might not be accurately estimated by the simple ML estimator (Jelinek, 1991). There are several studies devoted to estimating a more accurate query modeling, saying that it can be approached with the pseudo-relevance feedback process (Lavrenko and Croft, 2001; Zhai and Lafferty, 2001[b]). However, the success depends largely on the assumption that the set of top-ranked documents, $\mathbf{D}_{Top}=\{D_1,D_2,...,D_r,...\}$, obtained from an initial round of retrieval, are relevant and can be used to estimate a more accurate query language model.

2.2 Relevance Modeling

Under the notion of relevance modeling (RM, often referred to as RM-1), each query Q is assumed to be associated with an unknown relevance class R_Q, and documents that are relevant to the semantic content expressed in query are samples drawn from the relevance class R_Q. Since there is no prior knowledge about R_Q, we may use the top-ranked documents $\mathbf{D}_{Top}$ to approximate the relevance class R_Q. The corresponding relevance model can be estimated using the following equation (Lavrenko and Croft, 2001; Lavrenko, 2004):

$$P_{\mathrm{RM}}(w|Q) = \frac{\Sigma_{D_r \in \mathbf{D}_{Top}} P(D_r) P(w|D_r) \Pi_{w' \in Q} P(w'|D_r)}{\Sigma_{D_r'' \in \mathbf{D}_{Top}} P(D_r'') \Pi_{w' \in Q} P(w'|D_r'')}. \quad (2)$$

2.3 Simple Mixture Model

Another perspective of estimating an accurate query model with the top-ranked documents is the simple mixture model (SMM), which assumes that words in $\mathbf{D}_{Top}$ are drawn from a two-component mixture model: 1) One component is the query-specific topic model $P_{\mathrm{SMM}}(w|Q)$**,** and 2) the other is a generic background model $P(w|BG)$. By doing so, the SMM model $P_{\mathrm{SMM}}(w|Q)$ can be estimated by maximizing the likelihood over all the top-ranked documents (Zhai and Lafferty, 2001[b]; Tao and Zhai, 2006):

$$L = \prod_{D_r \in \mathbf{D}_{Top}} \prod_{w \in V} \left(\alpha \cdot P_{\mathrm{SMM}}(w|Q) + (1-\alpha) \cdot P(w|BG)\right)^{c(w,D_r)}, \quad (3)$$

where α is a pre-defined weighting parameter used to control the degree of reliance between $P_{\mathrm{SMM}}(w|Q)$ and $P(w|BG)$. This estimation will enable more specific words to receive more probability mass, thereby leading to a more discriminative query model $P_{\mathrm{SMM}}(w|Q)$.

Although the SMM modeling aims to extract extra word usage cues for enhanced query modeling, it may confront two intrinsic problems. One is the extraction of word usage cues from $\mathbf{D}_{Top}$ is not guided by the original query. The other is that the mixing coefficient α is fixed across all top-ranked documents albeit that different documents would potentially contribute different amounts of word usage cues to the enhanced query model. To mitigate these two problems, the regularized simple mixture model has been proposed and can be estimated by maximizing the likelihood function (Tao and Zhai, 2006; Dillon and Collins-Thompson, 2010)

$$L = \prod_{w \in V} P_{\mathrm{RSMM}}(w|Q)^{\mu \cdot P(w|Q)} \times \prod_{D_r \in \mathbf{D}_{Top}} \prod_{w \in V} \left(\alpha_{D_r} \cdot P_{\mathrm{RSMM}}(w|Q) + (1-\alpha_{D_r}) \cdot P(w|BG)\right)^{c(w,D_r)}, \quad (4)$$

where μ is a weighting factor indicating the confidence on the prior information.

3 The Proposed Modeling Framework

3.1 Fundamentals

It is obvious that the major difference among the

representative query models mentioned above is how to capitalize on the set of top-ranked documents and the original query. Several subtle relationships can be deduced through the following in-depth analysis. First, a direct inspiration of the LM-based query reformulation framework can be drawn from the celebrated Rocchio's formulation, while the former can be viewed as a probabilistic counterpart of the latter (Robertson, 1990; Ponte and Croft, 1998; Baeza-Yates and Ribeiro-Neto, 2011). Second, after some mathematical manipulation, the formulation of the RM model (*c.f.* Eq. (2)) can be rewritten as

$$P_{\mathrm{RM}}(w|Q) = \sum_{D_r \in \mathbf{D}_{Top}} P(w|D_r) \frac{P(Q|D_r)P(D_r)}{\sum_{D_r'' \in \mathbf{D}_{Top}} P(Q|D_r'')P(D_r'')}. \quad (5)$$

It becomes evident that the RM model is composed by mixing a set of document models $P(w|D_r)$. As such, the RM model bears a close resemblance to the Rocchio's formulation. Furthermore, based on Eq. (5), we can recast the estimation of the RM model as an optimization problem, and the likelihood (or objective) function is formulated as

$$L = \prod_{w \in V} \left(\sum_{D_r \in \mathbf{D}_{Top}} P(w|D_r)P(D_r|Q) \right)^{c(w,Q)}, \quad (6)$$
$$s.t. \sum_{D_r \in \mathbf{D}_{Top}} P(D_r|Q) = 1$$

where the document models $P(w|D_r)$ are known in advance; the conditional probability $P(D_r|Q)$ of each document D_r is unknown and leave to be estimated. Finally, a principled framework can be obtained to unify all of these query models, including RM (*c.f.* Eq. (6)), SMM (c.f. Eq. (3)) and RSMM (*c.f.* Eq. (4))), by using a generalized objective likelihood function:

$$L = \prod_{w \in V} \prod_{E_i \in \mathbf{E}} \left(\sum_{M_r \in \mathbf{M}} P(w|M_r)P(M_r) \right)^{c(w,E_i)}, \quad (7)$$
$$s.t. \sum_{M_r \in \mathbf{M}} P(M_r) = 1$$

where **E** represents a set of observations which we want to maximize their likelihood, and **M** denotes a set of mixture components.

3.2 Query-specific Mixture Modeling

The SMM model and the RSMM model are intended to extract useful word usage cues from $\mathbf{D}_{Top}$, which are not only relevant to the original query Q but also external to those already captured by the generic background model. However, we argue in this paper that the "generic information" should be carefully crafted for each query due mainly to the fact that users' information needs may be very diverse from one another. To crystallize the idea, a query-specific background model $P_Q(w|\mathrm{BG})$ for each query Q can be derived from $\mathbf{D}_{Top}$ directly. Another consideration is that since the original query model $P(w|Q)$ cannot be accurately estimated, it thus may not necessarily be the best choice for use in defining a conjugate Dirichlet prior for the enhanced query model to be estimated. We propose to use the RM model as a prior to guide the estimation of the enhanced query model. The enhanced query model is termed query-specific mixture model (QMM), and its corresponding training objective function can be expressed as

$$L = \prod_{w \in V} P_{\mathrm{QMM}}(w|Q)^{\mu \cdot P_{\mathrm{RM}}(w|Q)} \times \prod_{D_r \in \mathbf{D}_{Top}} \prod_{w \in V} \left(\alpha_{D_r} \cdot P_{\mathrm{QMM}}(w|Q) + (1-\alpha_{D_r}) \cdot P_Q(w|BG) \right)^{c(w,D_r)}. \quad (8)$$

4 Applications

4.1 Speech Recognition

Language modeling is a critical and integral component in any large vocabulary continuous speech recognition (LVCSR) system (Huang *et al.*, 2001; Jurafsky and Martin, 2008; Furui *et al.*, 2012). More concretely, the role of language modeling in LVCSR can be interpreted as calculating the conditional probability $P(w|H)$, in which H is a search history, usually expressed as a sequence of words $H=h_1, h_2,\ldots, h_L$, and w is one of its possible immediately succeeding words. Once the various aforementioned query modeling methods are applied to speech recognition, for a search history H, we can conceptually regard it as a query and each of its immediately succeeding words w as a (single-word) document. Then, we may leverage an IR procedure that takes H as a query and poses it to a retrieval system to obtain a set of top-ranked documents from a contemporaneous (or in-domain) corpus. Finally, the enhanced query model (that is $P(w|H)$ in speech recognition) can be estimated by RM, SMM, RSMM or QMM, and further combined with the background n-gram (e.g., trigram) language model to form an adaptive language model to guide the speech recognition process.

4.2 Speech Summarization

On the other hand, extractive speech summarization aims at producing a concise summary by selecting salient sentences or paragraphs from the original spoken document according to a predefined target summarization ratio (Carbonell and Goldstein, 1998; Mani and Maybury, 1999; Nenkova and McKeown, 2011; Liu and Hakkani-Tur, 2011). Intuitively, this task could be framed as an ad-hoc IR problem, where the spoken document is treated as an information need and each sentence of the document is regarded as a candidate information unit to be retrieved according to its relevance to the information need. Therefore, KLM can be used to quantify how close the document D and one of its sentences S are: the closer the sentence model $P(w|S)$ to the document model $P(w|D)$, the more

likely the sentence would be part of the summary. Due to that each sentence S of a spoken document D to be summarized usually consists of only a few words, the corresponding sentence model $P(w|S)$ might not be appropriately estimated by the ML estimation. To alleviate the deficiency, we can leverage the merit of the above query modeling techniques to estimate an accurate sentence model for each sentence to enhance the summarization performance.

5 Experimental Setup

The speech corpus consists of about 196 hours of Mandarin broadcast news collected by the Academia Sinica and the Public Television Service Foundation of Taiwan between November 2001 and April 2003 (Wang *et al.*, 2005), which is publicly available and has been segmented into separate stories and transcribed manually. Each story contains the speech of one studio anchor, as well as several field reporters and interviewees. A subset of 25-hour speech data compiled during November 2001 to December 2002 was used to bootstrap the acoustic model training. The vocabulary size is about 72 thousand words. The background language model was estimated from a background text corpus consisting of 170 million Chinese characters collected from the Chinese Gigaword Corpus released by LDC.

The dataset for use in the speech recognition experiments is compiled by a subset of 3-hour speech data from the corpus within 2003 (1.5 hours for development and 1.5 hours for test). The contemporaneous (in-domain) text corpus used for training the various LM adaptation methods was collected between 2001 and 2003 from the corpus (excluding the test set), which consists of one million Chinese characters of the orthographic broadcast news transcripts. In this paper, all the LM adaptation experiments were performed in word graph rescoring. The associated word graphs of the speech data were built beforehand with a typical LVCSR system (Ortmanns *et al.*, 1997; Young *et al.*, 2006).

In addition, the summarization task also employs the same broadcast news corpus as well. A subset of 205 broadcast news documents compiled between November 2001 and August 2002 was reserved for the summarization experiments (185 for development and 20 for test). A subset of about 100,000 text news documents, compiled during the same period as the documents to be summarized, was employed to estimate the related summarization models compared in this paper. We adopted three variants of the widely-used ROUGE metric (i.e., ROUGE-1, ROGUE-2 and ROUGE-L) for the assessment of summarization performance (Lin, 2003). The summarization ratio, defined as the ratio of the number of words in the automatic (or manual) summary to that in the reference transcript of a spoken document, was set to 10% in this research.

6 Experimental Results

In the first part of experiments, we evaluate the effectiveness of the various query models applied to the speech recognition task. The corresponding results with respect to different numbers of top-ranked documents being used for estimating their component models are shown in Table 1. Also worth mentioning is that the baseline system with the background trigram language model, which was trained with the SRILM toolkit (Stolcke, 2005) and Good-Turing smoothing (Jelinek, 1999), results in a Chinese character error rate (CER) of 20.08% on the test set. Consulting Table 1 we notice two particularities. One is that there is more fluctuation in the CER results of SMM than in those of RM. The reason might be that, for SMM, the extraction of relevance information from the top-ranked documents is conducted with no involvement of the test utterance (i.e., the query; or its corresponding search histories), as elaborated earlier in Section 2. When too many feedback documents are being used, there would be a concern for SMM to be distracted from being able to appropriate model the test utterance, which is probably caused by some dominant distracting (or irrelevant) feedback documents. The other interesting observation is that RSMM only achieves a comparable (even worse) result when compared to SMM. A possible reason is that the prior constraint of the RSMM may contain too much noisy information so as to bias the model estimation. Furthermore, it is evident that the proposed QMM is the best-performing method among all the query models compared in the paper. Although the improvements made by QMM are not as pronounced as expected, we believe that QMM has demonstrated its potential to be applied to other related applications. On the other hand, we compare the various query models with two well-practiced language models, namely the cache model (Cache) (Kuhn and Mori, 1990; Jelinek *et al.*, 1991) and the latent Dirichlet allocation (LDA) (Liu and Liu, 2007; Tam and Schultz, 2005). The CER results of these two models are also shown in Table 1, respectively. For the cache model, bigram cache was used since it can yield better results than the unigram and trigram cache models in our experiments. It is worthy to notice that the LDA model was trained with the entire set of contemporaneous text document collection (*c.f.* Section 4), while all of the query models explored in the paper were estimated based on a subset of the corpus selected by an initial round of retrieval. The results reveal that most of these query models can achieve superior performance over the two conventional language models.

In the second part of experiments, we evaluate the utilities of the various query models as applied to the speech summarization task. At the outset, we assess the performance level of the baseline KLM method by comparison with two well-practiced unsupervised methods, viz. the vector space model (VSM) (Gong and Liu, 2001), and its extension, maximal marginal relevance (MMR) (Carbonell and Goldstein, 1998). The corresponding results are shown in Table 2 and can be aligned with several related literature reviews. By looking at the results, we find that KLM outperforms VSM by a large margin, confirming the applicability of the language modeling framework for speech summarization. Furthermore, MMR that presents an extension of VSM performs on par with KLM for the text summarization task (TD) and exhibits superior performance over KLM for the speech summarization task (SD). We now turn to evaluate the effectiveness of the various query models (viz. RM, SMM, RSMM and QMM) in conjunction with the pseudo-relevance feedback process for enhancing the sentence model involved in the KLM method. The corresponding results are also shown in Table 2. Two noteworthy observations can be drawn from Table 2. One is that all these query models can considerably improve the summarization performance of the KLM method, which corroborates the advantage of using them for enhanced sentence representations. The other is that QMM is the best-performing one among all the formulations studied in this paper for both the TD and SD cases.

Going one step further, we explore to use extra prosodic features that are deemed complementary to the LM cue provided by QMM for speech summarization. To this end, a support vector machine (SVM) based summarization model is trained to integrate a set of 28 commonly-used prosodic features (Liu and Hakkani-Tur, 2011) for representing each spoken sentence, since SVM is arguably one of the state-of-the-art supervised methods that can make use of a diversity of indicative features for text or speech summarization (Xie and Liu, 2010; Chen *et al.*, 2013). The sentence ranking scores derived by QMM and SVM are in turn integrated through a simple log-linear combination. The corresponding results are shown in Table 2, demonstrating consistent improvements with respect to all the three variants of the ROUGE metric as compared to that using either QMM or SVM in isolation. We also investigate using SVM to additionally integrate a richer set of lexical and relevance features to complement QMM and further enhance the summarization effectiveness. However, due to space limitation, we omit the details here. As a side note, there is a sizable gap between the TD and SD cases, indicating room for further improvements. We may seek remedies, such as robust indexing schemes, to compensate for imperfect speech recognition.

Table 1. The speech recognition results (in CER (%)) achieved by various language models along with different numbers of latent topics/pseudo-relevance feedback documents.

	16	32	64	128
Baseline	20.08			
Cache	19.86			
LDA	19.29	19.30	19.28	19.15

QMM+ SVM	**0.492**	**0.395**	**0.448**	**0.398**	**0.261**	**0.358**

7 Conclusion and Outlook

In this paper, we have presented a systematic and thorough analysis of a few well-practiced query models for IR and extended their novel applicability to speech recognition and summarization in a principled way. Furthermore, we have proposed an extension of this research line by introducing query-specific mixture modeling; the utilities of the deduced model have been extensively compared with several existing query models. As to future work, we would like to investigate jointly integrating proximity and other different kinds of relevance and lexical/semantic information cues into the process of feedback document selection so as to improve the empirical effectiveness of such query modeling.

Abstract

We study the topic dynamics of interactions in political debates using the 2012 Republican presidential primary debates as data. We show that the tendency of candidates to shift topics changes over the course of the election campaign, and that it is correlated with their relative power. We also show that our topic shift features help predict candidates' relative rankings.

1 Introduction

The field of computational social sciences has created many interesting applications for natural language processing in recent years. One of the areas where NLP techniques have shown great promise is in the analysis of political speech. For example, researchers have applied NLP techniques to political texts for a variety of tasks such as predicting voting patterns (Thomas et al., 2006), identifying markers of persuasion (Guerini et al., 2008), capturing cues that signal charisma (Rosenberg and Hirschberg, 2009), and detecting ideological positions (Sim et al., 2013). Our work also analyzes political speech, more specifically, presidential debates. The contribution of this paper is to show that the topic shifting tendency of a presidential candidate changes over the course of the election campaign, and that it is correlated with his or her relative power. We also show that this insight can help computational systems that predict the candidates' relative rankings based on their interactions in the debates.

2 Motivation

The motivation for this paper stems from prior work done by the first author in collaboration with other researchers (Prabhakaran et al., 2013a; Prabhakaran et al., 2013b). Prabhakaran et al. (2013a) introduced the notion of power in the domain of presidential debates, and Prabhakaran et al. (2013b) followed it up with an automatic power ranker system based on interactions within the debates. The power that a candidate had at a certain point in the election campaign was modeled based on his or her recent poll standings: in elections, popularity is power. Those studies analyzed the 2012 Republican presidential primary debates and found that a candidate's power at the time of a debate correlates with the structure of interactions within the debate (e.g., turn frequency and interruption patterns). Another finding was that the candidates' power correlates with the distribution of topics they speak about in the debates: candidates with more power spoke significantly more about certain topics (e.g., economy) and less about certain other topics (e.g., energy). However, these findings relate to the specific election cycle that was analyzed and will not carry over to political debates in general.

A further dimension with relevance beyond a specific election campaign is how topics evolve during the course of an interaction (e.g., who attempts to shift topics). In (Prabhakaran et al., 2014), we explored this dimension and found that candidates with higher power introduce significantly more topics in the debates, but attempt to shift topics significantly less often while responding to a moderator. We used the basic LDA topic modeling method (with a filter for substantivity of turns) to assign topics to turns, which were then used to detect shifts in topics. However, segmenting interactions into coherent topic segments is an active area of research and a variety of topic modeling approaches have been proposed for that purpose. In this paper, we explore the utility of one such topic modeling approach to tackle this problem.

While most of the early approaches for topic segmenting in interactions have focused on the

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1481–1486,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

content of the contribution, Nguyen et al. (2012) introduced a system called Speaker Identity for Topic Segmentation (SITS) which also takes into account the topic shifting tendencies of the participants of the conversation. In later work, Nguyen et al. (2013) demonstrated the SITS system's utility in detecting influencers in Crossfire debates and Wikipedia discussions. They also applied the SITS system to the domain of political debates. However they were able to perform only a qualitative analysis of its utility in the debates domain since the debates data did not have influence annotations. In this paper, we use the SITS system to assign topics to turns and perform a quantitative analysis of how the topic shift features calculated using the SITS system relate to the notion of power as captured by (Prabhakaran et al., 2013a).

The SITS system associates each debate participant with a constant scalar value that captures his or her tendency to shift topics. However, since we want to investigate how each candidate's topic shifting tendency relates to his or her changing power over the course of the campaign, we introduce a variation of the SITS analysis in which we represent a different "persona" for each candidate in each debate. Once equipped with this notion of "persona", we find that the topic shifting tendency of a candidate does indeed show a great deal of fluctuation during the election campaign period. We also find that this fluctuation in topic shifting tendencies is significantly correlated with the candidates' power.

As an additional contribution of this paper, we demonstrate the utility of our topic shift features extracted using both types of SITS-based analyses in improving the performance of the automatic power ranker system presented in (Prabhakaran et al., 2013b). We also investigated the utility of topic shifting features described in (Prabhakaran et al., 2014) extracted using LDA based topic modeling. However, they did not improve the performance of the ranker, and hence we do not discuss them in detail in this paper.

3 Data

We use the presidential debates corpus released by Prabhakaran et al. (2013a), which contains manual transcripts of 20 debates held between May 2011 and February 2012 as part of the 2012 Republican presidential primaries. The corpus also captures each candidate's power at the time of each debate, computed based on their relative standing in recent public polls. The poll numbers capture how successful candidates are in convincing the electorate of their candidature, which in turn affects their confidence within the debates. These debates serve as a rich domain to explore manifestations of power since they are a medium through which candidates pursue and maintain power over other candidates. Prabhakaran et al. (2013b) offers a detailed description of how the relative standings in national and state-level polls from various sources are aggregated to obtain candidates' power.

The transcripts are originally obtained from The American Presidency Project, where each turn of the conversation is manually demarcated and their speakers identified. The turns in the corpus are preprocessed using the Stanford CoreNLP package to perform basic NLP steps such as tokenization, sentence segmentation, parts-of-speech tagging and lemmatization.

4 Modeling Topic Shifts

Topic segmentation, the task of segmenting interactions into coherent topic segments, is an important step in analyzing interactions. In addition to its primary purpose, topic segmentation also identifies the speaker turn where the conversation changed from one topic to another, i.e., where the topic shifted, which may shed light on the characteristics of the speaker who changed the topic. We use the SITS approach proposed by (Nguyen et al., 2012) to detect topic shifts. We also propose a different way of using SITS to obtain an analysis of our corpus, which we call SITS^{var}. We discuss both in turn, and then provide a discussion.

4.1 Segmentation using SITS

Most computational approaches towards automatic topic segmentation have focused mainly on the content of the contribution without taking into account the social aspects or speaker characteristics. Different discourse participants may have different tendencies to introduce or shift topics in interactions. In order to address this shortcoming, Nguyen et al. (2012) proposed a new topic segmentation model called Speaker Identity for Topic Segmentation (SITS), in which they explicitly model the individual's tendency to introduce new topics.

Like traditional topic modeling approaches, the SITS system also considers each turn to be a

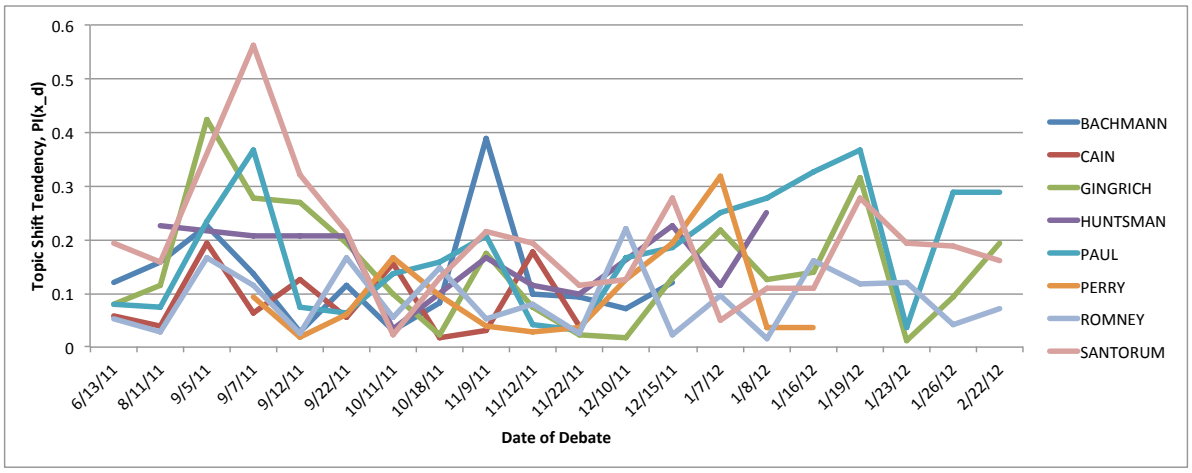

Figure 1: SITS$^{\text{var}}$ Topic shift tendency values across debates

bag of words generated from a mixture of topics. These topics themselves are multinomial distributions over terms. In order to account for the topic shifts that happen during the course of an interaction, they introduce a binary latent variable $l_{d;t}$ called the topic shift to indicate whether the speaker changed the topic or not in conversation d at turn t. To capture the individual speaker's topic shifting tendency, they introduced another latent variable called topic shift tendency (π_x) of speaker x. The π_x value represents the propensity of speaker x to perform a topic shift.

4.2 Segmentation using SITS$^{\text{var}}$

Within the SITS formulation, the topic shifting tendency of an individual (π_x) is considered a constant across conversations. While an individual may have an inherent propensity to shift topics or not, we argue that the topic shifting tendency he or she displays can vary based on the social settings in which he or she interacts and his or her status within those settings. In other words, the same discourse participant may behave differently in different social situations and at different points in time. This is especially relevant in the context of our dataset, where the debates happen over a period of 10 months, and the power and status of each candidate in the election campaign vary greatly within that time period.

We propose a variant of SITS which takes this issue into account. We consider each candidate to have a different "persona" in each debate. To accomplish this, we create new identities for each candidate x for each debate d, denoted by x_d. For example, 'ROMNEY_08-11-2011' denotes the persona of the candidate ROMNEY in the debate held on 08-11-2011. Running the SITS system using this formulation, we obtain different π_{x_d} values for candidate x for different debates, capturing different topic shift tendencies of x.

4.3 Execution

We perform both the SITS and SITS$^{\text{var}}$ analyses on the 20 debates in our corpus. We used the non-parametric version of SITS for both runs, since it systemically estimates the number of topics in the data. We set the maximum number of iterations at 5000, sample lag at 100 and initial number of topics at 25. We refer the reader to (Nguyen et al., 2013) for details on these parameters.

For each candidate, we calculate the mean and standard deviation of the topic shift tendency (π_{x_d}) of his or her personas across all debates he or she participated in. We then average these means and standard deviations, and obtain an average mean of 0.14 and an average standard deviation of 0.09. This shows that the topic shift tendencies of candidates vary by a considerable amount across debates. Figure 1 shows the π_{x_d} value fluctuating across different debates.

5 Analysis of Topic Shift Features

Nguyen et al. (2013) used the SITS analysis as a means to model influence in multi party conversations. They propose two features to detect influencers: Total Topic Shifts (TTS) and Weighted Topic Shifts (WTS). TTS(x, d) captures the expected number of topic shifts the individual x makes in conversation d. This expectation is calculated through the empirical average of samples

Feature Set	Feature	Correlation
TopSh	Total Topic Shifts (TTS)	0.12
	Weighted Topic Shifts (WTS)	0.16
$\text{TopSh}^{\text{var}}$	Total Topic Shifts (TTS^{var})	0.12
	Weighted Topic Shifts (WTS^{var})	0.15
	Topic Shift Tendency (PI^{var})	**-0.27**

Table 1: Pearson Correlations for Topical Features
boldface denotes statistical significance ($p < 0.05$)

from the Gibbs sampler, after a burn-in period. We refer the reader to (Nguyen et al., 2013) for more details on how this value is computed. WTS(x, d) is the value of TTS(x, d) weighted by $1 - \pi_x$. The intuition here is that a topic shift by a speaker with low topic shift tendency must be weighted higher than that by a speaker with a high topic shift tendency. We use these two features as well, and denote the set of these two features as TopSh.

We also extract the TTS and WTS features using our SITS^{var} variation of topic segmentation analysis and denote them as TTS^{var} and WTS^{var} respectively. In addition, we also use a feature $\text{PI}^{\text{var}}(x, d)$ which is the π_{x_d} value obtained by the SITS^{var} for candidate x in debate d. It captures the topic shifting tendency of candidate x in debate d. (We do not include the SITS π_x value in our correlation analysis since it is constant across debates.) We denote the set of these three features obtained from the SITS^{var} run as $\text{TopSh}^{\text{var}}$.

Table 1 shows the Pearson's product correlation between each topical feature and candidate's power. We obtain a highly significant ($p = 0.002$) negative correlation between topic shift tendency of a candidate (PI) and his/her power. In other words, the variation in the topic shifting tendencies is significantly correlated with the candidates' recent poll standings. Candidates who are higher up in the polls tend to stay on topic while the candidates with less power attempt to shift topics more often. This is in line with our previous findings from (Prabhakaran et al., 2014) that candidates with higher power attempt to shift topics less often than others when responding to moderators. It is also in line with the findings by Prabhakaran et al. (2013a) that candidates with higher power tend not to interrupt others. On the other hand, we did not obtain any significant correlation for the features proposed by Nguyen et al. (2013).

6 Topic Shift Features in Power Ranker

In this section, we investigate the utility of the SITS and SITS^{var} based topic shift features described above in the problem of automatically ranking the participants of debates based on their power. Prabhakaran et al. (2013b) define the problem as follows: given a debate d with a set of participants $C_d = \{x_1, x_2, ...x_n\}$ and corresponding power indices $P(x_i)$ for $1 < i < n$, find a ranking function $r : C_d \rightarrow \{1...n\}$ such that for all $1 < i, j < n$, $r(x_i) > r(x_j) \iff P(x_i) > P(x_j)$. For our experiments, we use the SVM^{rank} based supervised learned power ranker presented in that work to estimate this ranking function.

As we do in (Prabhakaran et al., 2013b), we here report Kendall's Tau and Normalized Discounted Cumulative Gain values (NDCG and NDCG@3) on 5-fold cross validation (at the debate level). All three metrics are based on the number of rank inversions between original and predicted ranking. While Tau treats all rank inversions equal, NDCG and NDCG@3 penalize the inversions happening in the top of the ranked list more than those happening in the bottom. NDCG@3 focuses only on the top 3 positions in the ranked list.

We use the best performing feature set of (Prabhakaran et al., 2013b) as the baseline (BL), which contains three features: Words Deviation (WD), Question Deviation (QD) and Mention Percentage (MP). WD and QD capture the deviation of percentage of words spoken by the candidate and questions addressed to the candidate from the expected fair share of those measures in the particular debate. The fair share for debate d is $1/|C_d|$ — the percentage each candidate would have gotten for each feature if it was equally distributed. This deviation measure is used instead of the raw per-

	Kendall's Tau	NDCG	NDCG@3
BL	0.55	0.962	0.932
TopSh	0.36	0.907	0.830
TopSh^{var}	0.39	0.919	0.847
BL + TopSh	0.59	0.967	0.929
BL + TopSh^{var}	**0.60**	**0.970**	**0.937**
BL + TopSh + TopSh^{var}	0.59	0.968	0.934

Table 2: Power Ranker results using topic shift features on 5-fold cross validation
BL: Baseline system (Prabhakaran et al., 2013b)
NDCG: Normalized Discounted Cumulative Gain

centage in order to handle the fact that the percentage values are dependent on the number of participants in a debate, which varied from 9 to 4. MP captures the percentage of mentions of the candidate within a debate.

Table 2 shows the results obtained using the baseline features (BL) as well as combinations of TopSh and TopSh^{var} features. The baseline system obtained a Kendall Tau of 0.55, NDCG of 0.962 and NDCG@3 of 0.932. The topic shift features by themselves performed much worse, with TopSh^{var} posting marginally better results than TopSh. Combining the topic shift and baseline features increases performance considerably. TopSh^{var} obtained better performance than TopSh across the board. BL + TopSh^{var} posted the overall best system obtaining a Tau of 0.60, NDCG of 0.970, and NDCG@3 of 0.937. These results demonstrates the utility of topic shift features in the power ranking problem, especially using the SITS^{var} formulation. We also experimented with all subsets of TopSh and TopSh^{var}; the best results were obtained using all features in each set.

7 Related Work

Studies in sociolinguistics (e.g., (Ng et al., 1993; Ng et al., 1995; Reid and Ng, 2000)) have long established that dialog structure in interactions relates to power and influence. Researchers in the NLP community have studied power and influence in various genres of interactions, such as organizational email threads (Bramsen et al., 2011; Gilbert, 2012; Prabhakaran and Rambow, 2013; Prabhakaran and Rambow, 2014), online discussion forums (Danescu-Niculescu-Mizil et al., 2012; Biran et al., 2012) and online chat dialogs (Strzalkowski et al., 2012). The correlates analyzed in these studies range from word and phrase patterns, to derivatives of such patterns such as linguistic coordination, to deeper dialogic features such as argumentation and dialog acts. Our work differs from these studies in that we study the correlates of power in topic dynamics. Furthermore, we analyze spoken interactions.

8 Conclusion

In this paper, we studied how topic shift patterns in the 2012 Republican presidential debates correlate with the power of candidates. We proposed an alternate formulation of the SITS topic segmentation system that captures fluctuations in each candidate's topic shifting tendencies, which we found to be correlated with their power. We also showed that features based on topic shift improve the prediction of the relative rankings of candidates. In future work, we will explore a model that captures individuals' inherent topic shift propensities, while also capturing their fluctuations due to social factors.

Abstract

We present power low rank ensembles (PLRE), a flexible framework for n-gram language modeling where ensembles of low rank matrices and tensors are used to obtain smoothed probability estimates of words in context. Our method can be understood as a generalization of n-gram modeling to non-integer n, and includes standard techniques such as absolute discounting and Kneser-Ney smoothing as special cases. PLRE training is efficient and our approach outperforms state-of-the-art modified Kneser Ney baselines in terms of perplexity on large corpora as well as on BLEU score in a downstream machine translation task.

1 Introduction

Language modeling is the task of estimating the probability of sequences of words in a language and is an important component in, among other applications, automatic speech recognition (Rabiner and Juang, 1993) and machine translation (Koehn, 2010). The predominant approach to language modeling is the n-gram model, wherein the probability of a word sequence $P(w_1, \ldots, w_\ell)$ is decomposed using the chain rule, and then a Markov assumption is made: $P(w_1, \ldots, w_\ell) \approx \prod_{i=1}^{\ell} P(w_i | w_{i-n+1}^{i-1})$. While this assumption substantially reduces the modeling complexity, parameter estimation remains a major challenge. Due to the power-law nature of language (Zipf, 1949), the maximum likelihood estimator massively overestimates the probability of rare events and assigns zero probability to legitimate word sequences that happen not to have been observed in the training data (Manning and Schütze, 1999).

Many smoothing techniques have been proposed to address the estimation challenge. These reassign probability mass (generally from overestimated events) to unseen word sequences, whose probabilities are estimated by interpolating with or backing off to lower order n-gram models (Chen and Goodman, 1999).

Somewhat surprisingly, these widely used smoothing techniques differ substantially from techniques for coping with data sparsity in other domains, such as collaborative filtering (Koren et al., 2009; Su and Khoshgoftaar, 2009) or matrix completion (Candès and Recht, 2009; Cai et al., 2010). In these areas, *low rank* approaches based on matrix factorization play a central role (Lee and Seung, 2001; Salakhutdinov and Mnih, 2008; Mackey et al., 2011). For example, in recommender systems, a key challenge is dealing with the sparsity of ratings from a single user, since typical users will have rated only a few items. By projecting the low rank representation of a user's (sparse) preferences into the original space, an estimate of ratings for new items is obtained. These methods are attractive due to their computational efficiency and mathematical well-foundedness.

In this paper, we introduce **power low rank ensembles** (PLRE), in which low rank tensors are used to produce smoothed estimates for n-gram probabilities. Ideally, we would like the low rank structures to discover semantic and syntactic relatedness among words and n-grams, which are used to produce smoothed estimates for word sequence probabilities. In contrast to the few previous low rank language modeling approaches, PLRE is not orthogonal to n-gram models, but rather a general framework where existing n-gram smoothing methods such as Kneser-Ney smoothing are special cases. A key insight is that PLRE does not compute low rank approximations of the original

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1487–1498,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

joint count matrices (in the case of bigrams) or tensors i.e. multi-way arrays (in the case of 3-grams and above), but instead altered quantities of these counts based on an element-wise power operation, similar to how some smoothing methods modify their lower order distributions.

Moreover, PLRE has two key aspects that lead to easy scalability for large corpora and vocabularies. First, since it utilizes the original n-grams, the ranks required for the low rank matrices and tensors tend to be remain tractable (e.g. around 100 for a vocabulary size $V \approx 1 \times 10^6$) leading to fast training times. This differentiates our approach over other methods that leverage an underlying latent space such as neural networks (Bengio et al., 2003; Mnih and Hinton, 2007; Mikolov et al., 2010) or soft-class models (Saul and Pereira, 1997) where the underlying dimension is required to be quite large to obtain good performance. Moreover, at test time, the probability of a sequence can be queried in time $O(\kappa_{max})$ where κ_{max} is the maximum rank of the low rank matrices/tensors used. While this is larger than Kneser Ney's virtually constant query time, it is substantially faster than conditional exponential family models (Chen and Rosenfeld, 2000; Chen, 2009; Nelakanti et al., 2013) and neural networks which require $O(V)$ for exact computation of the normalization constant. See Section 7 for a more detailed discussion of related work.

Outline: We first review existing n-gram smoothing methods (§2) and then present the intuition behind the key components of our technique: **rank** (§3.1) and **power** (§3.2). We then show how these can be interpolated into an ensemble (§4). In the experimental evaluation on English and Russian corpora (§5), we find that PLRE outperforms Kneser-Ney smoothing and all its variants, as well as class-based language models. We also include a comparison to the log-bilinear neural language model (Mnih and Hinton, 2007) and evaluate performance on a downstream machine translation task (§6) where our method achieves consistent improvements in BLEU.

2 Discount-based Smoothing

We first provide background on absolute discounting (Ney et al., 1994) and Kneser-Ney smoothing (Kneser and Ney, 1995), two common n-gram smoothing methods. Both methods can be formulated as back-off or interpolated models; we describe the latter here since that is the basis of our low rank approach.

2.1 Notation

Let $c(w)$ be the count of word w, and similarly $c(w, w_{i-1})$ for the joint count of words w and w_{i-1}. For shorthand we will define w_i^j to denote the word sequence $\{w_i, w_{i+1}, ..., w_{j-1}, w_j\}$. Let $\widehat{P}(w_i)$ refer to the maximum likelihood estimate (MLE) of the probability of word w_i, and similarly $\widehat{P}(w_i|w_{i-1})$ for the probability conditioned on a history, or more generally, $\widehat{P}(w_i|w_{i-n+1}^{i-1})$.

Let $N_-(w_i) := |\{w : c(w_i, w) > 0\}|$ be the number of distinct words that appear before w_i. More generally, let $N_-(w_{i-n+1}^i) = |\{w : c(w_{i-n+1}^i, w) > 0\}|$. Similarly, let $N_+(w_{i-n+1}^{i-1}) = |\{w : c(w, w_{i-n+1}^{i-1}) > 0\}|$. V denotes the vocabulary size.

2.2 Absolute Discounting

Absolute discounting works on the idea of interpolating higher order n-gram models with lower-order n-gram models. However, first some probability mass must be "subtracted" from the higher order n-grams so that the leftover probability can be allocated to the lower order n-grams. More specifically, define the following discounted conditional probability:

$$\widehat{P}_D(w_i|w_{i-n+1}^{i-1}) = \frac{\max\{c(w_i, w_{i-n+1}^{i-1}) - D, 0\}}{c(w_{i-n+1}^{i-1})}$$

Then absolute discounting $P_{\text{abs}}(\cdot)$ uses the following (recursive) equation:

$$P_{\text{abs}}(w_i|w_{i-n+1}^{i-1}) = \widehat{P}_D(w_i|w_{i-n+1}^{i-1}) + \gamma(w_{i-n+1}^{i-1}) P_{\text{abs}}(w_i|w_{i-n+2}^{i-1})$$

where $\gamma(w_{i-n+1}^{i-1})$ is the leftover weight (due to the discounting) that is chosen so that the conditional distribution sums to one: $\gamma(w_{i-n+1}^{i-1}) = \frac{D}{c(w_{i-n+1}^{i-1})} N_+(w_{i-n+1}^{i-1})$. For the base case, we set $P_{\text{abs}}(w_i) = \widehat{P}(w_i)$.

Discontinuity: Note that if $c(w_{i-n+1}^{i-1}) = 0$, then $\gamma(w_{i-n+1}^{i-1}) = \frac{0}{0}$, in which case $\gamma(w_{i-n+1}^{i-1})$ is set to 1. We will see that this discontinuity appears in PLRE as well.

2.3 Kneser Ney Smoothing

Ideally, the smoothed probability should preserve the observed unigram distribution:

$$\widehat{P}(w_i) = \sum_{w_{i-n+1}^{i-1}} P_{\text{sm}}(w_i|w_{i-n+1}^{i-1})\widehat{P}(w_{i-n+1}^{i-1}) \quad (1)$$

where $P_{\text{sm}}(w_i|w_{i-n+1}^{i-1})$ is the smoothed conditional probability that a model outputs. Unfortunately, absolute discounting does not satisfy this property, since it exclusively uses the unaltered MLE unigram model as its lower order model. In practice, the lower order distribution is only utilized when we are unsure about the higher order distribution (i.e., when $\gamma(\cdot)$ is large). Therefore, the unigram model should be altered to condition on this fact.

This is the inspiration behind Kneser-Ney (KN) smoothing, an elegant algorithm with robust performance in n-gram language modeling. KN smoothing defines alternate probabilities $P^{\text{alt}}(\cdot)$:

$$P_D^{\text{alt}}(w_i|w_{i-n'+1}^{i-1}) = \begin{cases} \widehat{P}_D(w_i|w_{i-n'+1}^{i-1}), & \text{if } n' = n \\ \frac{\max\{N_-(w_{i-n'+1}^{i})-D,0\}}{\sum_{w_i} N_-(w_{i-n'+1}^{i})}, & \text{if } n' < n \end{cases}$$

The base case for unigrams reduces to $P^{\text{alt}}(w_i) = \frac{N_-(w_i)}{\sum_{w_i} N_-(w_i)}$. Intuitively $P^{\text{alt}}(w_i)$ is proportional to the number of unique words that precede w_i. Thus, words that appear in many different contexts will be given higher weight than words that consistently appear after only a few contexts. These alternate distributions are then used with absolute discounting:

$$P_{\text{kn}}(w_i|w_{i-n+1}^{i-1}) = P_D^{\text{alt}}(w_i|w_{i-n+1}^{i-1}) + \gamma(w_{i-n+1}^{i-1})P_{\text{kn}}(w_i|w_{i-n+2}^{i-1}) \quad (2)$$

where we set $P_{\text{kn}}(w_i) = P^{\text{alt}}(w_i)$. By definition, KN smoothing satisfies the marginal constraint in Eq. 1 (Kneser and Ney, 1995).

3 Power Low Rank Ensembles

In n-gram smoothing methods, if a bigram count $c(w_i, w_{i-1})$ is zero, the unigram probabilities are used, which is equivalent to assuming that w_i and w_{i-1} are independent (and similarly for general n). However, in this situation, instead of backing off to a 1-gram, we may like to back off to a "1.5-gram" or more generally an order between 1 and 2 that captures a coarser level of dependence between w_i and w_{i-1} and does not assume full independence.

Inspired by this intuition, our strategy is to construct an ensemble of matrices and tensors that not only consists of MLE-based count information, but also contains quantities that represent levels of dependence in-between the various orders in the model. We call these combinations power low rank ensembles (PLRE), and they can be thought of as n-gram models with non-integer n. Our approach can be recursively formulated as:

$$\begin{aligned} P_{\text{plre}}(w_i|w_{i-n+1}^{i-1}) &= P_{\boldsymbol{D}_0}^{\text{alt}}(w_i|w_{i-n+1}^{i-1}) \\ &+ \gamma_0(w_{i-n+1}^{i-1})\Big(\boldsymbol{Z}_{\boldsymbol{D}_1}(w_i|w_{i-n+1}^{i-1}) + ... \\ &+ \gamma_{\eta-1}(w_{i-n+1}^{i-1})\Big(\boldsymbol{Z}_{\boldsymbol{D}_\eta}(w_i|w_{i-n+1}^{i-1}) \\ &+ \gamma_\eta(w_{i-n+1}^{i-1})\Big(P_{\text{plre}}(w_i|w_{i-n+2}^{i-1})\Big)\Big)...\Big) \end{aligned} \quad (3)$$

where $\boldsymbol{Z}_1, ..., \boldsymbol{Z}_\eta$ are conditional probability matrices that represent the intermediate n-gram orders[1] and $\boldsymbol{D}$ is a discount function (specified in §4).

This formulation begs answers to a few critical questions. How to construct matrices that represent conditional probabilities for intermediate n? How to transform them in a way that generalizes the altered lower order distributions in KN smoothing? How to combine these matrices such that the marginal constraint in Eq. 1 still holds? The following propose solutions to these three queries:

1. **Rank** (Section 3.1): *Rank* gives us a concrete measurement of the dependence between w_i and w_{i-1}. By constructing low rank approximations of the bigram count matrix and higher-order count tensors, we obtain matrices that represent coarser dependencies, with a rank one approximation implying that the variables are independent.

2. **Power** (Section 3.2): In KN smoothing, the lower order distributions are not the original counts but rather altered estimates. We propose a continuous generalization of this alteration by taking the element-wise *power* of the counts.

[1] with a slight abuse of notation, let $\boldsymbol{Z}_{\boldsymbol{D}_j}$ be shorthand for $\boldsymbol{Z}_{j,\boldsymbol{D}_j}$

3. **Creating the Ensemble** (Section 4): Lastly, PLRE also defines a way to interpolate the specifically constructed intermediate n-gram matrices. Unfortunately a constant discount, as presented in Section 2, will not in general preserve the lower order marginal constraint (Eq. 1). We propose a generalized discounting scheme to ensure the constraint holds.

3.1 Rank

We first show how rank can be utilized to construct quantities between an n-gram and an $n-1$-gram. In general, we think of an n-gram as an n^{th} order tensor i.e. a multi-way array with n indices $\{i_1, ..., i_n\}$. (A vector is a tensor of order 1, a matrix is a tensor of order 2 etc.) Computing a special rank one approximation of slices of this tensor produces the $n-1$-gram. Thus, taking rank κ approximations in this fashion allows us to represent dependencies between an n-gram and $n-1$-gram.

Consider the bigram count matrix $\boldsymbol{B}$ with N counts which has rank V. Note that $\widehat{P}(w_i|w_{i-1}) = \frac{\boldsymbol{B}(w_i,w_{i-1})}{\sum_w \boldsymbol{B}(w,w_{i-1})}$. Additionally, $\boldsymbol{B}$ can be considered a random variable that is the result of sampling N tuples of (w_i, w_{i-1}) and agglomerating them into a count matrix. Assuming w_i and w_{i-1} are independent, the expected value (with respect to the empirical distribution) $\mathbb{E}[\boldsymbol{B}] = NP(w_i)P(w_{i-1})$, which can be rewritten as being proportional to the outer product of the unigram probability vector with itself, and is thus rank one.

This observation extends to higher order n-grams as well. Let $\boldsymbol{C}^n$ be the n^{th} order tensor where $\boldsymbol{C}^n(w_i, ..., w_{i-n+1}) = c(w_i, ..., w_{i-n+1})$. Furthermore denote $\boldsymbol{C}^n(:, \tilde{w}_{i-n+2}^{i-1}, :)$ to be the $V \times V$ matrix slice of $\boldsymbol{C}^n$ where $w_{i-n+2}, ..., w_{i-1}$ are held fixed to a particular sequence $\tilde{w}_{i-n+2}, ..., \tilde{w}_{i-1}$. Then if w_i is conditionally independent of w_{i-n+1} given w_{i-n+2}^{i-1}, then $\mathbb{E}[\boldsymbol{C}^n(:, \tilde{w}_{i-n+2}^{i-1}, :)]$ is rank one $\forall \tilde{w}_{i-n+2}^{i-1}$.

However, it is rare that these matrices are actually rank one, either due to sampling variance or the fact that w_i and w_{i-1} are not independent. What we would really like to say is that the *best* rank one approximation $\boldsymbol{B}^{(1)}$ (under some norm) of $\boldsymbol{B}$ is $\propto \widehat{P}(w_i)\widehat{P}(w_{i-1})$. While this statement is not true under the ℓ_2 norm, it is true under generalized KL divergence (Lee and Seung, 2001): $gKL(\boldsymbol{A}||\boldsymbol{B}) = \sum_{ij}\Big(\boldsymbol{A}_{ij}\log(\frac{\boldsymbol{A}_{ij}}{\boldsymbol{B}_{ij}}) - \boldsymbol{A}_{ij} + \boldsymbol{B}_{ij})\Big)$.

In particular, generalized KL divergence preserves row and column sums: *if $\boldsymbol{M}^{(\kappa)}$ is the best rank κ approximation of $\boldsymbol{M}$ under gKL then the row sums and column sums of $\boldsymbol{M}^{(\kappa)}$ and $\boldsymbol{M}$ are equal* (Ho and Van Dooren, 2008). Leveraging this property, it is straightforward to prove the following lemma:

Lemma 1. *Let $\boldsymbol{B}^{(\kappa)}$ be the best rank κ approximation of $\boldsymbol{B}$ under gKL. Then $\boldsymbol{B}^{(1)} \propto \widehat{P}(w_i)\widehat{P}(w_{i-1})$ and $\forall w_{i-1}$ s.t. $c(w_{i-1}) \neq 0$:*

$$\widehat{P}(w_i) = \frac{\boldsymbol{B}^{(1)}(w_i, w_{i-1})}{\sum_w \boldsymbol{B}^{(1)}(w, w_{i-1})}$$

For more general n, let $\boldsymbol{C}^{n,(\kappa)}_{i-1,...,i-n+2}$ be the best rank κ approximation of $\boldsymbol{C}^n(:, \tilde{w}_{i-n+2}^{i-1}, :)$ under gKL. Then similarly, $\forall w_{i-n+1}^{i-1}$ s.t. $c(w_{i-n+1}^{i-1}) > 0$:

$$\widehat{P}(w_i|w_{i-1}, ..., w_{i-n+2}) = \frac{\boldsymbol{C}^{n,(1)}_{i-1,...,i-n+2}(w_i, w_{i-n+1}^{i-1})}{\sum_w \boldsymbol{C}^{n,(1)}_{i-1,...,i-n+2}(w, w_{i-n+1}^{i-1})} \quad (4)$$

Thus, by selecting $1 < \kappa < V$, we obtain count matrices and tensors between n and $n-1$-grams. The condition that $c(w_{i-n+1}^{i-1}) > 0$ corresponds to the discontinuity discussed in §2.2.

3.2 Power

Since KN smoothing alters the lower order distributions instead of simply using the MLE, varying the rank is not sufficient in order to generalize this suite of techniques. Thus, PLRE computes low rank approximations of altered count matrices. Consider taking the elementwise power ρ of the bigram count matrix, which is denoted by $\boldsymbol{B}^{\cdot\rho}$. For example, the observed bigram count matrix and associated row sum:

$$\boldsymbol{B}^{\cdot 1} = \begin{pmatrix} 1.0 & 2.0 & 1.0 \\ 0 & 5.0 & 0 \\ 2.0 & 0 & 0 \end{pmatrix} \overset{\text{row sum}}{\rightarrow} \begin{pmatrix} 4.0 \\ 5.0 \\ 2.0 \end{pmatrix}$$

As expected the row sum is equal to the unigram counts (which we denote as $\boldsymbol{u}$). Now consider $\boldsymbol{B}^{\cdot 0.5}$:

$$\boldsymbol{B}^{\cdot 0.5} = \begin{pmatrix} 1.0 & 1.4 & 1.0 \\ 0 & 2.2 & 0 \\ 1.4 & 0 & 0 \end{pmatrix} \overset{\text{row sum}}{\rightarrow} \begin{pmatrix} 3.4 \\ 2.2 \\ 1.4 \end{pmatrix}$$

Note how the row sum vector has been altered. In particular since w_1 (corresponding to the first

row) has a more diverse history than w_2, it has a higher row sum (compared to in $\boldsymbol{u}$ where w_2 has the higher row sum). Lastly, consider the case when $p = 0$:

$$\boldsymbol{B}^{\cdot 0} = \begin{pmatrix} 1.0 & 1.0 & 1.0 \\ 0 & 1.0 & 0 \\ 1.0 & 0 & 0 \end{pmatrix} \overset{\text{row sum}}{\rightarrow} \begin{pmatrix} 3.0 \\ 1.0 \\ 1.0 \end{pmatrix}$$

The row sum is now the number of unique words that precede w_i (since $\boldsymbol{B}^0$ is binary) and is thus equal to the (unnormalized) Kneser Ney unigram. This idea also generalizes to higher order n-grams and leads us to the following lemma:

Lemma 2. *Let $\boldsymbol{B}^{(\rho,\kappa)}$ be the best rank κ approximation of $\boldsymbol{B}^{\cdot\rho}$ under gKL. Then $\forall w_{i-1}$ s.t. $c(w_{i-1}) \neq 0$:*

$$P^{alt}(w_i) = \frac{\boldsymbol{B}^{(0,1)}(w_i, w_{i-1})}{\sum_w \boldsymbol{B}^{(0,1)}(w, w_{i-1})}$$

For more general n, let $\boldsymbol{C}^{n,(\rho,\kappa)}_{i-1,\ldots,i-n+2}$ be the best rank κ approximation of $\boldsymbol{C}^{n,(\rho)}(:, \tilde{w}^{i-1}_{i-n+2}, :)$ under gKL. Similarly, $\forall w^{i-1}_{i-n+1}$ s.t. $c(w^{i-1}_{i-n+1}) > 0$:

$$P^{alt}(w_i|w_{i-1}, ..., w_{i-n+2}) = \frac{\boldsymbol{C}^{n,(0,1)}_{i-1,\ldots,i-n+2}(w_i, w^{i-1}_{i-n+1})}{\sum_w \boldsymbol{C}^{n,(0,1)}_{i-1,\ldots,i-n+2}(w, w^{i-1}_{i-n+1})} \quad (5)$$

4 Creating the Ensemble

Recall our overall formulation in Eq. 3; a naive solution would be to set $\boldsymbol{Z}_1, ..., \boldsymbol{Z}_\eta$ to low rank approximations of the count matrices/tensors under varying powers, and then interpolate through constant absolute discounting. Unfortunately, the marginal constraint in Eq. 1 will generally not hold if this strategy is used. Therefore, we propose a generalized discounting scheme where each nonzero n-gram count is associated with a different discount $\boldsymbol{D}_j(w_i, w^{i-1}_{i-n'+1})$. The low rank approximations are then computed on the discounted matrices, leaving the marginal constraint intact.

For clarity of exposition, we focus on the special case where $n = 2$ with only one low rank matrix before stating our general algorithm:

$$P_{\text{plre}}(w_i|w_{i-1}) = \widehat{P}_{\boldsymbol{D}_0}(w_i|w_{i-1}) + \gamma_0(w_{i-1})\Big(\boldsymbol{Z}_{\boldsymbol{D}_1}(w_i|w_{i-1}) + \gamma_1(w_{i-1})P^{\text{alt}}(w_i)\Big) \quad (6)$$

Our goal is to compute $\boldsymbol{D}_0, \boldsymbol{D}_1$ and $\boldsymbol{Z}_1$ so that the following lower order marginal constraint holds:

$$\widehat{P}(w_i) = \sum_{w_{i-1}} P_{\text{plre}}(w_i|w_{i-1})\widehat{P}(w_{i-1}) \quad (7)$$

Our solution can be thought of as a two-step procedure where we compute the discounts $\boldsymbol{D}_0, \boldsymbol{D}_1$ (and the $\gamma(w_{i-1})$ weights as a by-product), followed by the low rank quantity $\boldsymbol{Z}_1$. First, we construct the following intermediate ensemble of powered, but full rank terms. Let $\boldsymbol{Y}^{\rho_j}$ be the matrix such that $\boldsymbol{Y}^{\rho_j}(w_i, w_{i-1}) := c(w_i, w_{i-1})^{\rho_j}$. Then define

$$P_{\text{pwr}}(w_i|w_{i-1}) := \boldsymbol{Y}^{(\rho_0=1)}_{\boldsymbol{D}_0}(w_i|w_{i-1}) + \gamma_0(w_{i-1})\Big(\boldsymbol{Y}^{(\rho_1)}_{\boldsymbol{D}_1}(w_i|w_{i-1}) + \gamma_1(w_{i-1})\boldsymbol{Y}^{(\rho_2=0)}(w_i|w_{i-1})\Big) \quad (8)$$

where with a little abuse of notation:

$$\boldsymbol{Y}^{\rho_j}_{\boldsymbol{D}_j}(w_i|w_{i-1}) = \frac{c(w_i, w_{i-1})^{\rho_j} - \boldsymbol{D}_j(w_i, w_{i-1})}{\sum_{w_i} c(w_i, w_{i-1})^{\rho_j}}$$

Note that $P^{\text{alt}}(w_i)$ has been replaced with $\boldsymbol{Y}^{(\rho_2=0)}(w_i|w_{i-1})$, based on Lemma 2, and will equal $P^{\text{alt}}(w_i)$ once the low rank approximation is taken as discussed in § 4.2).

Since we have only combined terms of different power (but all full rank), it is natural choose the discounts so that the result remains unchanged i.e., $P_{\text{pwr}}(w_i|w_{i-1}) = \widehat{P}(w_i|w_{i-1})$, since the low rank approximation (not the power) will implement smoothing. Enforcing this constraint gives rise to a set of linear equations that can be solved (in closed form) to obtain the discounts as we now show below.

4.1 Step 1: Computing the Discounts

To ensure the constraint that $P_{\text{pwr}}(w_i|w_{i-1}) = \widehat{P}(w_i|w_{i-1})$, it is sufficient to enforce the following two local constraints:

$$\boldsymbol{Y}^{(\rho_j)}(w_i|w_{i-1}) = \boldsymbol{Y}^{(\rho_j)}_{\boldsymbol{D}_j}(w_i|w_{i-1}) + \gamma_j(w_{i-1})\boldsymbol{Y}^{(\rho_{j+1})}(w_i|w_{i-1}) \text{ for } j = 0, 1 \quad (9)$$

This allows each $\boldsymbol{D}_j$ to be solved for independently of the other $\{\boldsymbol{D}_{j'}\}_{j' \neq j}$. Let $c_{i,i-1} = c(w_i, w_{i-1})$, $c^j_{i,i-1} = c(w_i, w_{i-1})^{\rho_j}$, and $d^j_{i,i-1} =$

$\boldsymbol{D}_j(w_i, w_{i-1})$. Expanding Eq. 9 yields that $\forall w_i, w_{i-1}$:

$$\frac{c^j_{i,i-1}}{\sum_i c^j_{i,i-1}} = \frac{c^j_{i,i-1} - d^j_{i,i-1}}{\sum_i c^j_{i,i-1}} + \left(\frac{\sum_i d^j_{i,i-1}}{\sum_i c^j_{i,i-1}}\right) \frac{c^{j+1}_{i,i-1}}{\sum_i c^{j+1}_{i,i-1}} \quad (10)$$

which can be rewritten as:

$$-d^j_{i,i-1} + \left(\sum_i d^j_{i,i-1}\right) \frac{c^{j+1}_{i,i-1}}{\sum_i c^{j+1}_{i,i-1}} = 0 \quad (11)$$

Note that Eq. 11 decouples across w_{i-1} since the only $d^j_{i,i-1}$ terms that are dependent are the ones that share the preceding context w_{i-1}.

It is straightforward to see that setting $d^j_{i,i-1}$ proportional to $c^{j+1}_{i,i-1}$ satisfies Eq. 11. Furthermore it can be shown that all solutions are of this form (i.e., the linear system has a null space of exactly one). Moreover, we are interested in a particular subset of solutions where a single parameter d_* (independent of w_{i-1}) controls the scaling as indicated by the following lemma:

Lemma 3. *Assume that $\rho_j \geq \rho_{j+1}$. Choose any $0 \leq d_* \leq 1$. Set $d^j_{i,i-1} = d_* c^{j+1}_{i,i-1}\ \forall i, j$. The resulting discounts satisfy Eq. 11 as well as the inequality constraints $0 \leq d^j_{i,i-1} \leq c^j_{i,i-1}$. Furthermore, the leftover weight γ_j takes the form:*

$$\gamma_j(w_{i-1}) = \frac{\sum_i d^j_{i,i-1}}{\sum_i c^j_{i,i-1}} = \frac{d_* \sum_i c^{j+1}_{i,i-1}}{\sum_i c^j_{i,i-1}}$$

Proof. Clearly this choice of $d^j_{i,i-1}$ satisfies Eq. 11. The largest possible value of $d^j_{i,i-1}$ is $c^{j+1}_{i,i-1}$. $\rho_j \geq \rho_{j+1}$, implies $c^j_{i,i-1} \geq c^{j+1}_{i,i-1}$. Thus the inequality constraints are met. It is then easy to verify that γ takes the above form. □

The above lemma generalizes to longer contexts (i.e. $n > 2$) as shown in Algorithm 1. Note that if $\rho_j = \rho_{j+1}$ then Algorithm 1 is equivalent to scaling the counts e.g. deleted-interpolation/Jelinek Mercer smoothing (Jelinek and Mercer, 1980). On the other hand, when $\rho_{j+1} = 0$, Algorithm 1 is equal to the absolute discounting that is used in Kneser-Ney. Thus, depending on ρ_{j+1}, our method generalizes different types of interpolation schemes to construct an ensemble so that the marginal constraint is satisfied.

Algorithm 1 Compute $\boldsymbol{D}$

In: Count tensor $\boldsymbol{C}^n$, powers ρ_j, ρ_{j+1} such that $\rho_j \geq \rho_{j+1}$, and parameter d_*.

Out: Discount $\boldsymbol{D}_j$ for powered counts $\boldsymbol{C}^{n,(\rho_j)}$ and associated leftover weight γ_j

1: Set $\boldsymbol{D}_j(w_i, w^{i-1}_{i-n+1}) = d_* c(w_i, w^{i-1}_{i-n+1})^{\rho_{j+1}}$.

2: $$\gamma_j(w_i, w^{i-1}_{i-n+1}) = \frac{d_* \sum_{w_i} c(w_i, w^{i-1}_{i-n+1})^{\rho_{j+1}}}{\sum_{w_i} c(w_i, w^{i-1}_{i-n+1})^{\rho_j}}$$

Algorithm 2 Compute $\boldsymbol{Z}$

In: Count tensor $\boldsymbol{C}^n$, power ρ, discounts $\boldsymbol{D}$, rank κ

Out: Discounted low rank conditional probability table $\boldsymbol{Z}^{(\rho,\kappa)}_{\boldsymbol{D}}(w_i|w^{i-1}_{i-n+1})$ (represented implicitly)

1: Compute powered counts $\boldsymbol{C}^{n,(\cdot\rho)}$.

2: Compute denominators $\sum_{w_i} c(w_i, w^{i-1}_{i-n+1})^\rho$ $\forall w^{i-1}_{i-n+1}$ s.t. $c(w^{i-1}_{i-n+1}) > 0$.

3: Compute discounted powered counts $\boldsymbol{C}^{n,(\cdot\rho)}_{\boldsymbol{D}} = \boldsymbol{C}^{n,(\cdot\rho)} - \boldsymbol{D}$.

4: For each slice $\boldsymbol{M}_{\tilde{w}^{i-1}_{i-n+2}} := \boldsymbol{C}^{n,(\cdot\rho)}_{\boldsymbol{D}}(:, \tilde{w}^{i-1}_{i-n+2}, :)$ compute

$$\boldsymbol{M}^{(\kappa)} := \min_{\boldsymbol{A} \geq 0 : rank(\boldsymbol{A}) = \kappa} \|\boldsymbol{M}_{\tilde{w}^{i-1}_{i-n+2}} - \boldsymbol{A}\|_{KL}$$

(stored implicitly as $\boldsymbol{M}^{(\kappa)} = \boldsymbol{LR}$)

Set $\boldsymbol{Z}^{(\rho,\kappa)}_{\boldsymbol{D}}(:, \tilde{w}^{i-1}_{i-n+2}, :) = \boldsymbol{M}^{(\kappa)}$

5: Note that

$$\boldsymbol{Z}^{(\rho,\kappa)}_{\boldsymbol{D}}(w_i|w^{i-1}_{i-n+1}) = \frac{\boldsymbol{Z}^{(\rho,\kappa)}_{\boldsymbol{D}}(w_i, w^{i-1}_{i-n+1})}{\sum_{w_i} c(w_i, w^{i-1}_{i-n+1})^\rho}$$

4.2 Step 2: Computing Low Rank Quantities

The next step is to compute low rank approximations of $\boldsymbol{Y}^{(\rho_j)}_{\boldsymbol{D}_j}$ to obtain $\boldsymbol{Z}_{\boldsymbol{D}_j}$ such that the intermediate marginal constraint in Eq. 7 is preserved. This constraint trivially holds for the intermediate ensemble $P_{\text{pwr}}(w_i|w_{i-1})$ due to how the discounts were derived in § 4.1. For our running bigram example, define $\boldsymbol{Z}^{(\rho_j,\kappa_j)}_{\boldsymbol{D}_j}$ to be the best rank κ_j approximation to $\boldsymbol{Y}^{(\rho_j,\kappa_j)}_{\boldsymbol{D}_j}$ according to gKL and let

$$\boldsymbol{Z}^{\rho_j,\kappa_j}_{\boldsymbol{D}_j}(w_i|w_{i-1}) = \frac{\boldsymbol{Z}^{\rho_j,\kappa_j}_{\boldsymbol{D}_j}(w_i, w_{i-1})}{\sum_{w_i} c(w_i, w_{i-1})^{\rho_j}}$$

Note that $\boldsymbol{Z}^{\rho_j,\kappa_j}_{\boldsymbol{D}_j}(w_i|w_{i-1})$ is a valid (discounted) conditional probability since gKL preserves row/column sums so the denominator remains unchanged under the low rank approximation. Then

using the fact that $\boldsymbol{Z}^{(0,1)}(w_i|w_{i-1}) = P^{\text{alt}}(w_i)$ (Lemma 2) we can embellish Eq. 6 as

$$P_{\text{plre}}(w_i|w_{i-1}) = P_{\boldsymbol{D}_0}(w_i|w_{i-1}) + \gamma_0(w_{i-1})\left(\boldsymbol{Z}_{\boldsymbol{D}_1}^{(\rho_1,\kappa_1)}(w_i|w_{i-1}) + \gamma_1(w_{i-1})P_{\text{alt}}(w_i)\right)$$

Leveraging the form of the discounts and row/column sum preserving property of gKL, we then have the following lemma (the proof is in the supplementary material):

Lemma 4. *Let $P_{plre}(w_i|w_{i-1})$ indicate the PLRE smoothed conditional probability as computed by Eq. 6 and Algorithms 1 and 2. Then, the marginal constraint in Eq. 7 holds.*

4.3 More general algorithm

In general, the principles outlined in the previous sections hold for higher order n-grams. Assume that the discounts are computed according to Algorithm 1 with parameter d_* and $\boldsymbol{Z}_{\boldsymbol{D}_j}^{(\rho_j,\kappa_j)}$ is computed according to Algorithm 2. Note that, as shown in Algorithm 2, for higher order n-grams, the $\boldsymbol{Z}_{\boldsymbol{D}_j}^{(\rho_j,\kappa_j)}$ are created by taking low rank approximations of slices of the (powered) count tensors (see Lemma 2 for intuition). Eq. 3 can now be embellished:

$$\begin{aligned} P_{\text{plre}}(w_i|w_{i-n+1}^{i-1}) &= P_{\boldsymbol{D}_0}^{\text{alt}}(w_i|w_{i-n+1}^{i-1}) \\ &+ \gamma_0(w_{i-n+1}^{i-1})\left(\boldsymbol{Z}_{\boldsymbol{D}_1}^{(\rho_1,\kappa_1)}(w_i|w_{i-n+1}^{i-1}) + ...\right. \\ &+ \gamma_{\eta-1}(w_{i-n+1}^{i-1})\left(\boldsymbol{Z}_{\boldsymbol{D}_\eta}^{(\rho_\eta,\kappa_\eta)}(w_i|w_{i-n+1}^{i-1})\right. \\ &\left.\left. + \gamma_\eta(w_{i-n+1}^{i-1})\left(P_{\text{plre}}(w_i|w_{i-n+2}^{i-1})\right)\right)...\right) \quad (12) \end{aligned}$$

Lemma 4 also applies in this case and is given in Theorem 1 in the supplementary material.

4.4 Links with KN Smoothing

In this section, we explicitly show the relationship between PLRE and KN smoothing. Rewriting Eq. 12 in the following form:

$$\begin{aligned} P_{\text{plre}}(w_i|w_{i-n+1}^{i-1}) &= P_{\text{plre}}^{\text{terms}}(w_i|w_{i-n+1}^{i-1}) \\ &+\gamma_{0:\eta}(w_{i-n+1}^{i-1})P_{\text{plre}}(w_i|w_{i-n+2}^{i-1}) \quad (13) \end{aligned}$$

where $P_{\text{plre}}^{\text{terms}}(w_i|w_{i-n+1}^{i-1})$ contains the terms in Eq. 12 except the last, and $\gamma_{0:\eta}(w_{i-n+1}^{i-1}) = \prod_{h=0}^{\eta}\gamma_h(w_{i-n+1}^{i-1})$, we can leverage the form of the discount, and using the fact that $\rho_{\eta+1} = 0$[2]:

$$\gamma_{0:\eta}(w_{i-n-1}^{i-1}) = \frac{{d_*}^{\eta+1}N_+(w_{i-n+1}^{i-1})}{c(w_{i-n+1}^{i-1})}$$

With this form of $\gamma(\cdot)$, Eq. 13 is remarkably similar to KN smoothing (Eq. 2) if KN's discount parameter D is chosen to equal $(d_*)^{\eta+1}$.

The difference is that $P^{\text{alt}}(\cdot)$ has been replaced with the alternate estimate $P_{\text{plre}}^{\text{terms}}(w_i|w_{i-n+1}^{i-1})$, which have been enriched via the low rank structure. Since these alternate estimates were constructed via our ensemble strategy they contain both very fine-grained dependencies (the original n-grams) as well as coarser dependencies (the lower rank n-grams) and is thus fundamentally different than simply taking a single matrix/tensor decomposition of the trigram/bigram matrices.

Moreover, it provides a natural way of setting d_* based on the Good-Turing (GT) estimates employed by KN smoothing. In particular, we can set d_* to be the $(\eta+1)^{\text{th}}$ root of the KN discount D that can be estimated via the GT estimates.

4.5 Computational Considerations

PLRE scales well even as the order n increases. To compute a low rank bigram, one low rank approximation of a $V \times V$ matrix is required. For the low rank trigram, we need to compute a low rank approximation of each slice $\boldsymbol{C}_{\boldsymbol{D}}^{n,(\cdot p)}(:, \tilde{w}_{i-1}, :)\ \forall \tilde{w}_{i-1}$. While this may seem daunting at first, in practice the *size* of each slice (number of non-zero rows/columns) is usually much, much smaller than V, keeping the computation tractable.

Similarly, PLRE also evaluates conditional probabilities at evaluation time efficiently. As shown in Algorithm 2, the normalizer can be precomputed on the sparse powered matrix/tensor. As a result our test complexity is $\mathcal{O}(\sum_{i=1}^{\eta_{\text{total}}}\kappa_i)$ where η_{total} is the total number of matrices/tensors in the ensemble. While this is larger than Kneser Ney's practically constant complexity of $\mathcal{O}(n)$, it is much faster than other recent methods for language modeling such as neural networks and conditional exponential family models where exact computation of the normalizing constant costs $O(V)$.

5 Experiments

To evaluate PLRE, we compared its performance on English and Russian corpora with several vari-

[2] for derivation see proof of Lemma 4 in the supplementary material

ants of KN smoothing, class-based models, and the log-bilinear neural language model (Mnih and Hinton, 2007). We evaluated with perplexity in most of our experiments, but also provide results evaluated with BLEU (Papineni et al., 2002) on a downstream machine translation (MT) task. We have made the code for our approach publicly available [3].

To build the hard class-based LMs, we utilized `mkcls`[4], a tool to train word classes that uses the maximum likelihood criterion (Och, 1995) for classing. We subsequently trained trigram class language models on these classes (corresponding to 2nd-order HMMs) using SRILM (Stolcke, 2002), with KN-smoothing for the class transition probabilities. SRILM was also used for the baseline KN-smoothed models.

For our MT evaluation, we built a hierarchical phrase translation (Chiang, 2007) system using `cdec` (Dyer et al., 2010). The KN-smoothed models in the MT experiments were compiled using KenLM (Heafield, 2011).

5.1 Datasets

For the perplexity experiments, we evaluated our proposed approach on 4 datasets, 2 in English and 2 in Russian. In all cases, the singletons were replaced with "<unk>" tokens in the training corpus, and any word not in the vocabulary was replaced with this token during evaluation. There is a general dearth of evaluation on large-scale corpora in morphologically rich languages such as Russian, and thus we have made the processed Large-Russian corpus available for comparison [3].

- **Small-English**: APNews corpus (Bengio et al., 2003): Train - 14 million words, Dev - 963,000, Test - 963,000. Vocabulary- 18,000 types.
- **Small-Russian**: Subset of Russian news commentary data from 2013 WMT translation task[5]: Train- 3.5 million words, Dev - 400,000 Test - 400,000. Vocabulary - 77,000 types.
- **Large-English**: English Gigaword, Training - 837 million words, Dev - 8.7 million, Test - 8.7 million. Vocabulary- 836,980 types.
- **Large-Russian**: Monolingual data from WMT 2013 task. Training - 521 million words, Validation - 50,000, Test - 50,000. Vocabulary- 1.3 million types.

[3] http://www.cs.cmu.edu/∼apparikh/plre.html

[4] http://code.google.com/p/giza-pp/

[5] http://www.statmt.org/wmt13/training-monolingual-nc-v8.tgz

For the MT evaluation, we used the parallel data from the WMT 2013 shared task, excluding the Common Crawl corpus data. The newstest2012 and newstest2013 evaluation sets were used as the development and test sets respectively.

5.2 Small Corpora

For the class-based baseline LMs, the number of classes was selected from $\{32, 64, 128, 256, 512, 1024\}$ (Small-English) and $\{512, 1024\}$ (Small-Russian). We could not go higher due to the computationally laborious process of hard clustering. For Kneser-Ney, we explore four different variants: back-off (BO-KN) interpolated (int-KN), modified back-off (BO-MKN), and modified interpolated (int-MKN). Good-Turing estimates were used for discounts. All models trained on the small corpora are of order 3 (trigrams).

For PLRE, we used one low rank bigram and one low rank trigram in addition to the MLE n-gram estimates. The powers of the intermediate matrices/tensors were fixed to be 0.5 and the discounts were set to be square roots of the Good Turing estimates (as explained in § 4.4). The ranks were tuned on the development set. For Small-English, the ranges were $\{1e-3, 5e-3\}$ (as a fraction of the vocabulary size) for both the low rank bigram and low rank trigram models. For Small-Russian the ranges were $\{5e-4, 1e-3\}$ for both the low rank bigram and the low rank trigram models.

The results are shown in Table 1. The best class-based LM is reported, but is not competitive with the KN baselines. PLRE outperforms all of the baselines comfortably. Moreover, PLRE's performance over the baselines is highlighted in Russian. With larger vocabulary sizes, the low rank approach is more effective as it can capture linguistic similarities between rare and common words.

Next we discuss how the maximum n-gram order affects performance. Figure 1 shows the relative percentage improvement of our approach over int-MKN as the order is increased from 2 to 4 for both methods. The Small-English dataset has a rather small vocabulary compared to the number of tokens, leading to lower data sparsity in the bigram. Thus the PLRE improvement is small for order $= 2$, but more substantial for order $= 3$. On the other hand, for the Small-Russian dataset, the vocabulary size is much larger and consequently the bigram counts are sparser. This leads to sim-

Dataset	class-1024(3)	BO-KN(3)	int-KN(3)	BO-MKN(3)	int-MKN(3)	PLRE(3)

Table 1: Perplexity results on small corpora for all methods.

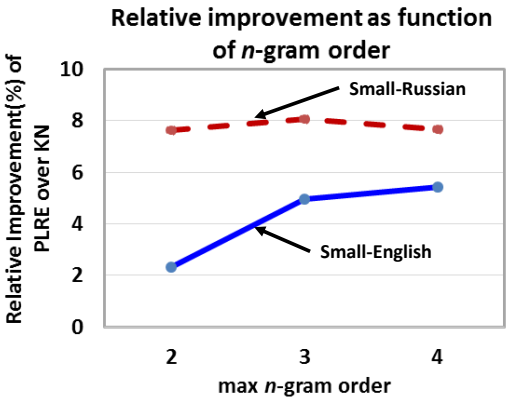

Figure 1: Relative percentage improvement of PLRE over int-MKN as the maximum n-gram order for both methods is increased.

ilar improvements for all orders (which are larger than that for Small-English).

On both these datasets, we also experimented with tuning the discounts for int-MKN to see if the baseline could be improved with more careful choices of discounts. However, this achieved only marginal gains (reducing the perplexity to 98.94 on the Small-English test set and 259.0 on the Small-Russian test set).

Comparison to LBL (Mnih and Hinton, 2007): Mnih and Hinton (2007) evaluate on the Small-English dataset (but remove end markers and concatenate the sentences). They obtain perplexities 117.0 and 107.8 using contexts of size 5 and 10 respectively. With this preprocessing, a 4-gram (context 3) PLRE achieves 108.4 perplexity.

5.3 Large Corpora

Results on the larger corpora for the top 2 performing methods "PLRE" and "int-MKN" are presented in Table 2. Due to the larger training size, we use 4-gram models in these experiments. However, including the low rank 4-gram tensor provided little gain and therefore, the 4-gram PLRE only has additional low rank bigram and low rank trigram matrices/tensors. As above, ranks were tuned on the development set. For Large-English, the ranges were $\{1e-4, 5e-4, 1e-3\}$ (as a fraction of the vocabulary size) for both the low rank bigram and low rank trigram models. For Small-Russian the ranges were $\{1e-5, 5e-5, 1e-4\}$ for both the low rank bigram and the low rank trigram models. For statistical validity, 10 test sets of size equal to the original test set were generated by randomly sampling sentences with replacement from the original test set. Our method outperforms "int-MKN" with gains similar to that on the smaller datasets. As shown in Table 3, our method obtains fast training times even for large datasets.

Dataset	int-MKN(4)	PLRE(4)
Large-English Dev	73.21	**71.21**
Large-English Test	77.90 $\pm$ 0.203	**75.66** $\pm$ 0.189
Large-Russian Dev	326.9	**297.11**
Large-Russian Test	289.63 $\pm$ 6.82	**264.59** $\pm$ 5.839

Table 2: Mean perplexity results on large corpora, with standard deviation.

Dataset	PLRE Training Time
Small-English	3.96 min (order 3) / 8.3 min (order 4)
Small-Russian	4.0 min (order 3) / 4.75 min (order 4)
Large-English	3.2 hrs (order 4)
Large-Russian	8.3 hrs (order 4)

Table 3: PLRE training times for a fixed parameter setting[6]. 8 Intel Xeon CPUs were used.

Method	BLEU
int-MKN(4)	17.63 $\pm$ 0.11
PLRE(4)	17.79 $\pm$ 0.07
Smallest Diff	PLRE+0.05
Largest Diff	PLRE+0.29

Table 4: Results on English-Russian translation task (mean $\pm$ stdev). See text for details.

6 Machine Translation Task

Table 4 presents results for the MT task, translating from English to Russian[7]. We used MIRA (Chiang et al., 2008) to learn the feature weights. To control for the randomness in MIRA, we avoid retuning when switching LMs - the set of feature weights obtained using int-MKN is the same, only the language model changes. The

[6]As described earlier, only the ranks need to be tuned, so only 2-3 low rank bigrams and 2-3 low rank trigrams need to be computed (and combined depending on the setting).

[7]the best score at WMT 2013 was 19.9 (Bojar et al., 2013)

procedure is repeated 10 times to control for optimizer instability (Clark et al., 2011). Unlike other recent approaches where an additional feature weight is tuned for the proposed model and used in conjunction with KN smoothing (Vaswani et al., 2013), our aim is to show the improvements that PLRE provides as a substitute for KN. On average, PLRE outperforms the KN baseline by 0.16 BLEU, and this improvement is consistent in that PLRE never gets a worse BLEU score.

7 Related Work

Recent attempts to revisit the language modeling problem have largely come from two directions: Bayesian nonparametrics and neural networks. Teh (2006) and Goldwater et al. (2006) discovered the connection between interpolated Kneser Ney and the hierarchical Pitman-Yor process. These have led to generalizations that account for domain effects (Wood and Teh, 2009) and unbounded contexts (Wood et al., 2009).

The idea of using neural networks for language modeling is not new (Miikkulainen and Dyer, 1991), but recent efforts (Mnih and Hinton, 2007; Mikolov et al., 2010) have achieved impressive performance. These methods can be quite expensive to train and query (especially as the vocabulary size increases). Techniques such as noise contrastive estimation (Gutmann and Hyvärinen, 2012; Mnih and Teh, 2012; Vaswani et al., 2013), subsampling (Xu et al., 2011), or careful engineering approaches for maximum entropy LMs (which can also be applied to neural networks) (Wu and Khudanpur, 2000) have improved training of these models, but querying the probability of the next word given still requires explicitly normalizing over the vocabulary, which is expensive for big corpora or in languages with a large number of word types. Mnih and Teh (2012) and Vaswani et al. (2013) propose setting the normalization constant to 1, but this is approximate and thus can only be used for downstream evaluation, not for perplexity computation. An alternate technique is to use word-classing (Goodman, 2001; Mikolov et al., 2011), which can reduce the cost of exact normalization to $O(\sqrt{V})$. In contrast, our approach is much more scalable, since it is trivially parallelized in training and does not require explicit normalization during evaluation.

There are a few low rank approaches (Saul and Pereira, 1997; Bellegarda, 2000; Hutchinson et al., 2011), but they are only effective in restricted settings (e.g. small training sets, or corpora divided into documents) and do not generally perform comparably to state-of-the-art models. Roark et al. (2013) also use the idea of marginal constraints for re-estimating back-off parameters for heavily-pruned language models, whereas we use this concept to estimate n-gram specific discounts.

8 Conclusion

We presented power low rank ensembles, a technique that generalizes existing n-gram smoothing techniques to non-integer n. By using ensembles of sparse as well as low rank matrices and tensors, our method captures both the fine-grained and coarse structures in word sequences. Our discounting strategy preserves the marginal constraint and thus generalizes Kneser Ney, and under slight changes can also extend other smoothing methods such as deleted-interpolation/Jelinek-Mercer smoothing. Experimentally, PLRE convincingly outperforms Kneser-Ney smoothing as well as class-based baselines.

Modeling Biological Processes for Reading Comprehension

Jonathan Berant[*], **Vivek Srikumar**[*], **Pei-Chun Chen, Brad Huang and Christopher D. Manning**

Abby Vander Linden and Brittany Harding
University of Washington, Seattle

Abstract

Machine reading calls for programs that read and understand text, but most current work only attempts to extract facts from redundant web-scale corpora. In this paper, we focus on a new reading comprehension task that requires complex reasoning over a single document. The input is a paragraph describing a biological process, and the goal is to answer questions that require an understanding of the relations between entities and events in the process. To answer the questions, we first predict a rich structure representing the process in the paragraph. Then, we map the question to a formal query, which is executed against the predicted structure. We demonstrate that answering questions via predicted structures substantially improves accuracy over baselines that use shallower representations.

1 Introduction

The goal of machine reading is to develop programs that read text to learn about the world and make decisions based on accumulated knowledge. Work in this field has focused mostly on macro-reading, i.e., processing large text collections and extracting knowledge bases of facts (Etzioni et al., 2006; Carlson et al., 2010; Fader et al., 2011). Such methods rely on redundancy, and are thus suitable for answering common factoid questions which have ample evidence in text (Fader et al., 2013). However, reading a single document (micro-reading) to answer comprehension questions that require deep reasoning is currently beyond the scope of state-of-the-art systems.

In this paper, we introduce a task where given a paragraph describing a process, the goal is to answer reading comprehension questions that test understanding of the underlying structure. In particular, we consider processes in biology textbooks such as this excerpt and the question that follows:

> "... **Water is split**, providing a source of electrons and protons (hydrogen ions, H^+) and giving off O_2 as a by-product. **Light absorbed** by chlorophyll drives a **transfer of the electrons and hydrogen ions** from water to an acceptor called $NADP^+$ ..."

Q What can the splitting of water lead to?

a Light absorption

b Transfer of ions

This excerpt describes a process in which a complex set of events and entities are related to one another. A system trying to answer this question must extract a rich structure spanning multiple sentences and reason that *water splitting* combined with *light absorption* leads to *transfer of ions*. Note that shallow methods, which rely on lexical overlap or text proximity, will fail. Indeed, both answers are covered by the paragraph and the wrong answer is closer in the text to the question.

We propose a novel method that tackles this challenging problem (see Figure 1). First, we train a supervised structure predictor that learns to extract entities, events and their relations describing the biological process. This is a difficult problem because events have complex interactions that span multiple sentences. Then, treating this structure as a small knowledge-base, we map questions to formal queries that are executed against the structure to provide the answer.

Micro-reading is an important aspect of natural language understanding (Richardson et al., 2013; Kushman et al., 2014). In this work, we focus specifically on modeling processes, where events and entities relate to one another through complex interactions. While we work in the biology

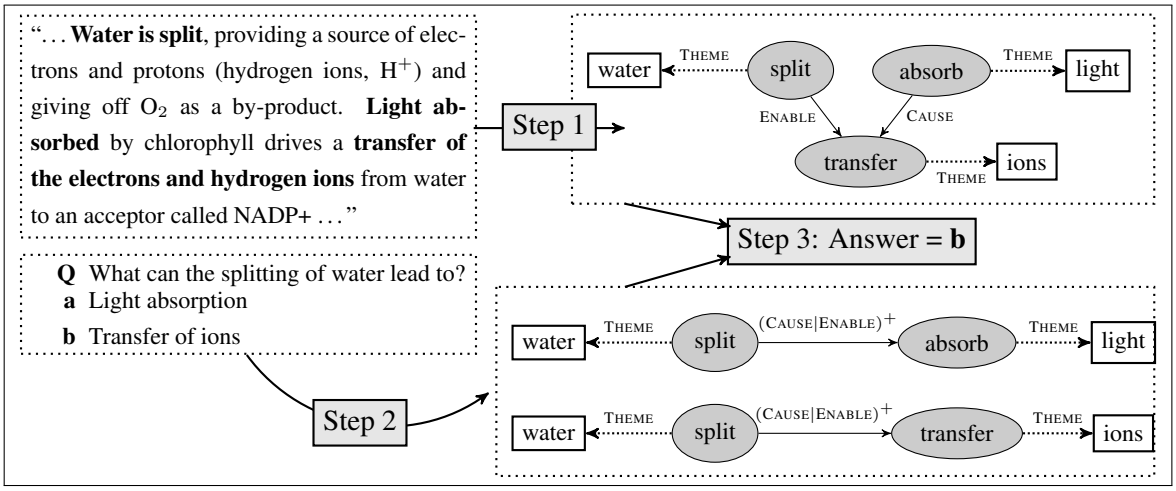

Figure 1: An overview of our reading comprehension system. First, we predict a structure from the input paragraph (the top right portion shows a partial structure skipping some arguments for brevity). Circles denote events, squares denote arguments, solid arrows represent event-event relations, and dashed arrows represent event-argument relations. Second, we map the question paired with each answer into a query that will be answered using the structure. The bottom right shows the query representation. Last, the two queries are executed against the structure, and a final answer is returned.

domain, processes are abundant in domains such as chemistry, economics, manufacturing, and even everyday events like shopping or cooking, and our model can be applied to these domains as well.

The contributions of this paper are:

1. We propose a reading comprehension task which requires deep reasoning over structures that represent complex relations between multiple events and entities.
2. We present PROCESSBANK, a new dataset consisting of descriptions of biological processes, fully-annotated with rich process structures, and accompanied by multiple-choice questions.
3. We present a novel method for answering questions, by predicting process structures and mapping questions to queries. We demonstrate that by predicting structures we can improve reading comprehension accuracy over baselines that do not exploit the underlying structure.

The data and code for this paper are available at `http://www-nlp.stanford.edu/software/bioprocess`.

2 Task Definition and Setup

This section describes the reading comprehension task we address and the accompanying dataset. We will use the example in Figure 1 as our running example throughout the paper.

Our goal is to tackle a complex reading comprehension setting that centers on understanding the underlying meaning of a process description. We target a multiple-choice setting in which each input consists of a paragraph of text describing a biological process, a question, and two possible answers. The goal is to identify the correct answer using the text (Figure 1, left). We used the 148 paragraphs from the textbook *Biology* (Campbell and Reece, 2005) that were manually identified by Scaria et al. (2013). We extended this set to 200 paragraphs by including additional paragraphs that describe biological processes. Each paragraph in the collection represents a single biological process and describes a set of events, their participants and their interactions.

Because we target understanding of paragraph meaning, we use the following desiderata for building the corpus of questions and answers:

1. The questions should focus on the events and entities participating in the process described in the paragraph, and answering the questions should require reasoning about the relations between those events and entities.
2. Both answers should have similar lexical overlap with the paragraph. Moreover, names of entities and events in the question and answers should appear as in the paragraph and not using synonyms. This is to ensure that the task revolves around reading comprehension rather than lexical variability.[1]

A biologist created the question-answer part of

[1]Lexical variability is an important problem in NLP, but is not the focus of this task.

the corpus comprising of 585 questions spread over the 200 paragraphs. A second annotator validated 326 randomly chosen questions and agreed on the correct answer with the first annotator in 98.1% of cases. We provide the annotation guidelines in the supplementary material.

Figure 1 (left) shows an excerpt of a paragraph describing a process and an example of a question based on it. In general, questions test an understanding of the interactions between multiple events (such as causality, inhibition, temporal ordering), or between events and entities (i.e., roles of entities in events), and require complex reasoning about chains of event-event and event-entity relations.

3 The Structure of Processes

A natural first step for answering reading comprehension questions is to identify a structured representation of the text. In this section, we define this structure. We broadly follow the definition of Scaria et al. (2013), but modify important aspects, highlighted at the end of this section.

A paragraph describing a process is a sequence of tokens that describes events, entities and their relations (see Figure 1, top right). A *process* is a directed graph $(\mathcal{T}, \mathcal{A}, \mathcal{E}_{tt}, \mathcal{E}_{ta})$, where the nodes $\mathcal{T}$ are labeled event triggers, the nodes $\mathcal{A}$ are arguments, $\mathcal{E}_{tt}$ are labeled edges describing event-event relations, and $\mathcal{E}_{ta}$ are labeled edges from triggers to arguments denoting semantic roles (see Figure 1 top right for a partial structure of the running example). The goal of process extraction is to generate the process graph given the input paragraph.

Triggers and arguments A trigger is a token span denoting the occurrence of an event. In Figure 1, *split*, *absorbed* and *transfer* are event triggers. In rare cases, a trigger denotes the *non-occurrence* of an event. For example, in *"sympatric speciation can occur when gene flow is blocked"*, *sympatric speciation* occurs if *gene flow* does *not* happen. Thus, nodes in $\mathcal{T}$ are labeled as either a T-YES or T-NO to distinguish triggers of events that occur from triggers of events that do not occur. Arguments are token spans denoting entities that participate in the process (such as *water*, *light* and *ions* in Figure 1).

Semantic roles The edges $\mathcal{E}_{ta}$ from triggers to arguments are labeled by the semantic roles AGENT, THEME, SOURCE, DESTINATION, LOCATION, RESULT, and OTHER for all other roles. Our running example shows three THEME semantic roles for the three triggers. For brevity, the figure does not show the RESULT of the event *split*, namely, both *source of electrons and protons (hydrogen ions, H^+)* and O_2.

Event-event relations The directed edges $\mathcal{E}_{tt}$ between triggers are labeled by one of eight possible event-event relations. These relations are central to answering reading comprehension questions, which test understanding of the dependencies and causal relations between the process events. We first define three relations that express a dependency between two event triggers u and v.

1. CAUSE denotes that u starts before v, and if u happens then v happens (Figure 1).
2. ENABLE denotes that u creates conditions necessary for the occurrence of v. This means that u starts before v and v can only happen if u happens (Figure 1).[2]
3. PREVENT denotes that u starts before v and if u happens, then v does not happen.

In processes, events sometimes depend on more than one other event. For example, in Figure 1 (right top) *transfer of ions* depends on both *water splitting* as well as *light absorption*. Conversely, in Figure 2, the *shifting* event results in either one of two events but not both. To express both conjunctions and disjunctions of related events we add the relations CAUSE-OR, ENABLE-OR and PREVENT-OR, which express disjunctions, while the default CAUSE, ENABLE, and PREVENT express conjunction (Compare the CAUSE-OR relations in Figure 2 with the relations in Figure 1).

We define the SUPER relation to denote that event u is part of event v. (In Figure 2, *slippage* is a sub-event of *replication*.) Last, we use the event coreference relation SAME to denote two event mentions referring to the same event.

Notice that the assignments of relation labels interact across different pairs of events. As an example, if event u causes event v, then v can not cause u. Our inference algorithm uses such structural constraints when predicting process structure (Section 4).

[2] In this work, we do not distinguish causation from facilitation, where u can help v but is not absolutely required. We instructed the annotators to ignore the inherent uncertainty in these cases and use CAUSE.

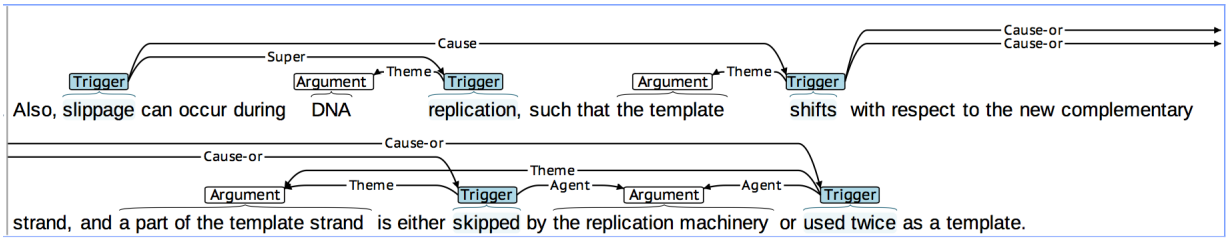

Figure 2: Partial example of a process, as annotated in our dataset.

	Avg	Min	Max
# of triggers	7.0	2	18
# of arguments	11.3	1	36
# of relation	7.9	1	37

Table 1: Statistics of triggers, arguments and relations over the 200 annotated paragraphs.

Three biologists annotated the same 200 paragraphs described in Section 2 using the brat annotation tool (Stenetorp et al., 2012). For each paragraph, one annotator annotated the process, and a second validated its correctness. Importantly, the questions and answers were authored separately by a different annotator, thus ensuring that the questions and answers are independent from the annotated structures. Table 1 gives statistics over the dataset. The annotation guidelines are included in the supplementary material.

Relation to Scaria et al. (2013) Scaria et al. (2013) also defined processes as graphs where nodes are events and edges describe event-event relations. Our definition differs in a few important aspects.

First, the set of event-event relations in that work included temporal relations in addition to causal ones. In this work, we posit that because events in a process are inter-related, causal dependencies are sufficient to capture the relevant temporal ordering between them. Figure 1 illustrates this phenomenon, where the temporal ordering between the events of *water splitting* and *light absorption* is unspecified. It does not matter whether one happens before, during, or after the other. Furthermore, the incoming causal links to *transfer* imply that the event should happen after *splitting* and *absorption*.

A second difference is that Scaria et al. (2013) do not include disjunctions and conjunctions of events in their formulation. Last, Scaria et al. (2013) predict only relations given input triggers, while we predict a full process structure.

4 Predicting Process Structures

We now describe the first step of our algorithm. Given an input paragraph we predict events, their arguments and event-event relations (Figure 1, top). We decompose this into three sub-problems:

1. Labeling trigger candidates using a multi-class classifier (Section 4.1).
2. For each trigger, identifying an over-complete set of possible arguments, using a classifier tuned for high recall (Section 4.2).
3. Jointly assigning argument labels and relation labels for all trigger pairs (Section 4.3).

The event-event relations CAUSE, ENABLE, CAUSE-OR and ENABLE-OR, form a semantic cluster: If (u, v) is labeled by one of these, then the occurrence of v depends on the occurrence of u. Since our dataset is small, we share statistics by collapsing all four labels to a single ENABLE label. Similarly, we collapse the PREVENT and PREVENT-OR labels, overall reducing the number of relations to four.

For brevity, in what follows we only provide a flavor of the features we extract, and refer the reader to the supplementary material for details.

4.1 Predicting Event Triggers

The first step is to identify the events in the process. We model the trigger detector as a multi-class classifier that labels all content words in the paragraph as one of T-YES, T-NO or NOT-TRIGGER (Recall that a word can trigger an event that occurred, an event that did not occur, or not be a trigger at all). For simplicity, we model triggers as single words, but in the gold annotation about 14% are phrases (such as *gene flow*). Thus, we evaluate trigger prediction by taking heads of gold phrases. To train the classifier, we extract

the lemma and POS tag of the word and adjacent words, dependency path to the root, POS tag of children and parent in the dependency tree, and clustering features from WordNet (Fellbaum, 1998), Nomlex (Macleod et al., 1998), Levin verb classes (Levin, 1993), and a list of biological processes compiled from Wikipedia.

4.2 Filtering Argument Candidates

Labeling trigger-argument edges is similar to semantic role labeling. Following the standard approach (Punyakanok et al., 2008), for each trigger we collect all constituents in the same sentence to build an over-complete set of plausible candidate arguments. This set is pruned with a binary classifier that is tuned for high recall (akin to the argument identifier in SRL systems). On the development set we filter more than half of the argument candidates, while achieving more than 99% recall. This classifier is trained using argument identification features from Punyakanok et al. (2008).

At the end of this step, each trigger has a set of candidate arguments which will be labeled during joint inference. In further discussion, the argument candidates for trigger t are denoted by $\mathcal{A}_t$.

4.3 Predicting Arguments and Relations

Given the output of the trigger classifier, our goal is to jointly predict event-argument and event-event relations. We model this as an integer linear program (ILP) instance described below. We first describe the inference setup assuming a model that scores inference decisions and defer description of learning to Section 4.4. The ILP has two types of decision variables: arguments and relations.

Argument variables These variables capture the decision that a candidate argument a, belonging to the set $\mathcal{A}_t$ of argument candidates, takes a label A (from Section 3). We denote the Boolean variables by $y_{t,a,A}$, which are assigned a score $b_{t,a,A}$ by the model. We include an additional label NULL-ARG, indicating that the candidate is not an argument for the trigger.

Event-event relation variables These variables capture the decision that a pair of triggers t_1 and t_2 are connected by a directed edge (t_1, t_2) labeled by the relation R. We denote these variables by $z_{t_1,t_2,R}$, which are associated with a score $c_{t_1,t_2,R}$. Again, we introduce a label NULL-REL to indicate triggers that are not connected by an edge.

Name	Description
Unique labels	Every argument candidate and trigger pair has exactly one label.
Argument overlap	Two arguments of the same trigger cannot overlap.
Relation symmetry	The SAME relation is symmetric. All other relations are anti-symmetric, i.e., for any relation label other than SAME, at most one of (t_i, t_j) or (t_j, t_i) can take that label and the other is assigned the label NULL-REL.
Max arguments per trigger	Every trigger can have no more than two arguments with the same label.
Max triggers per argument	The same span of text can not be an argument for more than two triggers.
Connectivity	The triggers must form a connected graph, framed as flow constraints as in Magnanti and Wolsey (1995) and Martins et al. (2009).
Shared arguments	If the same span of text is an argument of two triggers, then the triggers must be connected by a relation that is not NULL-REL. This ensures that triggers that share arguments are related.
Unique parent	For any trigger, at most one outgoing edge can be labeled SUPER.

Table 2: Constraints for joint inference.

Formulation Given the two sets of variables, the objective of inference is to find a global assignment that maximizes the score. That is, the objective can be stated as follows:

$$\max_{\mathbf{y},\mathbf{z}} \sum_{t,a\in\mathcal{A}_t,A} b_{t,a,A} \cdot y_{t,a,A} + \sum_{t_1,t_2,R} c_{t_1,t_2,R} \cdot z_{t_1,t_2,R}$$

Here, $\mathbf{y}$ and $\mathbf{z}$ refer to all the argument and relation variables respectively.

Clearly, all possible assignments to the inference variables are not feasible and there are both structural as well as prior knowledge constraints over the output space. Table 2 states the constraints we include, which are expressed as linear inequalities over output variables using standard techniques (e.g., (Roth and Yih, 2004)).

4.4 Learning in the Joint Model

We train both the trigger classifier and the argument identifier using L_2-regularized logistic regression. For the joint model, we use a linear model for the scoring functions, and train jointly using the structured averaged perceptron algorithm (Collins, 2002).

Since argument labeling is similar to semantic role labeling (SRL), we extract standard SRL features given the trigger and argument from the syntactic tree for the corresponding sentence. In addition, we add features extracted from an off-the-shelf SRL system. We also include all feature conjunctions. For event relations, we include the features described in Scaria et al. (2013), as well as context features for both triggers, and the dependency path between them, if one exists.

5 Question Answering via Structures

This section describes our question answering system that, given a process structure, a question and two answers, chooses the correct answer (steps 2 and 3 in Figure 1).

Our strategy is to treat the process structure as a small knowledge-base. We map each answer along with the question into a *structured query* that we compare against the structure. The query can prove either the correctness or incorrectness of the answer being considered. That is, either we get a valid match for an answer (proving that the corresponding answer is correct), or we get a refutation in the form of a contradicted causal chain (thus proving that the *other answer* is correct). This is similar to theorem proving approaches suggested in the past for factoid question answering (Moldovan et al., 2003).

The rest of this section is divided into three parts: Section 5.1 defines the queries we use, Section 5.2 describes a rule-based algorithm for converting a question and an answer into a query and finally, 5.3 describes the overall algorithm.

5.1 Queries over Processes

We model a query as a directed graph path with regular expressions over edge labels. The bottom right portion of Figure 1 shows examples of queries for our running example. In general, given a question and one of the answer candidates, one end of the path is populated by a trigger/argument found in the question and the other is populated with a trigger/ argument from the answer.

We define a query to consist of three parts:

1. A regular expression over relation labels, describing permissible paths,
2. A source trigger/argument node, and
3. A target trigger/argument node.

For example, the bottom query in Figure 1 looks for paths labeled with CAUSE or ENABLE edges from the event *split* to the event *transfer*.

Note that the representation of questions as directed paths is a modeling choice and did not influence the authoring of the questions. Indeed, while most questions do fit this model, there are rare cases that require a more complex query structure.

5.2 Query Generation

Mapping a question and an answer into a query involves identifying the components of the query listed above. We do this in two phases: (1) In the *alignment phase*, we align triggers and arguments in the question and answer to the process structure to give us candidate source and target nodes. (2) In the *query construction phase*, we identify the regular expression and the direction of the query using the question, the answer and the alignment.

We identify three broad categories of QA pairs (see Table 3) that can be identified using simple lexical rules: (a) *Dependency questions* ask which event or argument depends on another event or argument, (b) *Temporal questions* ask about temporal ordering of events, and (c) *True-false questions* ask whether some fact is true. Below, we describe the two phases of query generation primarily in the context of dependency questions with a brief discussion about temporal and true-false questions at the end of the section.

Alignment Phase We align triggers in the structure to the question and the answer by matching lemmas or nominalizations. In case of multiple matches, we use the context to disambiguate and resolve ties using the highest matching candidate in the syntactic dependency tree.

We align arguments in the question and the answer in a similar manner. Since arguments are typically several words long, we prefer maximal spans. Additionally, if a question (or an answer) contains an aligned trigger, we prefer to align words to its arguments.

Query Construction Phase We construct a query using the aligned question and answer triggers/arguments. We will explain query construction using our running example (reproduced as the dependency question in Table 3).

First, we identify the source and the target of the query. We select either the source or the target to be a question node and populate the other end of the query path with an answer node. To make the choice between source or target for the question node, we use the main verb in the question, its voice and relative position of the question word with respect to the main verb. In our example, the main verb *lead to* is in active voice and the question word *what* is not in subject position. This places the trigger from the question as the source of the query path (see both queries in the bottom right portion of the running example). In contrast, had the verb been *require*, the trigger would be the target of the query. We construct two verb clusters that indicate query direction using a small seed set

Type	Example	# (%)
Dependency	**Q**: What can the splitting of water lead to? **a**: Light absorption **b**: Transfer of ions	407 (69.57%)
Temporal	**Q**: What is the correct order of events? **a**: PDGF binds to tyrosine kinases, then cells divide, then wound healing **b**: Cells divide, then PDGF binds to tyrosine kinases, then wound healing	57 (9.74%)
True-False	**Q**: Cdk associates with MPF to become cyclin **a**: True **b**: False	121 (20.68%)

Table 3: Examples and statistics for each of the three coarse types of questions.

Is main verb trigger?

Yes

Condition	Regular Exp.
Wh- word subjective?	AGENT
Wh- word object?	THEME

No

Condition	Regular Exp.
default	(ENABLE|SUPER)$^+$
DIRECT	(ENABLE|SUPER)
PREVENT	(ENABLE|SUPER)* PREVENT(ENABLE|SUPER)*

Figure 3: Rules for determining the regular expressions for queries concerning two triggers. In each table, the **condition** column decides the regular expression to be chosen. In the left table, we make the choice based on the path from the root to the *Wh-* word in the question. In the right table, if the word *directly* modifies the main trigger, the DIRECT regular expression is chosen. If the main verb in the question is in the synset of *prevent*, *inhibit*, *stop* or *prohibit*, we select the PREVENT regular expression. Otherwise, the default one is chosen. We omit the relation label SAME from the expressions, but allow going through any number of edges labeled by SAME when matching expressions to the structure.

that we expand using WordNet.

The final step in constructing the query is to identify the regular expression for the path connecting the source and the target. Due to paucity of data, we do not map a question and an answer to arbitrary regular expressions. Instead, we construct a small set of regular expressions, and build a rule-based system that selects one. We used the training set to construct the regular expressions and we found that they answer most questions (see Section 6.4). We determine the regular expression based on whether the main verb in the sentence is a trigger and whether the source and target of the path are triggers or arguments. Figure 3 shows the possible regular expressions and the procedure for choosing one when both the source and target are triggers. If either of them are argument nodes, we append the appropriate semantic role to the regular expression, based on whether the argument is the source or the target of the path (or both).

True-false questions are treated similarly, except that both source and target are chosen from the question. For temporal questions, we seek to identify the ordering of events in the answers. We use the keywords *first*, *then*, or *simultaneously* to identify the implied order in the answer. We use the regular expression SUPER$^+$ for questions asking about simultaneous events and ENABLE$^+$ for those asking about sequential events.

5.3 Answering Questions

We match the query of an answer to the process structure to identify the answer. In case of a match, the corresponding answer is chosen. The matching path can be thought of as a *proof* for the answer.

If neither query matches the graph (or both do), we check if either answer contradicts the structure. To do so, we find an undirected path from the source to the target. In the event of a match, if the matching path traverses any ENABLE edge in the incorrect direction, we treat this as a *refutation* for the corresponding answer and select the other one. In our running example, in addition to the valid path for the second query, for the first query we see that there is an undirected path from *split* to *absorb* through *transfer* that matches the first query. This tells us that *light absorption* cannot be the answer because it is not along a causal path from *split*.

Finally, if none of the queries results in a match, we look for any unlabeled path between the source and the target, before backing off to a dependency-based proximity baseline described in Section 6. When there are multiple aligning nodes in the question and answer, we look for any proof or refutation before backing off to the baselines.

6 Empirical Evaluation

In this section we aim to empirically evaluate whether we can improve reading comprehension accuracy by predicting process structures. We first provide details of the experimental setup.

6.1 Experimental setup

We used 150 processes (435 questions) for training and 50 processes (150 questions) as the test set. For development, we randomly split the training set 10 times (80%/20%), and tuned hyper-parameters by maximizing average accuracy on question answering. We preprocessed the paragraphs with the Stanford CoreNLP pipeline version 3.4 (Manning et al., 2014) and Illinois SRL (Punyakanok et al., 2008; Clarke et al., 2012). We used the Gurobi optimization package[3] for inference.

We compare our system PROREAD to baselines that do not have access to the process structure:

1. BOW: For each answer, we compute the proportion of content word lemmas covered by the paragraph and choose the one with higher coverage. For true-false questions, we compute the coverage of the question statement, and answer "True" if it is higher than a threshold tuned on the development set.
2. TEXTPROX: For dependency questions, we align content word lemmas in both the question and answer against the text and select the answer whose aligned tokens are closer to the aligned tokens of the question. For temporal questions, we return the answer for which the order of events is identical to their order in the paragraph. For true-false questions, we return "True" if the number of bigrams from the question covered in the text is higher than a threshold tuned on the development set.
3. SYNTPROX: For dependency questions, we use proximity as in TEXTPROX, except that distance is measured using dependency tree edges. To support multiple sentences we connect roots of adjacent sentences with bidirectional edges. For temporal questions this baseline is identical to TEXTPROX. For true-false questions, we compute the number of dependency tree edges in the question statement covered by edges in the paragraph (an edge has a source lemma, relation, and target lemma), and answer "True" if the coverage is higher than a threshold tuned on the training set.

To separate the contribution of process structures from the performance of our structure predictor, we also run our QA system given manually annotated gold standard structures (GOLD).[4]

Method	Depen.	Temp.	True-false	All
PROREAD	**68.1**	**80.0**	**55.6**	**66.7**
SYNTPROX	61.9	70.0	48.1	60.0
TEXTPROX	58.4	70.0	33.3	54.7
BOW	47.8	40.0	44.4	46.7
GOLD	77.9	80.0	70.4	76.7

Table 4: Reading comprehension test set accuracy. The **All** column shows overall accuracy across all questions. The first three columns show accuracy for each coarse type.

6.2 Reading Comprehension Task

We evaluate our system using accuracy, i.e., the proportion of questions answered correctly. Table 4 presents test set results, where we break down questions by their coarse-type.

PROREAD improves accuracy compared to the best baseline by 6.7 absolute points (last column). Most of the gain is due to improvement on dependency questions, which are the most common question type. The performance of BOW indicates that lexical coverage alone does not distinguish the correct answer from the wrong answer. In fact, guessing the answer with higher lexical overlap results in performance that is slightly lower than random. Text proximity and syntactic proximity provide a stronger cue, but exploiting predicted process structures substantially outperforms these baselines.

Examining results using gold information highlights the importance of process structures independently of the structure predictor. Results of GOLD demonstrate that given gold structures we can obtain a dramatic improvement of almost 17 points compared to the baselines, using our simple deterministic QA system.

Results on true-false questions are low for PROREAD and all the baselines. True-false questions are harder for two main reasons. First, in dependency and temporal questions, we create a query for both answers, and can find a proof or a refutation for either one of them. In true-false

[3] http://www.gurobi.com/

[4] We also ran an experiment where gold triggers are given and arguments and relations are predicted. We found that this results in slightly higher performance compared to PROREAD.

	Precision	Recall	F_1
Triggers	75.4	73.9	74.6
Arguments	43.4	34.4	38.3
Relations	27.0	22.5	24.6

Table 5: Structured prediction test set results.

questions we must determine given a single statement whether it holds. Second, an analysis of true-false questions reveals that they focus less on relations between events and entities in the process, and require modeling lexical variability.[5]

6.3 Structure Prediction Task

Our evaluation demonstrates that gold structures improve accuracy substantially more than predicted structures. To examine this, we now directly evaluate the structure predictor by comparing micro-average precision, recall and F_1 between predicted and gold structures (Table 5).

While performance for trigger identification is reasonable, performance on argument and relation prediction is low. This explains the higher performance obtained in reading comprehension given gold structures. Note that errors in trigger prediction propagate to argument and relation prediction – a relation cannot be predicted correctly if either one of the related triggers is not previously identified. One reason for low performance is the small size of the dataset. Thus, training process predictors with less supervision is an important direction for future work. Furthermore, the task of process prediction is inherently difficult, because often relations are expressed only indirectly in text. For example, in Figure 1 the relation between *water splitting* and *transfer of ions* is only recoverable by understanding that water provides the ions that need to be transferred.

Nevertheless, we find that questions can often be answered correctly even if the structure contains some errors. For example, the gold structure for the sentence *"Some ... radioisotopes have long half-lives, allowing ..."*, contains the trigger *long half-lives*, while we predict *have* as a trigger and *long half-lives* as an argument. This is good enough to answer questions related to this part of the structure correctly, and overall, to improve performance using predicted structures.

[5]The low performance of TEXTPROX and SYNTPROX on true-false questions can also be attributed to the fact that we tuned a threshold parameter on the training set, and this did not generalize well to the test set.

Reason	GOLD	PROREAD
Alignment	35%	15%
Missing from annotation	25%	10%
Entity coreference	20%	10%
Missing regular expression	10%	
Lexical variability	5%	10%
Error in predicted structure		55%
Other	5%	

Table 6: Error analysis results. An explanation of the various categories are in the body of the paper.

6.4 Error Analysis

This section presents the results of an analysis of 20 sampled errors of GOLD (gold structures), and 20 errors of PROREAD (predicted structures). We have categorized the primary reason for error in Table 6.

As expected, the main problem when using predicted structures, is structure errors which account for more than half of the errors.

Errors in GOLD are distributed across various categories, which we briefly describe. *Alignment* errors occur due to multiple words aligning to multiple triggers and arguments. For example, in the question *"What is the result of gases being produced in the lysosome?"*, the answer *"engulfed pathogens are poisoned"* is incorrectly aligned to the trigger *engulfed* rather than to *poisoned*.

Another reason for errors are cases where questions are asked about parts of the paragraph that are *missing from annotation*. This is possible since questions were authored independently of structure annotation. Two other causes for errors are *entity coreference* errors, where a referent for an entity is missing from the structure, and *lexical variability*, where the author of questions uses names for triggers or arguments that are missing from the paragraph, and so alignment fails.

Last, in 10% of the cases in GOLD we found that the answer could not be retrieved using the set of regular expressions that are currently used by our QA system.

7 Discussion

This work touches on several strands of work in NLP including information extraction, semantic role labeling, semantic parsing and reading comprehension.

Event and relation extraction have been studied via the ACE data (Doddington et al., 2004) and related work. The BioNLP shared tasks (Kim et al., 2009; Kim et al., 2011; Riedel and McCal-

lum, 2011) focused on biomedical data to extract events and their arguments. Event-event relations have been mostly studied from the perspective of temporal ordering; e.g., (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; Do et al., 2012; McClosky and Manning, 2012). The process structure predicted in this work differs from these lines of work in two important ways: First, we predict events, arguments *and* their interactions from multiple sentences, while most earlier work focused on one or two of these components. Second, we model processes, and thus target causal relations between events, rather than temporal order only.

Our semantic role annotation is similar to existing SRL schemes such as PropBank (Palmer et al., 2005), FrameNet (Ruppenhofer et al., 2006) and BioProp (Chou et al., 2006). However, in contrast to PropBank and FrameNet, we do not allow all verbs to trigger events and instead let the annotators decide on biologically important triggers, which are not restricted to verbs (unlike BioProp, where 30 pre-specified verbs were selected for annotation). Like PropBank and BioProp, the argument labels are not trigger specific.

Mapping questions to queries is effectively a semantic parsing task. In recent years, several lines of work addressed semantic parsing using various formalisms and levels of supervision (Zettlemoyer and Collins, 2005; Wong and Mooney, 2006; Clarke et al., 2010; Berant et al., 2013). In particular, Krishnamurthy and Kollar (2013) learned to map natural language utterances to referents in an image by constructing a KB from the image and then mapping the utterance to a query over the KB. This is analogous to our process of constructing a process structure and performing QA by querying that structure. In our work, we parse questions into graph-based queries, suitable for modeling processes, using a rule-based heuristic. Training a statistical semantic parser that will replace the QA system is an interesting direction for future research.

Multiple choice reading comprehension tests are a natural choice for evaluating machine reading. Hirschman et al. (1999) presented a bag-of-words approach to retrieving sentences for reading comprehension. Richardson et al. (2013) recently released the MCTest reading comprehension dataset that examines understanding of fictional stories. Their work shares our goal of advancing micro-reading, but they do not focus on process understanding.

Developing programs that perform deep reasoning over complex descriptions of processes is an important step on the road to fulfilling the higher goals of machine reading. In this paper, we present an end-to-end system for reading comprehension of paragraphs which describe biological processes. This is, to the best of our knowledge, the first system to both predict a rich structured representation that includes entities, events and their relations, *and* utilize this structure for answering reading comprehension questions. We also created a new dataset, PROCESSBANK, which contains 200 paragraphs that are both fully-annotated with process structure, as well as accompanied by questions. We empirically demonstrated that modeling biological processes can substantially improve reading comprehension accuracy in this domain.

Acknowledgments

The authors would like to thank Luke Amuchastegui for authoring the multiple-choice questions, and also the anonymous reviewers for their constructive feedback. We thank the Allen Institute for Artificial Intelligence for assistance in funding this work.

Abstract

Connecting words with senses, namely, sight, hearing, taste, smell and touch, to comprehend the sensorial information in language is a straightforward task for humans by using commonsense knowledge. With this in mind, a lexicon associating words with senses would be crucial for the computational tasks aiming at interpretation of language. However, to the best of our knowledge, there is no systematic attempt in the literature to build such a resource. In this paper, we present a sensorial lexicon that associates English words with senses. To obtain this resource, we apply a computational method based on bootstrapping and corpus statistics. The quality of the resulting lexicon is evaluated with a gold standard created via crowdsourcing. The results show that a simple classifier relying on the lexicon outperforms two baselines on a sensory classification task, both at word and sentence level, and confirm the soundness of the proposed approach for the construction of the lexicon and the usefulness of the resource for computational applications.

1 Introduction

Sensorial information interpenetrates languages with various semantic roles in different levels since the main interaction instrument of humans with the outside world is the sensory organs. The transformation of the raw sensations that we receive through the sensory organs into our understanding of the world has been an important philosophical topic for centuries. According to a classification that dates back to Aristotle (Johansen, 1997), senses can be categorized into five modalities, namely, sight, hearing, taste, smell and touch. With the help of perception, we can process the data coming from our sensory receptors and become aware of our environment. While interpreting sensory data, we unconsciously use our existing knowledge and experience about the world to create a private experience (Bernstein, 2010).

Language has a significant role as our main communication device to convert our private experiences to shared representations of the environment that we perceive (Majid and Levinson, 2011). As a basic example, onomatopoeic words, such as *knock* or *woof*, are acquired by direct imitation of the sounds allowing us to share the experience of what we hear. As another example, where an imitation is not possible, is that giving a name to a color, such as *blue*, provides a tool to describe a visual feature of an object. In addition to the words that describe the direct sensorial features of objects, languages include many other lexical items that are connected to sensory modalities in various semantic roles. For instance, while some words can be used to describe a perception activity (e.g., *to sniff*, *to watch*, *to feel*), others can simply be physical phenomena that can be perceived by sensory receptors (e.g., *light*, *song*, *salt*, *smoke*).

Common usage of language, either written or spoken, can be very dense in terms of sensorial words. As an example, the sentence "*I felt the cold breeze.*" contains three sensorial words: *to feel* as a perception activity, *cold* as a perceived sensorial feature and *breeze* as a physical phenomenon. The connection to the sense modalities of the words might not be mutually exclusive, that is to say a word can be associated with more than one senses. For instance, the adjective *sweet* could be associated with both the senses of *taste* and *smell*. While we, as humans, have the ability to connect words with senses intuitively by using our commonsense knowledge, it is not straightforward for machines to interpret sensorial information.

Making use of a lexicon containing sensorial words could be beneficial for many computational scenarios. Rodriguez-Esteban and Rzhetsky

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1511–1521,

(2008) report that using words related to senses in a text could clarify the meaning of an abstract concept by facilitating a more concrete imagination. To this respect, an existing text could be automatically modified with sensory words for various purposes such as attracting attention or biasing the audience towards a specific concept. Additionally, sensory words can be utilized to affect private psychology by inducing a positive or negative sentiment (Majid and Levinson, 2011). For instance, de Araujo et al. (2005) show that the pleasantness level of the same odor can be altered by labeling it as *body odor* or *cheddar cheese*. As another motivation, the readability and understandability of text could also be enhanced by using sensory words (Rodriguez-Esteban and Rzhetsky, 2008). A compelling use case of a sensorial lexicon is that automatic text modification to change the density of a specific sense could help people with sensory disabilities. For instance, while teaching a concept to a congenitally blind child, an application that eliminates color-related descriptions would be beneficial. A sensorial lexicon could also be exploited by search engines to personalize the results according to user needs.

Advertising is another broad area which would benefit from such a resource especially by using synaesthesia[1], as it strengthens creative thinking and it is commonly exploited as an imagination boosting tool in advertisement slogans (Pricken, 2008). As an example, we can consider the slogans "*The taste of a paradise*" where the sense of sight is combined with the sense of taste or "*Hear the big picture*" where *sight* and *hearing* are merged.

Various studies have been conducted both in computational linguistics and cognitive science that build resources associating words with several cognitive features such as abstractness-concreteness (Coltheart, 1981; Turney et al., 2011), emotions (Strapparava and Valitutti, 2004; Mohammad and Turney, 2010), colors (Özbal et al., 2011; Mohammad, 2011) and imageability (Coltheart, 1981). However, to the best of our knowledge, there is no attempt in the literature to build a resource that associates words with senses. In this paper, we propose a computational method to automatically generate a sensorial lexicon that associates words in English with senses. Our method consists of two main steps. First, we generate a set of seed words for each sense category with the help of a bootstrapping approach. In the second step, we exploit a corpus based probabilistic technique to create the final lexicon. We evaluate this lexicon with the help of a gold standard that we obtain by using the crowdsourcing service of CrowdFlower[2].

The sensorial lexicon, which we named Sensicon, embodies 22,684 English lemmas together with their part-of-speech (POS) information that have been linked to one or more of the five senses. Each entry in this lexicon consists of a lemma-POS pair and a score for each sensory modality that indicates the degree of association. For instance, the verb *stink* has the highest score for *smell* as expected while the scores for the other four senses are very low. The noun *tree*, which is a concrete object and might be perceived by multiple senses, has high scores for *sight*, *touch* and *smell*.

The rest of the paper is organized as follows. We first review previous work relevant to this task in Section 2. Then in Section 3, we describe the proposed approach in detail. In Section 4, we explain the annotation process that we conducted and the evaluation strategy that we employed. Finally, in Section 5, we draw our conclusions and outline possible future directions.

2 Related Work

Since to the best of our knowledge there is no attempt in the literature to automatically associate words with human senses, in this section we will summarize the most relevant studies that focused on linking words with various other cognitive features.

There are several studies focusing on word-emotion associations. WordNet Affect Lexicon (Strapparava and Valitutti, 2004) maps WordNet (Fellbaum, 1998) synsets to various cognitive features (e.g., emotion, mood, behaviour). This resource is created by using a small set of synsets as seeds and expanding them with the help of semantic and lexical relations among these synsets. Yang et al. (2007) propose a collocation model with emoticons instead of seed words while creating an emotion lexicon from a corpus. Perrie et al. (2013) build a word-emotion association lexicon by using subsets of a human-annotated lexicon as seed sets. The authors use frequencies, counts, or unique seed words extracted from an n-gram corpus to create lexicons in different sizes. They pro-

[1] American Heritage Dictionary (`http://ahdictionary.com/`) defines synaesthesia in linguistics as the description of one kind of sense impression by using words that normally describe another.

[2] `http://www.crowdflower.com/`

pose that larger lexicons with less accurate generation method perform better than the smaller human annotated lexicons. While a major drawback of manually generated lexicons is that they require a great deal of human labor, crowdsourcing services provide an easier procedure for manual annotations. Mohammad and Turney (2010) generate an emotion lexicon by using the crowdsourcing service provided by Amazon Mechanical Turk[3] and it covers 14,200 term-emotion associations.

Regarding the sentiment orientations and subjectivity levels of words, Sentiwordnet (Esuli and Sebastiani, 2006) is constructed as an extension to WordNet and it provides sentiments in synset level. Positive, negative and neutral values are assigned to synsets by using ternary classifiers and synset glosses. Another study that has been inspirational for the design of our approach is Banea et al. (2008). The authors generate a subjectivity lexicon starting with a set of seed words and then using a similarity measure among the seeds and the candidate words.

Another cognitive feature relevant to sensorial load of the words is the association between colors and words. Mohammad (2011) builds a color-word association lexicon by organizing a crowdsourcing task on Amazon Mechanical Turk. Instead, Özbal et al. (2011) aim to automate this process and propose three computational methods based on image analysis, language models and latent semantic analysis (LSA) (Landauer and Dumais, 1997). The authors compare these methods against a gold standard obtained by the crowdsourcing service of Amazon Mechanical Turk. The best performance is obtained by using image features while LSA performs slightly better than the baseline.

Finally, there have been efforts in the literature about the association of words with their abstractness-concreteness and imageability levels. MRC Psycholinguistic Database (Coltheart, 1981) includes abstractness-concreteness and imageability ratings of a small set of words determined according to psycholinguistic experiments. Turney et al. (2011) propose to use LSA similarities of words with a set of seed words to automatically calculate the abstractness and concreteness degrees of words.

3 Automatic Association of Senses with Words

We adopt a two phased computational approach to construct a large sensorial lexicon. First, we employ a bootstrapping strategy to generate a sufficient number of sensory seed words from a small set of manually selected seed words. In the second phase, we perform a corpus based probabilistic method to estimate the association scores to build a larger lexicon.

3.1 Selecting Seed Words

The first phase of the lexicon construction process aims to collect *sensorial seed words*, which are directly related to senses (e.g., *sound*, *tasty* and *sightedness*). To achieve that, we utilized a lexical database called FrameNet (Baker et al., 1998), which is built upon *semantic frame*s of concepts in English and lexical units (i.e., words) that evoke these frames. The basic idea behind this resource is that meanings of words can be understood on the basis of a semantic frame. A semantic frame consists of semantic roles called frame elements, which are manually annotated in more than 170,000 sentences. We have considered FrameNet to be especially suitable for the collection of sensorial seed words since it includes semantic roles and syntactic features of sensational and perceptional concepts.

In order to determine the seed lemma-POS pairs in FrameNet, we first manually determined 31 frames that we found to be highly connected to senses such as *Hear*, *Color*, *Temperature* and *Perception_experience*. Then, we conducted an annotation task and asked 3 annotators to determine which senses the lemma-POS pairs evoking the collected frames are associated with. At the end of this task, we collected all the pairs (i.e. 277) with 100% agreement to constitute our initial seed set. This set contains 277 lemma-POS pairs associated with a specific sense such as the verb *click* with *hearing*, the noun *glitter* with *sight* and *aromatic* with *smell*.

3.2 Seed Expansion via Bootstrapping

In this step, we aim to extend the seed list that we obtained from FrameNet with the help of a bootstrapping approach. To achieve that, we adopt a similar approach to Dias et al. (2014), who propose a repetitive semantic expansion model to automatically build temporal associations of synsets in WordNet. Figure 1 provides an overview of the bootstrapping process. At each iteration, we

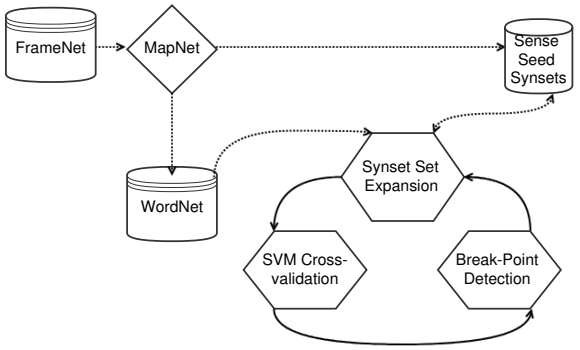

Figure 1: Bootstrapping procedure to expand the seed list.

first expand the seed list by using semantic relations provided by WordNet. We then evaluate the accuracy of the new seed list for sense classification by means of cross-validation against WordNet glosses. For each sense, we continue iterating until the cross-validation accuracy becomes stable or starts to decrease. The following sections explain the whole process in detail.

3.2.1 Extending the Seed List with WordNet

While the initial sensory seed list obtained from FrameNet contains only 277 lemma-POS pairs, we extend this list by utilizing the semantic relations provided by WordNet. To achieve that, we first map each lemma-POS pair in the seed list to WordNet synsets with the help of MapNet (Tonelli and Pighin, 2009), which is a resource providing direct mapping between WordNet synsets and FrameNet lexical units. Then, we add to the list the synsets that have WordNet relations *direct antonymy*, *similarity*, *derived-from*, *derivationally-related*, *pertains-to*, *attribute* and *also-see* with the already existing seeds. For instance, we add the synset containing the verb *laugh* for the synset of the verb *cry* with the relation *direct antonymy*, or the synset containing the adjective *chilly* for the synset of the adjective *cold* with the relation *similarity*. We prefer to use these relations as they might allow us to preserve the semantic information as much as possible during the extension process. It is worth mentioning that these relations were also found to be appropriate for preserving the affective connotation by Valitutti et al. (2004). Additionally, we use the relations *hyponym* and *hyponym-instance* to enrich the seed set with semantically more specific synsets. For instance, for the noun seed *smell*, we expand the list with the hyponyms of its synset such as the nouns *bouquet*, *fragrance*, *fragrancy*, *redolence* and *sweetness*.

3.2.2 Cross-validation of Sensorial Model

After obtaining new synsets with the help of WordNet relations in each bootstrapping cycle, we build a five-class sense classifier over the seed synsets defined by their glosses provided in WordNet. Similarly to Dias et al. (2014), we assume that the sense information of sensorial synsets is preserved in their definitions. Accordingly, we employ a support vector machine (SVM) (Boser et al., 1992; Vapnik, 1998) model with second degree polynomial kernel by representing the gloss of each synset as a vector of lemmas weighted by their counts. For each synset, its gloss is lemmatized by using Stanford Core NLP[4] and cleaned from the stop words. After each iteration cycle, we perform a 10-fold cross-validation in the updated seed list to detect the accuracy of the new sensorial model. For each sense class, we continue iterating and thereby expanding the seed list until the classifier accuracy steadily drops.

Table 1 lists the *precision* (*P*), *recall* (*R*) and *F1* values obtained for each sense after each iteration until the bootstrapping mechanism stops. While the iteration number is provided in the first column, the values under the last column group present the micro-average of the resulting multi-class classifier. The change in the performance values of each class in each iteration reveals that the number of iterations required to obtain the seed lists varies for each sense. For instance, the F1 value of *touch* continues to increase until the fourth cycle whereas *hearing* records a sharp decrease after the first iteration.

After the bootstrapping process, we create the final lexicon by repeating the expansion for each class until the optimal number of iterations is reached. The last row of Table 1, labeled as *Final*, demonstrates the accuracy of the classifier trained and tested on the final lexicon, i.e., using the seeds selected after iteration 2 for *Sight*, iteration 1 for *Hearing*, iteration 3 for *Taste* and *Smell* and iteration 4 for *Touch*. According to F1 measurements of each iteration, while *hearing* and *taste* have a lower value for the final model, *sight*, *smell* and *touch* have higher results. It should also be noted that the micro-average of the F1 values of the final model shows an increase when compared to the third iteration, which has the highest average F1 value among the iterations. At the end

[4] http://nlp.stanford.edu/software/corenlp.shtml

of this step we have a seed synset list consisting of 2572 synsets yielding the highest performance when used to learn a sensorial model.

3.3 Sensorial Lexicon Construction Using Corpus Statistics

After generating the seed lists consisting of synsets for each sense category with the help of a set of WordNet relations and a bootstrapping process, we use corpus statistics to create our final sensorial lexicon. More specifically, we exploit a probabilistic approach based on the co-occurrence of the seeds and the candidate lexical entries. Since working on the synset level would raise the data sparsity problem in synset tagged corpora such as SemCor (Miller et al., 1993) and we need a corpus that provides sufficient statistical information, we migrate from synset level to lexical level. Accordingly, we treat each POS role of the same lemmas as a distinct seed and extract 4287 lemma-POS pairs from 2572 synsets. In this section, we explain the steps to construct our final sensorial lexicon in detail.

3.3.1 Corpus and Candidate Words

As a corpus, we use a subset of English GigaWord 5th Edition released by Linguistic Data Consortium (LDC)[5]. This resource is a collection of almost 10 million English newswire documents collected in recent years, whose content sums up to nearly 5 billion words. The richly annotated GigaWord data comprises automatic parses obtained with the Stanford parser (Klein and Manning, 2003) so that we easily have access to the lemma and POS information of each word in the resource. For the scope of this study, we work on a randomly chosen subset that contains 79800 sentences and we define a co-occurrence event as the co-existence of a candidate word and a seed word within a window of 9 words(the candidate word, 4 words to its left and 4 words to its right). In this manner, we analyze the co-occurrence of each unique lemma-POS pair in the corpus with the sense seeds. We eliminate the candidates which have less than 5 co-occurrences with the sense categories.

3.3.2 Normalized Pointwise Mutual Information

For the co-occurrence analysis of the candidate words and seeds, we use pointwise mutual information (PMI), which is simply a measure of association between the probability of the co-occurrence of two events and their individual probabilities when they are assumed to be independent (Church and Hanks, 1990). PMI can be exploited as a semantic similarity measure (Han et al., 2013) and it is calculated as:

$$PMI(x,y) = \log\left[\frac{p(x,y)}{p(x)p(y)}\right] \quad (1)$$

To calculate the PMI value of a candidate word and a specific sense, we consider *p(x)* as the probability of the candidate word to occur in the corpus. Therefore, *p(x)* is calculated as $p(x) = c(x)/N$, where c(x) is the total count of the occurrences of the candidate word *x* in the corpus and N is the total co-occurrence count of all words in the corpus. Similarly, we calculate *p(y)* as the total occurrence count of all the seeds for the sense considered (*y*). *p(y)* can thus be formulated as $c(y)/N$. *p(x,y)* is the probability of the co-occurrence of a candidate word *x* with a sense event *y*.

A major shortcoming of PMI is its sensitivity for low frequency data (Bouma, 2009). As one possible solution, the author introduces Normalized Pointwise Mutual Information (NPMI), which normalizes the PMI values to the range (-1, +1) with the following formula:

$$NPMI(x,y) = \frac{PMI(x,y)}{-\log p(x,y)} \quad (2)$$

We adopt the proposed solution and calculate NPMI values for each candidate word and five sense events in the corpus. Sensicon covers 22,684 lemma-POS pairs and a score for each sense class that denotes their association degrees.

4 Evaluation

To evaluate the performance of the sensorial classification and the quality of Sensicon, we first created a gold standard with the help of a crowdsourcing task. Then, we compared the decisions coming from Sensicon against the gold standard. In this section, we explain the annotation process that we conducted and the evaluation technique that we adopted in detail. We also provide a brief discussion about the obtained results.

4.1 Crowdsourcing to Build a Gold Standard

The evaluation phase of Sensicon requires a gold standard data to be able to conduct a meaningful assessment. Since to our best knowledge there is no resource with sensory associations of words or

sentences, we designed our own annotation task using the crowdsourcing service of CrowdFlower. For the annotation task, we first compiled a collection of sentences to be annotated. Then, we designed two questions that the annotators were expected to answer for a given sentence. While the first question is related to the sense association of a whole sentence, the second asks the annotators to collect a fine-grained gold standard for word-sense associations.

We collected a dataset of 340 sentences consisting of 300 advertisement slogans from 11 advertisement categories (e.g., fashion, food, electronics) and 40 story sentences from a story corpus. We collected the slogans from various online resources such as `http://slogans.wikia.com/wiki` and `http://www.adslogans.co.uk/`. The story corpus is generated as part of a dissertation research (Alm, 2008) and it provides stories as a collection of sentences.

In both resources, we first determined the candidate sentences that had at least five tokens and contained at least one adjective, verb or noun. In addition, we replaced the brand names in the advertisement slogans with *X* to prevent any bias. For instance, the name of a well-known restaurant in a slogan might cause a bias towards *taste*. Finally, the slogans used in the annotation task were chosen randomly among the candidate sentences by considering a balanced number of slogans from each category. Similarly, 40 story sentences were selected randomly among the candidate story sentences. To give a more concrete idea, for our dataset we obtained an advertisement slogan such as "*X's Sugar Frosted Flakes They're Great!*" or a story sentence such as "*The ground is frozen, and besides the snow has covered everything.*"

In the crowdsourcing task we designed, the annotators were required to answer 2 questions for a given sentence. In the first question, they were asked to detect the human senses conveyed or directly described by a given sentence. To exemplify these cases, we provided two examples such as "*I saw the cat*" that directly mentions the action of seeing and "*The sun was shining on the blue water.*" that conveys the sense of sight by using visual descriptions or elements like "*blue*" or "*shine*" which are notable for their visual properties. The annotators were able to select more than one sense for each sentence and together with the five senses we provided another option as *None* which should be selected when an annotator could not associate a sentence with any sense. The second question was devoted do determining word-sense associations. Here, the annotators were expected to associate the words in each sentence with at least one sense. Again, annotators could choose *None* for every word that they could not confidently associate with a sense.

The reliability of the annotators was evaluated on the basis of 20 control sentences which were highly associated with a specific sense and which included at least one sensorial word. For instance, for the control sentence "*The skin you love to touch*", we only considered as reliable the annotators who associated the sentence with *touch* and the word *touch* with the sense *touch*[6]. Similarly, for the slogan "*The most colourful name in cosmetics.*", an annotator was expected to associate the sentence with at least the sense *sight* and the word *colorful* to at least the sense *sight*. The raters who scored at least 70% accuracy on average on

[6]If the annotators gave additional answers to the expected ones, we considered their answers as correct.

the control questions for the two tasks were considered to be reliable. Each unit was annotated by at least 10 reliable raters.

Similarly to Mohammad (2011) and Özbal et al. (2011), we calculated the majority class of each annotated item to measure the agreement among the annotators. Table 2 demonstrates the observed agreement at both word and sentence level. Since 10 annotators participated in the task, the annotations with a majority class greater than 5 can be considered as reliable (Özbal et al., 2011). Indeed, for 85.10% of the word annotations the absolute majority agreed on the same decision, while 77.58% of the annotations in the sentence level have majority class greater than 5. The high agreement observed among the annotators in both cases confirms the quality of the resulting gold standard data.

In Table 3, we present the results of the annotation task by providing the association percentage of each category with each sense, namely *sight (Si)*, *hear (He)*, *taste (Ta)*, *smell (Sm)* and *touch (To)*. As demonstrated in the table, while the sense of *sight* can be observed in almost every advertisement category and in *story*, *smell* and *taste* are very rare. We observe that the story sentences invoke all sensory modalities except *taste*, although the percentage of sentences annotated with *smell* is relatively low. Similarly, *personal care* category has an association with four of the senses while the other categories have either very low or no association with some of the sense classes. Indeed, the perceived sensorial effects in the sentences vary according to the category such that the slogans in the *travel* category are highly associated with *sight* whereas the *communication* category is highly associated with *hearing*. While the connection of the *food* and *beverages* categories with *taste* is very high as expected, they have no association with the sense of *smell*. This kind of analysis could be useful for copywriters to decide which sensory modalities to invoke while creating a slogan for a specific product category.

4.2 Evaluation Measures

Based on the annotation results of our crowdsourcing task, we propose an evaluation technique considering that a lemma-POS or a sentence might be associated with more than one sensory modalities. Similar to the evaluation framework defined by Özbal et al. (2011), we adapt the evaluation measures of SemEval-2007 English Lexical Substitution Task (McCarthy and Navigli, 2007), where a system generates one or more possible substitutions for a target word in a sentence preserving its meaning.

For a given lemma-POS or a sentence, which we will name as *item* in the rest of the section, we allow our system to provide as many sensorial associations as it determines by using a specific lexicon. While evaluating a sense-item association of a method, a *best* and an *oot* score are calculated by considering the number of the annotators who associate that sense with the given item, the number of the annotators who associate any sense with the given item and the number of the senses the system gives as an answer for that item. More specifically, *best* scoring provides a credit for the best answer for a given item by dividing it to the number of the answers of the system. *oot* scoring, on the other hand, considers only a certain number of system answers for a given item and does not divide the credit to the total number of the answers. Unlike the lexical substitution task, a limited set of labels (i.e., 5 sense labels and *none*) are allowed for the sensorial annotation of sentences or lemma-POS pairs. For this reason, we reformulate *out-of-ten (oot)* scoring used by McCarthy and Navigli (2007) as out-of-two.

In Equation 3, *best* score for a given item *i* from the set of items *I*, which consists of the items annotated with a specific sense by a majority of 5 annotators, is formulated where H_i is the multiset of gold standard sense associations for item *i* and S_i is the set of sense associations provided by the system. *oot* scoring, as formulated in Equation 4, accepts up to 2 sense associations s from the answers of system S_i for a given item *i* and the credit is not divided by the number of the answers of the

system.

$$best\,(i) = \frac{\sum_{s \in S_i} freq\,(s \in H_i)}{|H_i| \cdot |S_i|} \quad (3)$$

$$oot\,(i) = \frac{\sum_{s \in S_i} freq\,(s \in H_i)}{|H_i|} \quad (4)$$

As formulated in Equation 5, to calculate the precision of an item-sense association task with a specific method, the sum of the scores (i.e., *best* or *oot*) for each item is divided by the number of items *A*, for which the method can provide an answer. In recall, the denominator is the number of the items in the gold standard for which an answer is given by the annotators.

$$P = \frac{\sum_{i \in A} score_i}{|A|} \qquad R = \frac{\sum_{i \in I} score_i}{|I|} \quad (5)$$

4.3 Evaluation Method

For the evaluation, we compare the accuracy of a simple classifier based on Sensicon against two baselines on a sense classification task both at word and sentence level. To achieve that, we use the gold standard that we obtain from the crowdsourcing task and the evaluation measures *best* and *oot*. The lexicon-based classifier simply assigns to each word in a sentence the sense values found in the lexicon. The first baseline assigns the most frequently annotated sensory modality, which is *sight*, via crowdsourcing task with a float value of 1.0 to each lemma-POS pair in the sensorial lexicon. The second baseline instead builds the associations by using a Latent Semantic Analysis space generated from the same subset of LDC that we exploit for constructing Sensicon. More specifically, this baseline calculates the LSA similarities between each candidate lemma-POS pair and sense class by taking the cosine similarity between the vector of the target lemma-POS pair and the average of the vectors of the related sensory word (i.e., *see*, *hear*, *touch*, *taste*, and *smell*) for each possible POS tag. For instance, to get the association score of a lemma-POS pair with the sense sight, we first average the vectors of see (noun) and see (verb) before calculating its cosine similarity with the target lemma-POS pair.

For the first experiment, i.e., word-sense association, we automatically associate the lemma-POS pairs obtained from the annotated dataset with senses by using i) Sensicon, ii) the most-frequent-sense baseline (MFS), iii) the LSA baseline. To achieve that, we lemmatize and POS tag each sentence in the dataset by using Stanford Core NLP. In the end, for each method and target word, we obtain a list of senses sorted according to their sensorial association values in decreasing order. It is worth noting that we only consider the non-negative sensorial associations for Sensicon and both baselines. For instance, Sensicon associates the noun *wine* with [*smell, taste, sight*]. In this experiment, *best* scoring considers the associated senses as the best answer, *smell, taste, sight* according to the previous example, and calculates a score with respect to the best answer in the gold standard and the number of the senses in this answer. Instead, *oot* scoring takes the first two answers, *smell* and *taste* according to the previous example, and assigns the score accordingly.

To determine the senses associated with a sentence for the second experiment, we use a method similar to the one proposed by Turney (2002). For each sense, we simply calculate the average score of the lemma-POS pairs in a sentence. We set a threshold value of 0 to decide whether a sentence is associated with a given sense. In this manner, we obtain a sorted list of average sensory scores for each sentence according to the three methods. For instance, the classifier based on Sensicon associates the sentence *Smash it to pieces, love it to bits.* with [*touch*, *taste*]. For the *best* score, only *touch* would be considered, whereas *oot* would consider both *touch* and *taste*.

4.4 Evaluation Results

In Table 4, we list the F1 values that we obtained with the classifier using Sensicon and the two baselines (MFS and LSA) according to both *best* and *oot* measures. In addition, we provide the performance of Sensicon in two preliminary steps, before bootstrapping (BB) and after bootstrapping (AB) to observe the incremental progress of the lexicon construction method. As can be observed from the table, the best performance for both experiments is achieved by Sensicon when compared against the baselines.

While in the first experiment the lexicon generated after the bootstrapping step (AB) provides a very similar performance to the final lexicon according to the *best* measure, it can only build sense associations for 69 lemmas out of 153 appearing in the gold standard. Instead, the final lexicon attempts to resolve 129 lemma-sense associations and results in a better recall value. Additionally, AB yields a very high precision as expected,

since it is created by a controlled semantical expansion from manually annotated sensorial words. BB lexicon includes only 573 lemmas which are collected from 277 synsets and we can not obtain 2 sense association scores for *oot* in this lexicon since each lemma is associated with only one sense with a value of 1. The LSA baseline yields a very low performance in the *best* measure due to its tendency to derive positive values for all sensorial associations of a given lemma-POS tuple. Another observed shortcoming of LSA is its failure to correlate the names of the colors with *sight* while this association is explicit for the annotators. On the other hand, LSA baseline significantly improves the MFS baseline with a p-value of 0.0009 in *oot* measures. This result points out that even though LSA provides very similar positive association values for almost all the sensory modalities for a given item, the first two sensorial associations with the highest values yield a better performance on guessing the sensorial characteristics of a lemma-POS. Nevertheless, Sensicon significantly outperforms the LSA baseline in both *best* and *oot* measures with the p-values of 0.0009 and 0.0189 respectively. The statistical significance tests are conducted using one-sided bootstrap resampling (Efron and Tibshirani, 1994).

Concerning the sentence classification experiment, the classifier using Sensicon yields the highest performance in both measures. The very high F1 value obtained with the *oot* scoring indicates that the right answer for a sentence is included in the first two decisions in many cases. Sensicon significantly outperforms the LSA baseline on the *best* measure (p-value = 0.0069). On the other hand, when systems are allowed to provide two answers (*oot*), the performance of LSA comes close to Sensicon in terms of F1 measure.

After the manual analysis of Sensicon and gold standard data, we observe that the sensorial classification task could be nontrivial. For instance, a story sentence "*He went to sleep again and snored until the windows shook.*" has been most frequently annotated as *hearing*. While the sensorial-lexicon classifier associates this sentence with *touch* as the best answer, it can provide the correct association *hearing* as the second best answer. To find out the best sensorial association for a sentence, a classification method which exploits various aspects of sensorial elements in a sentence, such as the number of sensorial words or their dependencies, could be a better approach than using only the average sensorial values.

	Lemma		Sentence	
Model	*best*	*oot*	*best*	*oot*
Most-Frequent-Sense	33.33	33.33	38.90	38.90
LSA	18.80	70.38	53.44	76.51
Lexicon-BB	45.22	45.22	49.60	51.12
Lexicon-AB	55.85	55.85	59.89	63.21
Sensicon	55.86	80.13	69.76	80.73

Table 4: Evaluation results.

Based on our observations of the error cases, we believe that synaesthesia, which is one of the most common metaphoric transfers in language (Williams, 1976), should be further explored for sense classification. As an example observation, the advertisement slogan "*100% pure squeezed sunshine*" is associated with *touch* as the best answer by Sensicon and *taste* by LSA baseline while it is most frequently annotated as *sight* in the gold standard. This slogan is an example usage of synaesthesia and metaphors in advertising language. To clarify, a product from the category of *beverages*, which might be assumed to have a *taste* association, is described by a metaphorical substitution of a *taste*-related noun, most probably the name of a fruit, with a *sight*-related noun; *sunshine*. This metaphorical substitution, then used as the object of a *touch*-related verb, *to squeeze*, produces a synaesthetic expression with *touch* and *sight*.

5 Conclusion

In this paper we have presented the construction of Sensicon, a sensorial lexicon, which associates words with sensory modalities. This novel aspect of word semantics is captured by employing a two-step strategy. First, we collected seed words by using a bootstrapping approach based on a set of WordNet relations. Then, we performed a corpus based statistical analysis to produce the final lexicon. Sensicon consists of 22,684 lemma-POS pairs and their association degrees with five sensory modalities. To the best of our knowledge, this is the first systematic attempt to build a sensorial lexicon and we believe that our contribution constitutes a valid starting point for the community to consider sensorial information conveyed by text as a feature for various tasks and applications. The results that we obtain by comparing our lexicon against the gold standard and two baselines are promising even though not conclusive. The results confirm the soundness of the proposed approach for the construction of the lexicon and the useful-

ness of the resource for text classification and possibly other computational applications.

Sensicon is publicly available upon request to the authors so that the community can benefit from it for relevant tasks. From a resource point of view, we would like to explore the effect of using different kinds of WordNet relations during the bootstrapping phase. It would also be interesting to experiment with relations provided by other resources such as ConceptNet (Liu and Singh, 2004), which is a semantic network containing common sense, cultural and scientific knowledge. We would also like to use the sensorial lexicon for various applicative scenarios such as slanting existing text towards a specific sense with text modification. We believe that our resource could be extremely useful for automatic content personalization according to user profiles. As an example, one can imagine a system that automatically replaces hearing based expressions with sight based ones in pieces of texts for a hearing-impaired person. Automating the task of building sensorial associations could also be beneficial for various tasks that need linguistic creativity. For instance, copywriters can take advantage of a system detecting the sensorial load of a piece of text to generate more appropriate advertisement slogans for specific product categories. Finally, we plan to investigate the impact of using sensory information for metaphor detection and interpretation based on our observations during the evaluation. For instance, the synaesthetic metaphor *bittersweet symphony* could be detected by determining the sensorial characterizations of its components.

Abstract

Many forms of word relatedness have been developed, providing different perspectives on word similarity. We introduce a Bayesian probabilistic tensor factorization model for synthesizing a single word vector representation and per-perspective linear transformations from any number of word similarity matrices. The resulting word vectors, when combined with the per-perspective linear transformation, approximately recreate while also regularizing and generalizing, each word similarity perspective.

Our method can combine manually created semantic resources with neural word embeddings to separate synonyms and antonyms, and is capable of generalizing to words outside the vocabulary of any particular perspective. We evaluated the word embeddings with GRE antonym questions, the result achieves the state-of-the-art performance.

1 Introduction

In recent years, vector space models (VSMs) have been proved successful in solving various NLP tasks including named entity recognition, part-of-speech tagging, parsing, semantic role-labeling and answering synonym or analogy questions (Turney et al., 2010; Collobert et al., 2011). Also, VSMs are reported performing well on tasks involving the measurement of word relatedness (Turney et al., 2010). Many existing works are distributional models, based on the *Distributional Hypothesis*, that words occurring in similar contexts tend to have similar meanings (Harris, 1954). The limitation is that word vectors developed from distributional models cannot reveal word relatedness if its information does not lie in word distributions. For instance, they are believed to have difficulty distinguishing antonyms from synonyms, because the distribution of antonymous words are close, since the context of antonymous words are always similar to each other (Mohammad et al., 2013). Although some research claims that in certain conditions there do exist differences between the contexts of different antonymous words (Scheible et al., 2013), the differences are subtle enough that it can hardly be detected by such language models, especially for rare words.

Another important class of lexical resource for word relatedness is a lexicon, such as WordNet (Miller, 1995) or Roget's Thesaurus (Kipfer, 2009). Manually producing or extending lexicons is much more labor intensive than generating VSM word vectors using a corpus. Thus, lexicons are sparse with missing words and multi-word terms as well as missing relationships between words. Considering the synonym / antonym perspective as an example, WordNet answers less than 40% percent of the the GRE antonym questions provided by Mohammad et al. (2008) directly. Moreover, binary entries in lexicons do not indicate the degree of relatedness, such as the degree of lexical contrast between *happy* and *sad* or *happy* and *depressed*. The lack of such information makes it less fruitful when adopted in NLP applications.

In this work, we propose a Bayesian tensor factorization model (BPTF) for synthesizing a composite word vector representation by combining multiple different sources of word relatedness. The input is a set of word by word matrices, which may be sparse, providing a number indicating the presence or degree of relatedness. We treat word relatedness matrices from different perspectives as slices, forming a word relatedness tensor. Then the composite word vectors can be efficiently obtained by performing BPTF. Furthermore, given any two words and any trained relatedness perspective, we

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1522–1531,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

can create or recreate the pair-wise word relatedness with regularization via per-perspective linear transformation.

This method allows one set of word vectors to represent word relatednesses from many different perspectives (e.g. LSA for topic relatedness / corpus occurrences, ISA relation and YAGO type) It is able to bring the advantages from both word relatedness calculated by distributional models, and manually created lexicons, since the former have much more vocabulary coverage and many variations, while the latter covers word relatedness that is hard to detect by distributional models. We can use information from distributional perspectives to create (if does not exist) or re-create (with regularization) word relatedness from the lexicon's perspective.

We evaluate our model on distinguishing synonyms and antonyms. There are a number of related works (Lin and Zhao, 2003; Turney, 2008; Mohammad et al., 2008; Mohammad et al., 2013; Yih et al., 2012; Chang et al., 2013). A number of sophisticated methods have been applied, producing competitive results using diverse approaches. We use the GRE antonym questions (Mohammad et al., 2008) as a benchmark, and answer these questions by finding the most contrasting choice according to the created or recreated synonym / antonym word relatedness. The result achieves state-of-the-art performance.

The rest of this paper is organized as follows. Section 2 describes the related work of word vector representations, the BPTF model and antonymy detection. Section 3 presents our BPTF model and the sampling method. Section 4 shows the experimental evaluation and results with Section 5 providing conclusion and future work.

2 Related Work

2.1 Word Vector Representations

Vector space models of semantics have a long history as part of NLP technologies. One widely-used method is deriving word vectors using latent semantic analysis (LSA) (Deerwester et al., 1990), for measuring word similarities. This provides a topic based perspective on word similarity. In recent years, neural word embeddings have proved very effective in improving various NLP tasks (e.g. part-of-speech tagging, chunking, named entity recognition and semantic role labeling) (Collobert et al., 2011). The proposed neural models have a large number of variations, such as feed-forward networks (Bengio et al., 2003), hierarchical models (Mnih and Hinton, 2008), recurrent neural networks (Mikolov, 2012), and recursive neural networks (Socher et al., 2011). Mikolov et al. (2013) reported their vector-space word representation is able to reveal linguistic regularities and composite semantics using simple vector addition and subtraction. For example, "King$-$Man$+$Woman" results in a vector very close to "Queen". Luong et al. (2013) proposed a recursive neural networks model incorporating morphological structure, and has better performance for rare words.

Some non-VSM models[1] also generate word vector representations. Yih et al. (2012) apply polarity inducing latent semantic analysis (PILSA) to a thesaurus to derive the embedding of words. They treat each entry of a thesaurus as a document giving synonyms positive term counts, and antonyms negative term counts, and preform LSA on the signed TF-IDF matrix In this way, synonyms will have cosine similarities close to one and antonyms close to minus one.

Chang et al. (2013) further introduced Multi-Relational LSA (MRLSA), as as extension of LSA, that performs Tucker decomposition over a three-way tensor consisting of multiple relations (document-term like matrix) between words as slices, to capture lexical semantics. The purposes of MRLSA and our model are similar, but the different factorization techniques offer different advantages. In MRLSA, the k-th slice of tensor $\mathcal{W}$ is approximated by

$$\mathcal{W}_{:,:,k} \approx \mathcal{X}_{:,:,k} = \mathbf{U} S_{:,:,k} \mathbf{V}^T,$$

where $\mathbf{U}$ and $\mathbf{V}$ are both for the same word list but are not guaranteed (or necessarily desired) to be the same. Thus, this model has the ability to capture asymmetric relations, but this flexibility is a detriment for symmetric relatedness. In order to expand word relatedness coverage, MRLSA needs to choose a pivot slice (e.g. the synonym slice), thus there always must existence such a slice, and the model performance depends on the quality of this pivot slice. Also, while non-completeness is a pervasive issue in manually created lexicons, MRLSA is not flexible enough to treat the unknown entries as missing. Instead it just sets them

[1] As defined by Turney et al. (2010), VSM must be derived from event frequencies.

to zero at the beginning and uses the pivot slice to re-calculate them. In contrast, our method of BPTF is well suited to symmetric relations with many unknown relatedness entries.

2.2 BPTF Model

Salakhutdinov and Mnih (2008) introduced a Bayesian Probabilistic Matrix Factorization (BPMF) model as a collaborative filtering algorithm. Xiong et al. (2010) proposed a Bayesian Probabilistic Tensor Factorization (BPTF) model which further extended the original model to incorporate temporal factors. They modeled latent feature vector for users and items, both can be trained efficiently using Markov chain Monte Carlo methods, and they obtained competitive results when applying their models on real-world recommendation data sets.

2.3 Antonomy Detection

There are a number of previous works in detecting antonymy. Lin and Zhao (2003) identifies antonyms by looking for pre-identified phrases in corpus datasets. Turney (2008) proposed a supervised classification method for handling analogies, then apply it to antonyms by transforming antonym pairs into analogy relations. Mohammad et al. (Mohammad et al., 2008; Mohammad et al., 2013) proposed empirical approaches considering corpus co-occurrence statistics and the structure of a published thesaurus. Based on the assumption that the strongly related words of two words in a contrasting pair are also often antonymous, they use affix patterns (e.g. "un-", "in-" and "im-") and a thesaurus as seed sets to add contrast links between word categories. Their best performance is achieved by further manually annotating contrasting adjacent categories. This approach relies on the *Contrast Hypothesis*, which will increase false positives even with a carefully designed methodology. Furthermore, while this approach can expand contrast relationships in a lexicon, out-of-vocabulary words still pose a substancial challenge.

Yih et al. (2012) and Chang et al. (2013) also applied their vectors on antonymy detection, and Yih et al. achieves the state-of-the-art performance in answering GRE antonym questions. In addition to the word vectors generated from PILSA, they use morphology and k-nearest neighbors from distributional word vector spaces to derive the embeddings for out-of-vocabulary words. The latter is problematic since both synonyms and antonyms are distributionally similar. Their approach is two stage: polarity inducing LSA from a manually created thesaurus, then falling back to morphology and distributional similarity when the lexicon lacks coverage. In contrast, we focus on fusing the information from thesauruses and automatically induced word relatedness measures during the word vector space creation. Then prediction is done in a single stage, from the latent vectors capturing all word relatedness perspectives and the appropriate per-perspective transformation vector.

3 Methods

3.1 The Bayesian Probabilistic Tensor Factorization Model

Our model is a variation of the BPMF model (Salakhutdinov and Mnih, 2008), and is similar to the temporal BPTF model (Xiong et al., 2010). To model word relatedness from multiple perspectives, we denote the relatedness between word i and word j from perspective k as R_{ij}^k. Then we can organize these similarities to form a three-way tensor $\mathbf{R} \in \mathbb{R}^{N \times N \times K}$.

Table 1 shows an example, the first slice of the tensor is a $N \times N$ matrix consists of 1/-1 corresponding to the synonym/antonym entries in the Roget's thesaurus, and the second slice is a $N \times N$ matrix consists of the cosine similarity from neural word embeddings created by Luong et al. (2013), where N is the number of words in the vocabulary. Note that in our model the entries missing in Table 1a do not necessarily need to be treated as zero. Here we use the indicator variable I_{ij}^k to denote if the entry R_{ij}^k exists ($I_{ij}^k = 1$) or not ($I_{ij}^k = 0$). If $K = 1$, the BPTF model becomes to BPMF. Hence the key difference between BPTF and BPMF is that the former combines multiple complementary word relatedness perspectives, while the later only smooths and generalizes over one.

We assume the relatedness R_{ij}^k to be Gaussian, and can be expressed as the inner-product of three D-dimensional latent vectors:

$$R_{ij}^k | V_i, V_j, P_k \sim \mathcal{N}(< V_i, V_j, P_k >, \alpha^{-1}),$$

where $< \cdot, \cdot, \cdot >$ is a generalization of dot product:

$$< V_i, V_j, P_k > \equiv \sum_{d=1}^{D} V_i^{(d)} V_j^{(d)} P_k^{(d)},$$

	happy	joyful	lucky	sad	depressed
happy		1	1	-1	-1
joyful	1			-1	
lucky	1			-1	
sad	-1	-1	-1		1
depressed	-1			1	

(a) The first slice: synonym & antonym relatedness

	happy	joyful	lucky	sad	depressed
happy		.03	.61	.65	.13
joyful	.03		.25	.18	.23
lucky	.61	.25		.56	.31
sad	.65	.18	.56		-.01
depressed	.13	.23	.31	-.01	

(b) The second slice: distributional similarity

Table 1: Word Relatedness Tensor

and α is the precision, the reciprocal of the variance. V_i and V_j are the latent vectors of word i and word j, and P_k is the latent vector for perspective k.

We follow a Bayesian approach, adding Gaussian priors to the variables:

$$V_i \sim \mathcal{N}(\mu_V, \Lambda_V^{-1}),$$

$$P_i \sim \mathcal{N}(\mu_P, \Lambda_P^{-1}),$$

where μ_V and μ_P are D dimensional vectors and Λ_V and Λ_P are D-by-D precision matrices.

Furthermore, we model the prior distribution of hyper-parameters as conjugate priors (following the model by (Xiong et al., 2010)):

$$p(\alpha) = \mathcal{W}(\alpha|\hat{W}_0, \nu_0),$$

$$p(\mu_V, \Lambda_V) = \mathcal{N}(\mu_V|\mu_0, (\beta_0\Lambda_V)^{-1})\mathcal{W}(\Lambda_V|W_0, \nu_0),$$

$$p(\mu_P, \Lambda_P) = \mathcal{N}(\mu_P|\mu_0, (\beta_0\Lambda_P)^{-1})\mathcal{W}(\Lambda_P|W_0, \nu_0),$$

where $\mathcal{W}(W_0, \nu_0)$ is the Wishart distribution of degree of freedom ν and a D-by-D scale matrix W, and $\hat{W}_0$ is a 1-by-1 scale matrix for α. The graphical model is shown in Figure 1 (with β_0 set to 1). After choosing the hyper-priors, the only remaining parameter to tune is the dimension of the latent vectors.

Due to the existence of prior distributions, our model can capture the correlation between different perspectives during the factorization stage, then create or re-create word relatedness using this correlation for regularization and generalization. This advantage is especially useful when such correlation is too subtle to be captured by other methods. On the other hand, if perspectives (let's say k and l) are actually unrelated, our model can handle it as well by making P_k and P_l orthogonal to each other.

3.2 Inference

To avoid calculating intractable distributions, we use a numerical method to approximate the results. Here we use the Gibbs sampling algorithm

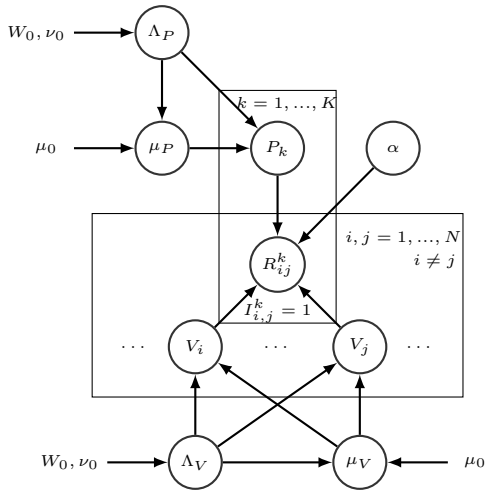

Figure 1: The graphical model for BPTF.

to perform the Markov chain Monte Carlo method. When sampling a block of parameters, all other parameters are fixed, and this procedure is repeated many times until convergence. The sampling algorithm is shown in Algorithm 1.

With conjugate priors, and assuming $I_{i,i}^k = 0, \forall i, k$ (we do not consider a word's relatedness to itself), the posterior distributions for each block of parameters are:

$$p(\alpha|\mathbf{R}, \mathbf{V}, \mathbf{P}) = \mathcal{W}(\hat{W_0}^*, \hat{\nu_0}^*) \quad (1)$$

Where:

$$\hat{\nu}_0^* = \hat{\nu}_0 + \sum_{k=1}^{2}\sum_{i,j=1}^{N} I_{ij}^k,$$

$$(\hat{W}_0^*)^{-1} = \hat{W}_0^{-1} + \sum_{k=1}^{2}\sum_{i,j=1}^{N} I_{ij}^k(R_{ij}^k - < V_i, V_j, P_k >)^2$$

$$p(\mu_V, \Lambda_V|\mathbf{V}) = \mathcal{N}(\mu_V|\mu_0^*, (\beta_0^*\Lambda_V)^{-1})\mathcal{W}(\Lambda_V|W_0^*, \nu_0^*) \tag{2}$$

Where:

$$\mu_0^* = \frac{\beta_0\mu_0 + N\bar{V}}{\beta_0 + N}, \beta_0^* = \beta_0 + N, \nu_0^* = \nu_0 + N,$$
$$(W_0^*)^{-1} = W_0^{-1} + N\bar{S} + \frac{\beta_0 N}{\beta_0 + N}(\mu_0 - \bar{V})(\mu_0 - \bar{V})^T,$$
$$\bar{V} = \frac{1}{N}\sum_{i=1}^{N} V_i, \bar{S} = \frac{1}{N}\sum_{i=1}^{N}(V_i - \bar{V})(V_i - \bar{V})^T$$

$$p(\mu_P, \Lambda_P|\mathbf{P}) = \mathcal{N}(\mu_P|\mu_0^*, (\beta_0^*\Lambda_P)^{-1})\mathcal{W}(\Lambda_P|W_0^*, \nu_0^*) \tag{3}$$

Which has the same form as $p(\mu_V, \Lambda_V|\mathbf{V})$.

$$p(V_i|\mathbf{R}, \mathbf{V}_{\neg i}, \mathbf{P}, \mu_V, \Lambda_V, \alpha) = \mathcal{N}(\mu_i^*, (\Lambda_i^*)^{-1}) \tag{4}$$

Where:

$$\mu_i^* = (\Lambda_i^*)^{-1}(\Lambda_V\mu_V + \alpha\sum_{k=1}^{2}\sum_{j=1}^{N} I_{ij}^k R_{ij}^k Q_{jk}),$$
$$\Lambda_i^* = \Lambda_V + \alpha\sum_{k=1}^{2}\sum_{j=1}^{N} I_{ij}^k Q_{jk}Q_{jk}^T,$$
$$Q_{jk} = V_j \odot P_k$$

$\odot$ is the element-wise product.

$$p(P_i|\mathbf{R}, \mathbf{V}, \mathbf{P}_{\neg i}, \mu_P, \Lambda_P, \alpha) = \mathcal{N}(\mu_i^*, (\Lambda_i^*)^{-1}) \tag{5}$$

Where:

$$\mu_k^* = (\Lambda_k^*)^{-1}(\Lambda_P\mu_P + \alpha\sum_{i,j=1}^{N} I_{ij}^k R_{ij}^k X_{ij}),$$
$$\Lambda_k^* = \Lambda_P + \alpha\sum_{i,j=1}^{N} I_{ij}^k X_{ij}X_{ij}^T,$$
$$X_{ij} = V_i \odot V_j$$

The influence each perspective k has on the latent word vectors is roughly propotional to the number of non-empty entries $n_k = \sum_{i,j} I_{i,j}^k$. If one wants to adjust the weight of each slices, this can easily achieved by adjusting (e.g. down sampling) the number of entries of each slice sampled at each iteration.

3.2.1 Out-of-Vocabulary words

It often occurs that some of the perspectives have greater word coverage than the others. For example, hand-labeled word relatedness usually has much less coverage than automatically acquired similarities. Of course, it is typically for the hand-labeled perspectives that the generalization is most desired. In this situation, our model can generalize word relatedness for the sparse perspective. For example, assume perspective k has larger vocabulary coverage N_k, while perspective l has a smaller coverage N_l.

There are two options for using the high vocabulary word relation matrix to generalize over the perspective with lower coverage. The most direct way simply considers the larger vocabulary in the BPTF $\mathbf{R} \in \mathbb{R}^{N_k \times N_k \times K}$ directly. A more efficient method trains on a tensor using the smaller vocabulary $\mathbf{R} \in \mathbb{R}^{N_l \times N_l \times K}$, then samples the $N_k - N_l$ word vectors using Equation 4.

Algorithm 1 Gibbs Sampling for BPTF

```
Initialize the parameters.
repeat
  Sample the hyper-parameters α, μ_V, Λ_V, μ_P,
  Λ_P (Equation 1, 2, 3)
  for i = 1 to N do
    Sample V_i (Equation 4)
  end for
  for k = 1 to 2 do
    Sample P_k (Equation 5)
  end for
until convergence
```

3.3 Predictions

With MCMC method, we can approximate the word relatedness distribution easily by averaging over a number of samples (instead of calculating intractable marginal distribution):

$$p(\hat{R}_{ij}^k|\mathbf{R}) \approx \frac{1}{M}\sum_{m=1}^{M} p(\hat{R}_{ij}^k|V_i^m, V_j^m, P_k^m, \alpha^m),$$

where m indicate parameters sampled from different sampling iterations.

3.4 Scalability

The time complexity of training our model is roughly $O(n \times D^2)$, where n is the number of observed entries in the tensor. If one is only interested in creating and re-creating word relatedness of one single slice rather than synthesizing word vectors, then entries in other slices can be down-sampled at every iteration to reduce the training time. In our model, the vector length D is not sensitive and does not necessarily need to be very long. Xiong et al. (2010) reported in their collaborative filtering experiment $D = 10$ usually gives satisfactory performance.

4 Experimental Evaluation

In this section, we evaluate our model by answering antonym questions. This task is especially suitable for evaluating our model since the performance of straight-forward look-up from the thesauruses we considered is poor. There are two major limitations:

1. The thesaurus usually only contains antonym information for word pairs with a strong contrast.

2. The vocabulary of the antonym entries in the thesaurus is limited, and does not contain many words in the antonym questions.

On the other hand, distributional similarities can be trained from large corpora and hence have a large coverage for words. This implies that we can treat the thesaurus data as the first slice, and the distributional similarities as the second slice, then use our model to create / recreate word relatedness on the first slice to answer antonym questions.

4.1 The GRE Antonym Questions

There are several publicly available test datasets to measure the correctness of our word embeddings. In order to be able to compare with previous works, we follow the widely-used GRE test dataset provided by (Mohammad et al., 2008), which has a development set (consisting of 162 questions) and a test set (consisting of 950 questions). The GRE test is a good benchmark because the words are relatively rare (19% of the words in Mohammad's test are not in the top 50,000 most frequent words from Google Books (Goldberg and Orwant, 2013)), thus it is hard to lookup answers from a thesaurus directly with high recall. Below is an example of the GRE antonym question:

adulterate: a. *renounce* b. *forbid*
c. *purify* d. *criticize* e. *correct*

The goal is to choose the most opposite word from the target, here the correct answer is *purify*.

4.2 Data Resources

In our tensor model, the first slice ($k = 1$) consists of synonyms and antonyms from public thesauruses, and the second slice ($k = 2$) consists of cosine similarities from neural word embeddings (example in Table 1)

4.2.1 Thesaurus

Two popular thesauruses used in other research are *the Macquarie Thesaurus* and *the Encarta Thesaurus*. Unfortunately, their electronic versions are not publicly available. In this work we use two alternatives:

WordNet Words in WordNet (version 3.0) are grouped into sense-disambiguated synonym sets (synsets), and synsets have links between each other to express conceptual relations. Previous works reported very different look-up performance using WordNet (Mohammad et al., 2008; Yih et al., 2012), we consider this difference as different understanding of the WordNet structure. By extending "indirect antonyms" defined in WordNet to nouns, verbs and adverbs that similar words share the antonyms,we achieve a look-up performance close to Yih et al. (2012). Using this interpretation of WordNet synonym and antonym structure we obtain a thesaurus containing 54,239 single-token words. Antonym entries are present for 21,319 of them with 16.5 words per entry on average, and 52,750 of them have synonym entries with 11.7 words per entry on average.

Roget's Only considering single-token words, *the Roget's Thesaurus* (Kipfer, 2009) contains 47,282 words. Antonym entries are present for 8,802 of them with 4.2 words per entry on average, and 22,575 of them have synonym entries with 20.7 words per entry on average. Although the Roget's Thesaurus has a less coverage on both vocabulary and antonym pairs, it has better look-up precision in the GRE antonym questions.

4.2.2 Distributional Similarities

We use cosine similarity of the *morphRNN* word representations[2] provided by Luong et al. (2013) as a distributional word relatedness perspective. They used morphological structure in training recursive neural networks and the learned models outperform previous works on word similarity tasks, especially a task focused on rare words. The vector space models were initialized from existing word embeddings trained on Wikipedia. We use word embeddings adapted from Collobert et al. (2011). This advantage complements the weakness of the thesaurus perspective – that it has less coverage on rare words. The word vector data contains 138,218 words, and it covers 86.9% of the words in the GRE antonym questions. Combining the two perspectives, we can cover 99.8% of the

Table 2: Development and test results on the GRE antonym questions. *Note: to allow comparison, in look-up we follow the approach used by (Yih et al., 2012): randomly guess an answer if the target word is in the vocabulary while none of the choices are. Asterisk indicates the look-up results without random guessing.

GRE antonym question words. Further using morphology information from WordNet, the coverage achieves 99.9%.

4.3 Tests

To answer the GRE questions, we calculate R^1_{ij} for word pair (i, j), where i is the target word and j is one of the question's candidates. The candidate with the smallest similarity is then the predicted answer. If a target word is missing in the vocabulary, that question will not be answered, while if a choice is missing, that choice will be ignored.

We first train on a tensor from a subset consisting of words with antonym entries, then add all other words using the out-of-vocabulary method described in Section 3. During each iteration, zeros are randomly added into the first slice to keep the model from overfitting. In the meantime, the second slice entries is randomly downsampled to match the number of non-empty entries in the first slice. This ensures each perspective has approximately equal influence on the latent word vectors.

We sample the parameters iteratively, and choose the burn-in period and vector length D according to the development set. We choose the vector length $D = 40$, the burn-in period starting from the 30[th] iterations, then averaging the relatedness over 200 runs. The hyper-priors used are $\mu_0 = 0$, $\nu_0 = \hat{\nu}_0 = D$, $\beta_0 = 1$ and $W_0 = \hat{W}_0 = \mathbf{I}$ (not tuned). Note that Yih et al. (2012) use a vector length of 300, which means our embeddings save considerable storage space and running time. Our model usually takes less than 30 minutes to meet the convergence criteria (on a machine with an Intel Xeon E3-1230V2 @ 3.3GHz CPU). In contrast, the MRLSA requires about 3 hours for tensor decomposition (Chang et al., 2013).

4.4 Results

The results are summarized in Table 2. We list the results of previous works (Yih et al., 2012; Chang et al., 2013) at the top of the table, where the best performance is achieved by PILSA on Encarta with further discriminative training and embedding. For comparison, we adopt the standard first used by (Mohammad et al., 2008), where *precision* is the number of questions answered correctly

[2]http://www-nlp.stanford.edu/ lmthang/morphoNLM/

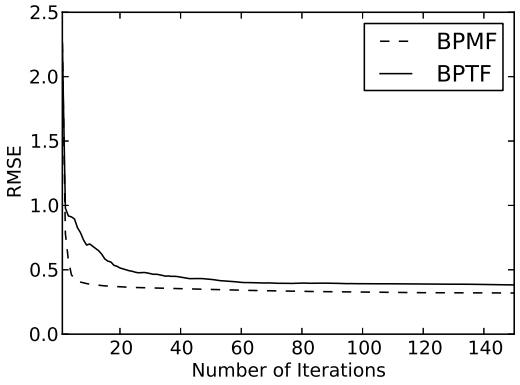

Figure 2: Convergence curves of BPMF and BPTF in training the W&R dataset. MAE is the mean absolute error over the synonym & antonym slice in the training tensor.

divided by the number of questions answered. *Recall* is the number of questions answered correctly divided by the total number of questions. BPMF (Bayesian Probabilistic Matrix Factorization) result is derived by only keeping the synonym & antonym slice in our BPTF model.

By using Roget's and WordNet together, our method increases the baseline look-up recall from 51% to 82% on the test set, while Yih's method increases the recall of Encarta from 56% to 80%. This state-of-the-art performance is achieved with the help of a neural network for fine tuning and multiple schemes of out-of-vocabulary embedding, while our method has inherent and straightforward "out-of-vocabulary embedding". While MRLSA, which has this character as well, only has a recall 77% when combining WordNet and Encarta together.

WordNet records less antonym relations for nouns, verbs and adverbs, while the GRE antonym questions has a large coverage of them. Although by extending these antonym relations using the "indirect antonym" concept achieves better look-up performance than Roget's, in contrast, the BPTF performance is actually much lower. This implies Roget's has better recording of antonym relations. Mohammad et al. (2008) reproted a 23% F-score look-up performance of WordNet which support this claim as well. Combining WordNet and Roget's together can improve the look-up performance further to 59% precision and 51% recall (still not as good as Encarta look-up).

Notably, if we strictly follow our BPTF approach but only use the synonym & antonym slice (i.e. a matrix factorization model instead of tensor factorization model), this single-slice model BPMF has performance that is only slightly better than look-up. Meanwhile Figure 1 shows the convergence curves of BPMF and BPTF. BPMF actually has lower MAE after convergence. Such behavior is caused by overfitting of BPMF on the training data. While known entries were recreated well, empty entries were not filled correctly. On the other hand, note that although our BPTF model has a higher MAE, it has much better performance in answering the GRE antonym questions. We interpret this as the regularization and generalization effect from other slice(s). Instead of focusing on one-slice training data, our model fills the missing entries with the help of inter-slice relations.

We also experimented with a linear metric learning method over the generated word vectors (to learn a metric matrix A to measure the word relatedness via $V_i^T A V_j$) using L-BFGS. By optimizing the mean square error on the synonym & antonym slice, we can reduce 8% of the mean square error on a held out test set, and improve the F-score by roughly 0.5% (of a single iteration). Although this method doesn't give a significant improvement, it is general and has the potential to boost the performance in other scenarios.

5 Conclusion

In this work, we propose a method to map words into a metric space automatically using thesaurus data, previous vector space models, or other word relatedness matrices as input, which is capable of handling out-of-vocabulary words of any particular perspective. This allows us to derive the relatedness of any given word pair and any perspective by the embedded word vectors with perperspective linear transformation. We evaluated the word embeddings with GRE antonym questions, and the result achieves the state-of-the-art performance.

For future works, we will extend the model and its applications in three main directions. First, in this model we only use a three-way tensor with two slices, while more relations may be able to add into it directly. Possible additional perspective slices include LSA for topic relatedness, and corpus occurrences in engineered or induced semantic patterns.

Second, we will apply the method to other tasks that require completing a word relatedness matrix. We evaluated the performance of our model on

creating / recreating one perspective of word relatedness: antonymy. Perhaps using vectors generated from many kinds of perspectives would improve the performance on other NLP tasks, such as term matching employed by textual entailment and machine translation metrics.

Third, if our model does learn the relation between semantic similarities and distributional similarities, there may be fruitful information contained in the vectors V_i and P_k that can be explored. One straight-forward idea is that the dot product of perspective vectors $P_k \cdot P_l$ should be a measurement of correlation between perspectives.

Also, a straightforward adaptation of our model has the potential ability to capture asymmetric word relatedness as well, by using a perperspective matrix instead of vector for the asymmetric slices (i.e. use $V_i^T A_k V_j$ instead of $\sum_{d=1}^{D} V_i^{(d)} P_k^{(d)} V_j^{(d)}$ for calculating word relatedness, where A_k is a square matrix).

GloVe: Global Vectors for Word Representation

Jeffrey Pennington, Richard Socher, Christopher D. Manning
Computer Science Department, Stanford University, Stanford, CA 94305
jpennin@stanford.edu, richard@socher.org, manning@stanford.edu

Abstract

Recent methods for learning vector space representations of words have succeeded in capturing fine-grained semantic and syntactic regularities using vector arithmetic, but the origin of these regularities has remained opaque. We analyze and make explicit the model properties needed for such regularities to emerge in word vectors. The result is a new global log-bilinear regression model that combines the advantages of the two major model families in the literature: global matrix factorization and local context window methods. Our model efficiently leverages statistical information by training only on the nonzero elements in a word-word co-occurrence matrix, rather than on the entire sparse matrix or on individual context windows in a large corpus. The model produces a vector space with meaningful substructure, as evidenced by its performance of 75% on a recent word analogy task. It also outperforms related models on similarity tasks and named entity recognition.

1 Introduction

Semantic vector space models of language represent each word with a real-valued vector. These vectors can be used as features in a variety of applications, such as information retrieval (Manning et al., 2008), document classification (Sebastiani, 2002), question answering (Tellex et al., 2003), named entity recognition (Turian et al., 2010), and parsing (Socher et al., 2013).

Most word vector methods rely on the distance or angle between pairs of word vectors as the primary method for evaluating the intrinsic quality of such a set of word representations. Recently, Mikolov et al. (2013c) introduced a new evaluation scheme based on word analogies that probes the finer structure of the word vector space by examining not the scalar distance between word vectors, but rather their various dimensions of difference. For example, the analogy "king is to queen as man is to woman" should be encoded in the vector space by the vector equation $king - queen = man - woman$. This evaluation scheme favors models that produce dimensions of meaning, thereby capturing the multi-clustering idea of distributed representations (Bengio, 2009).

The two main model families for learning word vectors are: 1) global matrix factorization methods, such as latent semantic analysis (LSA) (Deerwester et al., 1990) and 2) local context window methods, such as the skip-gram model of Mikolov et al. (2013c). Currently, both families suffer significant drawbacks. While methods like LSA efficiently leverage statistical information, they do relatively poorly on the word analogy task, indicating a sub-optimal vector space structure. Methods like skip-gram may do better on the analogy task, but they poorly utilize the statistics of the corpus since they train on separate local context windows instead of on global co-occurrence counts.

In this work, we analyze the model properties necessary to produce linear directions of meaning and argue that global log-bilinear regression models are appropriate for doing so. We propose a specific weighted least squares model that trains on global word-word co-occurrence counts and thus makes efficient use of statistics. The model produces a word vector space with meaningful substructure, as evidenced by its state-of-the-art performance of 75% accuracy on the word analogy dataset. We also demonstrate that our methods outperform other current methods on several word similarity tasks, and also on a common named entity recognition (NER) benchmark.

We provide the source code for the model as well as trained word vectors at `http://nlp.stanford.edu/projects/glove/`.

2 Related Work

Matrix Factorization Methods. Matrix factorization methods for generating low-dimensional word representations have roots stretching as far back as LSA. These methods utilize low-rank approximations to decompose large matrices that capture statistical information about a corpus. The particular type of information captured by such matrices varies by application. In LSA, the matrices are of "term-document" type, i.e., the rows correspond to words or terms, and the columns correspond to different documents in the corpus. In contrast, the Hyperspace Analogue to Language (HAL) (Lund and Burgess, 1996), for example, utilizes matrices of "term-term" type, i.e., the rows and columns correspond to words and the entries correspond to the number of times a given word occurs in the context of another given word.

A main problem with HAL and related methods is that the most frequent words contribute a disproportionate amount to the similarity measure: the number of times two words co-occur with *the* or *and*, for example, will have a large effect on their similarity despite conveying relatively little about their semantic relatedness. A number of techniques exist that addresses this shortcoming of HAL, such as the COALS method (Rohde et al., 2006), in which the co-occurrence matrix is first transformed by an entropy- or correlation-based normalization. An advantage of this type of transformation is that the raw co-occurrence counts, which for a reasonably sized corpus might span 8 or 9 orders of magnitude, are compressed so as to be distributed more evenly in a smaller interval. A variety of newer models also pursue this approach, including a study (Bullinaria and Levy, 2007) that indicates that positive pointwise mutual information (PPMI) is a good transformation. More recently, a square root type transformation in the form of Hellinger PCA (HPCA) (Lebret and Collobert, 2014) has been suggested as an effective way of learning word representations.

Shallow Window-Based Methods. Another approach is to learn word representations that aid in making predictions within local context windows. For example, Bengio et al. (2003) introduced a model that learns word vector representations as part of a simple neural network architecture for language modeling. Collobert and Weston (2008) decoupled the word vector training from the downstream training objectives, which paved the way for Collobert et al. (2011) to use the full context of a word for learning the word representations, rather than just the preceding context as is the case with language models.

Recently, the importance of the full neural network structure for learning useful word representations has been called into question. The skip-gram and continuous bag-of-words (CBOW) models of Mikolov et al. (2013a) propose a simple single-layer architecture based on the inner product between two word vectors. Mnih and Kavukcuoglu (2013) also proposed closely-related vector log-bilinear models, vLBL and ivLBL, and Levy et al. (2014) proposed explicit word embeddings based on a PPMI metric.

In the skip-gram and ivLBL models, the objective is to predict a word's context given the word itself, whereas the objective in the CBOW and vLBL models is to predict a word given its context. Through evaluation on a word analogy task, these models demonstrated the capacity to learn linguistic patterns as linear relationships between the word vectors.

Unlike the matrix factorization methods, the shallow window-based methods suffer from the disadvantage that they do not operate directly on the co-occurrence statistics of the corpus. Instead, these models scan context windows across the entire corpus, which fails to take advantage of the vast amount of repetition in the data.

3 The GloVe Model

The statistics of word occurrences in a corpus is the primary source of information available to all unsupervised methods for learning word representations, and although many such methods now exist, the question still remains as to how meaning is generated from these statistics, and how the resulting word vectors might represent that meaning. In this section, we shed some light on this question. We use our insights to construct a new model for word representation which we call GloVe, for Global Vectors, because the global corpus statistics are captured directly by the model.

First we establish some notation. Let the matrix of word-word co-occurrence counts be denoted by X, whose entries X_{ij} tabulate the number of times word j occurs in the context of word i. Let $X_i = \sum_k X_{ik}$ be the number of times any word appears in the context of word i. Finally, let $P_{ij} = P(j|i) = X_{ij}/X_i$ be the probability that word j appear in the

Table 1: Co-occurrence probabilities for target words *ice* and *steam* with selected context words from a 6 billion token corpus. Only in the ratio does noise from non-discriminative words like *water* and *fashion* cancel out, so that large values (much greater than 1) correlate well with properties specific to ice, and small values (much less than 1) correlate well with properties specific of steam.

Probability and Ratio	$k = solid$	$k = gas$	$k = water$	$k = fashion$
$P(k\|ice)$	1.9×10^{-4}	6.6×10^{-5}	3.0×10^{-3}	1.7×10^{-5}
$P(k\|steam)$	2.2×10^{-5}	7.8×10^{-4}	2.2×10^{-3}	1.8×10^{-5}
$P(k\|ice)/P(k\|steam)$	8.9	8.5×10^{-2}	1.36	0.96

context of word i.

We begin with a simple example that showcases how certain aspects of meaning can be extracted directly from co-occurrence probabilities. Consider two words i and j that exhibit a particular aspect of interest; for concreteness, suppose we are interested in the concept of thermodynamic phase, for which we might take $i = ice$ and $j = steam$. The relationship of these words can be examined by studying the ratio of their co-occurrence probabilities with various probe words, k. For words k related to ice but not steam, say $k = solid$, we expect the ratio P_{ik}/P_{jk} will be large. Similarly, for words k related to steam but not ice, say $k = gas$, the ratio should be small. For words k like *water* or *fashion*, that are either related to both ice and steam, or to neither, the ratio should be close to one. Table 1 shows these probabilities and their ratios for a large corpus, and the numbers confirm these expectations. Compared to the raw probabilities, the ratio is better able to distinguish relevant words (*solid* and *gas*) from irrelevant words (*water* and *fashion*) and it is also better able to discriminate between the two relevant words.

The above argument suggests that the appropriate starting point for word vector learning should be with ratios of co-occurrence probabilities rather than the probabilities themselves. Noting that the ratio P_{ik}/P_{jk} depends on three words i, j, and k, the most general model takes the form,

$$F(w_i, w_j, \tilde{w}_k) = \frac{P_{ik}}{P_{jk}}, \tag{1}$$

where $w \in \mathbb{R}^d$ are word vectors and $\tilde{w} \in \mathbb{R}^d$ are separate context word vectors whose role will be discussed in Section 4.2. In this equation, the right-hand side is extracted from the corpus, and F may depend on some as-of-yet unspecified parameters. The number of possibilities for F is vast, but by enforcing a few desiderata we can select a unique choice. First, we would like F to encode the information present the ratio P_{ik}/P_{jk} in the word vector space. Since vector spaces are inherently linear structures, the most natural way to do this is with vector differences. With this aim, we can restrict our consideration to those functions F that depend only on the difference of the two target words, modifying Eqn. (1) to,

$$F(w_i - w_j, \tilde{w}_k) = \frac{P_{ik}}{P_{jk}}. \tag{2}$$

Next, we note that the arguments of F in Eqn. (2) are vectors while the right-hand side is a scalar. While F could be taken to be a complicated function parameterized by, e.g., a neural network, doing so would obfuscate the linear structure we are trying to capture. To avoid this issue, we can first take the dot product of the arguments,

$$F\left((w_i - w_j)^T \tilde{w}_k\right) = \frac{P_{ik}}{P_{jk}}, \tag{3}$$

which prevents F from mixing the vector dimensions in undesirable ways. Next, note that for word-word co-occurrence matrices, the distinction between a word and a context word is arbitrary and that we are free to exchange the two roles. To do so consistently, we must not only exchange $w \leftrightarrow \tilde{w}$ but also $X \leftrightarrow X^T$. Our final model should be invariant under this relabeling, but Eqn. (3) is not. However, the symmetry can be restored in two steps. First, we require that F be a homomorphism between the groups $(\mathbb{R}, +)$ and $(\mathbb{R}_{>0}, \times)$, i.e.,

$$F\left((w_i - w_j)^T \tilde{w}_k\right) = \frac{F(w_i^T \tilde{w}_k)}{F(w_j^T \tilde{w}_k)}, \tag{4}$$

which, by Eqn. (3), is solved by,

$$F(w_i^T \tilde{w}_k) = P_{ik} = \frac{X_{ik}}{X_i}. \tag{5}$$

The solution to Eqn. (4) is $F = \exp$, or,

$$w_i^T \tilde{w}_k = \log(P_{ik}) = \log(X_{ik}) - \log(X_i). \tag{6}$$

Next, we note that Eqn. (6) would exhibit the exchange symmetry if not for the $\log(X_i)$ on the right-hand side. However, this term is independent of k so it can be absorbed into a bias b_i for w_i. Finally, adding an additional bias $\tilde{b}_k$ for $\tilde{w}_k$ restores the symmetry,

$$w_i^T \tilde{w}_k + b_i + \tilde{b}_k = \log(X_{ik}) \,. \tag{7}$$

Eqn. (7) is a drastic simplification over Eqn. (1), but it is actually ill-defined since the logarithm diverges whenever its argument is zero. One resolution to this issue is to include an additive shift in the logarithm, $\log(X_{ik}) \rightarrow \log(1 + X_{ik})$, which maintains the sparsity of X while avoiding the divergences. The idea of factorizing the log of the co-occurrence matrix is closely related to LSA and we will use the resulting model as a baseline in our experiments. A main drawback to this model is that it weighs all co-occurrences equally, even those that happen rarely or never. Such rare co-occurrences are noisy and carry less information than the more frequent ones — yet even just the zero entries account for 75–95% of the data in X, depending on the vocabulary size and corpus.

We propose a new weighted least squares regression model that addresses these problems. Casting Eqn. (7) as a least squares problem and introducing a weighting function $f(X_{ij})$ into the cost function gives us the model

$$J = \sum_{i,j=1}^{V} f\left(X_{ij}\right)\left(w_i^T \tilde{w}_j + b_i + \tilde{b}_j - \log X_{ij}\right)^2 \,, \tag{8}$$

where V is the size of the vocabulary. The weighting function should obey the following properties:

1. $f(0) = 0$. If f is viewed as a continuous function, it should vanish as $x \rightarrow 0$ fast enough that the $\lim_{x \rightarrow 0} f(x) \log^2 x$ is finite.

2. $f(x)$ should be non-decreasing so that rare co-occurrences are not overweighted.

3. $f(x)$ should be relatively small for large values of x, so that frequent co-occurrences are not overweighted.

Of course a large number of functions satisfy these properties, but one class of functions that we found to work well can be parameterized as,

$$f(x) = \begin{cases} (x/x_{\max})^\alpha & \text{if } x < x_{\max} \\ 1 & \text{otherwise} \end{cases} \,. \tag{9}$$

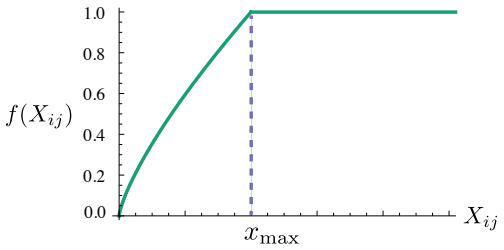

Figure 1: Weighting function f with $\alpha = 3/4$.

The performance of the model depends weakly on the cutoff, which we fix to $x_{\max} = 100$ for all our experiments. We found that $\alpha = 3/4$ gives a modest improvement over a linear version with $\alpha = 1$. Although we offer only empirical motivation for choosing the value 3/4, it is interesting that a similar fractional power scaling was found to give the best performance in (Mikolov et al., 2013a).

3.1 Relationship to Other Models

Because all unsupervised methods for learning word vectors are ultimately based on the occurrence statistics of a corpus, there should be commonalities between the models. Nevertheless, certain models remain somewhat opaque in this regard, particularly the recent window-based methods like skip-gram and ivLBL. Therefore, in this subsection we show how these models are related to our proposed model, as defined in Eqn. (8).

The starting point for the skip-gram or ivLBL methods is a model Q_{ij} for the probability that word j appears in the context of word i. For concreteness, let us assume that Q_{ij} is a softmax,

$$Q_{ij} = \frac{\exp(w_i^T \tilde{w}_j)}{\sum_{k=1}^{V} \exp(w_i^T \tilde{w}_k)} \,. \tag{10}$$

Most of the details of these models are irrelevant for our purposes, aside from the the fact that they attempt to maximize the log probability as a context window scans over the corpus. Training proceeds in an on-line, stochastic fashion, but the implied global objective function can be written as,

$$J = -\sum_{\substack{i \in \text{corpus} \\ j \in \text{context}(i)}} \log Q_{ij} \,. \tag{11}$$

Evaluating the normalization factor of the softmax for each term in this sum is costly. To allow for efficient training, the skip-gram and ivLBL models introduce approximations to Q_{ij}. However, the sum in Eqn. (11) can be evaluated much

more efficiently if we first group together those terms that have the same values for i and j,

$$J = -\sum_{i=1}^{V}\sum_{j=1}^{V} X_{ij} \log Q_{ij} \,, \tag{12}$$

where we have used the fact that the number of like terms is given by the co-occurrence matrix X.

Recalling our notation for $X_i = \sum_k X_{ik}$ and $P_{ij} = X_{ij}/X_i$, we can rewrite J as,

$$J = -\sum_{i=1}^{V} X_i \sum_{j=1}^{V} P_{ij} \log Q_{ij} = \sum_{i=1}^{V} X_i H(P_i, Q_i) \,, \tag{13}$$

where $H(P_i, Q_i)$ is the cross entropy of the distributions P_i and Q_i, which we define in analogy to X_i. As a weighted sum of cross-entropy error, this objective bears some formal resemblance to the weighted least squares objective of Eqn. (8). In fact, it is possible to optimize Eqn. (13) directly as opposed to the on-line training methods used in the skip-gram and ivLBL models. One could interpret this objective as a "global skip-gram" model, and it might be interesting to investigate further. On the other hand, Eqn. (13) exhibits a number of undesirable properties that ought to be addressed before adopting it as a model for learning word vectors.

To begin, cross entropy error is just one among many possible distance measures between probability distributions, and it has the unfortunate property that distributions with long tails are often modeled poorly with too much weight given to the unlikely events. Furthermore, for the measure to be bounded it requires that the model distribution Q be properly normalized. This presents a computational bottleneck owing to the sum over the whole vocabulary in Eqn. (10), and it would be desirable to consider a different distance measure that did not require this property of Q. A natural choice would be a least squares objective in which normalization factors in Q and P are discarded,

$$\hat{J} = \sum_{i,j} X_i \left(\hat{P}_{ij} - \hat{Q}_{ij}\right)^2 \tag{14}$$

where $\hat{P}_{ij} = X_{ij}$ and $\hat{Q}_{ij} = \exp(w_i^T \tilde{w}_j)$ are the unnormalized distributions. At this stage another problem emerges, namely that X_{ij} often takes very large values, which can complicate the optimization. An effective remedy is to minimize the squared error of the logarithms of $\hat{P}$ and $\hat{Q}$ instead,

$$\begin{aligned} \hat{J} &= \sum_{i,j} X_i \left(\log \hat{P}_{ij} - \log \hat{Q}_{ij}\right)^2 \\ &= \sum_{i,j} X_i \left(w_i^T \tilde{w}_j - \log X_{ij}\right)^2 . \end{aligned} \tag{15}$$

Finally, we observe that while the weighting factor X_i is preordained by the on-line training method inherent to the skip-gram and ivLBL models, it is by no means guaranteed to be optimal. In fact, Mikolov et al. (2013a) observe that performance can be increased by filtering the data so as to reduce the effective value of the weighting factor for frequent words. With this in mind, we introduce a more general weighting function, which we are free to take to depend on the context word as well. The result is,

$$\hat{J} = \sum_{i,j} f(X_{ij}) \left(w_i^T \tilde{w}_j - \log X_{ij}\right)^2 , \tag{16}$$

which is equivalent[1] to the cost function of Eqn. (8), which we derived previously.

3.2 Complexity of the model

As can be seen from Eqn. (8) and the explicit form of the weighting function $f(X)$, the computational complexity of the model depends on the number of nonzero elements in the matrix X. As this number is always less than the total number of entries of the matrix, the model scales no worse than $O(|V|^2)$. At first glance this might seem like a substantial improvement over the shallow window-based approaches, which scale with the corpus size, $|C|$. However, typical vocabularies have hundreds of thousands of words, so that $|V|^2$ can be in the hundreds of billions, which is actually much larger than most corpora. For this reason it is important to determine whether a tighter bound can be placed on the number of nonzero elements of X.

In order to make any concrete statements about the number of nonzero elements in X, it is necessary to make some assumptions about the distribution of word co-occurrences. In particular, we will assume that the number of co-occurrences of word i with word j, X_{ij}, can be modeled as a power-law function of the frequency rank of that word pair, r_{ij}:

$$X_{ij} = \frac{k}{(r_{ij})^\alpha} \,. \tag{17}$$

[1] We could also include bias terms in Eqn. (16).

The total number of words in the corpus is proportional to the sum over all elements of the co-occurrence matrix X,

$$|C| \sim \sum_{ij} X_{ij} = \sum_{r=1}^{|X|} \frac{k}{r^\alpha} = k H_{|X|,\alpha}\,, \qquad (18)$$

where we have rewritten the last sum in terms of the generalized harmonic number $H_{n,m}$. The upper limit of the sum, $|X|$, is the maximum frequency rank, which coincides with the number of nonzero elements in the matrix X. This number is also equal to the maximum value of r in Eqn. (17) such that $X_{ij} \geq 1$, i.e., $|X| = k^{1/\alpha}$. Therefore we can write Eqn. (18) as,

$$|C| \sim |X|^\alpha \, H_{|X|,\alpha}\,. \qquad (19)$$

We are interested in how $|X|$ is related to $|C|$ when both numbers are large; therefore we are free to expand the right hand side of the equation for large $|X|$. For this purpose we use the expansion of generalized harmonic numbers (Apostol, 1976),

$$H_{x,s} = \frac{x^{1-s}}{1-s} + \zeta(s) + O(x^{-s}) \quad \text{if} \quad s > 0,\, s \neq 1\,, \qquad (20)$$

giving,

$$|C| \sim \frac{|X|}{1-\alpha} + \zeta(\alpha)\,|X|^\alpha + O(1)\,, \qquad (21)$$

where $\zeta(s)$ is the Riemann zeta function. In the limit that X is large, only one of the two terms on the right hand side of Eqn. (21) will be relevant, and which term that is depends on whether $\alpha > 1$,

$$|X| = \begin{cases} O(|C|) & \text{if } \alpha < 1, \\ O(|C|^{1/\alpha}) & \text{if } \alpha > 1. \end{cases} \qquad (22)$$

For the corpora studied in this article, we observe that X_{ij} is well-modeled by Eqn. (17) with $\alpha = 1.25$. In this case we have that $|X| = O(|C|^{0.8})$. Therefore we conclude that the complexity of the model is much better than the worst case $O(V^2)$, and in fact it does somewhat better than the on-line window-based methods which scale like $O(|C|)$.

4 Experiments

4.1 Evaluation methods

We conduct experiments on the word analogy task of Mikolov et al. (2013a), a variety of word similarity tasks, as described in (Luong et al., 2013), and on the CoNLL-2003 shared benchmark dataset for NER (Tjong Kim Sang and De Meulder, 2003).

Table 2: Results on the word analogy task, given as percent accuracy. Underlined scores are best within groups of similarly-sized models; bold scores are best overall. HPCA vectors are publicly available[2]; (i)vLBL results are from (Mnih et al., 2013); skip-gram (SG) and CBOW results are from (Mikolov et al., 2013a,b); we trained SG† and CBOW† using the `word2vec` tool[3]. See text for details and a description of the SVD models.

Model	Dim.	Size	Sem.	Syn.	Tot.
ivLBL	100	1.5B	55.9	50.1	53.2

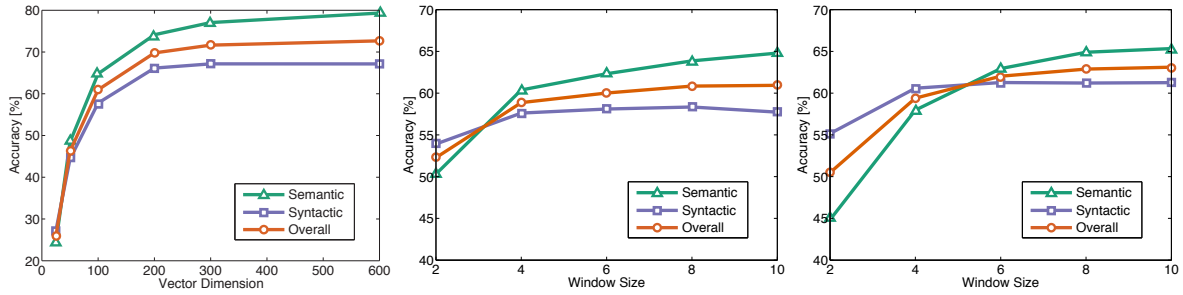
Word analogies. The word analogy task consists of questions like, "a is to b as c is to __?" The dataset contains 19,544 such questions, divided into a semantic subset and a syntactic subset. The semantic questions are typically analogies about people or places, like "Athens is to Greece as Berlin is to __?". The syntactic questions are typically analogies about verb tenses or forms of adjectives, for example "dance is to dancing as fly is to __?". To correctly answer the question, the model should uniquely identify the missing term, with only an exact correspondence counted as a correct match. We answer the question "a is to b as c is to __?" by finding the word d whose representation w_d is closest to $w_b - w_a + w_c$ according to the cosine similarity.[4]

[2] http://lebret.ch/words/

[3] http://code.google.com/p/word2vec/

[4] Levy et al. (2014) introduce a multiplicative analogy evaluation, 3CosMul, and report an accuracy of 68.24% on



(a) Symmetric context (b) Symmetric context (c) Asymmetric context

Figure 2: Accuracy on the analogy task as function of vector size and window size/type. All models are trained on the 6 billion token corpus. In (a), the window size is 10. In (b) and (c), the vector size is 100.

Word similarity. While the analogy task is our primary focus since it tests for interesting vector space substructures, we also evaluate our model on a variety of word similarity tasks in Table 3. These include WordSim-353 (Finkelstein et al., 2001), MC (Miller and Charles, 1991), RG (Rubenstein and Goodenough, 1965), SCWS (Huang et al., 2012), and RW (Luong et al., 2013).

Named entity recognition. The CoNLL-2003 English benchmark dataset for NER is a collection of documents from Reuters newswire articles, annotated with four entity types: person, location, organization, and miscellaneous. We train models on CoNLL-03 training data on test on three datasets: 1) ConLL-03 testing data, 2) ACE Phase 2 (2001-02) and ACE-2003 data, and 3) MUC7 Formal Run test set. We adopt the BIO2 annotation standard, as well as all the preprocessing steps described in (Wang and Manning, 2013). We use a comprehensive set of discrete features that comes with the standard distribution of the Stanford NER model (Finkel et al., 2005). A total of 437,905 discrete features were generated for the CoNLL-2003 training dataset. In addition, 50-dimensional vectors for each word of a five-word context are added and used as continuous features. With these features as input, we trained a conditional random field (CRF) with exactly the same setup as the CRF_{join} model of (Wang and Manning, 2013).

4.2 Corpora and training details

We trained our model on five corpora of varying sizes: a 2010 Wikipedia dump with 1 billion tokens; a 2014 Wikipedia dump with 1.6 billion tokens; Gigaword 5 which has 4.3 billion tokens; the combination Gigaword5 + Wikipedia2014, which has 6 billion tokens; and on 42 billion tokens of web data, from Common Crawl[5]. We tokenize and lowercase each corpus with the Stanford tokenizer, build a vocabulary of the 400,000 most frequent words[6], and then construct a matrix of co-occurrence counts X. In constructing X, we must choose how large the context window should be and whether to distinguish left context from right context. We explore the effect of these choices below. In all cases we use a decreasing weighting function, so that word pairs that are d words apart contribute $1/d$ to the total count. This is one way to account for the fact that very distant word pairs are expected to contain less relevant information about the words' relationship to one another.

For all our experiments, we set $x_{\text{max}} = 100$, $\alpha = 3/4$, and train the model using AdaGrad (Duchi et al., 2011), stochastically sampling nonzero elements from X, with initial learning rate of 0.05. We run 50 iterations for vectors smaller than 300 dimensions, and 100 iterations otherwise (see Section 4.6 for more details about the convergence rate). Unless otherwise noted, we use a context of ten words to the left and ten words to the right.

The model generates two sets of word vectors, W and $\tilde{W}$. When X is symmetric, W and $\tilde{W}$ are equivalent and differ only as a result of their random initializations; the two sets of vectors should perform equivalently. On the other hand, there is evidence that for certain types of neural networks, training multiple instances of the network and then combining the results can help reduce overfitting and noise and generally improve results (Ciresan et al., 2012). With this in mind, we choose to use

the analogy task. This number is evaluated on a subset of the dataset so it is not included in Table 2. 3CosMul performed worse than cosine similarity in almost all of our experiments.

[5]To demonstrate the scalability of the model, we also trained it on a much larger sixth corpus, containing 840 billion tokens of web data, but in this case we did not lowercase the vocabulary, so the results are not directly comparable.

[6]For the model trained on Common Crawl data, we use a larger vocabulary of about 2 million words.

the sum $W + \tilde{W}$ as our word vectors. Doing so typically gives a small boost in performance, with the biggest increase in the semantic analogy task.

We compare with the published results of a variety of state-of-the-art models, as well as with our own results produced using the `word2vec` tool and with several baselines using SVDs. With `word2vec`, we train the skip-gram (SG†) and continuous bag-of-words (CBOW†) models on the 6 billion token corpus (Wikipedia 2014 + Gigaword 5) with a vocabulary of the top 400,000 most frequent words and a context window size of 10. We used 10 negative samples, which we show in Section 4.6 to be a good choice for this corpus.

For the SVD baselines, we generate a truncated matrix X_{trunc} which retains the information of how frequently each word occurs with only the top 10,000 most frequent words. This step is typical of many matrix-factorization-based methods as the extra columns can contribute a disproportionate number of zero entries and the methods are otherwise computationally expensive.

The singular vectors of this matrix constitute the baseline "SVD". We also evaluate two related baselines: "SVD-S" in which we take the SVD of $\sqrt{X_{\text{trunc}}}$, and "SVD-L" in which we take the SVD of $\log(1+X_{\text{trunc}})$. Both methods help compress the otherwise large range of values in X.[7]

4.3 Results

We present results on the word analogy task in Table 2. The GloVe model performs significantly better than the other baselines, often with smaller vector sizes and smaller corpora. Our results using the `word2vec` tool are somewhat better than most of the previously published results. This is due to a number of factors, including our choice to use negative sampling (which typically works better than the hierarchical softmax), the number of negative samples, and the choice of the corpus.

We demonstrate that the model can easily be trained on a large 42 billion token corpus, with a substantial corresponding performance boost. We note that increasing the corpus size does not guarantee improved results for other models, as can be seen by the decreased performance of the SVD-L model on this larger corpus. The fact that this basic SVD model does not scale well to large corpora lends further evidence to the necessity of the type of weighting scheme proposed in our model.

Table 3: Spearman rank correlation on word similarity tasks. All vectors are 300-dimensional. The CBOW* vectors are from the `word2vec` website and differ in that they contain phrase vectors.

Model	Size	WS353	MC	RG	SCWS	RW
SVD	6B	35.3	35.1	42.5	38.3	25.6
SVD-S	6B	56.5	71.5	71.0	53.6	34.7
SVD-L	6B	65.7	72.7	75.1	56.5	37.0
CBOW†	6B	57.2	65.6	68.2	57.0	32.5
SG†	6B	62.8	65.2	69.7	58.1	37.2
GloVe	6B	65.8	72.7	77.8	53.9	38.1
SVD-L	42B	74.0	76.4	74.1	58.3	39.9
GloVe	42B	**75.9**	**83.6**	**82.9**	**59.6**	**47.8**
CBOW*	100B	68.4	79.6	75.4	59.4	45.5

Table 3 shows results on five different word similarity datasets. A similarity score is obtained from the word vectors by first normalizing each feature across the vocabulary and then calculating the cosine similarity. We compute Spearman's rank correlation coefficient between this score and the human judgments. CBOW* denotes the vectors available on the `word2vec` website that are trained with word and phrase vectors on 100B words of news data. GloVe outperforms it while using a corpus less than half the size.

Table 4 shows results on the NER task with the CRF-based model. The L-BFGS training terminates when no improvement has been achieved on the dev set for 25 iterations. Otherwise all configurations are identical to those used by Wang and Manning (2013). The model labeled *Discrete* is the baseline using a comprehensive set of discrete features that comes with the standard distribution of the Stanford NER model, but with no word vector features. In addition to the HPCA and SVD models discussed previously, we also compare to the models of Huang et al. (2012) (HSMN) and Collobert and Weston (2008) (CW). We trained the CBOW model using the `word2vec` tool[8]. The GloVe model outperforms all other methods on all evaluation metrics, except for the CoNLL test set, on which the HPCA method does slightly better. We conclude that the GloVe vectors are useful in downstream NLP tasks, as was first

[7] We also investigated several other weighting schemes for transforming X; what we report here performed best. Many weighting schemes like PPMI destroy the sparsity of X and therefore cannot feasibly be used with large vocabularies. With smaller vocabularies, these information-theoretic transformations do indeed work well on word similarity measures, but they perform very poorly on the word analogy task.

[8] We use the same parameters as above, except in this case we found 5 negative samples to work slightly better than 10.

Table 4: F1 score on NER task with 50d vectors. *Discrete* is the baseline without word vectors. We use publicly-available vectors for HPCA, HSMN, and CW. See text for details.

4.4 Model Analysis: Vector Length and Context Size

In Fig. 2, we show the results of experiments that vary vector length and context window. A context window that extends to the left and right of a target word will be called symmetric, and one which extends only to the left will be called asymmetric. In (a), we observe diminishing returns for vectors larger than about 200 dimensions. In (b) and (c), we examine the effect of varying the window size for symmetric and asymmetric context windows. Performance is better on the syntactic subtask for small and asymmetric context windows, which aligns with the intuition that syntactic information is mostly drawn from the immediate context and can depend strongly on word order. Semantic information, on the other hand, is more frequently non-local, and more of it is captured with larger window sizes.

4.5 Model Analysis: Corpus Size

In Fig. 3, we show performance on the word analogy task for 300-dimensional vectors trained on different corpora. On the syntactic subtask, there is a monotonic increase in performance as the corpus size increases. This is to be expected since larger corpora typically produce better statistics. Interestingly, the same trend is not true for the semantic subtask, where the models trained on the smaller Wikipedia corpora do better than those trained on the larger Gigaword corpus. This is likely due to the large number of city- and country-based analogies in the analogy dataset and the fact that Wikipedia has fairly comprehensive articles for most such locations. Moreover, Wikipedia's

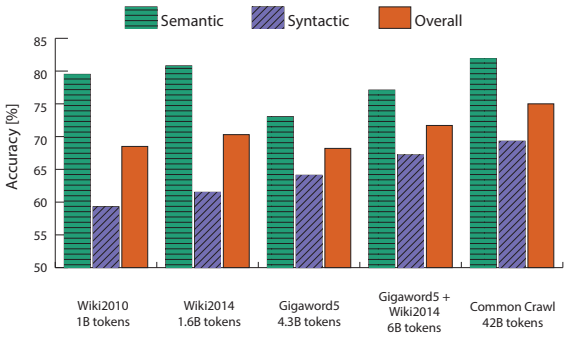

Figure 3: Accuracy on the analogy task for 300-dimensional vectors trained on different corpora.

entries are updated to assimilate new knowledge, whereas Gigaword is a fixed news repository with outdated and possibly incorrect information.

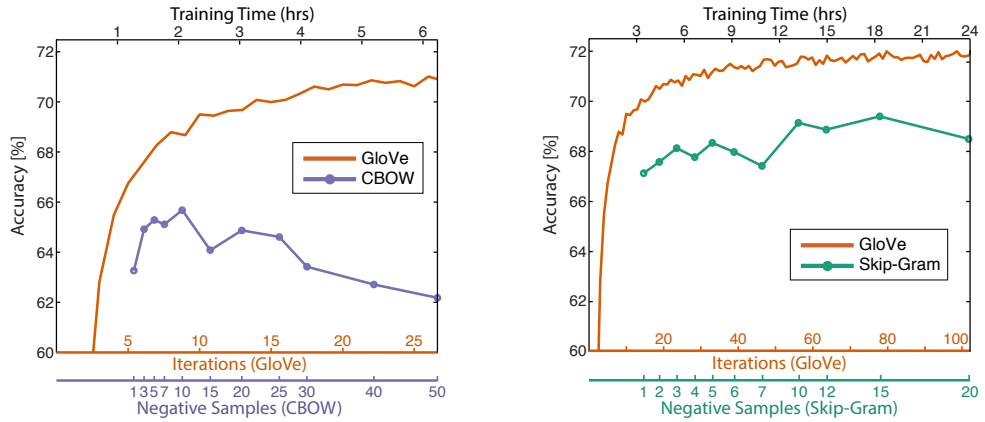
4.6 Model Analysis: Run-time

The total run-time is split between populating X and training the model. The former depends on many factors, including window size, vocabulary size, and corpus size. Though we did not do so, this step could easily be parallelized across multiple machines (see, e.g., Lebret and Collobert (2014) for some benchmarks). Using a single thread of a dual 2.1GHz Intel Xeon E5-2658 machine, populating X with a 10 word symmetric context window, a 400,000 word vocabulary, and a 6 billion token corpus takes about 85 minutes. Given X, the time it takes to train the model depends on the vector size and the number of iterations. For 300-dimensional vectors with the above settings (and using all 32 cores of the above machine), a single iteration takes 14 minutes. See Fig. 4 for a plot of the learning curve.

4.7 Model Analysis: Comparison with `word2vec`

A rigorous quantitative comparison of GloVe with `word2vec` is complicated by the existence of many parameters that have a strong effect on performance. We control for the main sources of variation that we identified in Sections 4.4 and 4.5 by setting the vector length, context window size, corpus, and vocabulary size to the configuration mentioned in the previous subsection.

The most important remaining variable to control for is training time. For GloVe, the relevant parameter is the number of training iterations. For `word2vec`, the obvious choice would be the number of training epochs. Unfortunately, the code is currently designed for only a single epoch:



(a) GloVe vs CBOW (b) GloVe vs Skip-Gram

Figure 4: Overall accuracy on the word analogy task as a function of training time, which is governed by the number of iterations for GloVe and by the number of negative samples for CBOW (a) and skip-gram (b). In all cases, we train 300-dimensional vectors on the same 6B token corpus (Wikipedia 2014 + Gigaword 5) with the same 400,000 word vocabulary, and use a symmetric context window of size 10.

it specifies a learning schedule specific to a single pass through the data, making a modification for multiple passes a non-trivial task. Another choice is to vary the number of negative samples. Adding negative samples effectively increases the number of training words seen by the model, so in some ways it is analogous to extra epochs.

We set any unspecified parameters to their default values, assuming that they are close to optimal, though we acknowledge that this simplification should be relaxed in a more thorough analysis.

In Fig. 4, we plot the overall performance on the analogy task as a function of training time. The two x-axes at the bottom indicate the corresponding number of training iterations for GloVe and negative samples for `word2vec`. We note that `word2vec`'s performance actually decreases if the number of negative samples increases beyond about 10. Presumably this is because the negative sampling method does not approximate the target probability distribution well.[9]

For the same corpus, vocabulary, window size, and training time, GloVe consistently outperforms `word2vec`. It achieves better results faster, and also obtains the best results irrespective of speed.

5 Conclusion

Recently, considerable attention has been focused on the question of whether distributional word representations are best learned from count-based methods or from prediction-based methods. Currently, prediction-based models garner substantial support; for example, Baroni et al. (2014) argue that these models perform better across a range of tasks. In this work we argue that the two classes of methods are not dramatically different at a fundamental level since they both probe the underlying co-occurrence statistics of the corpus, but the efficiency with which the count-based methods capture global statistics can be advantageous. We construct a model that utilizes this main benefit of count data while simultaneously capturing the meaningful linear substructures prevalent in recent log-bilinear prediction-based methods like `word2vec`. The result, GloVe, is a new global log-bilinear regression model for the unsupervised learning of word representations that outperforms other models on word analogy, word similarity, and named entity recognition tasks.

[9] In contrast, noise-contrastive estimation is an approximation which improves with more negative samples. In Table 1 of (Mnih et al., 2013), accuracy on the analogy task is a non-decreasing function of the number of negative samples.

Abstract

We introduce a novel compositional language model that works on Predicate-Argument Structures (PASs). Our model jointly learns word representations and their composition functions using bag-of-words and dependency-based contexts. Unlike previous word-sequence-based models, our PAS-based model composes arguments into predicates by using the category information from the PAS. This enables our model to capture long-range dependencies between words and to better handle constructs such as verb-object and subject-verb-object relations. We verify this experimentally using two phrase similarity datasets and achieve results comparable to or higher than the previous best results. Our system achieves these results without the need for pre-trained word vectors and using a much smaller training corpus; despite this, for the subject-verb-object dataset our model improves upon the state of the art by as much as $\sim$10% in relative performance.

1 Introduction

Studies on embedding single words in a vector space have made notable successes in capturing their syntactic and semantic properties (Turney and Pantel, 2010). These embeddings have also been found to be a useful component for Natural Language Processing (NLP) systems; for example, Turian et al. (2010) and Collobert et al. (2011) demonstrated how low-dimensional word vectors learned by Neural Network Language Models (NNLMs) are beneficial for a wide range of NLP tasks.

Recently, the main focus of research on vector space representation is shifting from word representations to phrase representations (Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Mitchell and Lapata, 2010; Socher et al., 2012). Combining the ideas of NNLMs and semantic composition, Tsubaki et al. (2013) introduced a novel NNLM incorporating verb-object dependencies. More recently, Levy and Goldberg (2014) presented a NNLM that integrated syntactic dependencies. However, to the best of our knowledge, there is no previous work on integrating a variety of syntactic and semantic dependencies into NNLMs in order to learn *composition functions* as well as word representations. The following question thus arises naturally:

> Can a variety of dependencies be used to jointly learn both stand-alone word vectors and their compositions, embedding them in the same vector space?

In this work, we bridge the gap between purely context-based (Levy and Goldberg, 2014; Mikolov et al., 2013b; Mnih and Kavukcuoglu, 2013) and compositional (Tsubaki et al., 2013) NNLMs by using the flexible set of categories from Predicate-Argument-Structures (PASs). More specifically, we propose a Compositional Log-Bilinear Language Model using PASs (PAS-CLBLM), an overview of which is shown in Figure 1. The model is trained by maximizing the accuracy of predicting target words from their bag-of-words *and* dependency-based context, which provides information about selectional preference. As shown in Figure 1 (b), one of the advantages of the PAS-CLBLM is that the model can treat not only word vectors but also composed vectors as contexts. Since the composed vectors

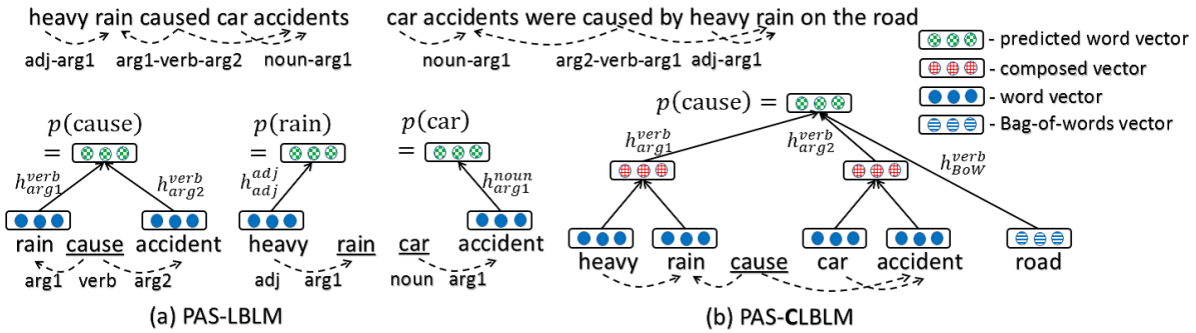

Figure 1: An overview of the proposed model: PAS-CLBLM. (a) The PAS-LBLM predicts target words from their bag-of-words and dependency-based context words. (b) The PAS-CLBLM predicts target words using not only context words but also composed vector representations derived from another level of predicate-argument structures. Underlined words are target words and we only depict the bag-of-words vector for the PAS-CLBLM.

are treated as input to the language model in the same way as word vectors, these composed vectors are expected to become similar to word vectors for words with similar meanings.

Our empirical results demonstrate that the proposed model has the ability to learn meaningful representations for adjective-noun, noun-noun, and (subject-) verb-object dependencies. On three tasks of measuring the semantic similarity between short phrases (adjective-noun, noun-noun, and verb-object), the learned composed vectors achieve scores (Spearman's rank correlation ρ) comparable to or higher than those of previous models. On a task involving more complex phrases (subject-verb-object), our learned composed vectors achieve state-of-the-art performance ($\rho = 0.50$) with a training corpus that is an order of magnitude smaller than that used by previous work (Tsubaki et al., 2013; Van de Cruys et al., 2013). Moreover, the proposed model does not require any pre-trained word vectors produced by external models, but rather induces word vectors jointly while training.

2 Related Work

There is a large body of work on how to represent the meaning of a word in a vector space. Distributional approaches assume that the meaning of a word is determined by the contexts in which it appears (Firth, 1957). The context of a word is often defined as the words appearing in a window of fixed-length (bag-of-words) and a simple approach is to treat the co-occurrence statistics of a word w as a vector representation for w (Mitchell and Lapata, 2008; Mitchell and Lapata, 2010); alternatively, dependencies between words can be used to define contexts (Goyal et al., 2013; Erk and Padó, 2008; Thater et al., 2010).

In contrast to distributional representations, NNLMs represent words in a low-dimensional vector space (Bengio et al., 2003; Collobert et al., 2011). Recently, Mikolov et al. (2013b) and Mnih and Kavukcuoglu (2013) proposed highly scalable models to learn high-dimensional word vectors. Levy and Goldberg (2014) extended the model of Mikolov et al. (2013b) by treating syntactic dependencies as contexts.

Mitchell and Lapata (2008) investigated a variety of compositional operators to combine word vectors into phrasal representations. Among these operators, simple element-wise addition and multiplication are now widely used to represent short phrases (Mitchell and Lapata, 2010; Blacoe and Lapata, 2012). The obvious limitation with these simple approaches is that information about word order and syntactic relations is lost.

To incorporate syntactic information into composition functions, a variety of compositional models have been proposed. These include recursive neural networks using phrase-structure trees (Socher et al., 2012; Socher et al., 2013b) and models in which words have a specific form of parameters according to their syntactic roles and composition functions are syntactically dependent on the relations of input words (Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Hashimoto et al., 2013; Hermann and Blunsom, 2013; Socher et al., 2013a).

More recently, syntactic dependency-based

compositional models have been proposed (Paperno et al., 2014; Socher et al., 2014; Tsubaki et al., 2013). One of the advantages of these models is that they are less restricted by word order. Among these, Tsubaki et al. (2013) introduced a novel compositional NNLM mainly focusing on verb-object dependencies and achieved state-of-the-art performance for the task of measuring the semantic similarity between subject-verb-object phrases.

3 PAS-CLBLM: A Compositional Log-Bilinear Language Model Using Predicate-Argument Structures

In some recent studies on representing words as vectors, word vectors are learned by solving word prediction tasks (Mikolov et al., 2013a; Mnih and Kavukcuoglu, 2013). More specifically, given target words and their context words, the basic idea is to train classifiers to discriminate between each target word and artificially induced negative target words. The feature vector of the classifiers are calculated using the context word vectors whose values are optimized during training. As a result, vectors of words in similar contexts become similar to each other.

Following these studies, we propose a novel model to jointly learn representations for words and their compositions by training word prediction classifiers using PASs. In this section, we first describe the predicate-argument structures as they serve as the basis of our model. We then introduce a Log-Bilinear Language Model using Predicate-Argument Structures (PAS-LBLM) to learn word representations using both bag-of-words and dependency-based contexts. Finally, we propose integrating compositions of words into the model. Figure 1 (b) shows the overview of the proposed model.

3.1 Predicate-Argument Structures

Due to advances in deep parsing technologies, syntactic parsers that can produce predicate-argument structures are becoming accurate and fast enough to be used for practical applications. In this work, we use the probabilistic HPSG parser *Enju* (Miyao and Tsujii, 2008) to obtain the predicate-argument structures of individual sentences. In its grammar, each word in a sentence is treated as a predicate of a certain category with zero or more arguments. Table 1 shows some examples of predicates of different categories.[1] For example, a predicate of the category *verb_arg12* expresses a verb with two arguments. A graph can be constructed by connecting words in predicate-argument structures in a sentence; in general, these graphs are acyclic.

Category	predicate	arg1	arg2
adj_arg1	heavy	rain	
noun_arg1	car	accident	
verb_arg12	cause	rain	accident
prep_arg12	at	eat	restaurant

Table 1: Examples of predicates of different categories from the grammar of the Enju parser. *arg1* and *arg2* denote the first and second arguments.

One of the merits of using predicate-argument structures is that they can capture dependencies between more than two words, while standard syntactic dependency structures are limited to dependencies between two words. For example, one of the predicates in the phrase "heavy rain caused car accidents" is the verb "cause", and it has two arguments ("rain" and "accident"). Furthermore, exactly the same predicate-argument structure (predicate: cause, first argument: rain, second argument: accident) is extracted from the passive form of the above phrase: "car accidents were caused by heavy rain". This is helpful when capturing semantic dependencies between predicates and arguments, and in extracting facts or relations described in a sentence, such as *who did what to whom*.

3.2 A Log-Bilinear Language Model Using Predicate-Argument Structures

3.2.1 PAS-based Word Prediction

The PAS-LBLM predicts a target word given its PAS-based context. We assume that each word w in the vocabulary $\mathbb{V}$ is represented with a d-dimensional vector $v(w)$. When a predicate of category c is extracted from a sentence, the PAS-LBLM computes the predicted d-dimensional vector $p(w_t)$ for the target word w_t from its context words $w_1, w_2, \ldots, w_m$:

$$p(w_t) = f\left(\sum_{i=1}^{m} h_i^c \odot v(w_i)\right), \qquad (1)$$

[1] The categories of the predicates in the Enju parser are summarized at `http://kmcs.nii.ac.jp/~yusuke/enju/enju-manual/enju-output-spec.html`.

where $h_i^c \in \mathbb{R}^{d \times 1}$ are category-specific weight vectors and $\odot$ denotes element-wise multiplication. f is a non-linearity function; in this work we define f as $\tanh$.

As an example following Figure 1 (a), when the predicate "cause" is extracted with its first and second arguments "rain" and "accident", the PAS-LBLM computes $p(\text{cause}) \in \mathbb{R}^d$ following Eq. (1):

$$p(\text{cause}) = f(h_{\text{arg1}}^{\text{verb\_arg12}} \odot v(\text{rain}) + h_{\text{arg2}}^{\text{verb\_arg12}} \odot v(\text{accident})). \quad (2)$$

In Eq. (2), the predicate is treated as the target word, and its arguments are treated as the context words. In the same way, an argument can be treated as a target word:

$$p(\text{rain}) = f(h_{\text{verb}}^{\text{verb\_arg12}} \odot v(\text{cause}) + h_{\text{arg2}}^{\text{verb\_arg12}} \odot v(\text{accident})). \quad (3)$$

Relationship to previous work. If we omit the the category-specific weight vectors h_i^c in Eq. (1), our model is similar to the CBOW model in Mikolov et al. (2013a). CBOW predicts a target word given its surrounding bag-of-words context, while our model uses its PAS-based context. To incorporate the PAS information in our model more efficiently, we use category-specific weight vectors. Similarly, the vLBL model of Mnih and Kavukcuoglu (2013) uses different weight vectors depending on the position relative to the target word. As with previous neural network language models (Collobert et al., 2011; Huang et al., 2012), our model and vLBL can use weight matrices rather than weight vectors. However, as discussed by Mnih and Teh (2012), using weight vectors makes the training significantly faster than using weight matrices. Despite the simple formulation of the element-wise operations, the category-specific weight vectors efficiently propagate PAS-based context information as explained next.

3.2.2 Training Word Vectors

To train the PAS-LBLM, we use a scoring function to evaluate how well the target word w_t fits the given context:

$$s(w_t, p(w_t)) = \tilde{v}(w_t)^{\mathrm{T}} p(w_t), \quad (4)$$

where $\tilde{v}(w_t) \in \mathbb{R}^{d \times 1}$ is the scoring weight vector for w_t. Thus, the model parameters in the PAS-LBLM are $(V, \tilde{V}, H)$. V is the set of word vectors $v(w)$, and $\tilde{V}$ is the set of scoring weight vectors $\tilde{v}(w)$. H is the set of the predicate-category-specific weight vectors h_i^c.

Based on the objective in the model of Collobert et al. (2011), the model parameters are learned by minimizing the following hinge loss:

$$\sum_{n=1}^{N} \max(1 - s(w_t, p(w_t)) + s(w_n, p(w_t)), 0), \quad (5)$$

where the negative sample w_n is a randomly sampled word other than w_t, and N is the number of negative samples. In our experiments we set $N = 1$. Following Mikolov et al. (2013b), negative samples were drawn from the distribution over unigrams that we raise to the power 0.75 and then normalize to once again attain a probability distribution. We minimize the loss function in Eq. (5) using AdaGrad (Duchi et al., 2011). For further training details, see Section 4.5.

Relationship to softmax regression models. The model parameters can be learned by maximizing the log probability of the target word w_t based on the softmax function:

$$p(w_t|context) = \frac{\exp(s(w_t, p(w_t)))}{\sum_{i=1}^{|\mathbb{V}|} \exp(s(w_i, p(w_t)))}. \quad (6)$$

This is equivalent to a softmax regression model. However, when the vocabulary $\mathbb{V}$ is large, computing the softmax function in Eq. (6) is computationally expensive. If we do not need probability distributions over words, we are not necessarily restricted to using the probabilistic expressions. Recently, several methods have been proposed to efficiently learn word representations rather than accurate language models (Collobert et al., 2011; Mikolov et al., 2013b; Mnih and Kavukcuoglu, 2013), and our objective follows the work of Collobert et al. (2011). Mikolov et al. (2013b) and Mnih and Kavukcuoglu (2013) trained their models using word-dependent scoring weight vectors which are the arguments of our scoring function in Eq. (4). During development we also trained our model using the negative sampling technique of Mikolov et al. (2013b); however, we did not observe any significant performance difference.

Intuition behind the PAS-LBLM. Here we briefly explain how each class of the model parameters of the PAS-LBLM contributes to learning word representations at each stochastic gradient

decent step. The category-specific weight vectors provide the PAS information for context word vectors which we would like to learn. During training, context word vectors having the same PAS-based syntactic roles are updated similarly. The word-dependent scoring weight vectors propagate the information on which words should, or should not, be predicted. In effect, context word vectors making similar contributions to word predictions are updated similarly. The non-linear function f provides context words with information on the other context words in the same PAS. In this way, word vectors are expected to be learned efficiently by the PAS-LBLM.

3.3 Learning Composition Functions

As explained in Section 3.1, predicate-argument structures inherently form graphs whose nodes are words in a sentence. Using the graphs, we can integrate relationships between multiple predicate-argument structures into our model.

When the context word w_i in Eq. (1), excluding predicate words, has another predicate-argument of category c' as a dependency, we replace $v(w_i)$ with the vector produced by the composition function for the predicate category c'. For example, as shown in Figure 1 (b), when the first argument "rain" of the predicate "cause" is also the argument of the predicate "heavy", we first compute the d-dimensional composed vector representation for "heavy" and "rain":

$$g_{c'}(v(\mathrm{heavy}), v(\mathrm{rain})), \tag{7}$$

where c' is the category *adj_arg1*, and $g_{c'}$ is a function to combine input vectors for the predicate-category c'. We can use any composition function that produces a representation of the same dimensionality as its inputs, such as element-wise addition/multiplication (Mitchell and Lapata, 2008) or neural networks (Socher et al., 2012). We then replace $v(\mathrm{rain})$ in Eq. (2) with $g_{c'}(v(\mathrm{heavy}), v(\mathrm{rain}))$. When the second argument "accident" in Eq. (2) is also the argument of the predicate "car", $v(\mathrm{accident})$ is replaced with $g_{c''}(v(\mathrm{car}), v(\mathrm{accident}))$. c'' is the predicate category *noun_arg1*. These multiple relationships of predicate-argument structures should provide richer context information. We refer to the PAS-LBLM with composition functions as PAS-**C**LBLM.

3.4 Bag-of-Words Sensitive PAS-CLBLM

Both the PAS-LBLM and PAS-CLBLM can take meaningful relationships between words into account. However, at times, the number of context words can be limited and the ability of other models to take ten or more words from a fixed context in a bag-of-words (BoW) fashion could compensate for this sparseness. Huang et al. (2012) combined local and global contexts in their neural network language models, and motivated by their work, we integrate bag-of-words vectors into our models. Concretely, we add an additional input term to Eq. (1):

$$p(w_t) = f\left(\sum_{i=1}^{m} h_i^c \odot v(w_i) + h_{\mathrm{BoW}}^c \odot v(\mathrm{BoW})\right), \tag{8}$$

where $h_{\mathrm{BoW}}^c \in \mathbb{R}^{d\times 1}$ are additional weight vectors, and $v(\mathrm{BoW}) \in \mathbb{R}^{d\times 1}$ is the average of the word vectors in the same sentence. To construct the $v(\mathrm{BoW})$ for each sentence, we average the word vectors of nouns and verbs in the same sentence, excluding the target and context words.

4 Experimental Settings

4.1 Training Corpus

We used the British National Corpus (BNC) as our training corpus, extracted 6 million sentences from the original BNC files, and parsed them using the Enju parser described in Section 3.1.

4.2 Word Sense Disambiguation Using Part-of-Speech Tags

In general, words can have multiple syntactic usages. For example, the word *cause* can be a noun or a verb depending on its context. Most of the previous work on learning word vectors ignores this ambiguity since word sense disambiguation could potentially be performed after the word vectors have been trained (Huang et al., 2012; Kartsaklis and Sadrzadeh, 2013). Some recent work explicitly assigns an independent vector for each word usage according to its part-of-speech (POS) tag (Hashimoto et al., 2013; Kartsaklis and Sadrzadeh, 2013). Alternatively, Baroni and Zamparelli (2010) assigned different forms of parameters to adjectives and nouns.

In our experiments, we combined each word with its corresponding POS tags. We used the base-forms provided by the Enju parser rather than

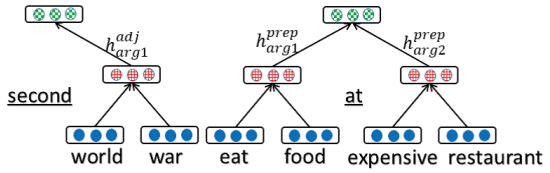

Figure 2: Two PAS-CLBLM training samples.

the surface-forms, and used the first two characters of the POS tags. For example, *VB*, *VBP*, *VBZ*, *VBG*, *VBD*, *VBN* were all mapped to *VB*. This resulted in two kinds of *cause*: *cause_NN* and *cause_VB* and we used the 100,000 most frequent lowercased word-POS pairs in the BNC.

4.3 Selection of Training Samples Based on Categories of Predicates

To train the PAS-LBLM and PAS-CLBLM, we could use all predicate categories. However, our preliminary experiments showed that these categories covered many training samples which are not directly relevant to our experimental setting, such as determiner-noun dependencies. We thus manually selected the categories used in our experiments. The selected predicates are listed in Table 1: *adj_arg1*, *noun_arg1*, *prep_arg12*, and *verb_arg12*. These categories should provide meaningful information on selectional preference. For example, the *prep_arg12* denotes prepositions with two arguments, such as "eat at restaurant" which means that the verb "eat" is related to the noun "restaurant" by the preposition "at". Prepositions are one of the predicates whose arguments can be verbs, and thus prepositions are important in training the composition functions for (subject-) verb-object dependencies as described in the next paragraph.

Another point we had to consider was how to construct the training samples for the PAS-CLBLM. We constructed compositional training samples as explained in Section 3.3 when c' was *adj_arg1*, *noun_arg1*, or *verb_arg12*. Figure 2 shows two examples in addition to the example in Figure 1 (b). Using such training samples, the PAS-CLBLM could, for example, recognize from the two predicate-argument structures, "eat food" and "eat at restaurant", that eating foods is an action that occurs at restaurants.

Model	Composition Function
Add_l	$v(w_1) + v(w_2)$
Add_nl	$\tanh(v(w_1) + v(w_2))$
Wadd_l	$m^c_\text{adj} \odot v(w_1) + m^c_\text{arg1} \odot v(w_2)$
Wadd_nl	$\tanh(m^c_\text{adj} \odot v(w_1) + m^c_\text{arg1} \odot v(w_2))$

Table 2: Composition functions used in this work. The examples are shown as the *adjective-noun* dependency between w_1 ="heavy" and w_2 ="rain".

4.4 Selection of Composition Functions

As described in Section 3.3, we are free to select any composition functions in Eq. (7). To maintain the fast training speed of the PAS-LBLM, we avoid dense matrix-vector multiplication in our composition functions. In Table 2, we list the composition functions used for the PAS-CLBLM. $\textbf{Add}_\text{l}$ is element-wise addition and $\textbf{Add}_\text{nl}$ is element-wise addition with the non-linear function $\tanh$. The subscripts l and nl denote the words *linear* and *non-linear*. Similarly, $\textbf{Wadd}_\text{l}$ is element-wise weighted addition and $\textbf{Wadd}_\text{nl}$ is element-wise weighted addition with the non-linear function $\tanh$. The weight vectors $m^c_i \in \mathbb{R}^{d \times 1}$ in Table 2 are predicate-category-specific parameters which are learned during training. We investigate the effects of the non-linear function $\tanh$ for these composition functions. In the formulations of the backpropagation algorithm, non-linear functions allow the input vectors to weakly interact with each other.

4.5 Initialization and Optimization of Model Parameters

We assigned a 50-dimensional vector for each word-POS pair described in Section 4.2 and initialized the vectors and the scoring weight vectors using small random values. In part inspired by the initialization method of the weight matrices in Socher et al. (2013a), we initialized all values in the compositional weight vectors of the Wadd_l and Wadd_nl as 1.0. The context weight vectors were initialized using small random values.

We minimized the loss function in Eq. (5) using mini-batch SGD and AdaGrad (Duchi et al., 2011). Using AdaGrad, the SGD's learning rate is adapted independently for each model parameter. This is helpful in training the PAS-LBLM and PAS-CLBLM, as they have conditionally dependent model parameters with varying frequencies.

The mini-batch size was 32 and the learning rate was 0.05 for each experiment, and no regularization was used. To verify the semantics captured by the proposed models during training and to tune the hyperparameters, we used the *WordSim-353*[2] word similarity data set (Finkelstein et al., 2001).

5 Evaluation on Phrase Similarity Tasks

5.1 Evaluation Settings

The learned models were evaluated on four tasks of measuring the semantic similarity between short phrases. We performed evaluation using the three tasks (AN, NN, and VO) in the dataset[3] provided by Mitchell and Lapata (2010), and the SVO task in the dataset[4] provided by Grefenstette and Sadrzadeh (2011).

The datasets include pairs of short phrases extracted from the BNC. AN, NN, and VO contain 108 phrase pairs of adjective-noun, noun-noun, and verb-object. SVO contains 200 pairs of subject-verb-object phrases. Each phrase pair has multiple human-ratings: the higher the rating is, the more semantically similar the phrases. For example, the subject-verb-object phrase pair of "student write name" and "student spell name" has a high rating. The pair "people try door" and "people judge door" has a low rating.

For evaluation we used the Spearman's rank correlation ρ between the human-ratings and the cosine similarity between the composed vector pairs. We mainly used *non-averaged* human-ratings for each pair, and as described in Section 5.3, we also used *averaged* human-ratings for the SVO task. Each phrase pair in the datasets was annotated by more than two annotators. In the case of averaged human ratings, we averaged multiple human-ratings for each phrase pair, and in the case of non-averaged human-ratings, we treated each human-rating as a separate annotation.

With the PAS-CLBLM, we represented each phrase using the composition functions listed in Table 2. When there was no composition present, we represented the phrase using element-wise addition. For example, when we trained the PAS-CLBLM with the composition function Wadd_{nl}, the composed vector for each phrase was computed using the Wadd_{nl} function, and when we trained the PAS-LBLM, we used the element-wise addition function. To compute the composed vectors using the Wadd_{l} and Wadd_{nl} functions, we used the categories of the predicates *adj_arg1*, *noun_arg1*, and *verb_arg12* listed in Table 1.

Model	AN	NN	VO
PAS-CLBLM (Add_{l})	**0.52**	0.44	0.35
PAS-CLBLM (Add_{nl})	**0.52**	0.46	**0.45**
PAS-CLBLM (Wadd_{l})	0.48	0.39	0.34
PAS-CLBLM (Wadd_{nl})	0.48	0.40	0.39
PAS-LBLM	0.41	0.44	0.39
word2vec	**0.52**	0.48	0.42
BL w/ BNC	0.48	**0.50**	0.35
HB w/ BNC	0.41	0.44	0.34
KS w/ ukWaC	n/a	n/a	**0.45**
K w/ BNC	n/a	n/a	0.41
Human agreement	0.52	0.49	0.55

Table 3: Spearman's rank correlation scores ρ for the three tasks: AN, NN, and VO.

As a strong baseline, we trained the *Skip-gram* model of Mikolov et al. (2013b) using the publicly available *word2vec*[5] software. We fed the POS-tagged BNC into word2vec since our models utilize POS tags and trained 50-dimensional word vectors using word2vec. For each phrase we then computed the representation using vector addition.

5.2 AN, NN, and VO Tasks

Table 3 shows the correlation scores ρ for the AN, NN, and VO tasks. *Human agreement* denotes the inter-annotator agreement. The word2vec baseline achieves unexpectedly high scores for these three tasks. Previously these kinds of models (Mikolov et al., 2013b; Mnih and Kavukcuoglu, 2013) have mainly been evaluated for word analogy tasks and, to date, there has been no work using these word vectors for the task of measuring the semantic similarity between phrases. However, this experimental result suggests that word2vec can serve as a strong baseline for these kinds of tasks, in addition to word analogy tasks.

In Table 3, **BL**, **HB**, **KS**, and **K** denote the work of Blacoe and Lapata (2012), Hermann and Blunsom (2013), Kartsaklis and Sadrzadeh (2013), and Kartsaklis et al. (2013) respectively. Among these,

Tsubaki et al. (2013)	ukWaC	n/a	0.47	n/a	n/a
Van de Cruys et al. (2013)	ukWaC	n/a	n/a	0.32	0.37
Human agreement		0.75		0.62	

Table 4: Spearman's rank correlation scores ρ for the SVO task. *Averaged* denotes the ρ calculated by averaged human ratings, and *Non-averaged* denotes the ρ calculated by non-averaged human ratings.

only Kartsaklis and Sadrzadeh (2013) used the ukWaC corpus (Baroni et al., 2009) which is an order of magnitude larger than the BNC. As we can see in Table 3, the PAS-CLBLM (Add_nl) achieves scores comparable to and higher than those of the baseline and the previous state-of-the-art results. In relation to these results, the Wadd_l and Wadd_nl variants of the PAS-CLBLM do not achieve great improvements in performance. This indicates that simple word vector addition can be sufficient to compose representations for phrases consisting of word pairs.

5.3 SVO Task

Table 4 shows the correlation scores ρ for the SVO task. The scores ρ for this task are reported for both *averaged* and *non-averaged* human ratings. This is due to a disagreement in previous work regarding which metric to use when reporting results. Hence, we report the scores for both settings in Table 4. Another point we should consider is that some previous work reported scores based on the similarity between composed representations (Grefenstette and Sadrzadeh, 2011; Van de Cruys et al., 2013), and others reported scores based on the similarity between composed representations and word representations of landmark verbs from the dataset (Tsubaki et al., 2013; Van de Cruys et al., 2013). For completeness, we report the scores for both settings: *SVO-SVO* and *SVO-V* in Table 4.

The results show that the weighted addition model with the non-linear function $\tanh$ (PAS-CLBLM (Wadd_nl)) is effective for the more complex phrase task. While simple vector addition is sufficient for phrases consisting of word pairs, it is clear from our experimental results that they fall short for more complex structures such as those involved in the SVO task.

Our PAS-CLBLM (Wadd_nl) model outperforms the previous state-of-the-art scores for the SVO task as reported by Tsubaki et al. (2013) and Van de Cruys et al. (2013). As such, there are three key points that we would like to emphasize:

(1) the difference of the training corpus size,

(2) the necessity of the pre-trained word vectors,

(3) the modularity of deep learning models.

Tsubaki et al. (2013) and Van de Cruys et al. (2013) used the ukWaC corpus. This means our model works better, despite using a considerably smaller corpora. It should also be noted that, like us, Grefenstette and Sadrzadeh (2011) used the BNC corpus.

The model of Tsubaki et al. (2013) is based on neural network language models which use syntactic dependencies between verbs and their objects. While their novel model, which incorporates the idea of *co-compositionality*, works well with pre-trained word vectors produced by external models, it is not clear whether the pre-trained vectors are required to achieve high scores. In contrast, we have achieved state-of-the-art results without the use of pre-trained word vectors.

Despite our model's scalability, we trained 50-dimensional vector representations for words and their composition functions and achieved high scores using this low dimensional vector space.

model	d	AN	NN	VO	SVO
Add_l	50	0.52	0.44	0.35	0.24
	1000	0.51	**0.51**	0.43	0.31
Add_nl	50	0.52	0.46	0.45	0.24
	1000	0.51	0.50	0.45	0.31
Wadd_l	50	0.48	0.39	0.34	0.21
	1000	0.50	0.49	0.43	0.32
Wadd_nl	50	0.48	0.40	0.39	0.34
	1000	0.51	0.48	**0.48**	0.34

Table 5: Comparison of the PAS-CLBLM between $d = 50$ and $d = 1000$.

model	BoW	AN	NN	VO	SVO
Add_l	w/	0.52	0.44	0.35	0.24
	w/o	0.48	0.46	0.38	0.23
Add_nl	w/	0.52	0.46	**0.45**	0.24
	w/o	0.50	0.47	0.41	0.15
Wadd_l	w/	0.48	0.39	0.34	0.21
	w/o	0.47	0.39	0.38	0.21
Wadd_nl	w/	0.48	0.40	0.39	**0.34**
	w/o	0.52	0.42	0.33	0.26

Table 6: Scores of the PAS-CLBLM with and without BoW contexts.

This maintains the possibility to incorporate recently developed deep learning composition functions into our models, such as recursive neural tensor networks (Socher et al., 2013b) and co-compositional neural networks (Tsubaki et al., 2013). While such complex composition functions slow down the training of compositional models, richer information could be captured during training.

5.4 Effects of the Dimensionality

To see how the dimensionality of the word vectors affects the scores, we trained the PAS-CLBLM for each setting using 1,000-dimensional word vectors and set the learning rate to 0.01. Table 5 shows the scores for all four tasks. Note that we only report the scores for the setting *non-averaged SVO-SVO* here. As shown in Table 5, the scores consistently improved with a few exceptions. The scores $\rho = 0.51$ for the NN task and $\rho = 0.48$ for the VO task are the best results to date. However, the score $\rho = 0.34$ for the SVO task did not improve by increasing the dimensionality. This means that simply increasing the dimensionality of the word vectors does not necessarily lead to better results for complex phrases.

5.5 Effects of Bag-of-Words Contexts

Lastly, we trained the PAS-CLBLM without the bag-of-words contexts described in Section 3.4 and used 50-dimensional word vectors. As can be seen in Table 6, large score improvements were observed only for the VO and SVO tasks by including the bag-of-words contexts and the non-linearity function. It is likely that the results depend on how the bag-of-words contexts are constructed. However, we leave this line of analysis as future work. Both adjective-noun and noun-noun phrase are noun phrases, and (subject-) verb-object phrases can be regarded as complete sentences. Therefore, different kinds of context information might be required for both groups.

6 Qualitative Analysis on Composed Vectors

An open question that remains is to what extent composition affects the representations produced by our PAS-CLBLM model. To evaluate this we assigned a vector for each composed representation. For example, the adjective-noun dependency "heavy rain" would be assigned an independent vector. We added the most frequent 100,000 adjective-noun, noun-noun, and (subject-) verb-object tuples to the vocabulary and the resulting vocabulary contained 400,000 tokens (100,000+3$\times$100,000). A similar method for treating frequent neighboring words as single words was introduced by Mikolov et al. (2013b). However, some dependencies, such as (subject-) verb-object phrases, are not always captured when considering only neighboring words.

Table 7 (*No composition*) shows some examples of predicate-argument dependencies with their closest neighbors in the vector space according to the cosine similarity. The table shows that the learned vectors of multiple words capture semantic similarity. For example, the vector of "heavy rain" is close to the vectors of words which express the phenomena *heavily raining*. The vector of "new york" captures the concept of a *major city*. The vectors of (subject-) verb-object dependencies also capture the semantic similarity, which is the main difference to previous approaches, such as that of Mikolov et al. (2013b), which only consider neighboring words. These results suggest that the PAS-CLBLM can learn meaningful composition

Query	No composition	Composition
(AN) heavy rain	rain	rain
	thunderstorm	sunshine
	downpour	storm
	blizzard	drizzle
	much rain	chill
(AN) chief executive	general manager	executive
	vice president	director
	executive director	representative
	project manager	officer
	managing director	administrator
(NN) world war	second war	war
	plane crash	world
	riot	race
	last war	holocaust
	great war	warfare
(NN) new york	oslo	york
	paris	toronto
	birmingham	paris
	moscow	edinburgh
	madrid	glasgow
(VO) make payment	make order	make
	carry survey	allow
	pay tax	demand
	pay	produce
	impose tax	bring
(VO) solve problem	achieve objective	solve
	bridge gap	alleviate
	improve quality	overcome
	deliver information	resolve
	encourage development	circumvent
(SVO) meeting take place	hold meeting	take
	event take place	get
	end season	win
	discussion take place	put
	do work	gain

Table 7: Nearest neighbor vectors for multiple words. POS-tags are not shown for simplicity.

category	predicate	arg1	arg2
adj_arg1	2.38	**6.55**	-
noun_arg1	3.37	**5.60**	-
verb_arg12	**6.78**	2.57	2.18

Table 8: L2-norms of the 50-dimensional weight vectors of the composition function Wadd_{nl}.

functions since the composition layers receive the same error signal via backpropagation.

We then trained the PAS-CLBLM using Wadd_{nl} to learn composition functions. Table 7 (*Composition*) shows the nearest neighbor words for each composed vector, and as we can see, the learned composition function emphasizes the head words and captures some sort of semantic similarity. We then inspected the L2-norms of the weight vectors of the composition function. As shown in Table 8, head words are strongly emphasized. Emphasizing head words is helpful in representing composed meanings, but in the case of verbs it may not always be sufficient. This can be observed in Table 3 and Table 4, which demonstrates that verb-related tasks are more difficult than noun-phrase tasks.

While *No composition* captures the semantic similarity well using independent parameters, there is the issue of data sparseness. As the size of the vocabulary increases, the number of tuples of word dependencies increases rapidly. In this experiment, we used only the 300,000 most frequent tuples. In contrast to this, the learned composition functions can capture similar information using only word vectors and a small set of predicate categories.

7 Conclusion and Future Work

We have presented a compositional log-bilinear language model using predicate-argument structures that incorporates both bag-of-words and dependency-based contexts. In our experiments the learned composed vectors achieve state-of-the-art scores for the task of measuring the semantic similarity between short phrases. For the subject-verb-object phrase task, the result is achieved without any pre-trained word vectors using a corpus an order of magnitude smaller than that of the previous state of the art. For future work, we will investigate how our models and the resulting vector representations can be helpful for other unsupervised and/or supervised tasks.

Abstract

Broad-coverage relation extraction either requires expensive supervised training data, or suffers from drawbacks inherent to distant supervision. We present an approach for providing partial supervision to a distantly supervised relation extractor using a small number of carefully selected examples. We compare against established active learning criteria and propose a novel criterion to sample examples which are both uncertain and representative. In this way, we combine the benefits of fine-grained supervision for difficult examples with the coverage of a large distantly supervised corpus. Our approach gives a substantial increase of 3.9% end-to-end F_1 on the 2013 KBP Slot Filling evaluation, yielding a net F_1 of 37.7%.

1 Introduction

Fully supervised relation extractors are limited to relatively small training sets. While able to make use of much more data, *distantly supervised* approaches either make dubious assumptions in order to simulate fully supervised data, or make use of latent-variable methods which get stuck in local optima easily. We hope to combine the benefits of supervised and distantly supervised methods by annotating a small subset of the available data using selection criteria inspired by active learning.

To illustrate, our training corpus contains 1 208 524 relation mentions; annotating all of these mentions for a fully supervised classifier, at an average of \$0.13 per annotation, would cost approximately \$160 000. Distant supervision allows us to make use of this large corpus without requiring costly annotation. The traditional approach is based on the assumption that every mention of an entity pair (e.g., *Obama* and *USA*) participates in the known relation between the two (i.e., *born in*). However, this introduces noise, as not every mention expresses the relation we are assigning to it.

We show that by providing annotations for only 10 000 informative examples, combined with a large corpus of distantly labeled data, we can yield notable improvements in performance over the distantly supervised data alone. We report results on three criteria for selecting examples to annotate: a baseline of sampling examples uniformly at random, an established active learning criterion, and a new metric incorporating both the *uncertainty* and the *representativeness* of an example. We show that the choice of metric is important – yielding as much as a 3% F_1 difference – and that our new proposed criterion outperforms the standard method in many cases. Lastly, we train a supervised classifier on these collected examples, and report performance comparable to distantly supervised methods. Furthermore, we notice that initializing the distantly supervised model using this supervised classifier is critical for obtaining performance improvements.

This work makes a number of concrete contributions. We propose a novel application of active learning techniques to distantly supervised relation extraction. To the best of the authors knowledge, we are the first to apply active learning to the class of latent-variable distantly supervised models presented in this paper. We show that annotating a proportionally small number of examples yields improvements in end-to-end accuracy. We compare various selection criteria, and show that this decision has a notable impact on the gain in performance. In many ways this reconciles our results with the negative results of Zhang et al. (2012), who show limited gains from naïvely annotating examples. Lastly, we make our annotations available to the research community.[1]

2 Background

2.1 Relation Extraction

We are interested in extracting a set of relations $y_1 \dots y_k$ from a fixed set of possible relations $\mathcal{R}$, given two entities e_1 and e_2. For example, we would like to extract that Barack Obama was born in Hawaii. The task is decomposed into two steps: First, sentences containing mentions of both e_1 and e_2 are collected. The set of these sentences x, marked with the *entity mentions* for e_1 and e_2, becomes the input to the relation extractor, which then produces a set of relations which hold between the mentions. We are predominantly interested in the second step – classifying a set of pairs of entity mentions into the relations they express. Figure 1 gives the general setting for relation extraction, with entity pairs *Barack Obama* and *Hawaii*, and *Barack Obama* and *president*.

Traditionally, relation extraction has fallen into one of four broad approaches: supervised classification, as in the ACE task (Doddington et al., 2004; GuoDong et al., 2005; Surdeanu and Ciaramita, 2007), distant supervision (Craven and Kumlien, 1999; Wu and Weld, 2007; Mintz et al., 2009; Sun et al., 2011; Roth and Klakow, 2013) deterministic rule-based systems (Soderland, 1997; Grishman and Min, 2010; Chen et al., 2010), and translation from open domain information extraction schema (Riedel et al., 2013). We focus on the first two of these approaches.

2.2 Supervised Relation Extraction

Relation extraction can be naturally cast as a supervised classification problem. A corpus of relation mentions is collected, and each mention x is annotated with the relation y, if any, it expresses. The classifier's output is then aggregated to decide the relations between the two entities.

However, annotating supervised training data is generally expensive to perform at large scale. Although resources such as Freebase or the TAC KBP knowledge base have on the order of millions of training tuples over entities it is not feasible to manually annotate the corresponding mentions in the text. This has led to the rise of *distantly supervised* methods, which make use of this indirect supervision, but do not necessitate mention-level supervision.

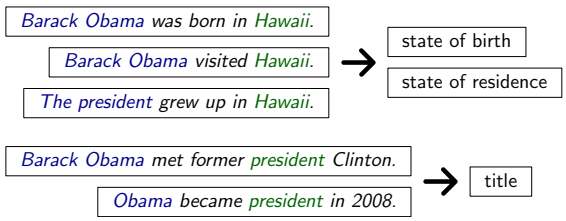

Figure 1: The relation extraction setup. For a pair of entities, we collect sentences which mention both entities. These sentences are then used to predict one or more relations between those entities. For instance, the sentences containing both *Barack Obama* and *Hawaii* should support the *state of birth* and *state of residence* relation.

2.3 Distant Supervision

Traditional distant supervision makes the assumption that for every triple (e_1, y, e_2) in a knowledge base, every sentence containing mentions for e_1 and e_2 express the relation y. For instance, taking Figure 1, we would create a datum for each of the three sentences containing BARACK OBAMA and HAWAII labeled with *state of birth*, and likewise with *state of residence*, creating 6 training examples overall. Similarly, both sentences involving *Barack Obama* and *president* would be marked as expressing the *title* relation.

While this allows us to leverage a large database effectively, it nonetheless makes a number of naïve assumptions. First – explicit in the formulation of the approach – it assumes that every mention expresses some relation, and furthermore expresses the known relation(s). For instance, the sentence *Obama visited Hawaii* would be erroneously treated as a positive example of the *born in* relation. Second, it implicitly assumes that our knowledge base is complete: entity mentions with no known relation are treated as negative examples.

The first of these assumptions is addressed by multi-instance multi-label (MIML) learning, described in Section 2.4. Min et al. (2013) address the second assumption by extending the MIML model with additional latent variables, while Xu et al. (2013) allow feedback from a coarse relation extractor to augment labels from the knowledge base. These latter two approaches are compatible with but are not implemented in this work.

2.4 Multi-Instance Multi-Label Learning

The multi-instance multi-label (MIML-RE) model of Surdeanu et al. (2012), which builds upon work

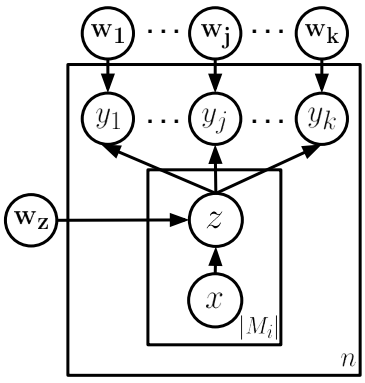

Figure 2: The MIML-RE model, as shown in Surdeanu et al. (2012). The outer plate corresponds to each of the n entity pairs in our knowledge base. Each entity pair has a set of mention pairs M_i, and a corresponding plate in the diagram for each mention pair in M_i. The variable x represents the input mention pair, whereas y represents the positive and negative relations for the given pair of entities. The latent variable z denotes a mention-level prediction for each input. The weight vector for the multinomial z classifier is given by $\mathbf{w}_z$, and there is a weight vector $\mathbf{w}_j$ for each binary y classifier.

by Hoffmann et al. (2011) and Riedel et al. (2010), addresses the assumptions of distantly supervised relations extractors in a principled way by positing a latent mention-level annotation.

The model groups mentions according to their entity pair – for instance, every mention pair with *Obama* and *Hawaii* would be grouped together. A latent variable z_i is created for every mention i, where $z_i \in \mathcal{R} \cup \{\text{None}\}$ takes a single relation label, or a *no relation* marker. We create $|\mathcal{R}|$ binary variables y representing the known positive and negative relations for the entity pair. A set of binary classifiers (log-linear factors in the graphical model) links the latent predictions $z_1 \ldots z_{|M_i|}$ and each y_j. These classifiers include two classes of features: first, a binary feature which fires if *at least one* of the mentions expresses a known relation between the entity pair, and second, a feature for each co-occurrence of relations for a given entity pair. Figure 2 describes the model.

2.5 Background on Active Learning

We describe preliminaries and prior work on active learning; we use this framework to propose two sampling schemes in Section 3 which we use to annotate mention-level labels for MIML-RE.

One way of expressing the generalization error of a hypothesis $\hat{h}$ is through its mean-squared error with the true hypothesis h:

$$\begin{aligned} &E[(h(x) - \hat{h}(x))^2] \\ &= E[E[(h(x) - \hat{h}(x))^2|x]] \\ &= \int_x E[(h(x) - \hat{h}(x))^2|x]p(x)\mathrm{d}x. \end{aligned}$$

The integrand can be further broken into bias and variance terms:

$$\begin{aligned} E[(h(x) - \hat{h}(x))^2] = (E[\hat{h}(x)] - h(x))^2 \\ + E[(\hat{h}(x) - E[\hat{h}(x)])^2] \end{aligned}$$

where for simplicity we've dropped the conditioning on x.

Many traditional sampling strategies, such as query-by-committee (QBC) (Freund et al., 1992; Freund et al., 1997) and uncertainty sampling (Lewis and Gale, 1994), work by decreasing the variance of the learned model. In QBC, we first create a 'committee' of classifiers by randomly sampling their parameters from a distribution based on the training data. These classifiers then make predictions on the unlabeled examples, and the examples on which there is the most disagreement are selected for labeling. This strategy can be seen as an attempt to decrease the *version space* – the set of classifiers that are consistent with the labeled data. Decreasing the version space should lower variance, since variance is inversely related to the size of the hypothesis space.

In most scenarios, active learning does not concern itself with the bias term. If a model is fundamentally misspecified, then no amount of additional training data can lower its bias. However, our paradigm differs from the traditional setting, in that we are annotating latent variables in a model with a non-convex objective. These annotations may help increase the convexity of our objective, leading us to a more accurate optimum and thereby lowering bias.

The other component to consider is $\int_x \cdots p(x)\mathrm{d}x$. This suggests that it is important to choose examples that are representative of the underlying distribution $p(x)$, as we want to label points that will improve the classifier's predictions on as many and as high-probability examples as possible. Incorporating a representativeness metric has been shown to provide a significant improvement over plain QBC or

uncertainty sampling (McCallum and Nigam, 1998; Settles, 2010).

2.6 Active Learning for Relation Extraction

Several papers have explored active learning for relation extraction. Fu and Grishman (2013) employ active learning to create a classifier quickly for new relations, simulated from the ACE corpus. Finn and Kushmerick (2003) compare a number of selection criteria – including QBC – for a supervised classifier. To the best of our knowledge, we are the first to apply active learning to distantly supervised relation extraction. Furthermore, we evaluate our selection criteria live in a real-world setting, collecting new sentences and evaluating on an end-to-end task.

For latent variable models, McCallum and Nigam (1998) apply active learning to semi-supervised document classification. We take inspiration from their use of QBC and the choice of metric for classifier disagreement. However their model assumes a fully Bayesian set-up, whereas ours does not require strong assumptions about the parameter distributions.

Settles et al. (2008) use active learning to improve a multiple-instance classifier. Their model is simpler in that it does not allow for unobserved variables or multiple labels, and the authors only evaluate on image retrieval and synthetic text classification datasets.

3 Example Selection

We describe three criteria for selection examples to annotate. The first – sampling uniformly – is a baseline for our hypothesis that intelligently selecting examples is important. For this criterion, we select mentions uniformly at random from the training set to annotate. This is the approach used in Zhang et al. (2012). The other two criteria rely on a metric for disagreement provided by QBC; we describe our adaptation of QBC for MIML-RE as a preliminary to introducing these criteria.

3.1 QBC For MIML-RE

We use a version of QBC based on bootstrapping (Saar-Tsechansky and Provost, 2004). To create the committee of classifiers, we re-sample the training set with replacement 7 times and train a model over each sampled dataset. We measure disagreement on z-labels among the classifiers using a generalized Jensen-Shannon divergence (McCallum and Nigam, 1998), taking the average KL divergence of all classifier judgments.

We first calculate the mention-level confidences. Note that $z_i^{(m)} \in M_i$ denotes the latent variable in entity pair i with index m; $\mathbf{z}_i^{(-m)}$ denotes the set of all latent variables except $z_i^{(m)}$:

$$p(z_i^{(m)}|\mathbf{y_i}, \mathbf{x_i}) = \frac{p(\mathbf{y_i}, z_i^{(m)}|\mathbf{x_i})}{p(\mathbf{y_i}|\mathbf{x_i})} = \frac{\sum_{\mathbf{z_i^{(-m)}}} p(\mathbf{y_i}, \mathbf{z_i}|\mathbf{x_i})}{\sum_{z_i^{(m)}} p(\mathbf{y_i}, z_i^{(m)}|\mathbf{x_i})}.$$

Notice that the denominator just serves to normalize the probability within a sentence group. We can rewrite the numerator as follows:

$$\begin{aligned}&\sum_{\mathbf{z_i^{(-m)}}} p(\mathbf{y_i}, \mathbf{z_i}|\mathbf{x_i}) \\ &= \sum_{\mathbf{z_i^{(-m)}}} p(\mathbf{y_i}|\mathbf{z_i}) p(\mathbf{z_i}|\mathbf{x_i}) \\ &= p(z_i^{(m)}|\mathbf{x_i}) \sum_{\mathbf{z_i^{(-m)}}} p(\mathbf{y_i}|\mathbf{z_i}) p(\mathbf{z_i^{(-m)}}|\mathbf{x_i}).\end{aligned}$$

For computational efficiency, we approximate $p(\mathbf{z_i^{(-m)}}|\mathbf{x_i})$ with a point mass at its maximum. Next, we calculate the Jensen-Shannon (JS) divergence from the k bootstrapped classifiers:

$$\frac{1}{k} \sum_{c=1}^{k} \mathrm{KL}(p_c(z_i^{(m)}|\mathbf{y_i}, \mathbf{x_i}) || p_{\text{mean}}(z_i^{(m)}|\mathbf{y_i}, \mathbf{x_i})) \quad (1)$$

where p_c is the probability assigned by each of the k classifiers to the latent $z_i^{(m)}$, and p_{mean} is the average of these probabilities. We use this metric to capture the *disagreement* of our model with respect to a particular latent variable. This is then used to inform our selection criteria.

We note that QBC may be especially useful in our situation as our objective is highly nonconvex. If two committee members disagree on a latent variable, it is likely because they converged to different local optima; annotating that example could help bring the classifiers into agreement.

The second selection criterion we consider is the most straightforward application of QBC – selecting the examples with the highest JS disagreement. This allows us to compare our criterion, described next, against an established criterion from the active learning literature.

3.2 Sample by JS Disagreement

We propose a novel active learning sampling criterion that incorporates not only disagreement but also *representativeness* in selecting examples to annotate. Prior work has taken a weighted combination of an example's disagreement and a score corresponding to whether the example is drawn from a dense portion of the feature space (e.g., McCallum and Nigam (1998)). However, this requires both selecting a criterion for defining density (e.g., distance metric in feature space), and tuning a parameter for the relative weight of disagreement versus representativeness.

Instead, we account for choosing representative examples by sampling without replacement proportional to the example's disagreement. Formally, we define the probability of selecting an example $z_i^{(m)}$ to be proportional to the Jensen-Shannon divergence in (1). Since the training set is an approximation to the prior distribution over examples, sampling uniformly over the training set is an approximation to sampling from the prior probability of seeing an input x. We can view our criterion as an approximation to sampling proportional to the product of two densities: a prior over examples x, and the JS divergence mentioned above.

4 Incorporating Sentence-Level Annotations

Following Surdeanu et al. (2012), MIML-RE is trained through hard discriminative Expectation Maximization, inferring the latent z values in the E-step and updating the weights for both the z and y classifiers in the M-step. During the E-step, we constrain the latent z to match our sentence-level annotations when available.

It is worth noting that even in the hard-EM regime, we can in principle incorporate annotator uncertainty elegantly into the model. At each E step, each z_i is set according to

$$z_i{}^{(m)*} \approx \arg\max_{z \in \mathcal{R}} \left[p(z \mid x_i^{(m)}, \mathbf{w}_z) \times \prod_r p(y_i^{(r)} \mid \mathbf{z}_i', \mathbf{w}_y^{(r)}) \right]$$

where $\mathbf{z}_i'$ contains the inferred labels from the previous iteration, but with its mth component replaced by $z_i^{(m)}$.

By setting the distribution $p(z \mid x_i^{(m)}, \mathbf{w}_z)$ to reflect uncertainty among annotators, we can leave open the possibility for the model to choose a relation which annotators deemed unlikely, but the model nonetheless prefers. For simplicity, however, we treat our annotations as a hard assignment.

In addition to incorporating annotations during training, we can also use this data to intelligently initialize the model. Since the MIML-RE objective is non-convex, the initialization of the classifier weights w_y and w_z is important. The y classifiers are initialized with the "at-least-once" assumption of Hoffmann et al. (2011); w_z can be initialized either using traditional distant supervision or from a supervised classifier trained on the annotated sentences. If initialized with a supervised classifier, the model can be viewed as augmenting this supervised model with a large distantly labeled corpus, providing both additional entity pairs to train from, and additional mentions for an annotated entity pair.

5 Crowdsourced Example Annotation

Most prior work on active learning is done by simulation on a fully labeled dataset; such a dataset doesn't exist for our case. Furthermore, a key aim of this paper is to practically improve state-of-the-art performance in relation extraction in addition to evaluating active learning criteria. Therefore, we develop and execute an annotation task for collecting labels for our selected examples.

We utilize Amazon Mechanical Turk to crowdsource annotations. For each task, the annotator (Turker) is presented with the task description, followed by 15 questions, 2 of which are randomly placed controls. For each question, we present Turkers with a relation mention and the top 5 relation predictions from our classifier. The Turker also has an option to freely specify a relation not presented in the first five options, or mark that there is no relation. We attempt to heuristically match common free-form answers to official relations.

To maintain the quality of the results, we discard all submissions in which both controls were answered incorrectly, and additionally discard all submissions from Turkers who failed the controls on more than $\frac{1}{3}$ of their submissions. Rejected tasks were republished for other workers to complete. We collect 5 annotations for each example, and use the most commonly agreed answer as the ground truth. Ties are broken arbitrarily, except in

Figure 3: The task shown to Amazon Mechanical Turk workers. A sentence along with the top 5 relation predictions from our classifier are shown to Turkers, as well as an option to specify a custom relation or manually enter "no relation." The correct response for this example should be either no relation or a custom relation.

the case of deciding between a relation and no relation, in which case the relation was always chosen.

A total of 23 725 examples were annotated, covering 10 000 examples for each of the three selection criteria. Note that there is overlap between the examples selected for the three criteria. In addition, 10 023 examples were annotated during development; these are included in the set of all annotated examples, but excluded from any of the three criteria. The compensation per task was 23 cents; the total cost of annotating examples was $3156, in addition to $204 spent on developing the task. Informally, Turkers achieved an accuracy of around 75%, as evaluated by a paper author, performing disproportionately well on identifying the *no relation* label.

6 Experiments

We evaluate the three high-level research contributions of this work: we show that we improve the accuracy of MIML-RE, we validate the effectiveness of our selection criteria, and we provide a corpus of annotated examples, evaluating a supervised classifier trained on this corpus. The training and testing methodology for evaluating these contributions is given in Sections 6.1 and 6.2; experiments are given in Section 6.3.

6.1 Training Setup

We adopt the setup of Surdeanu et al. (2012) for training the MIML-RE model, with minor modifications. We use both the 2010 and 2013 KBP official document collections, as well as a July 2013 dump of Wikipedia as our text corpus. We subsample negatives such that $\frac{1}{3}$ of our dataset consists of entity pairs with no known relations. In all experiments, MIML-RE is trained for 7 iterations of EM; for efficiency, the z classifier is optimized using stochastic gradient descent;[2] the y classifiers are optimized using L-BFGS.

Similarly to Surdeanu et al. (2011), we assign negative relations which are either incompatible with the known positive relations (e.g., relations whose co-occurrence would violate type constraints); or, are actually functional relations in which another entity already participates. For example, if we know that Obama was born in the United States, we could add *born in* as a negative relation to the pair Obama and Kenya.

Our dataset consists of 325 891 entity pairs with at least one positive relation, and 158 091 entity pairs with no positive relations. Pairs with at least one known relation have an average of 4.56 mentions per group; groups with no known relations have an average of 1.55 mentions per group. In total, 1 208 524 distinct mentions are considered; the annotated examples are selected from this pool.

6.2 Testing Methodology

We compare against the original MIML-RE model using the same dataset and evaluation methodology as Surdeanu et al. (2012). This allows for an evaluation where the only free variable between this and prior work is the predictions of the relation extractor.

Additionally, we evaluate the relation extractors in the context of Stanford's end-to-end KBP system (Angeli et al., 2014) using the NIST TAC-KBP 2013 English Slotfilling evaluation. In the end-to-end framework, the input to the system is a query entity and a set of articles, and the output is a set of *slot fills* – each slot fill is a candidate triple in the knowledge base, the first element of which is the query entity. This amounts to roughly populating a data structure like Wikipedia infoboxes automatically from a large corpus of text.

Importantly, an end-to-end evaluation in a top-performing full system gives a more accurate idea of the expected real-world gain from each model. Both the information retrieval component providing candidates to the relation extractor, as well as

[2]For the sake of consistency, the supervised classifiers and those in Mintz++ are trained identically to the z classifiers in MIML-RE.

Method	Init	Active Learning Criterion

	Sup	35.1	35.6	35.4	34.4	35.0	34.7	**46.2**	30.8	37.0	39.4	36.2	**37.7**	36.0	**37.1**	36.5
Supervised	—		—		**35.5**	28.9	31.9	31.3	33.2	32.2	33.5	**35.0**	**34.2**	32.9	33.4	33.2

Table 1: A summary of results on the end-to-end KBP 2013 evaluation for various experiments. The first column denotes the algorithm used: either traditional distant supervision (Mintz++), MIML-RE, or a supervised classifier. In the case of MIML-RE, the model may be initialized either using Mintz++, or the corresponding supervised classifier (the "Not Used" column is initialized with the "All" supervised classifier). One of five active learning scenarios are evaluated: no annotated examples provided, the three active learning criteria, and all available examples used. The entry in blue denotes the basic MIML-RE model; entries in gray perform worse than this model. The bold items denote the best performance among selection criteria.

the consistency and inference performed on the classifier output introduce bias in this evaluation's sensitivity to particular types of errors. Mistakes which are easy to filter, or are difficult to retrieve using IR are less important in this evaluation; in contrast, factors such as providing good confidence scores for consistency become more important.

For the end-to-end evaluation, we use the official evaluation script with two changes: First, all systems are evaluated with provenance ignored, so as not to penalize any system for finding a new provenance not validated in the official evaluation key. Second, each system reports its optimal F_1 along its P/R curve, yielding results which are optimistic when compared against other systems entered into the competition. However, this also yields results which are invariant to threshold tuning, and is therefore more appropriate for comparing between systems in this paper.

Development was done on the KBP 2010–2012 queries, and results are reported using the 2013 queries as a simulated test set. Our best system achieves an F_1 of 37.7; the top two teams at KBP 2013 (of 18 entered) achieved F_1 scores of 40.2 and 37.1 respectively, ignoring provenance.

6.3 Results

Table 1 summarizes all results for the end-to-end task; relevant features of the table are copied in subsequent sections to illustrate key trends. Models which perform worse than the original MIML-RE model (MIML-RE, initialized with "Dist," under "Not Used") are denoted in gray. The best performing model improves on the base model by 3.9 F_1 points on the end-to-end task.

MIML + Sup + SampleJS	**39.4**	**36.2**	**37.7**

Table 2: A summary of improvements to MIML-RE on the end-to-end slotfilling task, copied from Table 1. Mintz++ is the traditional distantly supervised model. The second row corresponds to the unmodified MIML-RE model. The third row corresponds to MIML-RE initialized with a supervised classifier (trained on all examples). The fourth row is MIML-RE with annotated examples incorporated during training (but not initialization). The last row shows the best results obtained by our model.

We evaluate each of the individual contributions of the paper: improving the accuracy of the MIML-RE relation extractor, evaluating our example selection criteria, and demonstrating the annotated examples' effectiveness for a fully-supervised relation extractor.

Improve MIML-RE Accuracy A key goal of this work is to improve the accuracy of the MIML-RE model; we show that we improve the model both on the end-to-end slotfilling task (Table 2) as well as on a standard evaluation (Figure 5). Similar to our work, recent work by Pershina et al.

MIML + Sup + SampleJS	39.4	36.2	37.7

Table 4: A comparison of the best performing supervised classifier with other systems. The top section compares the supervised classifier with prior work. The lower section highlights the improvements gained from initializing MIML-RE with a supervised classifier.

(2014) incorporates labeled data to guide MIML-RE during training. They make use of labeled data to extract *training guidelines*, which are intended to generalize across many examples. We show that we can match or outperform their improvements with our best criterion.

A few interesting trends emerge from the end-to-end results in Table 2. Using annotated sentences during training alone did not improve performance consistently, even hurting performance when the SampleJS criterion was used. This supports an intuition that the initialization of the model is important, and that it is relatively difficult to coax the model out of a local optimum if it is initialized poorly. This is further supported by the improvement in performance when the model is initialized with a supervised classifier, even when no examples are used during training. Similar trends are reported in prior work, e.g., Smith and Eisner (2007) Section 4.4.6.

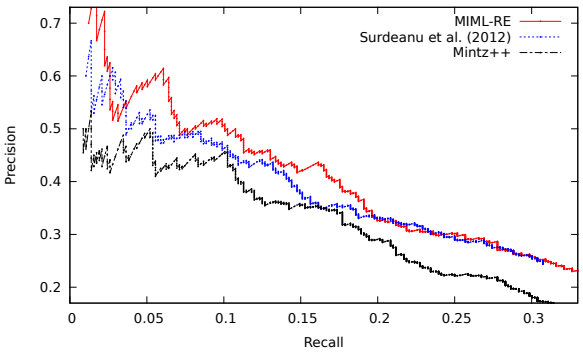

Figure 4: MIML-RE and Mintz++ evaluated according to Surdeanu et al. (2012). The original model from the paper is plotted for comparison, as our training methodology is somewhat different.

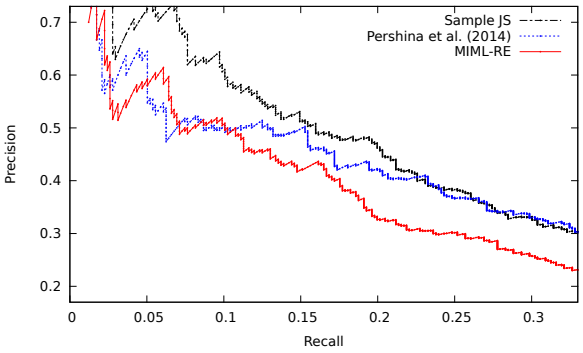

Figure 5: Our best active learning criterion evaluated against our version of MIML-RE, alongside the best system of Pershina et al. (2014).

Also interesting is the relatively small gain MIML-RE provides over traditional distant supervision (Mintz++) in this setting. We conjecture that the mistakes made by Mintz++ are often relatively easily filtered by the downstream consistency component. This is supported by Figure 4; we evaluate our trained MIML-RE model against Mintz++ and the results reported in Surdeanu et al. (2012). We show that our model performs as well or better than the original implementation, and consistently outperforms Mintz++.

Evaluate Selection Criteria A key objective of this work is to evaluate how much of an impact careful selection of annotated examples has on the overall performance of the system. We evaluate the three selection criteria from Section 3.2, showing the results for MIML-RE in Table 3; results for the supervised classifier are given in Table 1. In both cases, we show that the sampled JS cri-

terion performs comparably to or better than the other criteria.

At least two interesting trends can be noted from these results: First, the uniformly sampled criterion performed worse than MIML-RE initialized with a supervised classifier. This may be due to noise in the annotation: a small number of annotation errors on entity pairs with only a single corresponding mention could introduce dangerous noise into training. These singleton mentions will rarely have disagreement between the committee of classifiers, and therefore will generally only be selected in the uniform criterion.

Second, adding in the full set of examples did not improve performance – in fact, performance generally dropped in this scenario. We conjecture that this is due to the inclusion of the uniformly sampled examples, with performance dropping for the same reasons as above.

Both of these results can be reconciled with the results of Zhang et al. (2012); like this work, they annotated examples to analyze the trade-off between adding more data to a distantly supervised system, and adding more direct supervision. They conclude that annotations provide only a relatively small improvement in performance. However, their examples were uniformly selected from the training corpus, and did not make use of the structure provided by MIML-RE. Our results agree in that neither the uniform selection criterion nor the supervised classifier significantly outperformed the unmodified MIML-RE model; nonetheless, we show that if care is taken in selecting these labeled examples we can achieve noticeable improvements in accuracy.

We also evaluate our selection criteria on the evaluation of Surdeanu et al. (2012), both initialized with Mintz++ (Figure 7) and with the supervised classifier (Figure 6). These results mirror those in the end-to-end evaluation; when initialized with the supervised classifier the high disagreement (High JS) and sampling proportional to disagreement (Sample JS) criteria clearly outperform both the base MIML-RE model as well as the uniformly sampling criterion. Using the annotated examples only during training yielded no perceivable benefit over the base model (Figure 7).

Supervised Relation Extractor The examples collected can be used to directly train a supervised classifier, with results summarized in Table 4. The most salient insight is that the performance of the best supervised classifier is similar to that of the MIML-RE model, despite being trained on nearly two orders of magnitude less training data.

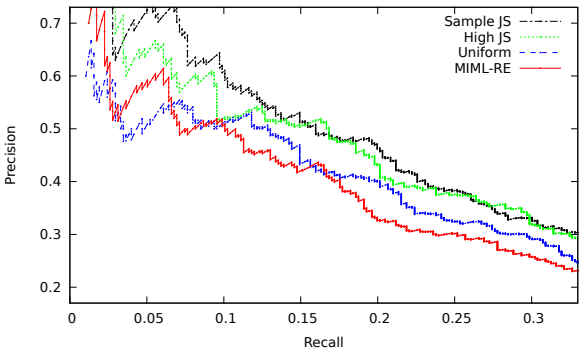

Figure 6: A comparison of models trained with various selection criteria on the evaluation of Surdeanu et al. (2012), all initialized with the corresponding supervised classifier.

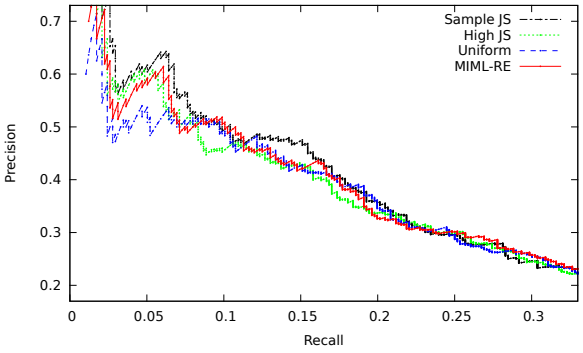

Figure 7: A comparison of models trained with various selection criteria on the evaluation of Surdeanu et al. (2012), all initialized with Mintz++.

More interestingly, however, the supervised classifier provides a noticeably better initialization for MIML-RE than Mintz++, yielding better results even without enforcing the labels during EM. These results suggest that the power gained from the the more sophisticated MIML-RE model is best used in conjunction with a small amount of training data. That is, using MIML-RE as a principled model for combining a large distantly labeled corpus and a small number of careful annotations yields significant improvement over using either of the two data sources alone.

Table 5: A summary of relations annotated, and end-to-end slotfilling performance by relation. The first column gives the relation; the second shows the number of examples annotated. The subsequent columns show the performance of the unmodified MIML-RE model and our best performing model (SampleJS). Changes in values are bolded; positive changes are shown in green and negative changes in red. The most frequent 10 relations in the evaluation are likewise bolded.

6.4 Analysis By Relation

In this section, we explore which of the KBP relations were shown to Turkers, and whether the improvements in accuracy correspond to these relations. We compare only the unmodified MIML-RE model, and our best model (MIML-RE initialized with the supervised classifier, under the SampleJS criterion). Results are shown in Table 5.

A few interesting trends emerge from this analysis. We note that annotating even 80+ examples for a relation seems to provide a consistent boost in accuracy, whereas relations with fewer annotated examples tended to show little or no change. However, the gains of our model are not universal across relation types, even dropping noticeably on some – for instance, F_1 drops on both *state of residence* and *country of birth*. This could suggest systematic noise from Turker judgments; e.g., for foreign geography (*state of residence*) or ambiguous relations (*top members*).

An additional insight from the table is the mismatch between examples chosen to be annotated, and the most popular relations in the KBP evaluation. For instance, by far the most popular KBP relation (*title*) had only 121 examples annotated.

7 Conclusion

We have shown that providing a relatively small number of mention-level annotations can improve the accuracy of MIML-RE, yielding an end-to-end improvement of 3.9 F_1 on the KBP task. Furthermore, we have introduced a new active learning criterion, and shown both that the choice of criterion is important, and that our new criterion performs well. Lastly, we make available a dataset of mention-level annotations for constructing a traditional supervised relation extractor.

Abstract

While relation extraction has traditionally been viewed as a task relying solely on textual data, recent work has shown that by taking as input existing facts in the form of entity-relation triples from both knowledge bases and textual data, the performance of relation extraction can be improved significantly. Following this new paradigm, we propose a tensor decomposition approach for knowledge base embedding that is highly scalable, and is especially suitable for relation extraction. By leveraging relational domain knowledge about entity type information, our learning algorithm is significantly faster than previous approaches and is better able to discover new relations missing from the database. In addition, when applied to a relation extraction task, our approach alone is comparable to several existing systems, and improves the weighted mean average precision of a state-of-the-art method by 10 points when used as a subcomponent.

1 Introduction

Identifying the relationship between entities from free text, *relation extraction* is a key task for acquiring new facts to increase the coverage of a structured knowledge base. Given a pre-defined database schema, traditional relation extraction approaches focus on learning a classifier using textual data alone, such as patterns between the occurrences of two entities in documents, to determine whether the entities have a particular relation. Other than using the existing known facts to label the text corpora in a distant supervision setting (Bunescu and Mooney, 2007; Mintz et al., 2009; Riedel et al., 2010; Ritter et al., 2013), an existing knowledge base is typically not involved in the process of relation extraction.

However, this paradigm has started to shift recently, as researchers showed that by taking existing facts of a knowledge base as an integral part of relation extraction, the model can leverage richer information and thus yields better performance. For instance, Riedel et al. (2013) borrowed the idea of *collective filtering* and constructed a matrix where each row is a pair of entities and each column is a particular relation. For a true entity-relation triple (e_1, r, e_2), either from the text corpus or from the knowledge base, the corresponding entry in the matrix is 1. A previously unknown fact (i.e., triple) can be discovered through matrix decomposition. This approach can be viewed as creating vector representations of each relation and candidate pair of entities. Because each entity does not have its own representation, relationships of any unpaired entities cannot be discovered. Alternatively, Weston et al. (2013) created two types of embedding – one based on textual similarity and the other based on knowledge base, where the latter maps each entity and relation to the same d-dimensional vector space using a model proposed by Bordes et al. (2013a). They also showed that combining these two models results in a significant improvement over the model trained using only textual data.

To make such an integrated strategy work, it is important to capture all existing entities and relations, as well as the known facts, from both textual data and large databases. In this paper, we propose a new knowledge base embedding model, TRESCAL, that is highly efficient and scalable, with relation extraction as our target application. Our work is built on top of RESCAL (Nickel et al., 2011), which is a tensor decomposition method that has proven its scalability by factoring YAGO (Biega et al., 2013) with 3 million entities

[*]Work conducted while interning at Microsoft Research.

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

and 41 million triples (Nickel et al., 2012). We improve the tensor decomposition model with two technical innovations. First, we exclude the triples that do not satisfy the relational constraints (e.g., both arguments of the relation *spouse-of* need to be *person* entities) from the loss, which is done by selecting sub-matrices of each slice of the tensor during training. Second, we introduce a mathematical technique that significantly reduces the computational complexity in both time and space when the loss function contains a regularization term. As a consequence, our method is more than four times faster than RESCAL, and is also more accurate in discovering unseen triples.

Our contributions are twofold. First, compared to other knowledge base embedding methods developed more recently, it is much more efficient to train our model. As will be seen in Sec. 5, when applied to a large knowledge base created using NELL (Carlson et al., 2010) that has 1.8M entity-relation triples, our method finishes training in 4 to 5 hours, while an alternative method (Bordes et al., 2013a) needs almost 3 days. Moreover, the prediction accuracy of our model is competitive to others, if not higher. Second, to validate its value to relation extraction, we apply TRESCAL to extracting relations from a free text corpus along with a knowledge base, using the data provided in (Riedel et al., 2013). We show that TRESCAL is complementary to existing systems and significantly improves their performance when using it as a subcomponent. For instance, this strategy improves the weighted mean average precision of the best approach in (Riedel et al., 2013) by 10 points (47% to 57%).

The remainder of this paper is organized as follows. We survey most related work in Sec. 2 and provide the technical background of our approach in Sec. 3. Our approach is detailed in Sec. 4, followed by the experimental validation in Sec. 5. Finally, Sec. 6 concludes the paper.

2 Related Work

Our approach of creating knowledge base embedding is based on tensor decomposition, which is a well-developed mathematical tool for data analysis. Existing tensor decomposition models can be categorized into two main families: the CP and Tucker decompositions. The CP (CANDECOMP/PARAFAC) decomposition (Kruskal, 1977; Kiers, 2000) approximates a tensor by a sum of rank-one tensors, while the Tucker decomposition (Tucker, 1966), also known as high-order SVD (De Lathauwer et al., 2000), factorizes a tensor into a core tensor multiplied by a matrix along each dimension. A highly scalable distributional algorithm using the Map-Reduce architecture has been proposed recently for computing CP (Kang et al., 2012), but not for the Tucker decomposition, probably due to its inherently more complicated model form.

Matrix and tensor decomposition methods have been applied to modeling multi-relational data. For instance, Speer et al. (2008) aimed to create vectors of latent components for representing concepts in a common sense knowledge base using SVD. Franz et al. (2009) proposed TripleRank to model the `subject-predicate-object` RDF triples in a tensor, and then applied the CP decomposition to identify hidden triples. Following the same tensor encoding, Nickel et al. (2011) proposed RESCAL, a restricted form of Tucker decomposition for discovering previously unknown triples in a knowledge base, and later demonstrated its scalability by applying it to YAGO, which was encoded in a 3M $\times$ 3M $\times$ 38 tensor with 41M triples (Nickel et al., 2012).

Methods that revise the objective function based on additional domain information have been proposed, such as MrWTD, a multi-relational weighted tensor decomposition method (London et al., 2013), coupled matrix and tensor factorization (Papalexakis et al., 2014), and collective matrix factorization (Singh and Gordon, 2008). Alternatively, instead of optimizing for the least-squares reconduction loss, a non-parametric Bayesian approach for 3-way tensor decomposition for modeling relational data has also been proposed (Sutskever et al., 2009). Despite the existence of a wide variety of tensor decomposition models, most methods do not scale well and have only been tested on datasets that are much smaller than the size of real-world knowledge bases.

Multi-relational data can be modeled by neural-network methods as well. For instance, Bordes et al. (2013b) proposed the Semantic Matching Energy model (SME), which aims to have the same d-dimensional vector representations for both entities and relations. Given the vectors of entities e_1, e_2 and relation r. They first learn the latent representations of (e_1, r) and (e_2, r). The score of (e_1, r, e_2) is determined by the inner product

of the vectors of (e_1, r) and (e_2, r). Later, they proposed a more scalable method called translating embeddings (TransE) (Bordes et al., 2013a). While both entities and relations are still represented by vectors, the score of (e_1, r, e_2) becomes the negative dissimilarity measure of the corresponding vectors $-\|\mathbf{e_i} + \mathbf{r_k} - \mathbf{e_j}\|$, motivated by the work in (Mikolov et al., 2013b; Mikolov et al., 2013a). Alternatively, Socher et al. (2013) proposed a Neural Tensor Network (NTN) that represents entities in d-dimensional vectors created separately by averaging pre-trained word vectors, and then learns a $d \times d \times m$ tensor describing the interactions between these latent components in each of the m relations. All these methods optimize for loss functions that are more directly related to the true objective – the prediction accuracy of correct entity-relation triples, compared to the mean-squared reconstruction error in our method. Nevertheless, they typically require much longer training time.

3 Background

In this section, we first describe how entity-relation triples are encoded in a tensor. We then introduce the recently proposed tensor decomposition method, RESCAL (Nickel et al., 2011) and explain how it adopts an alternating least-squares method, ASALSAN (Bader et al., 2007), to compute the factorization.

3.1 Encoding Binary Relations in a Tensor

Suppose we are given a knowledge base with n entities and m relation types, and the facts in the knowledge base are denoted as a set of entity-relation triples $\mathcal{T} = \{(e_i, r_k, e_j)\}$, where $i, j \in \{1, 2, \cdots n\}$ and $k \in \{1, 2, \cdots m\}$. A triple (e_i, r_k, e_j) simply means that the i-th entity and the j-th entity have the k-th relation. Following (Franz et al., 2009), these triples can naturally be encoded in a 3-way tensor $\mathcal{X} \in \{0, 1\}^{n \times n \times m}$, such that $\mathcal{X}_{i,j,k} = 1$ if and only if the triple $(e_i, r_k, e_j) \in \mathcal{T}$[1]. The tensor can be viewed as consisting of m slices, where each slice is an $n \times n$ square matrix, denoting the interactions of the entities of a particular relation type. In the remainder of this paper, we will use $\mathcal{X}_k$ to refer to the k-th slice of the tensor $\mathcal{X}$. Fig. 1 illustrates this representation.

[1]This representation can easily be extended for a probabilistic knowledge base by allowing nonnegative real values.

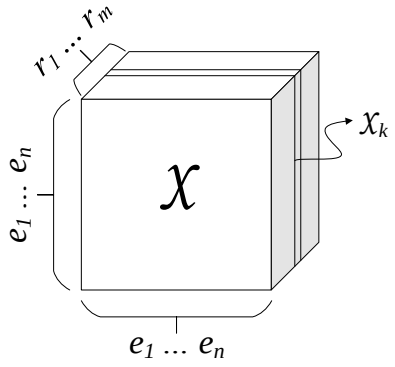

Figure 1: A tensor encoding of m binary relation types and n entities. A slice $\mathcal{X}_k$ denotes the entities having the k-th relation.

3.2 RESCAL

In order to identify latent components in a tensor for collective learning, Nickel et al. (2011) proposed RESCAL, which is a tensor decomposition approach specifically designed for the multi-relational data described in Sec. 3.1. Given a tensor $\mathcal{X}_{n \times n \times m}$, RESCAL aims to have a rank-r approximation, where each slice $\mathcal{X}_k$ is factorized as

$$\mathcal{X}_k \approx \mathbf{A}\mathcal{R}_k\mathbf{A}^T. \tag{1}$$

$\mathbf{A}$ is an $n \times r$ matrix, where the i-th row denotes the r latent components of the i-th entity. $\mathcal{R}_k$ is an asymmetric $r \times r$ matrix that describes the interactions of the latent components according to the k-th relation. Notice that while $\mathcal{R}_k$ differs in each slice, $\mathbf{A}$ remains the same.

$\mathbf{A}$ and $\mathcal{R}_k$ are derived by minimizing the loss function below.

$$\min_{\mathbf{A}, \mathcal{R}_k} f(\mathbf{A}, \mathcal{R}_k) + \lambda \cdot g(\mathbf{A}, \mathcal{R}_k), \tag{2}$$

where $f(\mathbf{A}, \mathcal{R}_k) = \frac{1}{2}\left(\sum_k \|\mathcal{X}_k - \mathbf{A}\mathcal{R}_k\mathbf{A}^T\|_F^2\right)$ is the mean-squared reconstruction error and $g(\mathbf{A}, \mathcal{R}_k) = \frac{1}{2}\left(\|\mathbf{A}\|_F^2 + \sum_k \|\mathcal{R}_k\|_F^2\right)$ is the regularization term.

RESCAL is a special form of Tucker decomposition (Tucker, 1966) operating on a 3-way tensor. Its model form (Eq. (1)) can also be regarded as a relaxed form of DEDICOM (Bader et al., 2007), which derives the low-rank approximation as: $\mathcal{X}_k \approx \mathbf{A}\mathcal{D}_k\mathbf{R}\mathcal{D}_k\mathbf{A}^T$. To compare RESCAL to other tensor decomposition methods, interested readers can refer to (Kolda and Bader, 2009).

The optimization problem in Eq. (2) can be solved using the efficient alternating least-squares (ALS) method. This approach alternatively fixes $\mathcal{R}_k$ to solve for $\mathbf{A}$ and then fixes $\mathbf{A}$ to solve $\mathcal{R}_k$. The whole procedure stops until $\frac{f(\mathbf{A},\mathcal{R}_k)}{\|\mathcal{X}\|_F^2}$ converges to some small threshold ϵ or the maximum number of iterations has been reached.

By finding the solutions where the gradients are 0, we can derive the update rules of $\mathbf{A}$ and $\mathcal{R}_k$ as below.

$$\mathbf{A} \leftarrow \left[\sum_k \mathcal{X}_k \mathbf{A}\mathcal{R}_k^T + \mathcal{X}_k^T \mathbf{A}\mathcal{R}_k\right]\left[\sum_k \mathcal{B}_k + \mathcal{C}_k + \lambda \mathbf{I}\right]^{-1},$$

where $\mathcal{B}_k = \mathcal{R}_k \mathbf{A}^T \mathbf{A} \mathcal{R}_k^T$ and $\mathcal{C}_k = \mathcal{R}_k^T \mathbf{A}^T \mathbf{A} \mathcal{R}_k$.

$$\mathbf{vec}(\mathcal{R}_k) \leftarrow \left(\mathbf{Z}^T\mathbf{Z} + \lambda \mathbf{I}\right)^{-1} \mathbf{Z}^T \mathbf{vec}(\mathcal{X}_k), \quad (3)$$

where $\mathbf{vec}(\mathcal{R}_k)$ is the vectorization of $\mathcal{R}_k$, $\mathbf{Z} = \mathbf{A} \otimes \mathbf{A}$ and the operator $\otimes$ is the Kronecker product.

Complexity Analysis Following the analysis in (Nickel et al., 2012), we assume that each $\mathcal{X}_k$ is a sparse matrix, and let p be the number of non-zero entries[2]. The complexity of computing $\mathcal{X}_k \mathbf{A} \mathcal{R}_k^T$ and $\mathcal{X}_k^T \mathbf{A} \mathcal{R}_k$ is $O(pr + nr^2)$. Evaluating $\mathcal{B}_k$ and $\mathcal{C}_k$ requires $O(nr^2)$ and the matrix inversion requires $O(r^3)$. Therefore, the complexity of updating $\mathbf{A}$ is $O(pr+nr^2)$ assuming $n \gg r$. The updating rule of R_k involves inverting an $r^2 \times r^2$ matrix. Therefore, directly computing the inversion requires time complexity $O(r^6)$ and space complexity $O(r^4)$. Although Nickel et al. (2012) considered using QR decomposition to simplify the updates, it is still time consuming with the time complexity $O(r^6 + pr^2)$. Therefore, the total time complexity is $O(r^6+pr^2)$ and the step of updating $\mathcal{R}_k$ is the bottleneck in the optimization process. We will describe how to reduce the time complexity of this step to $O(nr^2 + pr)$ in Section 4.2.

4 Approach

We describe how we leverage the relational domain knowledge in this section. By removing the incompatible entity-relation triples from the loss function, training can be done much more efficiently and results in a model with higher prediction accuracy. In addition, we also introduce a mathematical technique to reduce the computational complexity of the tensor decomposition methods when taking into account the regularization term.

4.1 Applying Relational Domain Knowledge

In the domain of knowledge bases, the notion of entity *types* is the side information that commonly exists and dictates whether some entities can be legitimate arguments of a given predicate. For instance, suppose the relation of interest is *born-in*, which denotes the birth *location* of a *person*. When asked whether an incompatible pair of entities, such as two *person* entities like `Abraham Lincoln` and `John Henry`, having this relation, we can immediately reject the possibility. Although the type information and the constraints are readily available, it is overlooked in the previous work on matrix and tensor decomposition models for knowledge bases (Riedel et al., 2013; Nickel et al., 2012). Ignoring the type information has two implications. Incompatible entity-relation triples still participate in the loss function of the optimization problem, which incurs unnecessary computation. Moreover, by choosing values for these incompatible entries we introduce errors in training the model that can reduce the quality of the model.

Based on this observation, we propose *Typed*-RESCAL, or TRESCAL, which leverages the entity type information to improve both the efficiency of model training and the quality of the model in term of prediction accuracy. We employ a direct and simple approach by excluding the triples of the incompatible entity types from the loss in Eq. (2). For each relation, let $\mathbb{L}_k$ and $\mathbb{R}_k$ be the set of entities with a compatible type to the k-th relation. That is, (e_i, r_k, e_j) is a feasible triple if and only if $e_i \in \mathbb{L}_k$ and $e_j \in \mathbb{R}_k$. For notational convenience, we use $\mathbf{A}_{k_l}, \mathbf{A}_{k_r}$ to denote the sub-matrices of $\mathbf{A}$ that consists of rows associated with $\mathbb{L}_k$ and $\mathbb{R}_k$, respectively. Analogously, let $\mathcal{X}_{k_{lr}}$ be the sub-matrix of $\mathcal{X}_k$ that consists of only the entity pairs compatible to the k-th relation. The rows and columns of $\mathcal{X}_{k_{lr}}$ map to the entities in $\mathbf{A}_{k_l}$ and $\mathbf{A}_{k_r}$, respectively. In other words, entries of $\mathcal{X}_k$ but not in $\mathcal{X}_{k_{lr}}$ do not satisfy the type constraint and are ignored from the computation.

[2]Notice that we use a slightly different definition of p from the one in (Nickel et al., 2012). The time complexity of multiplying an $n \times n$ sparse matrix $\mathcal{X}_k$ with p non-zero entries by an $n \times r$ dense matrix is $O(pr)$ assuming $n \gg r$.

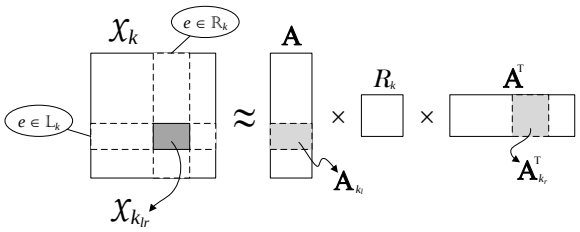

Figure 2: The construction of TRESCAL. Suppose the k-th relation is *born-in*. $\mathbb{L}_k$ is then a set of *person* entities and $\mathbb{R}_k$ is a set of *location* entities. Only the sub-matrix corresponds to the compatible entity pairs (i.e., $\mathcal{X}_{k_{lr}}$) and the sub-matrices of the associated entities (i.e., $\mathbf{A}_{k_l}$ and $\mathbf{A}^T_{k_r}$) will be included in the loss.

Fig. 2 illustrates this construction.

TRESCAL solves the following optimization problem:

$$\min_{\mathbf{A},\mathcal{R}_k} f'(\mathbf{A},\mathcal{R}_k) + \lambda \cdot g(\mathbf{A},\mathcal{R}_k), \qquad (4)$$

where $f'(\mathbf{A},\mathcal{R}_k) = \frac{1}{2}\sum_k \|\mathcal{X}_{k_{lr}} - \mathbf{A}_{k_l}\mathcal{R}_k\mathbf{A}^T_{k_r}\|^2_F$ and $g(\mathbf{A},\mathcal{R}_k) = \frac{1}{2}\left(\|\mathbf{A}\|^2_F + \sum_k \|\mathcal{R}_k\|^2_F\right)$.

Similarly, $\mathbf{A}$ and $\mathcal{R}_k$ can be solved using the alternating least-squares method. The update rule of $\mathbf{A}$ is

$$\mathbf{A} \leftarrow \left[\sum_k \left(\mathcal{X}_{k_{lr}}\mathbf{A}_{k_r}\mathcal{R}^T_k + \mathcal{X}^T_{k_{lr}}\mathbf{A}_{k_l}\mathcal{R}_k\right)\right] \times \left[\sum_k \mathcal{B}_{k_r} + \mathcal{C}_{k_l} + \lambda\mathbf{I}\right]^{-1},$$

where $\mathcal{B}_{k_r} = \mathcal{R}_k\mathbf{A}^T_{k_r}\mathbf{A}_{k_r}\mathcal{R}^T_k$ and $\mathcal{C}_{k_l} = \mathcal{R}^T_k\mathbf{A}^T_{k_l}\mathbf{A}_{k_l}\mathcal{R}_k$.

The update of $\mathcal{R}_k$ becomes:

$$\mathbf{vec}(\mathcal{R}_k) \leftarrow \left(\mathbf{A}^T_{k_r}\mathbf{A}_{k_r} \otimes \mathbf{A}^T_{k_l}\mathbf{A}_{k_l} + \lambda\mathbf{I}\right)^{-1} \times \mathbf{vec}({\mathbf{A}_{k_l}}^T\mathcal{X}_{k_{lr}}\mathbf{A}_{k_r}), \qquad (5)$$

Complexity Analysis Let $\bar{n}$ be the average number of entities with a compatible type to a relation. Follow a similar derivation in Sec. 3.2, the time complexity of updating $\mathbf{A}$ is $O(pr + \bar{n}r^2)$ and the time complexity of updating $\mathcal{R}_k$ remains to be $O(r^6 + pr^2)$.

4.2 Handling Regularization Efficiently

Examining the update rules of both RESCAL and TRESCAL, we can see that the most time-consuming part is the matrix inversions. For RESCAL, this is the term $(\mathbf{Z}^T\mathbf{Z}+\lambda\mathbf{I})^{-1}$ in Eq. (3), where $\mathbf{Z} = \mathbf{A} \otimes \mathbf{A}$. Nickel et al. (2011) made the observation that if $\lambda = 0$, the matrix inversion can be calculated by

$$(\mathbf{Z}^T\mathbf{Z})^{-1} = (\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A} \otimes (\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}.$$

Then, it only involves an inversion of an $r \times r$ matrix, namely $\mathbf{A}^T\mathbf{A}$. However, if $\lambda > 0$, directly calculating Eq. (3) requires to invert an $r^2 \times r^2$ matrix and thus becomes a bottleneck in solving Eq. (2).

To reduce the computational complexity of the update rules of $\mathcal{R}_k$, we compute the inversion $\left(\mathbf{Z}^T\mathbf{Z} + \lambda\mathbf{I}\right)^{-1}$ by applying singular value decomposition (SVD) to $\mathbf{A}$, such that $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, where $\mathbf{U}$ and $\mathbf{V}$ are orthogonal matrices and $\mathbf{\Sigma}$ is a diagonal matrix. Then by using properties of the Kronecker product we have:

$$\begin{aligned}
&\left(\mathbf{Z}^T\mathbf{Z} + \lambda\mathbf{I}\right)^{-1} \\
&\quad= \left(\lambda\mathbf{I} + \mathbf{V}\mathbf{\Sigma}^2\mathbf{V}^T \otimes \mathbf{V}\mathbf{\Sigma}^2\mathbf{V}^T\right)^{-1} \\
&\quad= \left(\lambda\mathbf{I} + (\mathbf{V}\otimes\mathbf{V})(\mathbf{\Sigma}^2\otimes\mathbf{\Sigma}^2)(\mathbf{V}\otimes\mathbf{V})^T\right)^{-1} \\
&\quad= (\mathbf{V}\otimes\mathbf{V})\left(\lambda\mathbf{I} + \mathbf{\Sigma}^2\otimes\mathbf{\Sigma}^2\right)^{-1}(\mathbf{V}\otimes\mathbf{V})^T.
\end{aligned}$$

The last equality holds because $\mathbf{V} \otimes \mathbf{V}$ is also an orthogonal matrix. We leave the detailed derivations in Appendix A. Notice that $\left(\lambda\mathbf{I} + \mathbf{\Sigma}^2 \otimes \mathbf{\Sigma}^2\right)^{-1}$ is a diagonal matrix. Therefore, the inversion calculation is trivial.

This technique can be applied to TRESCAL as well. By applying SVD to both $\mathbf{A}_{k_l}$ and $\mathbf{A}_{k_r}$, we have $\mathbf{A}_{k_l} = \mathbf{U}_{k_l}\mathbf{\Sigma}_{k_l}\mathbf{V}^T_{k_l}$ and $\mathbf{A}_{k_r} = \mathbf{U}_{k_r}\mathbf{\Sigma}_{k_r}\mathbf{V}^T_{k_r}$, respectively. The computation of $\left(\mathbf{A}^T_{k_r}\mathbf{A}_{k_r} \otimes \mathbf{A}^T_{k_l}\mathbf{A}_{k_l} + \lambda\mathbf{I}\right)^{-1}$ of Eq. (5) thus becomes:

$$(\mathbf{V}_{k_l} \otimes \mathbf{V}_{k_r})\left(\lambda\mathbf{I} + \mathbf{\Sigma}^2_{k_l} \otimes \mathbf{\Sigma}^2_{k_r}\right)^{-1}(\mathbf{V}_{k_l} \otimes \mathbf{V}_{k_r})^T.$$

The procedure of updating $\mathcal{R}$ is depicted in Algorithm 1.

Complexity Analysis For RESCAL, $\mathbf{V}$ and $\mathbf{\Sigma}$ can be computed by finding eigenvectors of $\mathbf{A}^T\mathbf{A}$. Therefore, computing SVD of $\mathbf{A}$ costs $O(nr^2 + r^3) = O(nr^2)$. Computing Step 4 in Algorithm 1 takes $O(nr^2 + pr)$. Step 5 and Step 6 require

Algorithm 1 Updating $\mathcal{R}$ in TRESCAL

Require: $\mathcal{X}$, $\mathbf{A}$, and entity sets $\mathbb{R}_k, \mathbb{L}_k, \forall k$
Ensure: $\mathcal{R}_k, \forall k$.

1: **for** $k = 1 \dots m$ **do**
2: $[\mathbf{U}_{k_l}, \mathbf{\Sigma}^2_{k_l}, \mathbf{V}_{k_l}] \leftarrow \text{SVD}(\mathbf{A}^T_{k_l}\mathbf{A}_{k_l})$.
3: $[\mathbf{U}_{k_r}, \mathbf{\Sigma}^2_{k_r}, \mathbf{V}_{k_r}] \leftarrow \text{SVD}(\mathbf{A}^T_{k_r}\mathbf{A}_{k_r})$.
4: $\mathbf{M}_1 \leftarrow \mathbf{V}^T_{k_l}\mathbf{A}^T_{k_l}\mathcal{X}_{k_{lr}}\mathbf{A}_{k_r}\mathbf{V}_{k_r}$.
5: $\mathbf{M}_2 \leftarrow \text{diag}(\mathbf{\Sigma}^2_{k_l})\,\text{diag}(\mathbf{\Sigma}^2_{k_r})^T + \lambda\mathbf{1}$.
(**1** is a matrix of all ones. Function diag converts the diagonal entries of a matrix to a vector.)
6: $\mathcal{R}_k \leftarrow \mathbf{V}_{k_l}(M_1./M_2)\mathbf{V}^T_{k_r}$.
(The operator "./" is element-wise division.)
7: **end for**

$O(r^2)$ and $O(r^3)$, respectively. The overall time complexity of updating $\mathcal{R}_k$ becomes $O(nr^2 + pr)$.

Using a similar derivation, the time complexity of updating $\mathcal{R}_k$ in TRESCAL is $O(\bar{n}r^2 + pr)$. Therefore, the total complexity of each iteration is $O(\bar{n}r^2 + pr)$.

5 Experiments

We conduct two sets of experiments. The first evaluates the proposed TRESCAL algorithm on inferring unknown facts using existing relation–entity triples, while the second demonstrates its application to relation extraction when a text corpus is available.

5.1 Knowledge Base Completion

We evaluate our approach on a knowledge base generated by the CMU Never Ending Language Learning (NELL) project (Carlson et al., 2010). NELL collects human knowledge from the web and has generated millions of entity-relation triples. We use the data generated from version 165 for training[3], and collect the new triples generated between NELL versions 166 and 533 as the development set and those generated between version 534 and 745 as the test set[4]. The data statistics of the training set are summarized in Table 1. The numbers of triples in the development and test sets are 19,665 and 117,889, respectively. Notice that this dataset is substantially larger than the datasets used in recent work. For example, the Freebase data used in (Socher et al., 2013) and (Bordes et al., 2013a) have 316k and 483k[5] triples, respectively, compared to 1.8M in this dataset.

NELL	
# entities	753k
# relation types	229
# entity types	300
# entity-relation triples	1.8M

Table 1: Data statistics of the training set from NELL in our experiments.

In the NELL dataset, the entity type information is encoded in a specific relation, called *Generalization*. Each entity in the knowledge base is assigned to at least one category presented by the Generalization relationship. Based on this information, the compatible entity type constraint of each relation can be easily identified. Specifically, we examined the entities and relations that occur in the triples of the training data, and counted all the types appearing in these instances of a given relation legitimate.

We implement RESCAL and TRESCAL in MATLAB with the Matlab tensor Toolbox (Bader et al., 2012). With the efficient implementation described in Section 4.2, all experiments can be conducted on a commodity PC with 16 GB memory. We set the maximal number of iterations of both RESCAL and TRESCAL to be 10, which we found empirically to be enough to generate a stable model. Note that Eq. (4) is non-convex, and the optimization process does not guarantee to converge to a global minimum. Therefore, initializing the model properly might be important for the performance. Following the implementation of RESCAL, we initialize $\mathbf{A}$ by performing singular value decomposition over $\bar{\mathcal{X}} = \sum_k(\mathcal{X}_k + \mathcal{X}_k^T)$, such that $\bar{\mathcal{X}} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$ and set $\mathbf{A} = \mathbf{U}$. Then, we apply the update rule of $\mathcal{R}_k$ to initialize $\{\mathcal{R}_k\}$. RESCAL and TRESCAL have two types of parameters: (1) the rank r of the decomposed tensor and (2) the regularization parameter λ. We tune the rank parameter on development set in a range of $\{100, 200, 300, 400\}$ and the regularization parameter in a range of $\{0.01, 0.05, 0.1, 0.5, 1\}$.

For comparison, we also use the code released by Bordes et al. (2013a), which is implemented using Python and the Theano library (Bergstra et al., 2010), to train a TransE model using the

[3] http://www.cs.cmu.edu/~nlao/
[4] http://bit.ly/trescal
[5] In (Bordes et al., 2013a), there is a much larger dataset, FB1M, that has 17.5M triples used for evaluation. However, this dataset has not been released.

	Entity Retrieval			Relation Retrieval		
	TransE	RESCAL	TRESCAL	TransE	RESCAL	TRESCAL
w/o type checking	51.41%‡	51.59%	54.79%	75.88%	73.15%†	76.12%
w/ type checking	67.56%	62.91%‡	69.26%	70.71%‡	73.08%†	75.70%

Table 2: Model performance in mean average precision (MAP) on *entity retrieval* and *relation retrieval*. † and ‡ indicate the comparison to TRESCAL in the same setting is statistically significant using a paired-t test on average precision of each query, with $p < 0.01$ and $p < 0.05$, respectively. Enforcing type constraints during test time improves entity retrieval substantially, but does not help in relation retrieval.

same NELL dataset. We reserved randomly 1% of the training triples for the code to evaluate the model performance in each iteration. As suggested in their paper, we experiment with several hyper-parameters, including learning rate of {0.01, 0.001}, the latent dimension of {50, 100} and the similarity measure of {L1, L2}. In addition, we also adjust the number of batches of {50, 100, 1000}. Of all the configurations, we keep the models picked by the method, as well as the final model after 500 training iterations. The final model is chosen by the performance on our development set.

5.1.1 Training Time Reduction

We first present experimental results demonstrating that TRESCAL indeed reduces the time required to factorize a knowledge database, compared to RESCAL. The experiment is conducted on NELL with $r = 300$ and $\lambda = 0.1$. When $\lambda \neq 0$, the original RESCAL algorithm described in (Nickel et al., 2011; Nickel et al., 2012) cannot handle a large r, because updating matrices $\{\mathcal{R}_k\}$ requires $O(r^4)$ memory. Later in this section, we will show that in some situation a large rank r is necessary for achieving good testing performance.

Comparing TRESCAL with RESCAL, each iteration of TRESCAL takes 1,608 seconds, while that of RESCAL takes 7,415 seconds. In other words, by inducing the entity type information and constraints, TRESCAL enjoys around 4.6 times speed-up, compared to an improved regularized version of RESCAL. When updating $\mathbf{A}$ and $\{\mathcal{R}_k\}$ TRESCAL only requires operating on sub-matrices of $\mathbf{A}$, $\{\mathcal{R}_k\}$ and $\{\mathcal{X}_k\}$, which reduces the computation substantially. In average, TRESCAL filters 96% of entity triples that have incompatible types.

In contrast, it takes TransE at least 2 days and 19 hours to finish training the model (the default 500 iterations)[6], while TRESCAL finishes the training in roughly 4 to 5 hours[7].

5.1.2 Test Performance Improvement

We consider two different types of tasks to evaluate the prediction accuracy of different models – *entity retrieval* and *relation retrieval*.

Entity Retrieval In the first task, we collect a set of entity-relation pairs $\{(e_i, r_k)\}$ and aim at predicting e_j such that the tuple (e_i, r_k, e_j) is a recorded triple in the NELL knowledge base. For each pair (e_i, r_k), we collect triples $\{(e_i, r_k, e_j^*)\}$ from the NELL test corpus as positive samples and randomly pick 100 entries e'_j to form negative samples $\{e_i, r_k, e'_j\}$. Given $\mathbf{A}$ and $\mathcal{R}_k$ from the factorization generated by RESCAL or TRESCAL, the score assigned to a triple $\{e_i, r_k, e'_j\}$ is computed by $a_i^T R_k a_j$ where a_i and a_j are the i-th and j-th rows of $\mathbf{A}$. In TransE, the score is determined by the negative dissimilarity measures of the learned embeddings: $-d(e_i, r_k, e'_j) = -\|\mathbf{e_i} + \mathbf{r_k} - \mathbf{e'_j}\|_2^2$.

We evaluate the performance using mean average precision (MAP), which is a robust and stable metric (Manning et al., 2008). As can be observed in Table 2 (left), TRESCAL achieves 54.79%, which outperforms 51.59% of RESCAL and 51.41% of TransE. Adding constraints during test time by assigning the lowest score to the entity triples with incompatible types improves results of all models – TRESCAL still performs the best (69.26%), compared to TransE (67.56%) and RESCAL (62.91%).

Relation Retrieval In the second task, given a relation type r_k, we are looking for the entity pairs (e_i, e_j) that have this specific relationship. To generate test data, for each relation type, we collect

[6]It took almost 4 days to train the best TransE model that is included in Table 2.

[7]We also tested the released code from (Socher et al., 2013) for training a neural tensor network model. However, we are not able to finish the experiments as each iteration of this method takes almost 5 hours.

gold entity pairs from the NELL knowledge base as positive samples and randomly pick a set of entity pairs as negative samples such that the number of positive samples are the same as negative ones.

Results presented in Table 2 (right) show that TRESCAL achieves 76.12%, while RESCAL and TransE are 73.15% and 75.88%, respectively. Therefore, incorporating the type information in training seems to help in this task as well. Enforcing the type constraints during test time does not help as in *entity retrieval*. By removing incompatible entity pairs, the performance of TRESCAL, RESCAL and TransE drop slightly to 75.70%, 73.08% and 70.71% respectively. One possible explanation is that the task of *relation retrieval* is easier than *entity retrieval*. The incorrect type information of some entities ends up filtering out a small number of entity pairs that were retrieved correctly by the model.

Notice that TRESCAL achieves different levels of performance on various relations. For example, it performs well on predicting *AthletePlaysSport* (81%) and *CoachesInLeague* (88%), but achieves suboptimal performance on predicting *WorksFor* (49%) and *BuildingLocatedInCity* (35%). We hypothesize that it is easier to generalize entity-relation triples when the relation has several related relations. For examples, *AthletePlaysForTeam* and *TeamPlaysSport* may help discover entity-relation triples of AthletePlaysSport.

5.1.3 Sensitivity to Parameters

We also study if TRESCAL is sensitive to the rank parameter r and the regularization parameter λ, where the detailed results can be found in Appendix B. In short, we found that increasing the rank r generally leads to better models. Also, while the model is not very sensitive to the value of the regularization parameter λ, tuning λ is still necessary for achieving the best performance.

5.2 Relation Extraction

Next, we apply TRESCAL to the task of extracting relations between entities, jointly from a text corpus and a structured knowledge base. We use a corpus from (Riedel et al., 2013) that is created by aligning the entities in NYTimes and Freebase. The corpus consists of a training set and a test set. In the training set, a list of entity pairs are provided, along with surface patterns extracted from NYTimes and known relations obtained from Freebase. In the test set, only the surface patterns are given. By jointly factoring a matrix consisting of the surface patterns and relations, Riedel et al. (2013) show that their model is able to capture the mapping between the surface patterns and the structured relations and hence is able to extract the entity relations from free text. In the following, we show that TRESCAL can be applied to this task.

We focus on the 19 relations listed in Table 1 of (Riedel et al., 2013) and only consider the surface patterns that co-occur with these 19 relations. We prune the surface patterns that occur less than 5 times and remove the entities that are not involved in any relation and surface pattern. Based on the training and test sets, we build a 80,698$\times$80,698$\times$1,652 tensor, where each slice captures a particular structured relation or a surface pattern between two entities. There are 72 fine types extracted from Freebase assigned to 53,836 entities that are recorded in Freebase. In addition, special types, PER, LOC, ORG and MISC, are assigned to the remaining 26,862 entities based on the predicted NER tags provided by the corpus. A type is considered incompatible to a relation or a surface pattern if in the training data, none of the argument entities of the relation belongs to the type. We use $r = 400$ and $\lambda = 0.1$ in TRESCAL to factorize the tensor.

We compare the proposed TRESCAL model to RI13 (Riedel et al., 2013), YA11 (Yao et al., 2011), MI09 (Mintz et al., 2009) and SU12 (Surdeanu et al., 2012)[8]. We follow the protocol used in (Riedel et al., 2013) to evaluate the results. Given a relation as query, the top 1,000 entity pairs output by each system are collected and the top 100 ones are judged manually. Besides comparing individual models, we also report the results of combined models. To combine the scores from two models, we simply normalize the scores of entity-relation tuples to zero mean and unit variance and take the average. The results are summarized in Table 3.

As can been seen in the table, using TRESCAL alone is not very effective and its performance is only compatible to MI09 and YA11, and is significantly inferior to RI13. This is understandable because the problem setting favors RI13 as only entity pairs that have occurred in the text or the database will be considered in RI13, both during model training and testing. In contrast, TRESCAL

predicts all the possible combinations between entities and relations, which makes the model less fit to the task. However, when combining TRESCAL with a pure text-based method, such as SU12, we can clearly see TRESCAL is complementary to SU12 (0.39 to 0.44 in weighted MAP score), which makes the results competitive to RI13.

Interestingly, although both TRESCAL and RI13 leverage information from the knowledge base, we find that by combining them, the performance is improved quite substantially (0.47 to 0.57). We suspect that the reason is that in our construction, each entity has its own vector representation, which is lacked in RI13. As a result, the new triples that TRESCAL finds are very different from those found by RI13. Nevertheless, combining more methods do not always yield an improvement. For example, combining TR, RI13 and SU12 together (not included in Table 3) achieves almost the same performance as TR+RI13.

6 Conclusions

In this paper we developed TRESCAL, a tensor decomposition method that leverages relational domain knowledge. We use relational domain knowledge to capture which triples are potentially valid and found that, by excluding the triples that are incompatible when performing tensor decomposition, we can significantly reduce the training time and improve the prediction performance as compared with RESCAL and TransE. Moreover, we demonstrated its effectiveness in the application of relation extraction. Evaluated on the dataset provided in (Riedel et al., 2013), the performance of TRESCAL alone is comparable to several existing systems that leverage the idea of distant supervision. When combined with the state-of-the-art systems, we found that the results can be further improved. For instance, the weighted mean average precision of the previous best approach in (Riedel et al., 2013) has been increased by 10 points (47% to 57%).

There are a number of interesting potential extensions of our work. First, while the experiments in this paper are on traditional knowledge bases and textual data, the idea of leveraging relational domain knowledge is likely to be of value to other linguistic databases as well. For instance, part-of-speech tags can be viewed as the "types" of words. Incorporating such information in other tensor decomposition methods (e.g., (Chang et al., 2013)) may help lexical semantic representations. Second, relational domain knowledge goes beyond entity types and their compatibility with specific relations. For instance, the entity-relation triple (e_1, *child-of*, e_2) can be *valid* only if $e_1.\text{type} = \text{person} \wedge e_2.\text{type} = \text{person} \wedge e_1.\text{age} < e_2.\text{age}$. It would be interesting to explore the possibility of developing efficient methods to leverage other types of relational domain knowledge. Finally, we would like to create more sophisticated models of knowledge base embedding, targeting complex in-

ference tasks to better support semantic parsing and question answering.

Acknowledgments

We thank Sebastian Riedel for providing the data for experiments. We are also grateful to the anonymous reviewers for their valuable comments.

Appendix A Detailed Derivation

We first introduce some lemmas that will be useful for our derivation. Lemmas 2, 3 and 4 are the basic properties of the Kronecker product. Their proofs can be found at (Laub, 2005).

Lemma 1. *Let* $\mathbf{V}$ *be an orthogonal matrix and* $\mathbf{\Sigma}$ *a diagonal matrix. Then* $(\mathbf{I} + \mathbf{V}\mathbf{\Sigma}\mathbf{V}^T)^{-1} = \mathbf{V}(\mathbf{I} + \mathbf{\Sigma})^{-1}\mathbf{V}^T$.

Proof.

$$\begin{aligned}(\mathbf{I} + \mathbf{V}\mathbf{\Sigma}\mathbf{V}^T)^{-1} &= (\mathbf{V}\mathbf{I}\mathbf{V}^T + \mathbf{V}\mathbf{\Sigma}\mathbf{V}^T)^{-1} \\ &= \mathbf{V}(\mathbf{I} + \mathbf{\Sigma})^{-1}\mathbf{V}^T \quad \square\end{aligned}$$

Lemma 2. $(\mathbf{A} \otimes \mathbf{B})(\mathbf{C} \otimes \mathbf{D}) = \mathbf{AC} \otimes \mathbf{BD}$.

Lemma 3. $(\mathbf{A} \otimes \mathbf{B})^T = \mathbf{A}^T \otimes \mathbf{B}^T$.

Lemma 4. *If* $\mathbf{A}$ *and* $\mathbf{B}$ *are orthogonal matrices, then* $\mathbf{A} \otimes \mathbf{B}$ *will also be an orthogonal matrix.*

Let $\mathbf{Z} = \mathbf{A} \otimes \mathbf{A}$ and apply singular value decomposition to $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$. The term $\left(\mathbf{Z}^T\mathbf{Z} + \lambda\mathbf{I}\right)^{-1}$ can be rewritten as:

$$\begin{aligned}&\left(\mathbf{Z}^T\mathbf{Z} + \lambda\mathbf{I}\right)^{-1} \\ &\quad= \left(\lambda\mathbf{I} + (\mathbf{A}^T \otimes \mathbf{A}^T)(\mathbf{A} \otimes \mathbf{A})\right)^{-1} && (6)\\ &\quad= \left(\lambda\mathbf{I} + \mathbf{A}^T\mathbf{A} \otimes \mathbf{A}^T\mathbf{A}\right)^{-1} && (7)\\ &\quad= \left(\lambda\mathbf{I} + \mathbf{V}\mathbf{\Sigma}^2\mathbf{V}^T \otimes \mathbf{V}\mathbf{\Sigma}^2\mathbf{V}^T\right)^{-1} && (8)\\ &\quad= \left(\lambda\mathbf{I} + (\mathbf{V} \otimes \mathbf{V})(\mathbf{\Sigma}^2 \otimes \mathbf{\Sigma}^2)(\mathbf{V} \otimes \mathbf{V})^T\right)^{-1} && (9)\\ &\quad= (\mathbf{V} \otimes \mathbf{V})\left(\lambda\mathbf{I} + \mathbf{\Sigma}^2 \otimes \mathbf{\Sigma}^2\right)^{-1}(\mathbf{V} \otimes \mathbf{V})^T && (10)\end{aligned}$$

Eq. (6) is from replacing $\mathbf{Z}$ with $\mathbf{A} \otimes \mathbf{A}$ and Lemma 3. Eq. (7) is from Lemma 2. Eq. (8) is from the properties of SVD, where $\mathbf{U}$ and $\mathbf{V}$ are orthonormal matrices. Eq. (9) is from Lemma 2 and Lemma 3. Finally, Eq. (10) comes from Lemma 1.

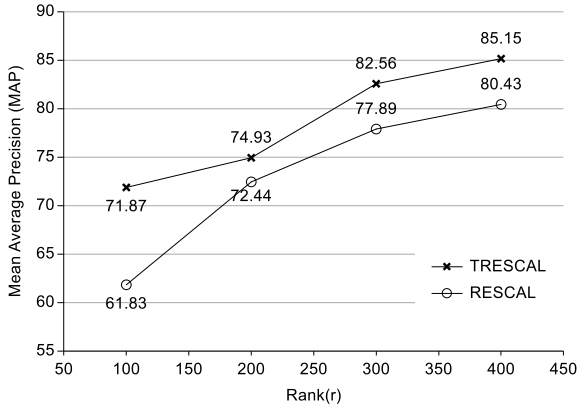

Figure 3: Prediction performance of TRESCAL and RESCAL with different rank (r).

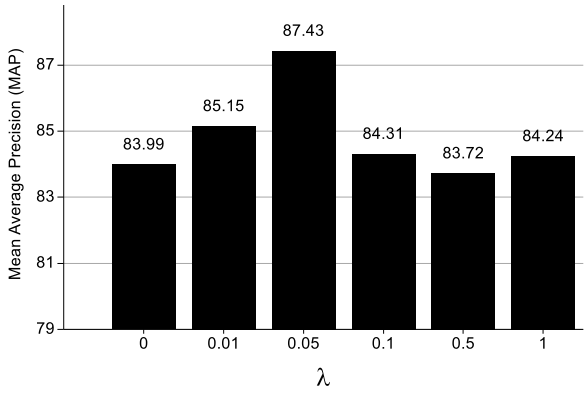

Figure 4: Prediction performance of TRESCAL with different regularization parameter (λ).

Appendix B Hyper-parameter Sensitivity

We study if TRESCAL is sensitive to the rank parameter r and the regularization parameter λ. We use the task of *relation retrieval* and present the model performance on the development set. Fig. 3 shows the performance of TRESCAL and RESCAL with different rank (r) values while fixing $\lambda = 0.01$. Results show that both TRESCAL and RESCAL achieve better performance when r is reasonably large. TRESCAL obtains a better model with smaller r than RESCAL, because TRESCAL only needs to fit the triples of the compatible entity types. Therefore, it allows to use smaller number of latent variables to fit the training data.

Fixing $r = 400$, Fig. 4 shows the performance of TRESCAL at different values of the regularization parameter λ, including no regularization at all ($\lambda = 0$). While the results suggest that the method is not very sensitive to λ, tuning λ is still necessary for achieving the best performance.

A convex relaxation for weakly supervised relation extraction

Édouard Grave
EECS Department
University of California, Berkeley
grave@berkeley.edu

Abstract

A promising approach to relation extraction, called weak or distant supervision, exploits an existing database of facts as training data, by aligning it to an unlabeled collection of text documents. Using this approach, the task of relation extraction can easily be scaled to hundreds of different relationships. However, distant supervision leads to a challenging multiple instance, multiple label learning problem. Most of the proposed solutions to this problem are based on non-convex formulations, and are thus prone to local minima. In this article, we propose a new approach to the problem of weakly supervised relation extraction, based on discriminative clustering and leading to a convex formulation. We demonstrate that our approach outperforms state-of-the-art methods on the challenging dataset introduced by Riedel et al. (2010).

1 Introduction

Information extraction refers to the broad task of automatically extracting structured information from unstructured documents. An example is the extraction of named entities and the relations between those entities from natural language texts. In the age of the world wide web and big data, information extraction is quickly becoming pervasive. For example, in 2013, more than $130,000$ scientific articles were published about cancer. Keeping track with that quantity of information is almost impossible, and it is thus of utmost importance to transform the knowledge contained in this massive amount of documents into structured databases.

Traditional approaches to information extraction relies on supervised learning, yielding high precision and recall results (Zelenko et al., 2003). Unfortunately, these approaches need large amount of labeled data, and thus do not scale well to the great number of different types of fact found on the Web or in scientific articles. A promising approach, called distant or weak supervision, is to exploit an existing database of facts as training data, by aligning it to an unlabeled collection of text documents (Craven and Kumlien, 1999).

Knowledge base

r	e_1	e_2
BornIn	Lichtenstein	New York City
DiedIn	Lichtenstein	New York City

Sentences	Latent labels
Roy Lichtenstein was born in New York City, into an upper-middle-class family.	BornIn
In 1961, Leo Castelli started displaying Lichtenstein's work at his gallery in New York.	None
Lichtenstein died of pneumonia in 1997 in New York City.	DiedIn

Figure 1: An example of a knowledge database comprising two facts and training sentences obtained by aligning this database to unlabeled text.

In this article, we are interested in weakly supervised extraction of binary relations. A challenge pertaining to weak supervision is that the obtained training data is noisy and ambiguous (Riedel et al., 2010). Let us start with an example: if the fact Attended(Turing, King's College) exists in the knowledge database and we observe the sentence

Turing studied as an undergraduate from 1931 to 1934 at King's College, Cambridge.

which contains mentions of both entities Turing

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1580–1590,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

and King's College, then this sentence might express the fact that Alan Turing attended King's College, and thus, might be a useful example for learning to extract the relation Attended. However, the sentence

Celebrations for the centenary of Alan Turing are being planned at King's College.

also contains mentions of Turing and King's College, but do not express the relation Attended. Thus, weak supervision lead to noisy examples. As noted by Riedel et al. (2010), such negative extracted sentences for existing facts can represent more than 30% of the data. Moreover, a given pair of entities, such as (Roy Lichtenstein, New York City), car verify multiple relations, such as BornIn and DiedIn. Weak supervision thus lead to ambiguous examples.

This challenge is illustrated in Fig. 1. A solution to address it is to formulate the task of weakly supervised relation extraction as a multiple instance, multiple label learning problem (Hoffmann et al., 2011; Surdeanu et al., 2012). However, these formulations are often non-convex and thus suffer from local minimum.

In this article, we make the following contributions:

- We propose a new convex relaxation for the problem of weakly supervised relation extraction, based on discriminative clustering,
- We propose an efficient algorithm to solve the associated convex program,
- We demonstrate that our approach obtains state-of-the-art results on the dataset introduced by Riedel et al. (2010).

To our knowledge, this paper is the first to propose a convex formulation for solving the problem of weakly supervised relation extraction.

2 Related work

Supervised learning. Many approaches based on supervised learning have been proposed to solve the problem of relation extraction, and the corresponding literature is to large to be summarized here. One of the first supervised method for relation extraction was inspired by syntactic parsing: the system described by Miller et al. (1998) combines syntactic and semantic knowledge, and thus, part-of-speech tagging, parsing, named entity recognition and relation extraction all happen at the same time. The problem of relation extraction was later formulated as a classification problem: Kambhatla (2004) proposed to solve this problem using maximum entropy models using lexical, syntactic and semantic features. Kernel methods for relation extraction, based on shallow parse trees or dependency trees were introduced by Zelenko et al. (2003), Culotta and Sorensen (2004) and Bunescu and Mooney (2005).

Unsupervised learning. The open information extraction paradigm, simultaneously proposed by Shinyama and Sekine (2006) and Banko et al. (2007), does not rely on any labeled data or even existing relations. Instead, open information extraction systems only use an unlabeled corpus, and output a set of extracted relations. Such systems are based on clustering (Shinyama and Sekine, 2006) or self-supervision (Banko et al., 2007). One of the limitations of these systems is the fact that they extract uncanonicalized relations.

Weakly supervised learning. Weakly supervised learning refers to a broad class of methods, in which the learning system only have access to partial, ambiguous and noisy labeling. Craven and Kumlien (1999) were the first to propose a weakly supervised relation extractor. They aligned a knowledge database (the Yeast Protein Database) with scientific articles mentioning a particular relation, and then used the extracted sentences to learn a classifier for extracting that relation.

Later, many different sources of weak labelings have been considered. Bellare and McCallum (2007) proposed a method to extract bibliographic relations based on conditional random fields and used a database of BibTex entries as weak supervision. Wu and Weld (2007) described a method to learn relations based on Wikipedia infoboxes. Knowledge databases, such as Freebase[1] (Mintz et al., 2009; Sun et al., 2011) and YAGO[2] (Nguyen and Moschitti, 2011) were also considered as a source of weak supervision.

Multiple instance learning. The methods we previously mentionned transform the weakly supervised problem into a fully supervised one, leading to noisy training datasets (see Fig. 1). Mul-

[1] www.freebase.com

[2] www.mpi-inf.mpg.de/yago-naga/yago

tiple instance learning (Dietterich et al., 1997) is a paradigm in which the learner receives bags of examples instead of individual examples. A positively labeled bag contains *at least one* positive example, but might also contains negative examples. In the context of relation extraction, Bunescu and Mooney (2007) introduced a kernel method for multiple instance learning, while Riedel et al. (2010) proposed a solution based on a graphical model.

Both these methods allow only one label per bag, which is an asumption that is not true for relation extraction (see Fig. 1). Thus, Hoffmann et al. (2011) proposed a multiple instance, multiple label method, based on an undirected graphical model, to solve the problem of weakly supervised relation extraction. Finally, Surdeanu et al. (2012) also proposed a graphical model to solve this problem. One of their main contributions is to capture dependencies between relation labels, such as the fact that two labels cannot be generated jointly (*e.g.* the relations `SpouseOf` and `BornIn`).

Discriminative clustering. Our approach is based on the discriminative clustering framework, introduced by Xu et al. (2004). The goal of discriminative clustering is to find a labeling of the data points leading to a classifier with low classification error. Different formulations of discriminative clustering have been proposed, based on support vector machines (Xu et al., 2004), the squared loss (Bach and Harchaoui, 2007) or the logistic loss (Joulin et al., 2010). A big advantage of discriminative clustering is that weak supervision or prior information can easily be incorporated. Our work is closely related to the method proposed by Bojanowski et al. (2013) for learning the names of characters in movies.

3 Weakly supervised relation extraction

In this article, our goal is to extract *binary relations* between entities from natural language text. Given a set of entities, a binary relation r is a collection of ordered pairs of entities. The statement that a pair of entities (e_1, e_2) belongs to the relation r is denoted by $r(e_1, e_2)$ and this triple is called a *fact* or *relation instance*. For example, the fact that Ernest Hemingway was born in Oak Park is denoted by `BornIn(Ernest Hemingway, Oak Park)`. A given pair of entities, such as (`Edouard Manet`, `Paris`), can belong to different relations, such as `BornIn` and `DiedIn`.

An *entity mention* is a contiguous sequence of tokens refering to an entity, while a *pair mention* or *relation mention candidate* is a sequence of text in which a pair of entities is mentioned. In the following, relation mention candidates will be restricted to pair of entities that are mentioned in the same sentence. For example, the sentence:

Ernest Hemingway was born in Oak Park.

contains two entity mentions, corresponding to two relation mention candidates. Indeed, the pairs (`Hemingway`, `Oak Park`) and (`Oak Park`, `Hemingway`) are two distinct pairs of entities, where only the first one verifies the relation `BornIn`.

Given a text corpus, *aggregate extraction* corresponds to the task of extracting a set of facts, such that each extracted fact is expressed at least once in the corpus. On the other hand, the task of *sentential extraction* corresponds to labeling each relation mention candidate by the relation it expresses, or by a `None` label if it does not express any relation. Given a solution to the sentential extraction problem, it is possible to construct a solution for the aggregate extraction problem by returning all the facts that were detected. We will follow this approach, by building an instance level classifier, and aggregating the results by extracting the facts that were detected at least once in the corpus.

In the following, we will describe a method to learn such a classifier using a database of facts instead of a set of labeled sentences. This setting is known as *distant supervision* or *weak supervision*, since we do not have access to labeled data on which we could directly train a sentence level relation extractor.

4 General approach

In this section, we propose a two step procedure to solve the problem of weakly supervised relation extraction:

1. First, we describe a method to infer the relation labels corresponding to each relation mention candidate of our training set,

2. Second, we train a supervised instance level relation extractor, using the labels infered during step 1.

In the second step of our approach, we will simply use a multinomial logistic regression model. We

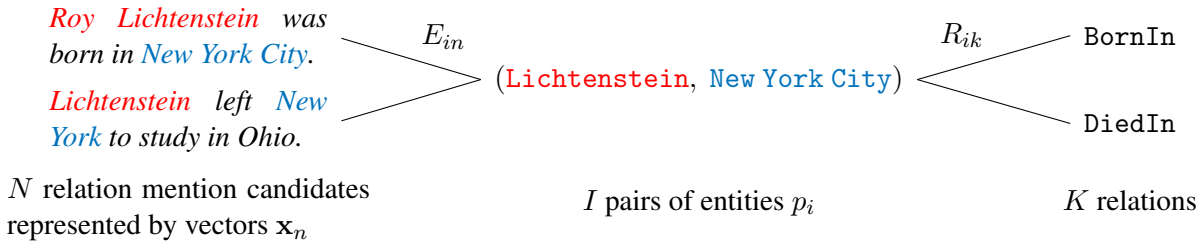

Figure 2: Instance of the weakly supervised relation extraction problem, with notations used in the text.

now describe the approach we propose for the first step.

4.1 Notations

Let $(p_i)_{1\leq i\leq I}$ be a collection of I pairs of entities. We suppose that we have N relation mention candidates, represented by the vectors $(\mathbf{x}_n)_{1\leq n\leq N}$. Let $\mathbf{E}\in\mathbb{R}^{I\times N}$ be a matrix such that $E_{in}=1$ if the relation mention candidate n corresponds to the pair of entities i, and $E_{in}=0$ otherwise. The matrix $\mathbf{E}$ thus indicates which relation mention candidate corresponds to which pair of entities. We suppose that we have K relations, indexed by the integers $\{1,...,K\}$. Let $\mathbf{R}\in\mathbb{R}^{I\times K}$ be a matrix such that $R_{ik}=1$ if the pair of entities i verifies the relation k, and $R_{ik}=0$ otherwise. The matrix $\mathbf{R}$ thus represents the knowledge database. See Fig. 2 for an illustration of these notations.

4.2 Problem formulation

Our goal is to infer a binary matrix $\mathbf{Y}\in\{0,1\}^{N\times(K+1)}$, such that $Y_{nk}=1$ if the relation mention candidate n express the relation k and $Y_{nk}=0$ otherwise (and thus, the integer $K+1$ represents the relation `None`).

We take an approach inspired by the discriminative clustering framework of Xu et al. (2004). We are thus looking for a $(K+1)$-class indicator matrix $\mathbf{Y}$, such that the classification error of an optimal multiclass classifier f is minimum. Given a multiclass loss function ℓ and a regularizer Ω, this problem can be formulated as:

$$\min_{\mathbf{Y}}\min_{f}\ \sum_{n=1}^{N}\ell(\mathbf{y}_n,f(\mathbf{x}_n))+\Omega(f),$$
$$\text{s.t.}\quad \mathbf{Y}\in\mathcal{Y}$$

where $\mathbf{y}_n$ is the nth line of $\mathbf{Y}$. The constraints $\mathbf{Y}\in\mathcal{Y}$ are added in order to take into account the information from the weak supervision. We will describe in the next section what kind of constraints are considered.

4.3 Weak supervision by constraining $\mathbf{Y}$

In this section, we show how the information from the knowledge base can be expressed as constraints on the matrix $\mathbf{Y}$.

First, we suppose that each relation mention candidate express exactly one relation (including the `None` relation). This means that the matrix $\mathbf{Y}$ contains exactly one 1 per line, which is equivalent to the constraint:

$$\forall n\in\{1,...,N\},\ \sum_{k=1}^{K}Y_{nk}=1.$$

Second, if the pair i of entities verifies the relation k we suppose that *at least one* relation mention candidate indeed express that relation. Thus we want to impose that for at least one relation mention candidate n such that $E_{in}=1$, we have $Y_{nk}=1$. This is equivalent to the constraint:

$$\forall(i,k)\text{ such that }R_{ik}=1,\sum_{n=1}^{N}E_{in}Y_{nk}\geq 1.$$

Third, if the pair i of entities does not verify the relation k, we suppose that no relation mention candidate express that relation. Thus, we impose that for all mention candidate n such that $E_{in}=1$, we have $Y_{nk}=0$. This is equivalent to the constraint:

$$\forall(i,k)\text{ such that }R_{ik}=0,\sum_{n=1}^{N}E_{in}Y_{nk}=0.$$

Finally, we do not want too many relation mention candidates to be classified as `None`. We thus impose

$$\forall i\in\{1,...,I\},\ \sum_{n=1}^{N}E_{in}Y_{n(K+1)}\leq c\sum_{n=1}^{N}E_{in},$$

where c is the proportion of relation mention candidates that do not express a relation, for entity pairs that appears in the knowledge database.

We can rewrite these constraints using only matrix operations in the following way:

$$\begin{aligned} &\mathbf{Y1} = \mathbf{1} \\ &(\mathbf{EY}) \circ \mathbf{S} \geq \tilde{\mathbf{R}}, \end{aligned} \tag{1}$$

where $\circ$ is the Hadamard product (a.k.a. the elementwise product), the matrix $\mathbf{S} \in \mathbb{R}^{I \times (K+1)}$ is defined by

$$S_{ik} = \begin{cases} 1 & \text{if } R_{ik} = 1 \\ -1 & \text{if } R_{ik} = 0 \text{ or } k = K+1, \end{cases}$$

and the matrix $\tilde{\mathbf{R}} \in \mathbb{R}^{I \times (K+1)}$ is defined by

$$\tilde{\mathbf{R}} = [\mathbf{R}, -c\mathbf{E1}].$$

The set $\mathcal{Y}$ is thus defined as the set of matrices $\mathbf{Y} \in \{0,1\}^{N \times (K+1)}$ that verifies those two linear constraints. It is important to note that besides the boolean constraints, the two other constraints are convex.

5 Squared loss and convex relaxation

In this section, we describe the problem we obtain when using the squared loss, and its associated convex relaxation. We then introduce an efficient algorithm to solve this problem, by computing its dual.

5.1 Primal problem

Following Bach and Harchaoui (2007), we use linear classifiers $\mathbf{W} \in \mathbb{R}^{D \times (K+1)}$, the squared loss and the squared ℓ_2-norm as the regularizer. In that case, our formulation becomes:

$$\begin{aligned} \min_{\mathbf{Y},\mathbf{W}} \quad & \frac{1}{2}\|\mathbf{Y} - \mathbf{XW}\|_F^2 + \frac{\lambda}{2}\|\mathbf{W}\|_F^2, \\ \text{s.t.} \quad & \mathbf{Y} \in \{0,1\}^{N \times (K+1)} \\ & \mathbf{Y1} = \mathbf{1}, \\ & (\mathbf{EY}) \circ \mathbf{S} \geq \mathbf{R}. \end{aligned}$$

where $\|\cdot\|_F$ is the Frobenius norm and the matrix $\mathbf{X} = [\mathbf{x}_1, ..., \mathbf{x}_N]^\top \in \mathbb{R}^{N \times D}$ represents the relation mention candidates. Thanks to using the squared loss, we have a closed form solution for the matrix $\mathbf{W}$:

$$\mathbf{W} = (\mathbf{X}^\top\mathbf{X} + \lambda\mathbf{I}_D)^{-1}\mathbf{X}^\top\mathbf{Y}.$$

Replacing the matrix $\mathbf{W}$ by its optimal solution, we obtain the following cost function:

$$\min_{\mathbf{Y}} \frac{1}{2}\mathbf{Y}^\top(\mathbf{I}_N - \mathbf{X}(\mathbf{X}^\top\mathbf{X} + \lambda\mathbf{I}_D)^{-1}\mathbf{X}^\top)\mathbf{Y}.$$

Then, by applying the Woodbury matrix identity and relaxing the constraint $\mathbf{Y} \in \{0,1\}^{N \times (K+1)}$ into $\mathbf{Y} \in [0,1]^{N \times (K+1)}$, we obtain the following convex quadratic problem in $\mathbf{Y}$:

$$\begin{aligned} \min_{\mathbf{Y}} \quad & \frac{1}{2}\text{tr}\left(\mathbf{Y}^\top(\mathbf{XX}^\top + \lambda\mathbf{I}_N)^{-1}\mathbf{Y}\right), \\ \text{s.t.} \quad & \mathbf{Y} \geq \mathbf{0}, \\ & \mathbf{Y1} = \mathbf{1}, \\ & (\mathbf{EY}) \circ \mathbf{S} \geq \mathbf{R}. \end{aligned}$$

Since the inequality constraints might be infeasible, we add the penalized slack variables $\xi \in \mathbb{R}^{I \times (K+1)}$, finally obtaining:

$$\begin{aligned} \min_{\mathbf{Y},\xi} \quad & \frac{1}{2}\text{tr}\left(\mathbf{Y}^\top(\mathbf{XX}^\top + \lambda\mathbf{I}_N)^{-1}\mathbf{Y}\right) + \mu\|\xi\|_1 \\ \text{s.t.} \quad & \mathbf{Y} \geq \mathbf{0}, \quad \xi \geq 0, \\ & \mathbf{Y1} = \mathbf{1}, \\ & (\mathbf{EY}) \circ \mathbf{S} \geq \mathbf{R} - \xi. \end{aligned}$$

This convex problem is a quadratic program. In the following section, we will describe how to solve this problem efficiently, by exploiting the structure of its dual problem.

5.2 Dual problem

The matrix $\mathbf{Q} = (\mathbf{XX}^\top + \lambda\mathbf{I}_N)$ appearing in the quadratic program is an N by N matrix, where N is the number of mention relation candidates. Computing its inverse is thus expensive, since N can be large. Instead, we propose to solve the dual of this problem. Introducing dual variables $\Lambda \in \mathbb{R}^{I \times (K+1)}$, $\Sigma \in \mathbb{R}^{N \times (K+1)}$ and $\nu \in \mathbb{R}^N$, the dual problem is equal to

$$\begin{aligned} \min_{\Lambda,\Sigma,\nu} \quad & \frac{1}{2}\text{tr}\left(\mathbf{Z}^\top\mathbf{QZ}\right) - \text{tr}\left(\Lambda^\top\mathbf{R}\right) - \nu^\top 1 \\ \text{s.t.} \quad & 0 \leq \Lambda_{ik} \leq \mu, \quad 0 \leq \Sigma_{nk}, \end{aligned}$$

where

$$\mathbf{Z} = \mathbf{E}^\top(\mathbf{S} \circ \Lambda) + \Sigma + \nu\mathbf{1}^\top.$$

The derivation of this dual problem is given in Appendix A.

Solving the dual problem instead of the primal has two main advantages. First, the dual does not depend on the inverse of the matrix $\mathbf{Q}$, while the primal does. Since traditional features used for relation extraction are indicators of lexical, syntactic and named entities properties of the relation mention candidates, the matrix $\mathbf{X}$ is extremely sparse.

Using the dual problem, we can thus exploit the sparsity of the matrix $\mathbf{X}$ in the optimization procedure. Second, the constraints imposed on dual variables are simpler than constraints imposed on primal variables. Again, we will exploit this structure in the proposed optimization procedure.

Given a solution of the dual problem, the associated primal variable $\mathbf{Y}$ is equal to:

$$\mathbf{Y} = (\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I}_N)\mathbf{Z}.$$

Thus, we do not need to compute the inverse of the matrix $(\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I}_N)$ to obtain a solution to the primal problem once we have solved the dual.

5.3 Optimization of the dual problem

We propose to solve the dual problem using the accelerated projected gradient descent algorithm (Nesterov, 2007; Beck and Teboulle, 2009). Indeed, computing the gradient of the dual cost function is efficient, since the matrix $\mathbf{X}$ is sparse. Moreover, the constraints on the dual variables are simple and it is thus efficient to project onto this set of constraints. See Appendix B for more details.

Complexity. The overall complexity of one step of the accelerated projected gradient descent algorithm is $O(NFK)$, where F is the average number of features per relation mention candidate. This means that the complexity of solving the quadratic problem corresponding to our approach is linear with respect to the number N of relation mention candidates, and thus our algorithm can scale to large datasets.

5.4 Discussion

Before moving to the experimental sections of this article, we would like to discuss some properties of our approach.

Kernels. First of all, one should note that our proposed formulation only depends on the (linear) kernel matrix $\mathbf{X}\mathbf{X}^T$. It is thus possible to replace this matrix by any other kernel. However, in the case of a general kernel, the optimization algorithm presented in the previous section has a quadratic complexity $O(KN^2)$ with respect to the number N of relation mention candidates, and it is thus not applicable *as is*. We plan to explore the use of kernels in future work.

Rounding. Given a continuous solution $\mathbf{Y} \in [0,1]^{N\times(K+1)}$ of the relaxed problem, a very simple way to obtain a relation label for each relation mention candidate of the training set is to compute the orthogonal projection of the matrix $\mathbf{Y}$ on the set of indicator matrices

$$\left\{\mathbf{M} \in \{0,1\}^{N\times(K+1)} \mid \mathbf{M}\mathbf{1} = \mathbf{1}\right\}.$$

This projection consists in taking the maximum value along the rows of the matrix $\mathbf{Y}$. It should be noted that the obtained matrix does not necessarily verify the inequality constraints defined in Eq. 1. In the following, we will use this rounding, refered to as *argmax rounding*, to obtain relation labels for each relation mention candidate.

6 Dataset and features

In this section, we describe the dataset used in the experimental section and the features used to represent the data.

6.1 Dataset

We consider the dataset introduced by Riedel et al. (2010). This dataset consists of articles from the New York Times corpus (Sandhaus, 2008), from which named entities where extracted and tagged using the Stanford named entity recognizer (Finkel et al., 2005). Consecutive tokens with the same category were treated as a single mention. These named entity mentions were then aligned with the Freebase knowledge database, by using a string match between the mentions and the canonical names of entities in Freebase.

6.2 Features

We use the features extracted by Riedel et al. (2010), which were first introduced by Mintz et al. (2009). These features capture how two entity mentions are related in a given sentence, based on syntactic and lexical properties. Lexical features include: the sequence of words between the two entities, a window of k words before the first entity and after the second entity, the corresponding part-of-speech tags, *etc.*. Syntactic features are based on the dependency tree of the sentence, and include: the path between the two entities, neighbors of the two entities that do not belong to the path. The OpenNLP[3] part-of-speech tagger and the Malt parser (Nivre et al., 2007) were used to extract those features.

[3] `opennlp.apache.org`

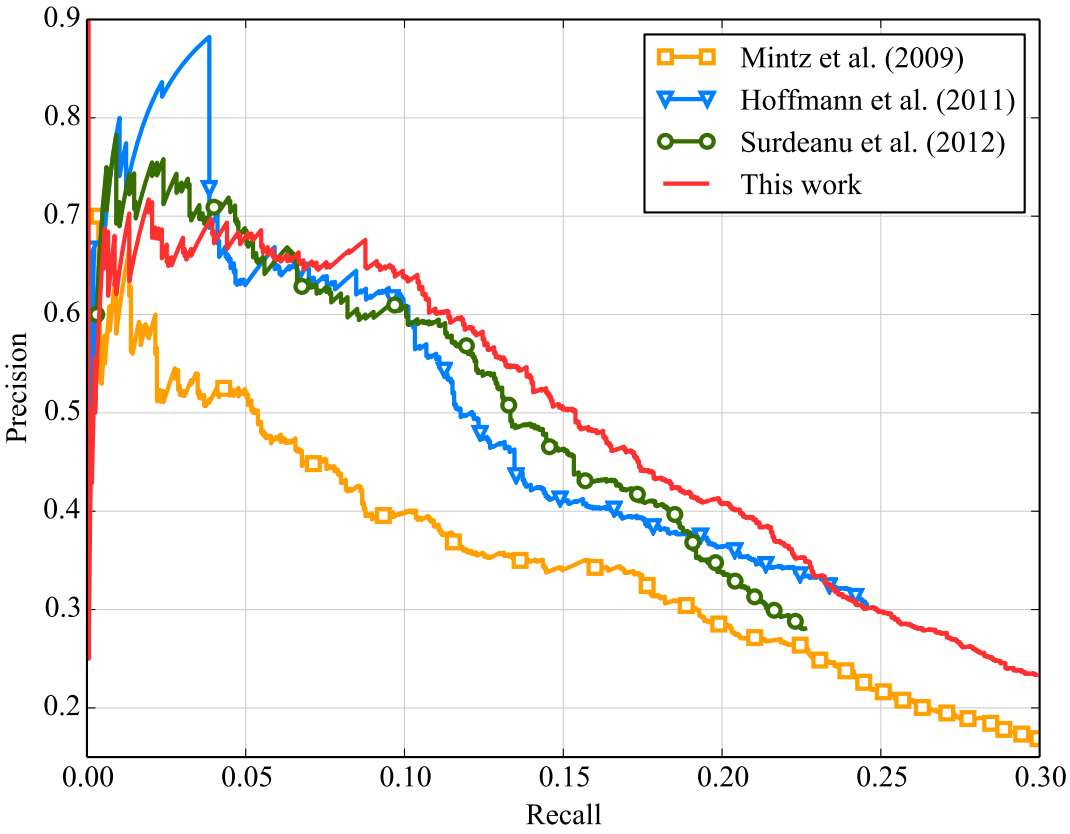

Figure 3: Precision/recall curves for different methods on the Riedel et al. (2010) dataset, for the task of aggregate extraction.

6.3 Implementation details

In this section, we discuss some important implementation details.

Kernel normalization. We normalized the kernel matrix $\mathbf{X}\mathbf{X}^\top$, so that its diagonal coefficients are equal to 1. This corresponds to normalizing the vectors $\mathbf{x}_n$ so that they have a unit ℓ_2-norm.

Choice of parameters. We kept 20% of the examples from the training set as a validation set, in order to choose the parameters of our method. We then re-train a model on the whole training set, using the chosen parameters.

7 Experimental evaluation

In this section, we evaluate our approach to weakly supervised relation extraction by comparing it to state-of-the art methods.

7.1 Baselines

We now briefly present the different methods we compare to.

Mintz et al. This baseline corresponds to the method described by Mintz et al. (2009). We use the implementation of Surdeanu et al. (2012), which slightly differs from the original method: each relation mention candidate is treated independently (and not collapsed across mentions for a given entity pair). This strategy allows to predict multiple labels for a given entity pair, by OR-ing the predictions for the different mentions.

Hoffmann et al. This method, introduced by Hoffmann et al. (2011), is based on probabilistic graphical model of multi-instance multi-label learning. They proposed a learning method for this model, based on the perceptron algorithm (Collins, 2002) and a greedy search for the inference. We use the publicly available code of Hoffmann *et al.*[4].

Surdeanu et al. Finally, we compare our method to the one described by Surdeanu et al. (2012). This method is based on a two-layer graphical model, the first layer corresponding to

[4] www.cs.washington.edu/ai/raphaelh/mr/

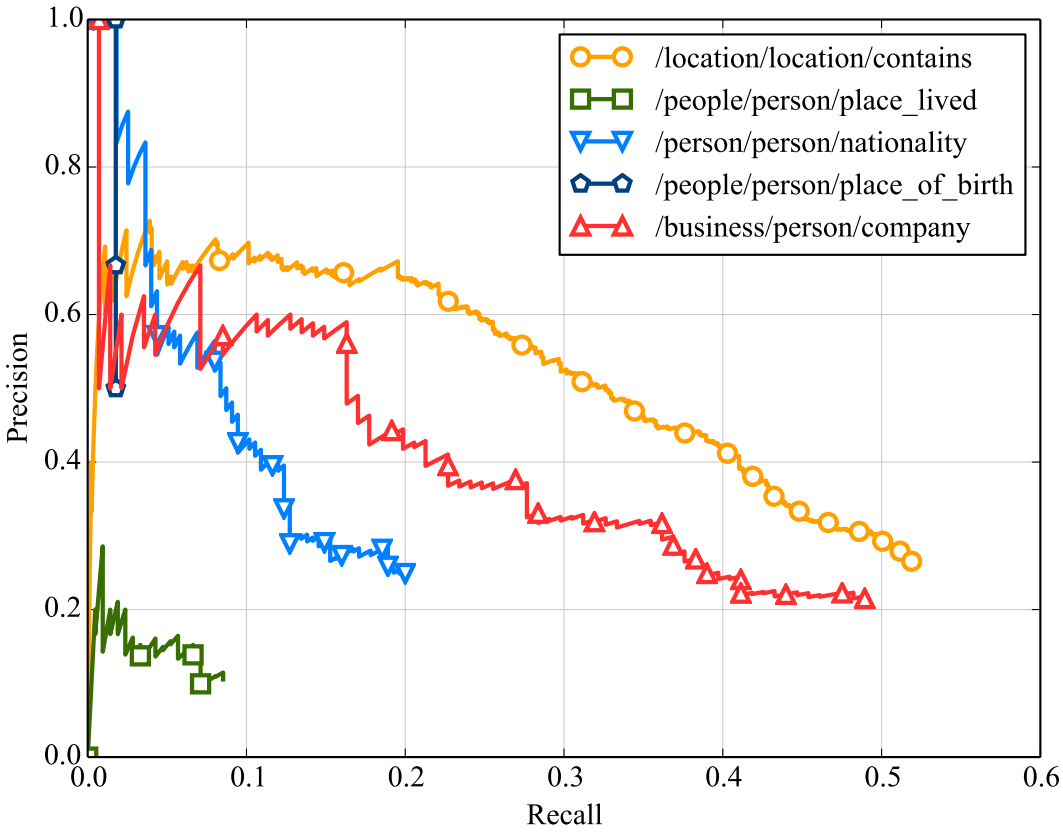

Figure 4: Precision/recall curves per relation for our method, on the Riedel et al. (2010) dataset, for the task of aggregate extraction.

a relation classifier at the mention level, while the second layer is aggregating the different prediction for a given entity pair. In particular, this second layer capture dependencies between relation labels, such as the fact that two labels cannot be generated jointly (*e.g.* the relations `SpouseOf` and `BornIn`). This model is trained by using hard discriminative Expectation-Maximization. We use the publicly available code of Surdeanu *et al.*[5].

7.2 Precision / recall curves

Following standard practices in relation extraction, we report precision/recall curves for the different models. In order to rank aggregate extractions for our model, the score of an extracted fact $r(e_1, e_2)$ is set to the maximal score of the different extractions of that fact. This is sometimes refered to as the soft-OR function.

7.3 Discussion

Comparison with the state-of-the-art. We report results for the different methods on the dataset introduced by Riedel et al. (2010) in Fig. 3. We observe that our approach generally outperforms the state of the art. Indeed, at equivalent recall, our method achieves better (or similar) precision than the other methods, except for very low recall (smaller than 0.05). The improvement over the methods proposed by Hoffmann et al. (2011) and Surdeanu et al. (2012), which are currently the best published results on this dataset, can be as high as 5 points in precision for the same recall point. Moreover, our method achieves a higher recall (0.30) than these two methods (0.25).

Performance per relation. The dataset introduced by Riedel et al. (2010) is highly unbalanced: for example, the most common relation, `/location/location/contains`, represents almost half of the positive relations, while some relations are mentioned less than ten times. We thus decided to also report precision/recall curves for the five most common relations of that dataset in Fig. 4. First, we observe that the perfomances vary a lot from a relation to another. The frequence of the different relations is not the

[5] `nlp.stanford.edu/software/mimlre.shtml`

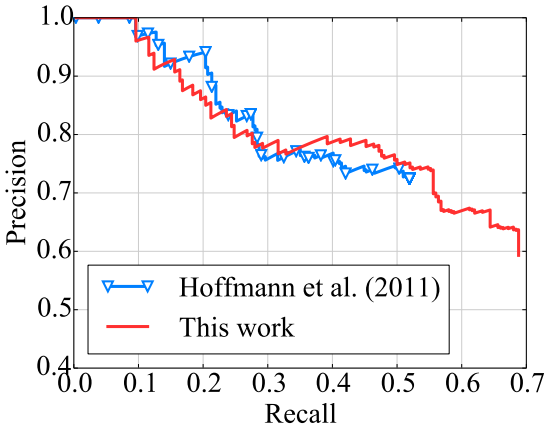

Figure 5: Precision/recall curves for the task of sentential extraction, on the manually labeled dataset of Hoffmann et al. (2011).

only factor in those discrepancies. Indeed, the relation /people/person/place_lived and the relation /people/person/place_of_birth are more frequent than the relation /business/person/company, but the extraction of the later works much better than the extraction of the two first.

Upon examination of the data, this can partly be explained by the fact that almost no sentences extracted for the relation /people/person/place_of_birth in fact express this relation. In other words, many facts present in Freebase are not expressed in the corpus, and are thus impossible to extract. On the other hand, most facts for the relation /people/person/place_lived are missing in Freebase. Therefore, many extractions produced by our system are considered false, but are in fact true positives. The problem of incomplete knowledge base was studied by Min et al. (2013).

Sentential extraction. We finally report precision/recall curves for the task of sentential extraction, in Fig. 5, using the manually labeled dataset of Hoffmann et al. (2011). We observe that for most values of recall, our method achieves similar precision that the one proposed by Hoffmann et al. (2011), while extending the highest recall from 0.52 to 0.68. Thanks to this higher recall, our method achieves a highest F1 score of 0.66, compared to 0.61 obtained by the method proposed by Hoffmann et al. (2011).

Method	Runtime
Mintz et al. (2009)	7 min

8 Conclusion

In this article, we introduced a new formulation for weakly supervised relation extraction. Our method is based on a constrained discriminative formulation of the multiple instance, multiple label learning problem. Using the squared loss, we obtained a convex relaxation of this formulation, allowing us to obtain an approximate solution to the initial integer quadratic program. Thus, our method is not sensitive to initialization. We demonstrated the competitiveness of our approach on the dataset introduced by Riedel et al. (2010), on which our method outperforms the state of the art methods for weakly supervised relation extraction, on both aggregate and sentential extraction.

As noted earlier, another advantage of our method is the fact that it is easily kernelizable. We would like to explore the use of kernels, such as the ones introduced by Zelenko et al. (2003), Culotta and Sorensen (2004) and Bunescu and Mooney (2005), in future work. We believe that such kernels could improve the relatively low recall obtained so far by weakly supervised method for relation extraction.

Appendix A Derivation of the dual

In this section, we derive the dual problem of the quadratic program of section 5. We introduce dual variables $\Lambda \in \mathbb{R}^{I\times(K+1)}$, $\Sigma \in \mathbb{R}^{N\times(K+1)}$, $\Omega \in \mathbb{R}^{I\times(K+1)}$ and $\nu \in \mathbb{R}^N$, such that $\Lambda \geq 0$, $\Sigma \geq 0$ and $\Omega \geq 0$.

The Lagrangian of the problem is

$$\begin{aligned}\frac{1}{2}\text{tr}\left(\mathbf{Y}^\top(\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N)^{-1}\mathbf{Y}\right) + \mu\sum_{i,k}\xi_{ik} \\ - \text{tr}\left(\Lambda^\top((\mathbf{E}\mathbf{Y})\circ\mathbf{S} - \mathbf{R} + \xi)\right) \\ - \text{tr}(\Sigma^\top\mathbf{Y}) - \text{tr}(\Omega^\top\xi) - \nu^\top(\mathbf{Y}\mathbf{1} - \mathbf{1}).\end{aligned}$$

To find the dual function g we minimize the Lagrangian over $\mathbf{Y}$ and ξ. Minimizing over ξ, we find that the dual function is equal to $-\infty$ unless $\mu - \Lambda_{ik} - \Omega_{ik} = 0$, in which case, we are left with

$$\begin{aligned}\frac{1}{2}\text{tr}\left(\mathbf{Y}^\top(\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N)^{-1}\mathbf{Y}\right) \\ - \text{tr}((\Lambda\circ\mathbf{S})^\top\mathbf{E}\mathbf{Y}) - \text{tr}(\Sigma^\top\mathbf{Y}) - \text{tr}(\mathbf{1}\nu^\top\mathbf{Y}) \\ + \text{tr}(\Lambda^\top\mathbf{R}) + \nu^\top\mathbf{1}.\end{aligned}$$

Minimizing over $\mathbf{Y}$, we then obtain

$$\mathbf{Y} = (\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N)(\mathbf{E}^\top(\mathbf{S}\circ\Lambda) + \Sigma + \nu\mathbf{1}^\top).$$

Replacing $\mathbf{Y}$ by its optimal value, we then obtain the dual function

$$-\frac{1}{2}\text{tr}\left(\mathbf{Z}^\top\mathbf{Q}\mathbf{Z}\right) + \text{tr}\left(\Lambda^\top\mathbf{R}\right) + \nu^\top\mathbf{1}.$$

where

$$\begin{aligned}\mathbf{Q} &= (\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N), \\ \mathbf{Z} &= \mathbf{E}^\top(\mathbf{S}\circ\Lambda) + \Sigma + \nu\mathbf{1}^\top.\end{aligned}$$

Thus, the dual problem is

$$\begin{aligned}\max_{\Lambda,\Sigma,\nu} \quad & -\frac{1}{2}\text{tr}\left(\mathbf{Z}^\top\mathbf{Q}\mathbf{Z}\right) + \text{tr}\left(\Lambda^\top\mathbf{R}\right) + \nu^\top 1 \\ \text{s.t.} \quad & 0 \leq \Lambda_{ik}, \quad 0 \leq \Sigma_{nk}, \quad 0 \leq \Omega_{ik}, \\ & \mu - \Lambda_{ik} - \Omega_{ik} = 0.\end{aligned}$$

We can then eliminate the dual variable Ω, since the constraints $\Omega_{ik} = \mu - \Lambda_{ik}$ and $\Omega_{ik} \geq 0$ are equivalent to $\mu \geq \Lambda_{ik}$. We finally obtain

$$\begin{aligned}\max_{\Lambda,\Sigma,\nu} \quad & -\frac{1}{2}\text{tr}\left(\mathbf{Z}^\top\mathbf{Q}\mathbf{Z}\right) + \text{tr}\left(\Lambda^\top\mathbf{R}\right) + \nu^\top 1 \\ \text{s.t.} \quad & 0 \leq \Lambda_{ik} \leq \mu, \quad 0 \leq \Sigma_{nk}.\end{aligned}$$

Appendix B Optimization details

Gradient of the dual cost function. The gradient of the dual cost function f with respect to the dual variables Σ, Λ and ν is equal to

$$\begin{aligned}\nabla_\Sigma f &= (\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N)\mathbf{Z}, \\ \nabla_\Lambda f &= \left((\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N)\mathbf{Z}\mathbf{E}^\top\right)\circ\mathbf{S} - \mathbf{R}, \\ \nabla_\nu f &= (\mathbf{X}\mathbf{X}^\top + \lambda\mathbf{I}_N)\mathbf{Z}\mathbf{1} - \mathbf{1}.\end{aligned}$$

The most expensive step to compute those gradients is to compute the matrix product $\mathbf{X}\mathbf{X}^\top\mathbf{Z}$. Since the matrix $\mathbf{X}$ is sparse, we efficiently compute this product by first computing the product $\mathbf{X}^\top\mathbf{Z}$, and then by left multiplying the result by $\mathbf{X}$. The complexity of these two operations is $O(NFK)$, where F is the average number of features per relation mention candidate.

Projecting Σ and Λ. The componentwise projection operators associated to the constraints on Σ and Λ are defined by:

$$\begin{aligned}\text{proj}_\Sigma(\Sigma_{nk}) &= \max(0, \Sigma_{nk}), \\ \text{proj}_\Lambda(\Lambda_{ik}) &= \max(0, \min(\mu, \Lambda_{ik})).\end{aligned}$$

The complexity of projecting Σ and Λ is $O(NK)$. Thus, the cost of those operations is ne gligible compared to the cost of computing the gradients of the dual cost function.

Knowledge Graph and Text Jointly Embedding

Abstract

We examine the embedding approach to reason new relational facts from a large-scale knowledge graph and a text corpus. We propose a novel method of jointly embedding entities and words into the same continuous vector space. The embedding process attempts to preserve the relations between entities in the knowledge graph and the concurrences of words in the text corpus. Entity names and Wikipedia anchors are utilized to align the embeddings of entities and words in the same space. Large scale experiments on Freebase and a Wikipedia/NY Times corpus show that jointly embedding brings promising improvement in the accuracy of predicting facts, compared to separately embedding knowledge graphs and text. Particularly, jointly embedding enables the prediction of facts containing entities out of the knowledge graph, which cannot be handled by previous embedding methods. At the same time, concerning the quality of the word embeddings, experiments on the analogical reasoning task show that jointly embedding is comparable to or slightly better than word2vec (Skip-Gram).

1 Introduction

Knowledge graphs such as Freebase (Bollacker et al., 2008) and WordNet (Miller, 1995) have become important resources for many AI & NLP applications such as Q & A. Generally, a knowledge graph is a collection of relational facts that are often represented in the form of a triplet (head entity, relation, tail entity), e.g., "(Obama, Born-in, Honolulu)". An urgent issue for knowledge graphs is the coverage, e.g., even the largest knowledge graph of Freebase is still far from complete.

Recently, targeting knowledge graph completion, a promising paradigm of embedding was proposed, which is able to reason new facts only from the knowledge graph (Bordes et al., 2011; Bordes et al., 2013; Socher et al., 2013; Wang et al., 2014). Generally, in this series of methods, each entity is represented as a k-dimensional vector and each relation is characterized by an operation in $\Re^k$ so that a candidate fact can be asserted by simple vector operations. The embeddings are usually learnt by minimizing a global loss function of all the entities and relations in the knowledge graph. Thus, the vector of an entity may encode global information from the entire graph, and hence scoring a candidate fact by designed vector operations plays a similar role to long range "reasoning" in the graph. However, since this requires the vectors of both entities to score a candidate fact, this type of methods can only complete missing facts for which both entities exist in the knowledge graph. However, a missing fact often contains entities out of the knowledge graph (called *out-of-kb* for short in this paper), e.g., one or both entities are phrases appearing in web text but not included in the knowledge graph yet. How to deal with these facts is a significant obstacle to widely applying the embedding paradigm.

In addition to knowledge embedding, another interesting approach is the word embedding method word2vec (Mikolov et al., 2013b), which shows that learning word embeddings from an unlabeled text corpus can make the vectors connecting the pairs of words of some certain relation almost parallel, e.g., vec("China") $-$ vec("Beijing") $\approx$ vec("Japan") $-$ vec("Tokyo"). However, it does not know the exact relation between the pairs. Thus, it cannot be directly applied to complete knowledge graphs.

The capabilities and limitations of knowledge embedding and word embedding have inspired us to design a mechanism to mosaic the knowledge

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1591–1601,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

graph and the "word graph" together in a vector space so that we can score any candidate relational facts between entities and words[1]. Therefore, we propose a novel method to jointly embed entities and words into the same vector space. In our solution, we define a coherent probabilistic model for both knowledge and text, which is composed of three components: the knowledge model, text model, and alignment model. Both the knowledge model and text model use the same core translation assumption for the fact modeling: a candidate fact (h, r, t) is scored based on $\|\mathbf{h} + \mathbf{r} - \mathbf{t}\|$. The only difference is, in the knowledge model the relation r is explicitly supervised and the goal is to fit the fact triplets, while in the text model we assume any pair of words h and t that concur in some text windows are of certain relation r but r is a hidden variable, and the goal is to fit the concurring pairs of words. The alignment model guarantees the embeddings of entities and words/phrases lie in the same space and impels the two models to enhance each other. Two mechanisms of alignment are introduced in this paper: utilizing names of entities and utilizing Wikipedia anchors. This way of jointly embedding knowledge and text can be considered to be semi-supervised knowledge embedding: the knowledge graph provides explicit supervision of facts while the text corpus provides much more "relation-unlabeled" pairs of words.

We conduct extensive large scale experiments on Freebase and Wikipedia corpus, which show jointly embedding brings promising improvements to the accuracy of predicting facts, compared to separately embedding the knowledge graph and the text corpus, respectively. Particularly, jointly embedding enables the prediction of a candidate fact with out-of-kb entities, which can not be handled by any existing embedding methods. We also use embeddings to provide a prior score to help fact extraction on the benchmark data set of Freebase+NYTimes and also observe very promising improvements. Meanwhile, concerning the quality of word embeddings, experiments on the analogical reasoning task show that jointly embedding is comparable to or slightly better than word2vec (Skip-Gram).

[1]We do not distinguish between "words" and "phrases", i.e., "words" means "words/phrases".

2 Related Work

Knowledge Embedding. A knowledge graph is embedded into a low-dimensional continuous vector space while certain properties of it are preserved (Bordes et al., 2011; Bordes et al., 2013; Socher et al., 2013; Chang et al., 2013; Wang et al., 2014). Generally, each entity is represented as a point in that space while each relation is interpreted as an operation over entity embeddings. For instance, TransE (Bordes et al., 2013) interprets a relation as a *translation* from the head entity to the tail entity. The embedding representations are usually learnt by minimizing a global loss function involving all entities and relations so that each entity embedding encodes both local and global connectivity patterns of the original graph. Thus, we can reason new facts from learnt embeddings.

Word Embedding. Generally, word embeddings are learned from a given text corpus without supervision by predicting the context of each word or predicting the current word given its context (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013a; Mikolov et al., 2013b). Although relations between words are not explicitly modeled, continuous bag-of-words (CBOW) and Skip-gram (Mikolov et al., 2013a; Mikolov et al., 2013b) learn word embeddings capturing many syntactic and semantic relations between words where a relation is also represented as the *translation* between word embeddings.

Relational Facts Extraction. Another pivotal channel for knowledge graph completion is extracting relational facts from external sources such as free text (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Zhang et al., 2013; Fan et al., 2014). This series of methods focuses on identifying local text patterns that express a certain relation and making predictions based on them. However, they have not fully utilized the evidences from a knowledge graph, e.g., knowledge embedding is able to reason new facts without any external sources. Actually, knowledge embedding is very complementary to traditional extraction methods, which was first confirmed by (Weston et al., 2013). To estimate the plausibility of a candidate fact, they added scores from embeddings to scores from an extractor, which showed significant improvement. However, as pointed out in the introduction, their knowledge embedding method cannot predict facts involving out-of-kb entities.

3 Jointly Embedding Knowledge and Text

We will first describe the notation used in this paper. A knowledge graph Δ is a set of triplets in the form $(h, r, t), h, t \in \mathcal{E}$ and $r \in \mathcal{R}$ where $\mathcal{E}$ is the entity vocabulary and $\mathcal{R}$ is a collection of predefined relations. We use bold letters $\mathbf{h}, \mathbf{r}, \mathbf{t}$ to denote the corresponding embedding representations of h, r, t. A text corpus is a sequence of words drawn from the word vocabulary $\mathcal{V}$. Note that we perform some preprocessing to detect phrases in the text and the vocabulary here already includes the phrases. For simplicity's sake, without special explanation, when we say "word(s)", it means "word(s)/phrase(s)". Since we consider triplets involving not only entities but also words, we denote $\mathcal{I} = \mathcal{E} \cup \mathcal{V}$. Additionally, we denote anchors by $\mathcal{A}$.

3.1 Modeling

Our model is composed of three components: the knowledge model, text model, and alignment model.

Before defining the component models, we first define the element model for a fact triplet. Inspired by TransE, we also represent a relation r as a vector $\mathbf{r} \in \Re^k$ and score a fact triplet (h, r, t) by $z(\mathbf{h}, \mathbf{r}, \mathbf{t}) = b - \frac{1}{2}\|\mathbf{h} + \mathbf{r} - \mathbf{t}\|^2$ where b is a constant for bias designated for adjusting the scale for better numerical stability and $b = 7$ is a sensible choice. $z(\mathbf{h}, \mathbf{r}, \mathbf{t})$ is expected to be large if the triplet is true. Based on the same element model of fact, we define the component models as follows.

3.1.1 Knowledge Model

We define the following conditional probability of a fact (h, r, t) in a knowledge graph:

$$\Pr(h|r,t) = \frac{\exp\{z(\mathbf{h}, \mathbf{r}, \mathbf{t})\}}{\sum_{\tilde{h} \in \mathcal{I}} \exp\{z(\tilde{\mathbf{h}}, \mathbf{r}, \mathbf{t})\}} \quad (1)$$

and we have named our model *pTransE* (Probabilistic TransE) to show respect to TransE. We also define $\Pr(r|h,t)$ and $\Pr(t|h,r)$ in the same way by choosing corresponding normalization terms respectively. We define the likelihood of observing a fact triplet as:

$$\begin{aligned}\mathcal{L}_f(h,r,t) = \log \Pr(h|r,t) + \log \Pr(t|h,r) \\ + \log \Pr(r|h,t)\end{aligned} \quad (2)$$

The goal of the knowledge model is to maximize the conditional likelihoods of existing fact triplets in the knowledge graph:

$$\mathcal{L}_K = \sum_{(h,r,t) \in \Delta} \mathcal{L}_f(h,r,t) \quad (3)$$

3.1.2 Text Model

We propose the following key assumption for modeling text, which connects word embedding and knowledge embedding: there are relations between words although we do not know what they are.

Relational Concurrence Assumption. *If two words w and v concur in some context, e.g., a window of text, then there is a relation r_{wv} between the two words. That is, we can state the triplet of (w, r_{wv}, v) is a fact.*

We define the conditional probability $\Pr(w|r_{wv}, v)$ following the same formulation of Eq.(1) to model why two words concur in some context. In contrast to knowledge embedding, here r_{wv} is a hidden variable rather than explicitly supervised.

The challenge is to deal with the hidden variable r_{wv}. Obviously, without any more assumptions, the number of distinct r_{wv} is around $|\mathcal{V}| \times \bar{N}$, where $\bar{N}$ is the average number of unique words concurred with each word. This number is extremely large. Thus it is almost impossible to estimate a vector for each r_{wv}. And the problem is actually ill-posed. We need to constrain the freedom degree of r_{wv}. Here we use auxiliary variables to reduce the size of variables we need to estimate: let $\mathbf{w}' = \mathbf{w} + \mathbf{r}_{wv}$, then

$$z(\mathbf{w}, \mathbf{r}_{wv}, \mathbf{v}) \triangleq z(\mathbf{w}', \mathbf{v}) = b - \frac{1}{2}\|\mathbf{w}' - \mathbf{v}\|^2 \quad (4)$$

and

$$\Pr(w|r_{wv}, v) \triangleq \Pr(w|v) = \frac{\exp\{z(\mathbf{w}', \mathbf{v})\}}{\sum_{\tilde{w} \in \mathcal{V}} \exp\{z(\tilde{\mathbf{w}}', \mathbf{v})\}} \quad (5)$$

In this way we need to estimate vectors $\mathbf{w}$ and $\mathbf{w}'$ for each word w, and a total of $2 \times |\mathcal{V}|$ vectors.

The goal of the text model is to maximize the likelihood of the concurrences of pairs of words in text windows:

$$\mathcal{L}_T = \sum_{(w,v) \in \mathcal{C}} n_{wv} \log \Pr(w|v). \quad (6)$$

In the above equation, $\mathcal{C}$ is all the distinct pairs of words concurring in text windows of a fixed size. And n_{wv} is the number of concurrences of the pair (w, v). Interestingly, as explained in Sec.(3.3), this text model is almost equivalent to Skip-Gram.

3.1.3 Alignment Model

If we only have the knowledge model and text model, the entity embeddings and word embeddings will be in different spaces and any computing between them is meaningless. Thus we need mechanisms to align the two spaces into the same one. We propose two mechanisms in this paper: utilizing Wikipedia anchors, and utilizing names of entities.

Alignment by Wikipedia Anchors. This model is based on the connection between Wikipedia and Freebase: for most Wikipedia (English) pages, there is an unique corresponding entity in Freebase. As a result, for most of the anchors in Wikipedia, each of which refers to a Wikipedia page, we know that the surface phrase v of an anchor actually refers to the Freebase entity e_v. Thus, we define a likelihood for this part of anchors as Eq.(6) but replace the word pair (w, v) with the word-entity pair (w, e_v), i.e., using the corresponding entity e_v rather than the surface word v in Eq.(5):

$$\mathcal{L}_{AA} = \sum_{(w,v)\in\mathcal{C}, v\in\mathcal{A}} \log \Pr(w|e_v) \tag{7}$$

where $\mathcal{A}$ denotes the set of anchors.

In addition to Wikipedia anchors, we can also use an entity linking system with satisfactory performance to produce the pseudo anchors.

Alignment by Names of Entities. Another way is to use the names of entities. For a fact triplet $(h, r, t) \in \Delta$, if h has a name w_h and $w_h \in \mathcal{V}$, then we will generate a new triplet of (w_h, r, t) and add it to the graph. Similarly, we also add (h, r, w_t) and (w_h, r, w_t) into the graph if the names exist and belong to the word vocabulary. We call this sub-graph containing names the *name graph* and define a likelihood for the name graph by observing its triplets:

$$\mathcal{L}_{AN} = \sum_{(h,r,t)\in\Delta} \mathbf{I}_{[w_h\in\mathcal{V}\wedge w_t\in\mathcal{V}]}\cdot\mathcal{L}_f(w_h, r, w_t)+ \mathbf{I}_{[w_h\in\mathcal{V}]}\cdot\mathcal{L}_f(w_h, r, t) + \mathbf{I}_{[w_t\in\mathcal{V}]}\cdot\mathcal{L}_f(h, r, w_t) \tag{8}$$

Both alignment models have advantages and disadvantages. Alignment by names of entities is straightforward and does not rely on additional data sources. The number of triplets generated by the names is also large and can significantly change the results. However, this model is risky. On the one hand, the name of an entity is ambiguous because different entities sometimes have the same name so that the name graph may contaminate the knowledge embedding. On the other hand, an entity often has several different aliases when mentioned in the text but we do not have the complete set, which will break the semantic balance of word embedding. For example, for the entity Apple Inc., suppose we only have the standard name "Apple Inc." but do not have the alias "apple". And for the entity Apple that is fruit, suppose we have the name "apple" included in the name graph. Then the vector of the word "apple" will be biased to the concept of fruit rather than the company. But if no name graph intervenes, the unsupervised word embedding is able to learn a vector that is closer to the concept of the company due to the polarities. Alignment by anchors relies on the additional data source of Wikipedia anchors. Moreover, the number of matched Wikipedia anchors (∼40M) is relatively small compared to the total number of word pairs (∼2.0B in Wikipedia) and hence the contribution is limited. However, the advantage is that the quality of the data is very high and there are no ambiguity/completeness issues.

Considering the above three component models together, the likelihood we maximize is:

$$\mathcal{L} = \mathcal{L}_K + \mathcal{L}_T + \mathcal{L}_A \tag{9}$$

where $\mathcal{L}_A$ could be $\mathcal{L}_{AA}$ or $\mathcal{L}_{AN}$ or $\mathcal{L}_{AA} + \mathcal{L}_{AN}$.

3.2 Training

3.2.1 Approximation to the Normalizers

It is difficult to directly compute the normalizers in $\Pr(h|r, t)$ (or $\Pr(t|h, r)$, $\Pr(r|h, t)$) and $\Pr(w|v)$ as the normalizers sum over $|\mathcal{I}|$ or $|\mathcal{V}|$ terms where both $|\mathcal{I}|$ and $|\mathcal{V}|$ reach tens of millions. To prevent having to exactly calculate the normalizers, we use negative sampling (NEG) (Mikolov et al., 2013b) to transform the original objective, i.e., Eq.(9) to a simple objective of the binary classification problem—differentiating the observed data from noise.

First, we define: (i) the probability of a given triplet (h, r, t) to be true ($D = 1$); and (ii) the probability of a given word pair (w, v) to co-occur ($D = 1$):

$$\Pr(D = 1|h, r, t) = \sigma(z(\mathbf{h}, \mathbf{r}, \mathbf{t})) \tag{10}$$

$$\Pr(D = 1|w, v) = \sigma(z(\mathbf{w}', \mathbf{v})) \tag{11}$$

where $\sigma(x) = \frac{1}{1+\exp\{-x\}}$ and $D \in \{0, 1\}$.

Instead of maximizing $\log \Pr(h|r,t)$ in Eq.(2), we maximize:

$$\log \Pr(1|h,r,t) + \sum_{i=1}^{c} \mathbb{E}_{\tilde{h}_i \sim \Pr_{\text{neg}}(\tilde{h}_i)} [\Pr(0|\tilde{h}_i,r,t)] \quad (12)$$

where c is the number of negative examples to be discriminated for each positive example. NEG guarantees that maximizing Eq.(12) can approximately maximize $\log \Pr(h|r,t)$. Thus, we also replace $\log \Pr(r|h,t)$, $\log \Pr(t|r,h)$ in Eq.(2), and $\log \Pr(w|v)$ in Eq.(6) in the same way by choosing corresponding negative distributions respectively. As a result, the objectives of both the knowledge model $\mathcal{L}_K$ (Eq.(3)) and text model $\mathcal{L}_T$ (Eq.(6)) are free from cumbersome normalizers.

3.2.2 Optimization

We use stochastic gradient descent (SGD) to maximize the simplified objectives.

Knowledge model. Δ is randomly traversed multiple times. When a positive example $(h,r,t) \in \Delta$ is considered, to maximize (12), we construct c negative triplets by sampling elements from an uniform distribution over $\mathcal{I}$ and replacing the head of (h,r,t). The transformed objective of $\log \Pr(r|h,t)$ is maximized in the same manner, but by sampling from a uniform distribution over $\mathcal{R}$ and corrupting the relation of (h,r,t). After a mini-batch, computed gradients are used to update the involved embeddings.

Text model. The text corpus is traversed one or more times. When current word v and a context word w are considered, c words are sampled from the unigram distribution raised to the 3/4rd power and regarded as negative examples $(\tilde{w}, v)$ that are never concurrent. Then we compute and update the related gradients.

Alignment model. $\mathcal{L}_{AA}$ and $\mathcal{L}_{AN}$ are absorbed by the text model and knowledge model respectively, since anchors are considered to predict context given an entity and the name graph are homogeneous to the original knowledge graph.

Joint. All three component objectives are *simultaneously* optimized. To deal with large-scale data, we implement a multi-thread version with shared memory. Each thread is in charge of a portion of the data (either knowledge or text corpus), and traverses through them, calculates gradients and commits the update to the global model and is stored in a block of shared memory. For the sake of efficiency, no lock is used on the shared memory.

Table 1: **Data**: triplets used in our experiments.

#$\mathcal{R}$	#$\mathcal{E}$	#Triplet (Train/Valid/Test)		
4,490	43,793,608	123,062,855	40,528,963	40,528,963

3.3 Connections to Related Models

TransE. (Bordes et al., 2013) proposed to model a relation r as a translation vector $\mathbf{r} \in \Re^k$ which is expected to connect $\mathbf{h}$ and $\mathbf{t}$ with low error if $(h,r,t) \in \Delta$. We also follow it. However, TransE uses a margin based ranking loss $\{\|\mathbf{h}+\mathbf{r}-\mathbf{t}\|^2+\gamma-\|\tilde{\mathbf{h}}+\mathbf{r}-\tilde{\mathbf{t}}\|^2\}_+$. It is not a probabilistic model and hence it needs to restrict the norm of either entity embedding and/or relation embedding. Bordes et al. (2013) intuitively addresses this problem by simply normalizing the entity embeddings to the unit sphere before computing gradients at each iteration. We define pTransE as a probabilistic model, which doesn't need additional constraints on the norms of embeddings of entities/words/relations, and thus eliminates the normalization operations.

Skip-gram. (Mikolov et al., 2013a; Mikolov et al., 2013b) defines the probability of the concurrence of two words in a window as:

$$\Pr(w|v) = \frac{\exp\{\mathbf{w}'^{\mathrm{T}}\mathbf{v}\}}{\sum_{\tilde{w}\in\mathcal{V}} \exp\{\tilde{\mathbf{w}}'^{\mathrm{T}}\mathbf{v}\}} \quad (13)$$

which is based on the inner product, while our text model (Eqs. (4), (5)) is based on distance. If we constrain $\|\mathbf{w}\| = 1$ for each w, then $\mathbf{w}'^{\mathrm{T}}\mathbf{v} = 1 - \frac{1}{2}\|\mathbf{w}' - \mathbf{v}\|^2$. It is easy to see that our text model is equivalent to Skip-gram in this case. Our distance-based text model is directly derived from the triplet fact model, which clearly explains why it is able to make the pairs of entities of a certain relation parallel in the vector space.

4 Experiments

We empirically evaluate and compare related models with regards to three tasks: triplet classification (Socher et al., 2013), improving relation extraction (Weston et al., 2013), and the analogical reasoning task (Mikolov et al., 2013a). The related models include: for knowledge embedding alone, TransE (Bordes et al., 2013), pTransE (proposed in this paper); for word embedding alone, Skip-gram (Mikolov et al., 2013b); for both

Table 2: **Data**: the number of $e-e$, $w-e$, $e-w$, $w-w$ triplets/analogies where w represents the out-of-kb entity, which is regarded as word and replaced by its corresponding entity name.

Type	#Triplet (Valid/Test)		#Analogy
$e-e$	12,305,200	12,305,200	71,441
$w-e$	3,655,164	3,654,404	70,878
$e-w$	3,643,914	3,642,978	70,442
$w-w$	460,762	451,381	40,980

knowledge and text, we use "respectively" to refer to the embeddings learnt by TransE/pTransE and Skip-gram, respectively, "jointly" to refer to our jointly embedding method, in which "anchor" and "name" refer to "Alignment by Wikipedia Anchors" and "Alignment by Names of Entities", respectively.

4.1 Data

To learn the embedding representations of entities and words, we use a knowledge graph, a text corpus, and some connections between them.

Knowledge. We adopt Freebase as our knowledge graph. First, we remove the user profiles, version control, and meta data, leaving 52,124,755 entities, 4,490 relations, and 204,120,782 triplets. We call this graph *main facts*. Then we held out 8,331,147 entities from main facts and regard them as out-of-kb entities. Under such a setting, from main facts, we held out all the triplets involving out-of-kb entities, as well as 24,610,400 triplets that don't contain out-of-kb entities. Held-out triplets are used for validation and testing; the remaining triplets are used for training. See Table 1 for the statistics.

We regard out-of-kb entities as words/phrases and thus divide the held-out triplets into four types: no out-of-kb entity ($e-e$), the head is out-of-kb entity but the tail is not ($w-e$), the tail is out-of-kb entity but the head is not ($e-w$), and both the head and tail are out-of-kb entities ($w-w$). Then we replace the out-of-kb entities among the held-out triplets by their corresponding entity names. The mapping from a Freebase entity identifier to its name is done through the Freebase predicate—"/type/object/name". Since some entity names are not present in our vocabulary $\mathcal{V}$, we remove triplets involving these names (see Table 2). In such a way, besides the missing edges between existing entities, the related models can be evaluated on triplets involving words/phrases as their head and/or tail.

Table 3: **Triplet Classification**: comparison between TransE and pTransE over $e-e$ triplets.

Method	Accuracy (%)	Area under PR curve
TransE	93.1	0.86
pTransE	**93.4**	**0.97**

Text. We adopt the Wikipedia (English) corpus. After removing pages designated for navigation, disambiguation, or discussion purposes, there are 3,469,024 articles left. We apply sentence segmentation, tokenization, Part-of-Speech (POS) tagging, and named entity recognition (NER) to these articles using Apache OpenNLP package[2]. Then we conduct some simple chunking to acquire phrases: if several consecutive tokens are identically tagged as "Location"/"Person"/"Organization", or covered by an anchor, we combine them as a chunk. After the preprocessing, our text corpus contain 73,675,188 sentences consisting of 1,522,291,723 chunks. Among them, there are around 20 millions distinct chunks, including words and phrases. We filter out punctuation and rare words/phrases that occur less than three times in the text corpus, reducing $|\mathcal{V}|$ to 5,240,003.

Alignment. One of our alignment models needs Wikipedia anchors. There are around 45 million such anchors in our text corpus and 41,970,548 of them refer to entities in $\mathcal{E}$. Another mechanism utilizes the name graph constructed through names of entities. Specifically, for each training triplet (h,r,t), suppose h and t have entity names w_h and w_t, respectively and $w_h, w_t \in \mathcal{V}$, the training triplet contributes (w_h,r,w_t), (w_h,r,t), and (h,r,w_t) to the name graph. There are 81,753,310 triplets in our name graphs. Note that there is no overlapping between the name graph and held-out triplets of $e-w$, $w-e$, and $w-w$ types.

4.2 Triplet Classification

This task judges whether a triplet (h,r,t) is true or false, i.e., binary classification of a triplet.

Evaluation protocol. Following the same protocol in NTN (Socher et al., 2013), for each true triplet, we construct a false triplet for it by randomly sampling an element from $\mathcal{I}$ to corrupt its head or tail. Since $|\mathcal{E}|$ is significantly larger than $|\mathcal{V}|$ in our data, sampling from a uniform distri-

[2]https://opennlp.apache.org

Table 4: **Triplet classification**: accuracy (%) over various types of triplets.

Type	$e-e$	$w-e$	$e-w$	$w-w$	all
respectively	93.4	52.1	51.4	71.0	77.5
jointly (anchor)	94.4	67.0	66.7	79.8	81.9
jointly (name)	94.5	80.5	80.0	89.0	87.7
jointly (anchor+name)	**95.0**	**82.0**	**81.5**	**90.0**	**88.8**

bution over $\mathcal{I}$ will let triplets involving no word dominate the false triplets. To avoid that, when we corrupt the head of (h, r, t), if $h \in \mathcal{E}$, h' is sampled from $\mathcal{E}$ while if $h \in \mathcal{V}$, h' is sampled from $\mathcal{V}$. The same rule is applied when we corrupt the tail of (h, r, t). In this way, for each of the four types of triplets, we ensure the number of true triplets is equal to that of false ones.

To classify a triplet (h, r, t), we first use the considered methods to score it. TransE scores it by $-|\mathbf{h} + \mathbf{r} - \mathbf{t}|$. Our models score it by $\Pr(D = 1|h, r, t)$ (see Eq.(10)). Then the considered methods label a triplet (h, r, t) as true if its score is larger than the relation-specific threshold of r, as false otherwise. The relation-specific thresholds are chosen to maximize the classification accuracy over the validation set.

We report the classification accuracy. Additionally, we rank all the testing triplets by their scores in descending order. Then we draw a precision-recall (PR) curve based on this ranking and report the area under the PR curve.

Implementation. We implement TransE (Bordes et al., 2013), Skip-gram (Mikolov et al., 2013a), and our models.

First, we train TransE and pTransE over our training triplets with embedding dimension k in $\{50, 100, 150\}$. Adhering to (Bordes et al., 2013), we use the fixed learning rate α in $\{0.005, 0.01, 0.05\}$ for TransE during its 300 epochs. For pTransE, we use the number of negative examples per positive example c among $\{5, 10\}$, the learning rate α among $\{0.01, 0.025\}$ where α decreases along with its 40 epochs. The optimal configurations of TransE are: $k = 100$, $\alpha = 0.01$. The optimal configurations of pTransE are: $k = 100$, $c = 10$, and $\alpha = 0.025$.

Then we train Skip-gram with the embedding dimension k in $\{50, 100, 150\}$, the max skip-range s in $\{5, 10\}$, the number of negative examples per positive example c in $\{5, 10\}$, and learning rate $\alpha = 0.025$ linearly decreasing along with the 6 epochs over our text corpus. Popular words whose frequencies are larger than 10^{-5} are subsampled according to the trick proposed in (Mikolov et al., 2013b). The optimal configurations of Skip-gram are: $k = 150$, $s = 5$, and $c = 10$.

Combining entity embeddings and word embeddings learnt by pTransE and Skip-gram respectively, "respectively" model can score all types of held-out triplets. For our jointly embedding model, we consider various alignment mechanisms and use equal numbers of threads for knowledge model and text model. The best configurations of "jointly" model are: $k = 150$, $s = 5$, $c = 10$, and $\alpha = 0.025$ which linearly decreases along with the 6 epochs of traversing text corpus.

Results. We first illustrate the comparison between TransE and pTransE over $e - e$ type triplets in Table 3. Observing the scores assigned to true triplets by TransE, we notice that triplets of popular relations generally have larger scores than those of rare relations. In contrast, pTransE, as a probabilistic model, assigns comparable scores to true triplets of both popular and rare relations. When we use a threshold to separate true triplets from false triplets of the same relation, there is no obvious difference between the two models. However, when all triplets are ranked together, assigning scores in a more uniform scale is definitely an advantage. Thus, the contradiction stems from the different training strategies of the two models and the consideration of relation-specific thresholds.

Classification accuracies over various types of held-out triplets are presented in Table 4. The "jointly" model outperforms the "respectively" model no matter which alignment mechanism(s) are used. Actually, for the "respectively" model, there is no interaction between entity embeddings and word embeddings during training and thus its predictions, over triplets that involve both entity and word at the same time, are not much better than random guessing. It is also a natural result that alignment by names is more effective than alignment by anchors. The number of anchors is much smaller than the number of overall chunks in our text corpus. In addition, the number of entities mentioned by anchors is very limited com-

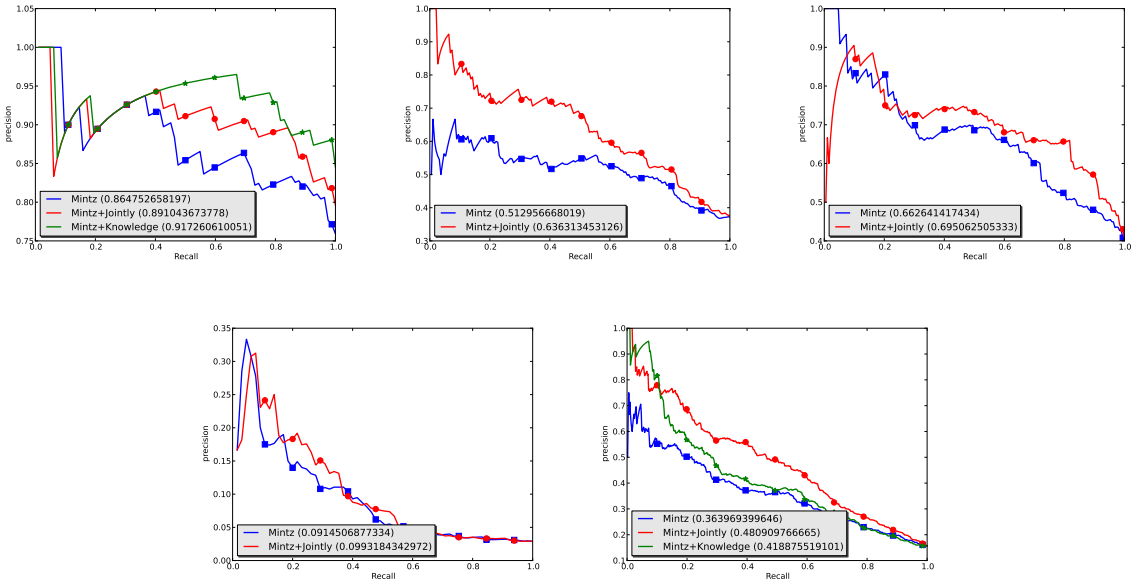

Figure 1: **Improving Relation Extraction**: PR curves of Mintz alone or combined with knowledge (pTransE) / jointly model over (a) $e-e$, (b) $w-e$, (c) $e-w$, (d) $w-w$, and (e) all triplets.

pared with $|\mathcal{E}|$. Thus, interactions brought in by anchors are not as significant as that of the name graph.

4.3 Improving Relation Extraction

It has been shown that embedding models are very complementary to extractors (Weston et al., 2013). However, some entities detected from text are out-of-kb entities. In such a case, triplets involving these entities cannot be handled by any existing knowledge embedding method, but our jointly embedding model can score them. As our model can cover more candidate triplets provided by extractors, it is expected to provide more significant improvements to extractors than any other embedding model. We confirm this point as follow.

Evaluation protocol. For relation extraction, we use a public dataset—NYT+FB (Riedel et al., 2010)[3], which distantly labels the NYT corpus by Freebase facts. We consider (Mintz et al., 2009) and Sm2r (Weston et al., 2013) as our extractors to provide candidate triplets as well as their plausibilities estimated according to text features.

For embedding, we first held out triplets from our training set that appear in the test set of NYT+FB. Then we train TransE, pTransE and the "jointly" model on the remaining training triplets as well as on our text corpus. Then we use these models to score each candidate triplet in the same way as the previous triplet classification experiment.

For combination, we first divide each candidate triplet into one of these categories: $e-e$, $e-w$, $w-e$, $w-w$, and "out-of-vocabulary". Because there is no embedding model that can score triplets involving out-of-vocabulary word/phrase, we just ignore these triplets.Please note that, for our jointly embedding model, there are no "out-of-vocabulary" triplets if we include the NYT corpus for training. We use the embedding models to score candidate triplets and combine the scores given by the embedding model with scores given by the extractors. For each type $e-e$, $e-w$, $w-e$, $w-w$ and their union (i.e. *all*), we rank the candidate triplets by their revisited scores and draw PR curve to observe which embedding method provides the most significant improvements to the extractors.

Implementation. For (Mintz et al., 2009), we use the implementation in (Surdeanu et al., 2012)[4]. We implement Sm2r by ourselves with the best hyperparameters introduced in (Weston et al., 2013). For TransE, pTransE, and the "jointly" model, we use the same implementations, scoring schemes, and optimal configurations as the triplet classification experiment.

To combine extractors with embedding mod-

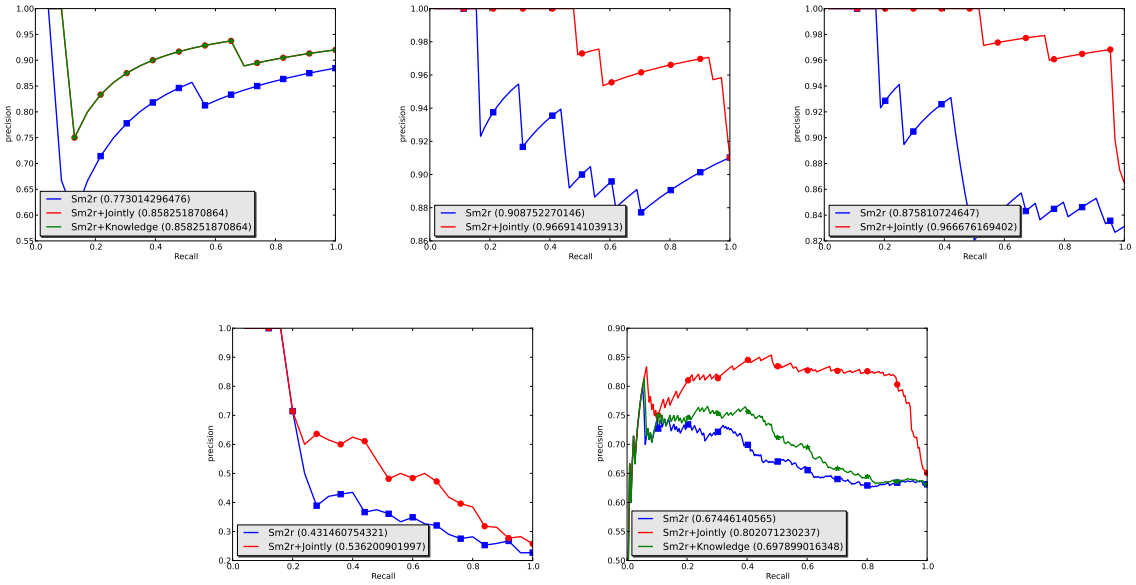

Figure 2: **Improving Relation Extraction**: PR curves of Sm2r alone or combined with knowledge (TransE) / jointly model over (a) $e - e$, (b) $w - e$, (c) $e - w$, (d) $w - w$, and (e) all triplets.

els, we consider two schemes. Since Mintz scores candidate triplets in a probabilistic manner, we linearly combine its scores with the scores given by pTransE or the "jointly" model: $\beta \Pr_{\text{Mintz}} + (1-\beta) \Pr_{\text{pTransE/Jointly}}$ where β is enumerated from 0 to 1 with 0.025 as a search step. On the other hand, neither Sm2r nor TransE is a probabilistic model. Thus, we combine Sm2r with TransE or the "jointly" model according to the scheme proposed in (Weston et al., 2013) where for each candidate (h, r, t), if $\sum_{r' \neq r} \delta(\text{Score}(h, r, t) < \text{Score}(h, r', t))$ is less than τ, we increase $\text{Score}_{Sm2r}(h, r, t)$ by p. We search for the best β, τ, and p on another dataset—Wikipedia corpus distantly labeled by Freebase.

Result. We present the PR curves in Fig. (1, 2). Over candidate triplets provided by either Mintz or Sm2r, the "jointly" model is consistently comparable with the "knowledge" model (TransE/pTransE) over $e - e$ triplets while it outperforms the "knowledge" model by a considerable margin over triplets of other types. These results confirm the advantage of jointly embedding and are actually straightforward results of our triplet classification experiment because the only difference is that the triplets here are provided by the extractor.

Table 6: **Phrases Analogical Reasoning Task**.

Method	Accuracy (%)	Hits@10 (%)
Skip-gram	18.0	56.1

Jointly (name)	11.3	40.6
Jointly (anchor+name)	18.3	54.0

Table 7: **Constructed Analogical Reasoning Task**.

Method	Accuracy (%)	Hits@10 (%)
Skip-gram	10.5	14.1
Jointly (anchor)	10.5	14.3
Jointly (name)	11.5	16.2
Jointly (anchor+name)	**11.6**	**16.5**

4.4 Analogical Reasoning Task

We compare our method with Skip-gram on this task to observe and study the influences of both knowledge embedding and alignment mechanisms on the quality of word embeddings.

Evaluation protocol. We use the same public datasets as in (Mikolov et al., 2013b): 19,544 word analogies[5]; 3,218 phrase analogies[6]. We also construct analogies from our held-out triplets (see Table 2) by first concatenating two entity pairs of the same relation to form an analogy and

[5] code.google.com/p/word2vec/source/browse/trunk/questions-words.txt

[6] code.google.com/p/word2vec/source/browse/trunk/questions-phrases.txt

Table 5: **Words Analogical Reasoning Task**.

Method	Accuracy (%)			Hits@10 (%)		
	Semantic	Syntactic	Total	Semantic	Syntactic	Total
Skip-gram	71.4	69.0	70.0	90.4	89.3	89.8
Jointly (anchor)	75.3	68.3	**71.2**	91.5	88.9	**89.9**
Jointly (name)	54.5	54.2	59.0	75.8	86.5	82.1
Jointly (anchor+name)	56.5	65.7	61.9	78.1	87.6	83.6

then replacing the entities by corresponding entity names, e.g., "(Obama, Honolulu, David Beckham, London)" where the relation is "Born-in".

Following (Mikolov et al., 2013b), we only consider analogies that consist of the top-K most frequent words/phrases in the vocabulary. For each analogy denoted by (h_1, t_1, h_2, t_2), we enumerate all the top-K most frequent words/phrases w except for h_1, t_1, h_2, and calculate the distance (Cosine/Euclidean according to specific model) between $\mathbf{h}_2 + (\mathbf{t}_1 - \mathbf{h}_1)$ and $\mathbf{w}$. Ordering all these words/phrases by their distances in ascending order, we obtain the rank of the correct answer t_2. Finally, we report *Hits@10* (i.e., the proportion of correct answers whose ranks are not larger than 10) and *accuracy* (i.e., Hits@1). For word analogies and constructed analogies, we set $K = 200,000$; while for phrase analogies, we set $K = 1,000,000$ to recall sufficient analogies.

Implementation. For Skip-gram and the "Jointly" (anchor/name/anchor+name) model, we use the same implementations and optimal configurations as the triplet classification experiment.

Results. Jointly embedding using Wikipedia anchors for alignment consistently outperforms Skip-gram (Table 5, 6, 7) showing that the influence of knowledge embedding, injected into word embedding through Wikipedia anchors, is beneficial. The vector of an ambiguous word is often a mixture of its several meanings but, in a specific context, the word is disambiguated and refers to a specific meaning. Using global word embedding to predict words within a specific context may pollute the embeddings of surrounding words. Alignment by anchors enables entity embeddings to alleviate the propagation of ambiguities and thus improves the quality of word embeddings.

Using entity names for alignment hurts the performance of analogies of words and phrases (Table 5, 6). The main reason is that these analogies are popular facts frequently mentioned in text while a name graph forces word embeddings to satisfy both popular and rare facts. Another reason stems from the versatility of mentioning an entity. Consider "(Japan, yen, Europe, euro)" for example. Knowledge embedding is supposed to give significant help to completing this analogy as "/location/country/currency"$\in \mathcal{R}$. However, the entity of Japanese currency is named "Japanese yen" rather than "yen" and thus the explicit translation learnt from knowledge embedding is not directly imposed on the word embedding of "yen". In contrast, using entity names for alignment improves the performances on constructed analogies (Table 7). Since there is a relation $r \in \mathcal{R}$ for each constructed analogy $(w_{h_1}, w_{t_1}, w_{h_2}, w_{t_2})$, although neither (w_{h_1}, r, w_{t_1}) nor (w_{h_2}, r, w_{t_2}) is present in the name graph, other facts involving these words act on the vectors of these words, in the same manner of traditional knowledge embedding.

Overall, any high-quality entity linking system can be used to further improve the performance.

5 Conclusions

In this paper, we introduced a novel method of jointly embedding knowledge graphs and a text corpus so that entities and words/phrases are represented in the same vector space. In such a way, our method can perform prediction on any candidate facts between entities/words/phrases, going beyond previous knowledge embedding methods, which can only predict facts whose entities exist in knowledge graph. Extensive, large-scale experiments show that the proposed method is very effective at reasoning new facts. In addition, we also provides insights into word embedding, especially on the capability of analogical reasoning. In this aspect, we empirically observed some hints that jointly embedding also helps word embedding.

Abstract

We propose a novel abstractive summarization system for product reviews by taking advantage of their discourse structure. First, we apply a discourse parser to each review and obtain a discourse tree representation for every review. We then modify the discourse trees such that every leaf node only contains the aspect words. Second, we aggregate the aspect discourse trees and generate a graph. We then select a subgraph representing the most important aspects and the rhetorical relations between them using a PageRank algorithm, and transform the selected subgraph into an aspect tree. Finally, we generate a natural language summary by applying a template-based NLG framework. Quantitative and qualitative analysis of the results, based on two user studies, show that our approach significantly outperforms extractive and abstractive baselines.

1 Introduction

Most existing works on sentiment summarization focus on predicting the overall rating on an entity (Pang et al., 2002; Pang and Lee, 2004) or estimating ratings for product features (Lu et al., 2009; Lerman et al., 2009; Snyder and Barzilay, 2007; Titov and McDonald, 2008)). However, the opinion summaries in such systems are extractive, meaning that they generate a summary by concatenating extracts that are representative of opinion on the entity or its aspects.

Comparing extractive and abstractive summaries for evaluative texts has shown that an abstractive approach is more appropriate for summarizing evaluative text (Carenini et al., 2013; Di Fabbrizio et al., 2014). This finding is also supported by a previous study in the context of summarizing news articles (Barzilay et al., 1999). To the best of our knowledge, there are only three previous works on abstractive opinion summarization (Ganesan et al., 2010; Carenini et al., 2013; Di Fabbrizio et al., 2014). The first work (Ganesan et al., 2010) proposes a graph-based method for generating ultra concise opinion summaries that are more suitable for viewing on devices with small screens. This method does not provide a well-formed grammatical abstract and the generated summary only contains words that occur in the original texts. Therefore, this approach is more extractive than abstractive. Another limitation is that the generated summaries do not contain any information about the distribution of opinions.

In the second work, (Carenini et al., 2013) addresses some of the aforementioned problems and generates well-formed grammatical abstracts that describe the distribution of opinion over the entity and its features. However, for each product, this approach requires a feature taxonomy handcrafted by humans as an input, which is not scalable. To partially address this problem (Mukherjee and Joshi, 2013) has proposed a method for the automatic generation of a product attribute hierarchy that leverages ConceptNet (Liu and Singh, 2004). However, the resulting ontology tree has been used only for sentiment classification and not for classification.

In the third and most recent study, (Di Fabbrizio et al., 2014) proposed Starlet-H as a hybrid abstractive/extractive sentiment summarizer. Starlet-H uses extractive summarization techniques to select salient quotes from the input reviews and embeds them into the abstractive summary to exemplify, justify or provide evidence for the aggregate positive or negative opinions. However, Starlet-H assumes a limited number of aspects as input and needs a large amount of training data to learn the

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ordering of aspects for summary generation.

Highlighting the reasons behind opinions in reviews was also previously proposed in (Kim et al., 2013). However, their approach is extractive and similar to (Ganesan et al., 2010) does not cover the distribution of opinions. Furthermore, it aims to explain the opinion on only one aspect, rather than explaining the overall opinion on the product, its aspects and how they affect each other.

To address some of the above mentioned limitations , in this paper we propose a novel abstractive summarization framework that generates an aspect-based abstract from multiple reviews of a product. In our framework, anything that is evaluated in the review is considered an aspect, including the product itself. We propose a natural language generation (NLG) framework that takes aspects and their structured relation as input and generates an abstractive summary. However, unlike (Carenini et al., 2013), our method assumes no domain knowledge about the entity in terms of a user-defined feature taxonomy. On the other hand, in contrast with Starlet-H, we do not limit the input reviews to a small number of aspects and our aspect ordering method takes advantage of rhetorical information and does not require any training data. Our method relies on the discourse structure and discourse relations of reviews to infer the *importance of aspects* as well as the *association* between them (e.g., which aspects relate to each other).

Researchers have recently started using the discourse structure of text in sentiment analysis and have shown its advantage in improving sentiment classification accuracy (e.g., (Lazaridou et al., 2013; Trivedi and Eisenstein, 2013; Somasundaran et al., 2009; Asher et al., 2008)). However, to the best of our knowledge, none of the existing works have looked into exploiting discourse structure in abstractive review summarization.

In our work, *importance of aspects*, derived from the reviews' discourse structure and relations, is used to rank and select aspects to be included in the summary. More specifically, we start with the most important (highest ranked) aspects to generate a summary and add more aspects to the system until a summary of desired length is obtained. *Aspect association* is considered to better explain how the opinions on aspects affect each other (e.g., opinion over specific aspects affect the opinion over the more general ones). Consider the following sentence as an example summary generated by our system for the entity **Camera Canon G3**: "*All reviewers who commented on the camera, thought that it was really good mainly because of the photo quality.*" This summary encapsulates all the following key pieces of information: 1) *camera* and *photo quality* are the most important aspects, 2) People have positive opinion on *camera* in general and on *photo quality* as one of its features, and finally 3) *photo quality* is the main reason behind users satisfaction on *camera*. Such summary helps users understand the reason behind a rating of a product or its aspects without going through all reviews or reading scattered opinions on different aspects in multiple sentences of an extractive summary.

This paper makes the following contributions:
1. We propose a novel content selection and structuring strategy for review summarization, that assumes no prior domain knowledge, by taking advantage of the discourse structure of reviews.
2. We propose a novel product-independent template-based NLG framework to generate an abstract based on the selected content, without relying on deep syntactic knowledge or sophisticated NLG methods. Our framework, similarly to (Carenini et al., 2013), can effectively convey the distribution of opinions.
3. We present the first study that investigates the use of discourse structure information in both content selection and abstract generation for multi-document summarization.

Quantitative and qualitative analysis over evaluation results of two user studies on a set of user reviews on twelve different products show that our system is an effective abstractive system for review summarization.

2 Summarization Framework

At a high-level, our summarization framework involves generating a summary from multiple input reviews based on an Aspect Hierarchy Tree (AHT) that reflects the importance of aspects as well as the relationships between them. In our framework, an AHT is generated automatically from the set of input reviews, where each sentence of every review is marked by the aspects presented in that sentence and the polarity of opinions over them. There are various methods for extracting the aspects and predicting the polarity of opinion (Hu and Liu, 2004b; Hu and Liu,

2006; Kim et al., 2011). In this paper we do not focus on aspect extraction and sentiment prediction but rather consider the aspect and their polarity/strength (P/S) information given as input to the system. P/S scores are integer values in the range [-3, +3], where +3 is the most positive and -3 is the most negative polarity value. We also do not attempt to automatically resolve coreferences between aspects. For example, the aspect *"g3"*, *"canon g3"* and *"canon"* were manually collapsed as into *"camera"*. This preprocessing step helps to reduce the noise generated by inaccurate aspect labeling in our reviews. Figure 1 shows two sample input reviews where the aspects and their P/S scores are identified. For example, in R1, aspects *camera*, *photo quality* and *auto mode* are mentioned. The P/S values for the three aspects are [+2], [+3] and [+2] respectively which indicate positive opinion on all aspects.

The first component of our system applies a discourse parser to each review and obtains a discourse tree representation for every review (e.g. Figure 1 (a) and (b)). The discourse trees are then modified such that every leaf node only contains the aspect words. The output of the first component is an aspect-based discourse tree (ADT) for every review (e.g. Figure 1 (c) and (d)). In the second component, we aggregate the ADTs and generate a graph called Aggregated Rhetorical Relation Graph (ARRG) (e.g. Figure 1 (f)). The third component of our framework, is responsible for content selection and structuring. It takes ARRG as input, runs Weighted PageRank, and selects a subgraph (e.g. Figure 1 (g)) representing the most important aspects. Finally it transforms the selected subgraph into a tree and provides an AHT as output (e.g. Figure 1 (h)). The generated AHT is the input of the last component which generates a natural language summary by applying micro planning and sentence realization. We now describe each component of our framework in more detail.

3 Discourse Parsing

Any coherent text is structured so that we can derive and interpret the information. This structure shows how discourse units (text spans such as sentences or clauses) are connected and relate to each other. Discourse analysis aims to reveal this structure. Several theories have been proposed in the past to describe the discourse structure, among which the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is one of the most popular. RST divides a text into minimal atomic units, called Elementary Discourse Units (EDUs). It then forms a tree representation of a discourse called a Discourse Tree (DT) using rhetorical relations (e.g., *Elaboration*, *Explanation*, etc) as edges, and EDUs as leaves. EDUs linked by a rhetorical relation are also distinguished based on their relative importance in conveying the author's message: *nucleus* is the central part, whereas *satellite* is the peripheral part.

We use a publicly available state-of-the-art discourse parser (Joty et al., 2013)[1] to generate a DT for each product review. Figure 1 (a) and (b) show DTs for two sample reviews where dotted edges identify the satellite spans. DT1 in Figure 1 (a) shows that review R1 consists of three EDUs with two relations *Elaboration* and *Background* between them. It also shows that the first EDU (i.e. *I love camera*) is the nucleus (shown by solid line) of the relation *Elaboration* and so the rest of the document (EDUs 2 and 3) is less important and aims at elaborating on what the author meant in the first EDU. Similarly, the structure shows that the third EDU is mentioned as background information for EDU2 and so is less important for realizing the core meaning of the document.

After obtaining the DTs, we remove all words from the text spans of each EDU, except the aspect words. Thus, for each review, we have a DT where a leaf node represents the aspects occurring in the corresponding EDU. Note that there may be EDUs containing no aspects in a review. In such cases, we keep the corresponding node and mark it with no aspect. We call the resulting tree an Aspect-based Discourse Tree (ADT) which will be used in the next components. Figure 1 (c) and (d) show ADTs generated from DTs.

4 Aspect Rhetorical Relation Graph (ARRG)

In the second component, we aim at generating an ARRG for a product, based on the ADTs which are the output from the previous component. There are two motivations behind aggregating the ADTs and building the ARRG: *i*) while each ADT can be rather noisy because of the informal language of the reviews and inaccuracies from

[1] http://alt.qcri.org/discourse/Discourse_Parser_Dist.tar.gz

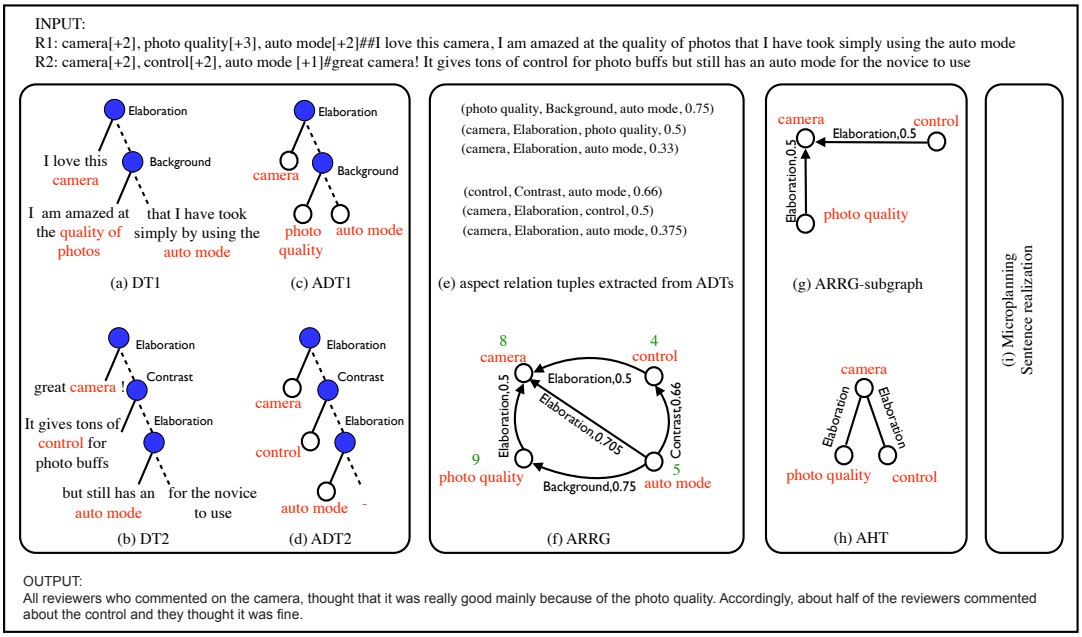

Figure 1: A simple example illustrating different components of our summarization framework.

automatic discourse parsing, aggregating all the ADTs can reveal more reliable information; and *ii*) the aggregated information highlights the most important aspects overall as well as the strongest connection between the aspects. This information can effectively drive the content selection and abstract generation phases.

$ARRG$ is a directed graph in which we allow multiple edges between two vertices. In ARRG, vertices represent aspects. We associate to each aspect/node an importance measure that aggregates all the P/S values that the aspect receives in all the reviews. By following (Carenini et al., 2013), let $PS(a)$ be the set of P/S values that an aspect a receives. The direct measure of importance of the aspect is defined as:

$$dir\text{-}moi(a) = \sum_{ps \in PS(a)} ps^2 \qquad (1)$$

In ARRG, edges indicate existence of a rhetorical relation between text spans of a review in which the aspects occurred. Edges are labeled with the type of the relation as well as a weight indicating our confidence in the presence of the relation between the two aspects. In ARRG, an edge with label r, w from node u to node v, $u \xrightarrow{\text{r, w}} v$, indicates the existance of a relation r with confidence w between two aspects u and v. Also, the direction of the arrow indicates that u and v occurred in the *satellite* and *nucleus* spans respectively. For example, *photo quality* $\xrightarrow{\text{elaboration, 0.8}}$ *camera* indicates that there is a high confidence (0.8) that aspect *photo quality* was used in a text span to elaborate aspect *camera*. Moreover, *camera* is a more important aspect compared to *photo quality*.

To build ARRG, we use all the ADTs that are output of the previous component (one for each review). From each ADT_j, we extract all tuples of the form (u, r, v, w) in which u is an aspect occurring in a satellite span, v is an aspect occurring in a nucleus span, r is a relation type and w is the weight of the tuple computed as follows:

$$w = 1 - 0.5\frac{|\text{EDUs between u and v}|}{|\text{total EDUs in } ADT_j|} - 0.5\frac{d_r}{d} \qquad (2)$$

where, $|.|$ indicates cardinality of a set. d indicates the depth of the ADT_j and d_r indicates the depth of the sub-tree of ADT_j rooted at relation r. Equation 2 weighs a tuple based on two factors: (i) the relative distance of the EDUs in which the two aspects u and v participating in relation r occur. The intuition is that aspects occurring in close proximity to each other are more related; and (ii) the depth of the sub-tree at the point of the relation relative to the depth of the whole ADT_j. This is because as we move from leaves to the root of a DT, the accuracy of the rhetorical structure has been shown to decrease. Also, at higher levels of an ADT (intra-sentential relations), it is more

likely that aspects are related through non adjacent EDUs and so are less strongly related. Figure 1 (e) shows tuples extracted from sample ADTs.

Notice that every two aspects u and v may be related by the same relation more than once in an ADT for a review. Thus, we might have i tuples with the same u,r, and v but confidence weights which are not necessarily the same. From every ADT_j, we extract all (u, r, v, w_{ij}) and select the one with maximum confidence. We then aggregate the selected tuples extracted from different reviews. Putting these two steps together, for every two aspects u and v related by relation r, we obtain a single tuple $(u, r, v, \hat{w})$ where

$$\hat{w} = \sum_j \max_i w_{ij} \quad (3)$$

Figure 1 (f) shows an example ARRG built for the sample reviews.

5 Content Selection and Structuring

The content of the summary is selected by extracting from ARRG a subgraph containing the most important aspects. Such content is then structured by transforming the subgraph into an aspect hierarchy.

5.1 Subgraph Extraction

In ARRG aspects/nodes are weighted by how frequently and strongly they are evaluated in the reviews (i.e, dir-moi) and edges are weighted by how frequently and strongly the corresponding aspects are rhetorically related in the discourse trees (Equation 3). In content selection, we want to extract aspects that not only have high weight, but that are also linked with heavy edges to other heavy aspects. This problem can be effectively addressed by Weighted Page Rank (WPR) (Xing and Ghorbani, 2004). WPR takes the importance of both the in-links and out-links of the aspects into account and distributes rank scores based on the weights of relations between aspects. In this way, the heavier aspect nodes, that are either in the nuclei of many relations or in the satellites of relations with other heavy aspects, are promoted. We then update the weight of nodes (aspects) with the new score from WPR. Finally, we rank nodes based on their updated score moi and select the top *N* aspects.

$$moi(a) = \alpha dir\text{-}moi(a) + (1 - \alpha)WPR(a) \quad (4)$$

Here α is a coefficient that can be tuned on a development set or can be set to 0.5 without tuning. Figure 1 (g) shows an example subgraph selected from the sample ARRG.

5.2 Aspects Subgraph to Aspects Hierarchy Transformation

In this step, we generate a hierarchical tree structure for aspects. Such a tree structure helps to navigate over aspects and can be easily traversed to find certain aspects and their relation to their parent or children. The hierarchy of aspects also matches the intuition that the root node is the most frequent and general aspect (often the product) and as the depth increases, nodes represent more specific aspects of the product with less frequency and weight.

To obtain a hierarchical tree structure from the extracted subgraph, we first build an undirected graph as follows: we merge the edges connecting two nodes and consider the sum of their weights as the weight of the merged graph. We also ignore the relation direction for the purpose of generating the tree. We then find the Maximum Spanning Tree of the undirected subgraph and set the highest weighted aspect as the root of the tree. This process results in a useful knowledge structure of aspects with their associated weight and sentiment polarity connected with the rhetorical relations called Aspect Hierarchical Tree (AHT). Figure 1 (h) shows the generated AHT from the sub-graph.

6 Abstract Generation

The automatic generation of a natural language summary in our system involves the following tasks (Reiter and Dale, 2000): (*i*) microplanning, which covers lexical selection; and (*ii*) sentence realization, which produces english text from the output of the microplanner.

6.1 Microplanning

Once the content is selected and structured, it is passed to the microplanning module which performs lexical choice. Lexical choice is an important component of microplanning. Lexical choice is formulated in our system based on a "*formal*" style, language "*variability*" and "*fluent*" connectivity among other lexical units. Table 1 demonstrates our lexical choice strategy.

Quantifiers:
if (relative-number == 1) : ["All users (x people) who commented about the aspect", "All costumers (x people) that reviewed the aspect", ...]
if (relative-number >= 0.8) : ["Almost all users commented about the aspect and they", "Almost all costumers mentioned the aspect and they", ...]
if (relative-number >= 0.6) : ["Most users commented about the aspect and they mainly", "Most shoppers mentioned aspect and they", ...]
if (relative-number >= 0.45) : ["Almost half of the users commented about the aspect and they", 'Almost 50% of the shoppers mentioned the aspect and they", ...]
if (relative-number >= 0.2) : ["About y% of the reviewers commented about the aspect and they", "Around y% of the shoppers mentioned the aspect and they", ...]
if (relative-number >= 0.0) : ["z reviewers commented about the aspect and in overall they", "z shoppers mentioned about the aspect and they", ...]
Polarity verbs:
if (controversial(aspect)) : ["had controversial opinions about it", "expressed controversial opinions about this feature", ...]
else: if (average <= −2) : ["hated it", "felt that it was very poor', 'thought that it was very poor", ...]
if (average <= −1) : ["disliked it", "felt that it was poor", "thought that it was poor", ...]
if (average < 0) : ["did not like it", "felt that it was weak", "thought that it was weak", ...]
if (average == 0) : ["did not express any strong positive or negative opinion about it", ...]
if (average <= +1) : ["liked it", "felt that it was fine", "thought that it was satisfactory", ...]
if (average <= +2) : ["absolutely liked it", "really liked this feature", "felt that it was a really good feature", "thought that it was really good", ...]
if (average <= +3) : ["loved it", "felt that it was great", "thought that it was great", ...]
Connectives
["Also, related to the aspect", "Accordingly, ", "Moreover, regarding the aspect, " ,"In relation to the aspect, ", "Talking about the aspect, ", ...]

Table 1: Microplanning strategy for lexical choice. The selected lexical items will fill the template in the realization step.

Sentence realization templates:
First sentence templates:
if (polarity-agreement(root,highest-weighted-child) & connecting-relation == [elaboration, explain, cause, summary, same-unit, background, evidence, justify]): *"quantifier + polarity-verb +* 'mainly because of the' *+ highest-weighted-child"*
else: "quantifier + polarity-verb"
First level children (aspects) sentences templates:
"connective + ', ' + quantifier + ' ' + polarity-verb"
Supporting sentences templates:
if (#children(aspect)==1): "connective + quantifier + verb "
elseif (#children(aspect)>1 & polarity-agreement(children)): "connective + quantifier + verb + [and, similarly, while, ...] + quantifier + verb"
elseif (#children(aspect)>1 & !polarity-agreement(children)): "connective + quantifier + verb + [but, in contrast, on contrary, ...] + quantifier + verb"

Table 2: Sentence realization templates.

Quantifiers: for each aspect, a quantifier is selected based on both the absolute and relative number of users whose opinions contributed to the evaluation of the aspect.

Polarity verbs: for each aspect, a polarity verb is selected based on the average sentiment polarity strength for that aspect. Although the average, in most cases, can be a good metric to evaluate the polarity of an aspect, it fails when the distribution of evaluations is centered on zero, for instance, if there are equal numbers of positive and negative evaluations (i.e., controversial). To partially solve this problem, we first check whether the aspect evaluation is controversial by applying the formula proposed by (Carenini and Cheung, 2008). In the case of controversiality, our microplanner selects a lexical item to express the controversiality of the aspect. In other cases, we use the average and select the polarity verb based on that.

Connectives: in order to form more fluent and readable sentences and to increase the language variability, we randomly select our connectives from the list shown in Table 1. Moreover, when a parent aspect (excluding the root in AHT) has two children, they are connected by one of the coordinating conjunction "[and, similarly]" if they agree on polarity, and they will be connected by a choice of "[on the contrary, in contrast]" otherwise (see Supporting sentences templates in Table 2). As an alternative we could have selected connectives based on the discourse relations specified in the aspects tree. However, this is left as future work.

6.2 Sentence Realization

The realization of our abstract generation is performed by applying a rather simple and comprehensive template-based strategy. Depending on the specific lexical choice in microplanning step, an appropriate template and corresponding fillers are selected as shown in Table 2. We develop three different templates: *i)* generates the first abstract sentence; *ii)* generates the abstract sentence for the aspects with no children; and *iii)* generates supporting sentences for aspects with children.

For illustration, assuming that we apply this strategy to a 5-node variation of the AHT in Figure 1 (h), where the aspect "*control*" has two children "*auto mode*" and "*setting*", we obtain "*All reviewers (45 people) who commented on the camera, thought that it was really good mainly because of the photo quality. Accordingly, about 24% of the reviewers commented about the control and they*

thought it was fine. Also, related to the control, 7 users expressed their opinion about the auto mode and they liked it, similarly, 6 shoppers commented about the setting and they thought that it was satisfactory."

7 Experimental Setup

7.1 Dataset and Baselines

We conduct our experiments using the customer reviews of twelve products obtained from (Hu and Liu, 2004a): 4 digital cameras, 1 DVD player, 1 MP3 player, 2 routers, 2 phones, 1 diaper and 1 antivirus. The reviews were collected from Amazon.com and Cnet.com. We use manually annotated aspects and their associated sentiment from the same dataset.

We compare the summaries generated by our system with two state-of-the-art extractive baselines and a simpler version of our abstractive system, as follows:

1) MEAD-LexRank (LR): we use the LexRank (Erkan and Radev, 2004) implementation inside the MEAD summarization framework (Radev et al., 2004), which outperforms other algorithms implemented in the MEAD framework.

2) MEADStar (MEAD*): a state-of-the-art extractive opinion summarization system (Carenini et al., 2013), which is adapted from the open source summarization framework MEAD. MEAD* orders aspects by the number of sentences evaluating that aspect, and selects a sentence from each aspect until it reaches the word limit. The sentence that is selected for each aspect is the one with the highest sum of polarity/strength evaluations for any aspect.

3) Simple Abstractive (SA): we sort the aspects of each product based on $dir\text{-}moi$ (Equation 1). Then, for each aspect, we generate a sentence based on a simple template "*quantifier* + *polarity-verb*" until the summary reaches the word limit.

We limit the length of our summaries to 150 words. In our experiment we use the default parameter in Equation 4 without tuning (i.e. $\alpha = 0.5$). Our system starts the content selection process with 10 aspects and generates a summary based on a AHT with 10 aspects. We add one aspect, reproduce the AHT and regenerate the summary. We repeat this process until the word limit is reached.

7.2 Evaluation Framework

On one hand, the lack of product reviews datasets with human written summaries, and on the other hand, the difficulty of generating human-written summaries for reviews, makes review summary evaluation a very challenging task.

We evaluate the summaries generated by our system by performing two user studies based on pairwise preferences using a popular crowdsourcing service.[2] The user preference evaluation is an effective method for opinion summarization (e.g., (Lerman et al., 2009)). The main motivations behind pairwise preferences evaluation is two-fold: *i*) raters can make a preference decision more efficiently than a scoring judgment; and *ii*) rater agreement is higher in preference decisions than in scoring judgments (Ariely et al., 2003).

In both user studies, for each product, we run six pairwise comparisons for four summaries. In each rating assignment, two summaries of the same product were placed in random order. Raters were shown the name of each product along with the relevant summaries and were asked to express their preference for one summary over the other using a simple set of criteria. For two summaries S_1 and S_2 raters should choose one of the following three options: 1) Prefer S_1, 2) Prefer S_2, 3) No preference.

Raters were specifically instructed that their rating should express "*overall satisfaction with the information provided by the summary*". Raters were also asked to provide a brief comment justifying their choice. Over 48 raters participated in each study, and each comparison was evaluated by at least five raters generating more than 360 judgments for each user study. We pre-select the high skilled raters to ensure a higher quality results.

The main difference between the two user studies is that in "user study 1", we show two summaries to the raters and ask them to choose the one they prefer without showing them the original reviews. In contrast, in "user study 2", we show two summaries with links to the full text of the reviews for the raters to explore. In order to make sure that the raters read the reviews, we ask them to write a short summary of the reviews before rating the automatic summaries. We ran two different user studies because: *i*) for each product there might be many reviews to be included; *ii*) there is no guaranty that raters, in various evaluation settings, read

System I vs System II	Agreement		No preference		Preferred Sys I		Preferred Sys II	
User Studies	1	2	1	2	1	2	1	2
LR vs MEAD*	0.33	0.75	7%	6%	35%	20%	58%	74%
LR vs SA	0.42	0.83	0%	0%	38%	21%	*62%*	*79%*
LR vs Our System	0.50	1.00	0%	3%	26%	13%	***74%***	***84%***
MEAD* vs SA	0.58	0.83	0%	0%	38%	20%	*62%*	*80%*
MEAD* vs Our System	0.67	0.50	0%	3%	25%	30%	***75%***	***67%***
SA vs Our System	0.42	0.50	12%	11%	23%	32%	**65%**	**57%**

Table 3: Results of pairwise preference user studies. Statistically significant improvements ($p < 0.01$) over the baselines are demonstrated by bold fonts. Italic fonts indicate statistical significance ($p < 0.01$) of abstractive methods (SA and Our System) over extractive approaches (LR and MEAD*).

Systems	LR		MEAD*		SA		Our System	
User Studies	1	2	1	2	1	2	1	2
Preference	33%	18%	41%	41%	49%	63%	**71%**	**69%**

Table 4: System preference results. Statistically significant improvements ($p < 0.01$) over the baselines are demonstrated by bold fonts.

the reviews (partially or completely); and *iii*) there is no evidence regarding the depth that each rater would look into the reviews. Therefore, choosing between user study 1 and 2 is not a straightforward decision. In other words, designing the two user studies in this way helps us to answer the question: "*Does the fact that raters can read all the reviews affect their ratings?*".

8 Results

This section provides a quantitative and qualitative analysis of the evaluation results[3].

8.1 Quantitative Analysis

Quantitative results for both user studies are shown in Table 3. The second column indicates the percentage of judgments for which the raters were in agreement. Agreement here is a weak agreement, where four (out of five) raters are defined to be in agreement if they all gave the same rating. The next three columns indicate the percentage of judgments for each preference category, grouped into two user studies. In addition, we measure the preference for each system in both user studies (Table 4). For each system, the preference is the number of times raters prefer the system, divided by the total number of judgments for that system (e.g., if A is preferred over B 10 out of 30 times, and A is preferred over C 15 out of 20 times, the overall preference of A is (10+15)/(30+20)=50%)

Abstractive vs. Extractive: the results of our system and SA in Table 3 show statistically significant improvements in pairwise preference over extractive baselines (LR and MEAD*) in both user studies.[4] Moreover, the results of overall preference in Table 4 demonstrates that two abstractive systems are preferred over the extractive ones in both studies. This further supports the findings in the previous studies (e.g., (Carenini et al., 2013)) that users prefer abstractive summarization. We can observe that, in both user studies, raters prefer our system over other abstractive and extractive baselines. Also, the highest pairwise preference percentages occur comparing an extractive and an abstractive system (e.g., LR vs Our System).

Abstractive Systems: the raters prefer our system over SA in both user studies (65% and 57%), and our system ranks first in our pairwise preference user studies. Knowing that both systems are abstractive and the differences between them comes from using the rhetorical structure in the content selection and abstract generation phases, proves the effectiveness of using rhetorical structure and relations in abstractive summarization of reviews.

Extractive Systems: the result in Table 3 and 4 demonstrate that raters prefer MEAD* over LR. Although both systems are extractive, the MEAD* system has been proposed for extractive opinion

[3]The evaluation results and summaries obtained from CrowdFlower are publicly available and can be downloaded from: `https://www.cs.ubc.ca/cs-research/lci/research-groups/natural-language-processing/reviews/user_study_results.zip`

[4]The statistical significance tests was calculated by approximate randomization, as described in (Yeh, 2000).

Preference Sys 1 to Sys 2	Reasons	Examples of preference justification taken from the raters comments
Our System to LR and MEAD*	Readability, coverage of aspects, aggregation of opinions	*better wording, more objective, more depth, I like the stats, more detail about people opinion, less personal experience, detail comparison from different reviews, a summary in a summary, mentions more features, ...*
LR and MEAD* to Our System	Descriptiveness, personal point of views, product capabilities	*explain how the product is positive, good characteristics about the product, has lot more to tell, more descriptive about features, personal perspective, not only characteristics but also ability, more true to the product itself, ...*
Our System to SA	The relations between the aspects, more language variability	*provides a bit more information, is very complete, not repetitive, more elegant, coherent, ...*
SA to Our System	Simpler structure, more aspects	*written better, has touched variety of features, ...*

Table 5: System preference results. The reasons are classified based on raters justifications preferring the underlined systems.

summarization. In contrast, LR is a generic extractive summarization system which is not optimized for opinion summarization. This also further demonstrates the need for opinion and reviews summarization systems.

User Study 1 vs. User Study 2: the first interesting observation is that, although the overall ranking of systems in both user studies does not change, there are some changes in the results. This indicates that reading the reviews effects preference decisions. We can observe that in all cases except one (MEAD* vs Our System) the agreement between the raters increases significantly when they are given the reviews. This can be interpreted as reading the reviews helps the rater to choose a better summary easier and more effectively. Moreover, we calculate the overall agreement for both user studies.[5] Case study 2 reports a higher overall agreement (70%) in comparison with the user study 1 (65%). This further proves our finding that showing the reviews can help the raters with their preference judgment.

In Table 3, the preference of sys 2 (last column) significantly rises for all cases when compared with the LR system. This proves that raters strongly prefer the summaries that cover opinionated sentences, specifically when they are exposed to the reviews. The same result is reflected in Table 4, where the overall preference of LR drops when the raters are given the reviews. We also observe a significant rise in preference of sys 2 when MEAD* is compared with SA (Table 3) and in the overall preference of SA (Table 4) in user study 2. This proves that raters become more confident in preferring an abstractive summary over an extractive one when the reviews are given to them. In contrast, we notice that the preference of sys 2 drops comparing "MEAD* vs Our System" and "SA vs Our System". Knowing that the drop is not significant and the the overall ranking of systems remains unchanged, this case is less straight forward to interpret.

[5]The agreement is calculated based on 100 randomly sampled units selected from our crowdsourcing job.

8.2 Qualitative Analysis

We collect and group the rater justifications in the results we obtain by crowdsourcing our evaluation framework, when preferring a summary over another, in Table 5. To make the comparison more clear, Example 1 shows the summaries generated by MEAD* and our system.

Comparing our system with the extractive baselines, raters' justifications are classified in three main categories. Although the language of the extractive summaries is less formal, raters often prefer our system in terms of presentation and language. They justify their selections by expressing phrases such as "*better grammar*" or "*fewer errors*". They also comment about the coverage of aspects in the summaries generated by our system and they realize that our system was capable of aggregating the opinions for each aspect. In contrast, when they prefer the extractive summaries, they like the descriptive language of the summary and the technical details of the products that were missing in our system summaries.

We also notice that raters realize the usage of structure (AHT) in our system (both of content selection and summary generation) and they appreciate it by expressing phrases such as "*very complete*", "*more elegant*" or "*related features*". In contrast, they sometimes appreciate a simpler language in summaries generated by SA. Moreover, few raters prefer the higher coverage in SA summaries. This is mainly because not using connectives and structure in SA leaves more space to include more aspects.

Product: Nikon Coolpix 4300
MEAD*: it is very compact but the controls are so well designed that they 're still easy to use . It 's easy for beginners to use , but has features that more serious photographers will love , so it 's an excellent camera to grow into . But overall this is a good camera with a ' really good ' picture clarity ; an exceptional close-up shooting capability .The battery life is very good , i got about 90 minutes with the lcd turned on all the time , the first time around , and i have been using it with the lcd off every now and then , and have yet needed to recharge it . Yes , the picture quality and features which are too numerous to mention are unmatched for any camera in this price range.
Our System: All reviewers (34 people), who commented on the camera, felt that it was really good mainly because of the picture. Around 26% of the reviewers expressed their opinion about the picture quality and they really liked it. Around 24% of the reviewers noted the use and they thought that it was satisfactory. Talking about the use, around 24% of the reviewers expressed their opinion about the size and they felt that it was fine. Only 6 reviewers commented about the scene mode and in overall they thought that it was satisfactory. Moreover, regarding the scene mode, 4 shoppers mentioned about the manual mode and they thought that it was satisfactory, and similarly only 4 reviewers commented about the auto mode and in overall they did not express any strong positive or negative opinion about it. Only 4 costumers mentioned the software and they felt that it was really good.

Example 1. Summaries generated by our system and MEAD* baseline for the Nikon Coolpix 4300 camera. For brevity we exclude other baselines.

9 Conclusions

We have presented a framework for abstractive summarization of product reviews based on discourse structure. For content selection, we propose a graph model based on the importance and association relations between aspects, that assumes no prior domain knowledge, by taking advantage of the discourse structure of reviews. For abstract generation, we propose a product independent template-based natural language generation (NLG) framework that takes aspects and their structured relation as input and generates an abstractive summary. Quantitative evaluation results, based on two pairwise preference user studies, show substantial improvement over extractive and abstractive baselines, including MEAD*, which is considered a state-of-the-art opinion extractive summarization system, and a simpler version of our abstractive system. In future work, we plan to extend the microplanning phase by taking advantage of the highly weighted rhetorical relations between the aspects and select connective phrases based on the discourse relations specified in the aspects tree. In addition, we plan to develop and evaluate an end-to-end system, in which the aspect extraction and polarity estimation of aspects are automated. In this way, we can achieve an end-to-end automatic summarizaion system for product reviews.

Abstract

Clustering aspect-related phrases in terms of product's property is a precursor process to aspect-level sentiment analysis which is a central task in sentiment analysis. Most of existing methods for addressing this problem are context-based models which assume that domain synonymous phrases share similar co-occurrence contexts. In this paper, we explore a novel idea, *sentiment distribution consistency*, which states that different phrases (e.g. "price", "money", "worth", and "cost") of the same aspect tend to have consistent sentiment distribution. Through formalizing *sentiment distribution consistency* as soft constraint, we propose a novel unsupervised model in the framework of Posterior Regularization (PR) to cluster aspect-related phrases. Experiments demonstrate that our approach outperforms baselines remarkably.

1 Introduction

Aspect-level sentiment analysis has become a central task in sentiment analysis because it can aggregate various opinions according to a product's properties, and provide much detailed, complete, and in-depth summaries of a large number of reviews. Aspect finding and clustering, a precursor process of aspect-level sentiment analysis, has attracted more and more attentions (Mukherjee and Liu, 2012; Chen et al., 2013; Zhai et al., 2011a; Zhai et al., 2010).

Aspect finding and clustering has never been a trivial task. People often use different words or phrases to refer to the same product property (also called *product aspect or feature* in the literature). Some terms are lexically dissimilar while semantically close, which makes the task more challenging. For example, "price", "money" , "worth" and "cost" all refer to the aspect "price" in reviews. In order to present aspect-specific summaries of opinions, we first of all, have to cluster different aspect-related phrases. It is expensive and time-consuming to manually group hundreds of aspect-related phrases. In this paper, we assume that the aspect phrases have been extracted in advance and we keep focused on clustering domain synonymous aspect-related phrases.

Existing studies addressing this problem are mainly based on the assumption that different phrases of the same aspect should have similar co-occurrence contexts. In addition to the traditional assumption, we develop a new angle to address the problem, which is based on *sentiment distribution consistency* assumption that different phrases of the same aspect should have consistent sentiment distribution, which will be detailed soon later.

Pros:	***LCD***, *nice* ***touch screen***, *longer* **battery life**
Cons:	*Horrible* ***picture quality***
Review:	The ***touch screen*** was the selling feature for me. The ***LCD touch screen*** is nice and large. This camera also has very impressive ***battery life***. However the ***picture quality*** is very grainy.

Figure 1: A semi-structured Review.

This new angle is inspired by this simple observation (as illustrated in Fig. 1): two phrases within the same cluster are not likely to be simultaneously placed in Pros and Cons of the same review. A straightforward way to use this information is to formulate cannot-link knowledge in clustering algorithms (Chen et al., 2013; Zhai et al., 2011b). However, we have a particularly different manner to leverage the knowledge.

Due to the availability of large-scale semi-structured customer reviews (as exemplified in Fig. 1) that are supported by many web sites, we can easily get the estimation of sentiment distribution for each aspect phrase by simply counting how many times a phrase appears in *Pros* and

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1614–1623,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

Cons respectively. As illustrated in Fig. 2, we can see that the estimated sentiment distribution of a phrase is close to that of its aspect. The above observation suggests the *sentiment distribution consistency* assumption: **different phrases of the same aspect tend to have the same sentiment distribution, or to have statistically close distributions**. This assumption is also verified by our data: for most (above 91.3%) phrase with relatively reliable estimation (whose occurrence $\geq$50), the KL-divergence between the sentiment distribution of a phrase and that of its corresponding aspect is less than 0.05.

	Pros	Cons

phrase-battery life	37	74
phrase-power	17	37
...	...	...

Figure 2: The sentiment distribution of aspect "battery" and its related-phrases on *nokia 5130* with a large amount of reviews.

It is worth noting that, the sentiment distribution of a phrase can be estimated accurately only when we obtain a sufficient number of reviews. When the number of reviews is limited, however, the estimated sentiment distribution for each phrase is unreliable (as shown in Fig. 3). A key issue, arisen here, is how to formulate this assumption in a statistically robust manner. The proposed model should be robust when only a limited number of reviews are available.

	Pros	Cons
phrase-battery	1	4
phrase-battery life	2	2
phrase-power	1	0
...	...	...

Figure 3: The sentiment distribution of aspect "battery" and its related-phrases on *nokia 3110c* with a small mumber of reviews.

To deal with this issue, we model *sentiment distribution consistency* as soft constraint, integrated into a probabilistic model that maximizes the data likelihood. We design the constraint to work in the following way: when we have sufficient observations, the constraint becomes tighter, which plays a more important role in the learning process; when we have limited observations, the constraint becomes very loose so that it will have less effect on the model.

In this paper, we propose a novel unsupervised model, Sentiment Distribution Consistency Regularized Multinomial Naive Bayes (SDC-MNB). The context part is modeled by Multinomial Naive Bayes in which aspect is treated as latent variable, and *Sentiment distribution consistency* is encoded as soft constraint within the framework of Posterior Regularization (PR) (Graca et al., 2008). The main contributions of this paper are summarized as follows:

- We study the problem of clustering phrases by integrating both context information and sentiment distribution of aspect-related phrases.
- We explore a novel concept, *sentiment distribution consistency(SDC)*, and model it as soft constraint to guide the clustering process.
- Experiments show that our model outperforms the state-of-art approaches for aspect clustering.

The rest of this paper is organized as follows. We introduce the SDC-MNB model in Section 2. We present experiment results in Section 3. In Section 4, we survey related work. We summarize the work in Section 5.

2 Sentiment Distribution Consistency Regularized Multinomial Naive Bayes

In this section, we firstly introduce our assumption *sentiment distribution consistency* formally and show how to model the above assumption as soft constraint , which we term SDC-constraint. Secondly, we show how to combine SDC-constraint with the probabilistic context model. Finally, we present the details for context and sentiment extraction.

2.1 Sentiment Distribution Consistency

We define *aspect* as a set of phrases that refer to the same property of a product and each phrase is termed *aspect-related phrase* (or *aspect phrase* in short). For example, the aspect "battery" contains aspect phrases such as "battery", "battery life", "power", and so on.

F	the aspect phrase set
f_j	the j^{th} aspect phrase
y_j	the aspect for aspect phrase f_j
A	the aspect set
a_i	the i^{th} aspect
D	the set of context documents
d_j	the context document of f_j
V	the word vocabulary
w_t	the t^{th} word in vocabulary V
$w_{d_j,k}$	the k^{th} word in d_j
N_{tj}	the number of times word w_t occurs in d_j
P	the product set
p_k	the k^{th} product
u_{ik}	the *sentiment distribution parameter* of aspect a_i on p_k
$\hat{s}_{jk}$	the estimated *sentiment distribution parameter* of phrase f_j on p_k
n_{jk}	the occurrence times of aspect phrase f_j on p_k
$\hat{\sigma}_{jk}$	the sample standard deviation
θ	the model parameters
$p_\theta(a_i\|d_j)$	the posterior distribution of a_i given d_j
$q(y_j = a_i)$	the projected posterior distribution of a_i given d_j

Table 1: Notations

Let us consider the sentiment distribution on a certain aspect a_i. In a large review dataset, aspect a_i could receive many comments from different reviewers. For each comment, we assume that people either praise or complain about the aspect. So each comment on the aspect can be seen as a Bernoulli trial, where the aspect receives positive comments with probability p_{a_i}[1]. We introduce a *random variable* X_{a_i} to denote the sentiment on aspect a_i, where $X_{a_i} = 1$ means that aspect a_i receives positive comments, $X_{a_i} = 0$ means that aspect a_i receives negative comments. Obviously, the sentiment on aspect a_i follows the Bernoulli distribution,

$$Pr(X_{a_i}) = p_{a_i}^{X_{a_i}} * (1 - p_{a_i})^{1 - X_{a_i}}, X_{a_i} \in \{0, 1\}. \quad (1)$$

Or in short,

$$X_{a_i} \sim Bernoulli(p_{a_i})$$

Let us see the case for aspect phrase f_j, where $f_j \in$ aspect a_i. Similarly, each comment on an aspect phrase f_j can also be seen as a Bernoulli trial. We introduce a *random variable* X_{f_j} to denote the sentiment on aspect phrase f_j, where $X_{f_j} = 1$ means that aspect f_j receives positive comments, $X_{f_j} = 0$ means that aspect f_j receives negative comments. As just discussed, we assume that each aspect phrase follows the same distribution with the corresponding aspect. This leads to the following formal description:

- ***Sentiment Distribution Consistency*** : The sentiment distribution of *aspect phrase* is the same as that of the corresponding *aspect*. Formally, for all aspect phrase $f_j \in$ aspect a_i, $X_{f_j} \sim Bernoulli(p_{a_i})$.

2.2 Sentiment Distribution Consistency Constraint

Assuming the sentiment distribution of aspect a_i is given in advance, we need to judge whether an aspect phrase f_j belongs to the aspect a_i with limited observations for f_j. Let's consider the example in Fig. 4. For aspect phrase 3, we have no definite answer due to the limited number of observations. For aspect phrase 1, it seems that the sentiment distribution is consistent with that of the left aspect. However, we can not say that the phrase belongs to the aspect because the distribution may be the same for two different aspects. For aspect phrase 2, we are confident that its sentiment distribution is different from that of the left aspect, given sufficient observations.

	pros	cons	Belong to left aspect?
Aspect phrase1	21	10	Reliable estimation, Use to judge. =>maybe
Aspect phrase2	3	100	Reliable estimation, Use to judge. => not likely
Aspect phrase3	1	2	Unreliable estimation =>maybe

Figure 4: Sentiment distribution of an aspect, and observations on aspect phrases.

To be concise, *we judge an aspect phrase doesn't belong to certain aspect only when we are confident that they follow different sentiment distributions*.

Inspired by the intuition, we conduct interval parameter estimation for parameter p_{f_j}(sentiment distribution for phrase f_j) with limited observations, and thus get a confidence interval for p_{f_j}. If p_{a_i}(sentiment distribution for aspect a_i) is not in the confidence interval of p_{f_j}, we then are confident that they follow different distributions. In other words, if aspect phrase $f_j \in$ aspect a_i, we are confident that p_{a_i} is in the confidence interval of p_{f_j}.

More formally, we use u_{ik} to denote the sentiment distribution parameter of aspect a_i on product p_k, and assume that u_{ik} is given in advance.

[1] *positive comment* means that an aspect term is observed in *Pros* of a review.

We want to know whether the sentiment distribution on aspect phrase f_j is the same as that of aspect a_i on product p_k given a limited number of observations (samples). It's straightforward to calculate the confidence interval for parameter s_{jk} in the Bernoulli distribution function. Let the sample mean of n_{jk} samples be $\hat{s}_{jk}$, and the sample standard deviation be $\hat{\sigma}_{jk}$. Since the sample size is small here, we use the Student-t distribution to calculate the confidence interval. According to our assumption, we are confident that u_{ik} is in the confidence interval if $f_j \in a_i$.

$$\hat{s}_{jk} - C\frac{\hat{\sigma}_{jk}}{\sqrt{n_{jk}}} \leq u_{ik} \leq \hat{s}_{jk} + C\frac{\hat{\sigma}_{jk}}{\sqrt{n_{jk}}}, \forall f_j \in a_i, \forall k. \quad (2)$$

where we look for t-table to find C corresponding to a certain confidence level(such as 95%) with the freedom of $n_{jk} - 1$. For simplicity, we represent the above confidence interval by $[\hat{s}_{jk} - d_{jk}, \hat{s}_{jk} + d_{jk}]$, where $d_{jk} = C\frac{\hat{\sigma}_{jk}}{\sqrt{n_{jk}}}$.

We introduce an indicator variable z_{ij} to represent whether the aspect phrase f_j belongs to aspect a_i, as follows:

$$z_{ji} = \begin{cases} 1 & ;\text{if } f_j \in a_i \\ 0 & ;\text{otherwise} \end{cases} \quad (3)$$

This leads to our SDC-constraint function.

$$\phi = z_{ji}|u_{ik} - \hat{s}_{jk}| \leq d_{jk}, \forall i, j, k \quad (4)$$

SDC-constraint are flexible for modeling Sentiment Distribution Consistency. The more observations we have, the smaller d_{jk} is. For frequent aspect phrase, the constraint can be very informative because it can filter unrelated aspects for aspect phrase f_j. The less observations we have, the larger d_{jk} is. For rare aspect phrases, the constraint can be very loose, and will not have much effect on the clustering process for aspect phrase f_j. In this way, the model can work very robustly.

SDC-constraints are data-driven constraints. Usually we have many reviews about hundreds of products in our dataset. For each aspect phrase, there are $|A| * |P|$ constraints (the number of aspects times the number of product). With thousands of constraints about which aspect it is not likely to belong to, the model learns to which aspect a phrase f_j should be assigned. Although most constraints may be loose because of the limited observations, SDC-constraint can still play an important role in the learning process.

2.3 Sentiment Distribution Consistency Regularized Multinomial Naive Bayes (SDC-MNB)

In this section, we present our probabilistic model which employs both context information and sentiment distribution.

First of all, we extract a context document d for each aspect phrase, which will be described in Section 2.5. In other word, a phrase is represented by its context document. Assuming that the documents in D are independent and identically distributed, the probability of generating D is then given by:

$$p_\theta(D) = \prod_{j=1}^{|D|} p_\theta(d_j) = \prod_{j=1}^{|D|} \sum_{y_j \in A} p_\theta(d_j, y_j) \quad (5)$$

where y_j is a latent variable indicating the aspect label for aspect phrase f_j, and θ is the model parameter.

In our problem, we are actually more interested in the posterior distribution over aspect, i.e., $p_\theta(y_j|d_j)$. Once the learned parameter θ is obtained, we can get our clustering result from $p_\theta(y_j|d_j)$, by assigning aspect a_i with the largest posterior to phrase f_j. We can also enforce SDC-constraint in expectation(on posterior p_θ). We use $q(Y)$ to denote the valid posterior distribution that satisfy our SDC-constraint, and Q to denote the valid posterior distribution space, as follows:

$$Q = \{q(Y) : E_q[z_{ji}|u_{ik} - \hat{s}_{jk}|] \leq d_{jk}, \forall i, j, k\}. \quad (6)$$

Since posterior plays such an important role in joining the context model and SDC-constraint, we formulate our problem in the framework of Posterior Regularization (PR). PR is an efficient framework to inject constraints on the posteriors of latent variables. Instead of restricting p_θ directly, which might not be feasible, PR penalizes the distance of p_θ to the constraint set Q. The posterior-regularized objective is termed as follows:

$$\max_\theta \{\log p_\theta(D) - \min_{q \in Q} KL(q(Y)||p_\theta(Y|D))\} \quad (7)$$

By trading off the data likelihood of the observed context documents (as defined in the first term), and the KL divergence of the posteriors to the valid posterior subspace defined by SDC-constraint (as defined in the second term), the objective encourages models with both desired posterior distribution and data likelihood. In essence, the model attempts to maximize data likelihood of context subject (softly) to SDC-constraint.

2.3.1 Multinomial Naive Bayes

In spirit to (Zhai et al., 2011a), we use Multinomial Naive Bayes (MNB) to model the context document. Let $w_{d_j,k}$ denotes the k^{th} word in document d_j, where each word is from the vocabulary $V = \{w_1, w_2, ..., w_{|V|}\}$. For each aspect phrase f_j, the probability of its latent aspect being a_i and generating context document d_i is

$$p_\theta(d_j, y_j = a_i) = p(a_i) \prod_{k=1}^{|d_j|} p(w_{d_j,k}|a_i) \quad (8)$$

where $p(a_i)$ and $p(w_{d_j,k}|a_i)$ are parameters of this model. Each word $w_{d_j,k}$ is conditionally independent of all other words given the aspect a_i.

Although MNB has been used in existing work for aspect clustering, all of the studies used it in a semi-supervised manner, with labeled data or pseudo-labeled data. In contrast, MNB proposed here is used in an unsupervised manner for aspect-related phrases clustering.

2.3.2 SDC-constraint

As mentioned above, the constraint posterior set Q is defined by

$$Q = \{q(Y) : q(y_j = a_i)|u_{ik} - \hat{s}_{jk}| \leq d_{jk}, \forall i, j, k\}. \quad (9)$$

We can see that Q denotes a set of linear constraints on the projected posterior distribution q. Note that we do not directly observe u_{ik}, the sentiment distribution of aspect a_i on product p_k. For aspect phrase f_j that belongs to aspect a_i, we estimate u_{ik} by counting all sentiment samples. We use the posterior $p_\theta(a_i|d_j)$ to approximately represent how likely phrase f_j belongs to aspect a_i.

$$u_{ik} = \frac{1}{\sum_{j=1}^{|D|} n_{jk} p_\theta(a_i|d_j)} \sum_{j=1}^{|D|} n_{jk} p_\theta(a_i|d_j) \hat{s}_{jk} \quad (10)$$

where $p_\theta(a_i|d_j)$ is short for $p_\theta(y_j = a_i|d_j)$, the probability that aspect phrase f_j belongs to a_i given the context document d_j. We estimate u_{ik} in this way because observations for aspect are relatively sufficient for a reliable estimation since observations for an aspect are aggregated from those for all phrases belonging to that aspect.

2.4 The Optimization Algorithm

The optimization algorithm for the objective (see Eq. 7) is an EM-like two-stage iterative algorithm.

In E-step, we first calculate the posterior distribution $p_\theta(a_i|d_j)$, then project it onto the valid posterior distribution space Q. Given the parameters θ, the posterior distribution can be calculated by Eq. 11.

$$p_\theta(a_i|d_j) = \frac{p(a_i) \prod_{k=1}^{|d_j|} p(w_{d_j,k}|a_i)}{\sum_{r=1}^{|A|} p(a_r) \prod_{k=1}^{|d_j|} p(w_{d_j,k}|a_r)} \quad (11)$$

We use the above posterior distribution to update the sentiment parameter for each aspect by Eq. 10. The projected posterior distribution q is calculated by

$$q = \underset{q \in Q}{argmin}\, \mathbf{KL}(q(Y)||p_\theta(Y|D)) \quad (12)$$

For each instance, there are $|A| * |P|$ constraints. However, we can prune a large number of useless constraints derived from limited observations. All constraints with $d_{jk} > 1$ can be pruned, due to the fact that the parameter u_{ik}, $\hat{s_{jk}}$ is within [0,1], and the difference can not be larger than 1. This optimization problem in Eq. 12 is easily solved via the dual form by the projected gradient algorithm (Boyd and Vandenberghe, 2004):

$$\max_{\lambda \geq 0} \Bigg(-\sum_{i=1}^{|A|} \sum_{k=1}^{|P|} \lambda_{ik} d_{jk} - \log \sum_{i=1}^{|A|} p_\theta(a_i|d_j) exp\{-\sum_{k=1}^{|P|} \lambda_{ik}|u_{ik} - \hat{s}_{jk}|\} - \epsilon\|\lambda\| \Bigg) \quad (13)$$

where ϵ controls the slack size for constraint. After solving the above optimization problem and obtaining the optimal λ, we can calculate the projected posterior distribution q by

$$q(y_j = a_i) = \frac{1}{Z} p_\theta(a_i|d_j) exp\{-\sum_{k=1}^{|P|} \lambda_{ik}|u_{ik} - \hat{s}_{jk}|\} \quad (14)$$

where Z is the normalization factor. Note that *sentiment distribution consistency* is actually modeled as instance-level constraint here, which makes it very efficient to solve.

In M-step, the projected posteriors $q(Y)$ are then used to compute sufficient statistics and update the models parameters θ. Given the projected posteriors $q(Y)$, the parameters can be updated by Eq. 15,16.

$$p(a_i) = \frac{1 + \sum_{j=1}^{|D|} q(y_j = a_i)}{|A| + |D|} \quad (15)$$

$$p(w_t|a_i) = \frac{1 + \sum_{j=1}^{|D|} N_{ti} q(y_j = a_i)}{|V| + \sum_{m=1}^{|V|} \sum_{j=1}^{|D|} N_{mj} q(y_j = a_i)} \quad (16)$$

where N_{tj} is the number of times that the word w_t occurs in document d_j.

The parameters are initialized randomly, and we repeat E-step and M-step until convergence.

2.5 Data Extraction

2.5.1 Context Extraction

In order to extract the context document d for each aspect phrase, we follow the approach in Zhai et al. (2011a). For each aspect phrase, we generate its context document by aggregating the surrounding texts of the phrase in all reviews. The preceding and following t words of a phrase are taken as the context where we set $t = 3$ in this paper. Stopwords and other aspect phrases are removed. For example, the following review contains two aspect phrases, "*screen*" and "*picture*",

The LCD ***screen*** *gives clear* ***picture***.

For "*screen*", the surrounding texts are {the, LCD, gives, clear, picture}. We remove stopwords "the", and the aspect term "*picture*", and the resultant context of "*screen*" in this review is

context(*screen*) ={LCD, screen, gives, clear}.

Similarly, the context of "*picture*" in this review is

context(*picture*) ={gives, clear}.

By aggregating the contexts of all the reviews that contain aspect phrase f_j, we obtain the corresponding context document d_j.

2.5.2 Sentiment Extraction

Since we use semi-structured reviews, we obtain the estimated sentiment distribution by simply counting how many times each aspect phrase appears in *Pros* and *Cons* reviews for each product respectively. So for each aspect phrase f_j, let n^+_{jk} denotes the times that f_j appears in *Pros* of all reviews for product p_k, and let n^-_{jk} denotes the times that f_j appears in *Cons* of all reviews for product p_k. So the total number of occurrence of a phrase is $n_{jk} = n^+_{jk} + n^-_{jk}$. We have samples like (1,1,1,0,0) where 1 means a phrase occurs in *Pros* of a review, and 0 in *Cons*. Given a sequence of such observations, the sample mean is easily computed as $\hat{s}_{jk} = \frac{n^+_{jk}}{n^+_{jk}+n^-_{jk}}$. And the sample standard deviation is $\hat{\sigma}_{jk} = \sqrt{\frac{(1-\hat{s}_{jk})^2 * n^+_{jk} + (\hat{s}_{jk})^2 * n^-_{jk}}{n_{jk}-1}}$.

3 Experiments

3.1 Data Preparation

The details of our review corpus are given in Table 2. This corpus contains semi-structured customer reviews from four domains: *Camera*, *Cellphone*, *Laptop*, and *MP3*. These reviews were crawled from the following web sites: www.amazon.cn, www.360buy.com, www.newegg.com.cn, and www.zol.com. The aspect label of each aspect phrases is annotated by human curators.

	Camera	Cellphone	Laptop	MP3
#Products	449	694	702	329
#Reviews	101,235	579,402	102,439	129,471
#Aspect Phrases	236	230	238	166
#Aspect	12	10	14	8

Table 2: Statistics of the review corpus. # denotes the size.

3.2 Evaluation Measures

We adapt three measures *Purity*, *Entropy*, and *Rand Index* for performance evaluation. These measures have been commonly used to evaluate clustering algorithms.

Given a data set DS, suppose its gold-standard partition is $G = \{g_1, ..., g_j, ..., g_k\}$, where k is the number of clusters. A clustering algorithm partitions DS into k disjoint subsets, say $DS_1, DS_2, ..., DS_k$.

Entropy: For each resulting cluster, we can measure its entropy using Eq. 17, where $P_i(g_j)$ is the proportion of data points of class g_j in DS_i. The entropy of the entire clustering result is calculated by Eq. 18.

$$entropy(DS_i) = -\sum_{j=1}^{k} P_i(g_j) log_2 P_i(g_j) \quad (17)$$

$$entropy(DS) = \sum_{i=1}^{k} \frac{|DS_i|}{|DS|} entropy(DS_i) \quad (18)$$

Purity: *Purity* measures the extent that a cluster contains only data from one gold-standard partition. The cluster purity is computed with Eq. 19. The total purity of the whole clustering result (all clusters) is computed with Eq. 20.

$$purity(DS_i) = \max_j P_i(g_j) \quad (19)$$

$$purity(DS) = \sum_{i=1}^{k} \frac{|DS_i|}{|DS|} purity(DS_i) \quad (20)$$

RI: The *Rand Index(RI)* penalizes both false positive and false negative decisions during clustering. Let TP (True Positive) denotes the number of pairs of elements that are in the same set in DS and in the same set in G. TN (True Negative) denotes number of pairs of elements that are in different sets in DS and in different sets in G. FP (False

	Camera			Cellphone			Laptop			MP3		
	P	RI	E	P	RI	E	P	RI	E	P	RI	E

Table 3: Comparison to unsupervised baselines. (P is short for purity, E for entropy, and RI for random index.)

Positive) denotes number of pairs of elements in S that are in the same set in DS and in different sets in G. FN (False Negative) denotes number of pairs of elements that are in different sets in DS and in the same set in G. The *Rand Index(RI)* is computed with Eq. 21.

$$RI(DS) = \frac{TP + TN}{TP + TN + FP + FN} \tag{21}$$

3.3 Evaluation Results

3.3.1 Comparison to unsupervised baselines

We compared our approach with several existing unsupervised methods. Some of the methods augmented unsupervised models by incorporating lexical similarity and other domain knowledge. All of them are context-based models.[2] We list these models as follows.

- ***Kmeans***: Kmeans is the most popular clustering algorithm. Here we use the context distributional similarity (cosine similarity) as the similarity measure.

- ***L-EM***: This is a state-of-the-art unsupervised method for clustering aspect phrases (Zhai et al., 2011a). L-EM employed lexical knowledge to provide a better initialization for EM.

- ***LDA***: LDA is a popular topic model(Blei et al., 2003). Given a set of documents, it outputs groups of terms of different topics. In our case, each aspect phrase is processed as a term. [3] Each sentence in a review is considered as a document. Each aspect is considered as a topic. In LDA, a term may belong to more than one topic/group, but we take the topic/group with the maximum probability.

- ***Constraint-LDA***: Constraint-LDA (Zhai et al., 2011b) is a state-of-the-art LDA-based method that incorporates must-link and cannot-link constraints for this task. We set the damping factor $\lambda = 0.3$ and relaxation factor $\eta = 0.9$, as suggested in the original reference.

For all methods that depend on the random initiation, we use the average results of 10 runs as the final result. For all LDA-based models, we choose $\alpha = 50/T$, $\beta = 0.1$, and run 1000 iterations.

Experiment results are shown in Table 3. We can see that our approach almost outperforms all unsupervised baseline methods by a large margin on all domains. In addition, we have the following observations:

- LDA and Kmeans perform poorly due to the fact that the two methods do not use any prior knowledge. It is also shown that only using the context distributional information is not sufficient for clustering aspect phrases.

- Constraint-LDA and L-EM that utilize prior knowledge perform better. We can see that Constraint-LDA outperforms LDA in terms of RI (Rand Index) on all domains. L-EM achieves the best results against the baselines. This demonstrates the effectiveness to incorporate prior knowledge.

- SDC-MNB produces the optimal results among all models for clustering. Methods that use must-links and cannot-links may suffer from noisy links. For L-EM, we find that it is sensitive to noisy must-links. As L-EM assumes that must-link is transitive, several noisy must-links may totally mislabel the softly annotated data. For Constraint-LDA, it is more robust than L-EM, because it doesn't assume the transitivity of must-link. However, it only promotes the RI (Rand Index) consistently by leveraging pair-wise prior knowledge, but sometimes it hurts the

[2] In our method, we collect context document for each aspect phrase. This process is conducted for L-EM and K-means. But for LDA and Constraint-LDA, we take each sentence of reviews as a document. This setting for the LDA baselines is adapted from previous work.

[3] Each aspect phrase is pre-processed as a single word (e.g., "battery life" is treated as battery-life). Other words are normally used in LDA.

performance with respect to purity or entropy. Our method is consistently better on almost all domains, which shows the advantages of the proposed model.

- SDC-MNB is remarkably better than baselines, particularly for the *cellphone* domain. We argue that this is because we have the largest number of reviews for each product in the *cellphone* domain. The larger dataset gives us more observations on each phrase, so that we obtain more reliable estimation of model parameters.

3.3.2 Comparison to supervised baselines

We further compare our methods with two supervised models. For each supervised model, we provide a proportion of manually labeled data for training, which is randomly selected from gold-standard annotations. However, we didn't use any labeled data for our approach.

- ***MNB***: The labeled seeds are used to train a MNB classifier to classify all unlabeled aspect phrases into different classes.

- ***L-Kmeans***: In L-Kmeans, the clusters of the labeled seeds are fixed at the initiation and remain unchanged during iteration.

	Purity	RI	Entropy
MNB-5%	53.21%	85.77%	1.854
MNB-10%	**59.55%**	**86.70%**	**1.656**
MNB-15%	66.06%	88.39%	1.449
L-Kmeans-10%	53.54%	86.15%	1.745
L-Kmeans-15%	**57.00%**	**86.89%**	**1.643**
L-Kmeans-20%	60.97%	87.63%	1.528
SDC-MNB	**59.49%**	**88.26%**	**1.580**

Table 4: Comparison to supervised baselines. MNB-5% means MNB with 5% labeled data.

We experiment with several settings: taking 5%, 10% and 15% of the manually labeled aspect phrases for training, and the remainder as unlabeled data. Experiment results is shown in Table 4 (the results are averaged over 4 domains). We can see that our unsupervised approach is roughly as good as the supervised MNB with 10% labeled data. Our unsupervised approach is also slightly better than L-Kmeans with 15% labeled data. This result further demonstrates the effectiveness of our model.

3.3.3 Influence of parameters

We vary the confidence level from 90% to 99.9% to see how it impacts on the performance of SDC-MNB. The results are presented in Fig. 5 (the results are averaged over 4 domains). We can see that the performance of clustering is fairly stable when changing the confidence level, which implies the robustness of our model.

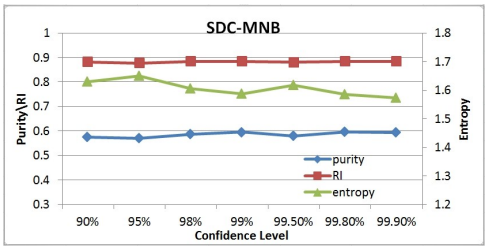

Figure 5: Influence of the confidence level on SDC-MNB.

3.3.4 Analysis of SDC-constraint

As mentioned in Section 2.2, SDC-constraint is dependent on the number of observations. More observations we get, more informative the constraint is, which means the constraint is tighter and d_{jk} (see Eq.4) is smaller. For all k, we count how many d_{jk} is less than 0.2 (and 1) on average for each aspect phrase f_j. d_{jk} is calculated with a confidence level of 99%. The statistics of constraints is given in Table 5. We can see that the cellphone domain has the most informative and largest constraint set, that may explain why SDC-MNB achieves the largest purity gain(over L-EM) in cellphone domain.

	$\#(d_{jk} < 0.2)$	$\#(0.2 < d_{jk} < 1)$	purity gain
Camera	3.02	8.78	1.53%
Cellphone	17.29	30.5	15.99%
Laptop	4.6	13.22	6.58%
MP3MP4	6.1	10.7	13.82%

Table 5: Constraint statistics on different domains.

4 Related Work

Our work is related to two important research topics: aspect-level sentiment analysis, and constraint-driven learning. For aspect-level sentiment analysis, aspect extraction and clustering are key tasks. For constraint-driven learning, a variety of frameworks and models for sentiment analysis have been studied extensively.

There have been many studies on clustering aspect-related phrases. Most existing studies are

based on context information. Some works also encoded lexical similarity and synonyms as prior knowledge. Carenini et al. (2005) proposed a method that was based on several similarity metrics involving string similarity, synonyms, and lexical distances defined with WordNet. Guo et al. (2009) proposed a multi-level latent semantic association model to capture expression-level and context-level topic structure. Zhai et al. (2010) proposed an EM-based semi-supervised learning method to group aspect expressions into user-specified aspects. They employed lexical knowledge to provide a better initialization for EM. In Zhai et al. (2011a), an EM-based unsupervised version was proposed. The so-called L-EM model first generated softly labeled data by grouping feature expressions that share words in common, and then merged the groups by lexical similarity. Zhai et al. (2011b) proposed a LDA-based method that incorporates must-link and cannot-link constraints.

Another line of work aimed to extract and cluster aspect words simultaneously using topic modeling. Titov and McDonald (2008) proposed the multi-grain topic models to discover global and local aspects. Branavan et al. (2008) proposed a method which first clustered the key-phrases in Pros and Cons into some aspect categories based on distributional similarity, then built a topic model modeling the topics or aspects. Zhao et al. (2010) proposed the MaxEnt-LDA (a Maximum Entropy and LDA combination) hybrid model to jointly discover both aspect words and aspect-specific opinion words, which can leverage syntactic features to separate aspects and sentiment words. Mukherjee and Liu (2012) proposed a semi-supervised topic model which used user-provided seeds to discover aspects. Chen et al. (2013) proposed a knowledge-based topic model to incorporate must-link and cannot-link information. Their model can adjust topic numbers automatically by leveraging cannot-link.

Our work is also related to general constraint-driven(or knowledge-driven) learning models. Several general frameworks have been proposed to fully utilize various prior knowledge in learning. Constraint-driven learning (Chang et al., 2008) (CODL) is an EM-like algorithm that incorporates per-instance constraints into semi-supervised learning. Posterior regularization (Graca et al., 2007) (PR) is a modified EM algorithm in which the E-step is replaced by the projection of the model posterior distribution onto the set of distributions that satisfy auxiliary expectation constraints. Generalized expectation criteria (Druck et al., 2008) (GE) is a framework for incorporating preferences about model expectations into parameter estimation objective functions. Liang et al. (2009) developed a Bayesian decision-theoretic framework to learn an exponential family model using general measurements on the unlabeled data. In this paper, we model our problem in the framework of posterior regularization.

Many works promoted the performance of sentiment analysis by incorporating prior knowledge as weak supervision. Li and Zhang (2009) injected lexical prior knowledge to non-negative matrix tri-factorization. Shen and Li (2011) further extended the matrix factorization framework to model dual supervision from both document and word labels. Vikas Sindhwani (2008) proposed a general framework for incorporating lexical information as well as unlabeled data within standard regularized least squares for sentiment prediction tasks. Fang (2013)proposed a structural learning model with a handful set of aspect signature terms that are encoded as weak supervision to extract latent sentiment explanations.

5 Conclusions

Aspect finding and clustering is an important task for aspect-level sentiment analysis. In order to cluster aspect-related phrases, this paper has explored a novel concept, *sentiment distribution consistency*. We formalize the concept as soft constraint, integrate the constraint with a context-based probabilistic model, and solve the problem in the posterior regularization framework. The proposed model is also designed to be robust with both sufficient and insufficient observations. Experiments show that our approach outperforms state-of-the-art baselines consistently.

Automatic Generation of Related Work Sections in Scientific Papers: An Optimization Approach

Yue Hu and Xiaojun Wan
Institute of Computer Science and Technology
The MOE Key Laboratory of Computational Linguistics
Peking University, Beijing, China
{ayue.hu,wanxiaojun}@pku.edu.cn

Abstract

In this paper, we investigate a challenging task of automatic related work generation. Given multiple reference papers as input, the task aims to generate a related work section for a target paper. The generated related work section can be used as a draft for the author to complete his or her final related work section. We propose our Automatic Related Work Generation system called ARWG to address this task. It first exploits a PLSA model to split the sentence set of the given papers into different topic-biased parts, and then applies regression models to learn the importance of the sentences. At last it employs an optimization framework to generate the related work section. Our evaluation results on a test set of 150 target papers along with their reference papers show that our proposed ARWG system can generate related work sections with better quality. A user study is also performed to show ARWG can achieve an improvement over generic multi-document summarization baselines.

1 Introduction

The related work section is an important part of a paper. An author often needs to help readers to understand the context of his or her research problem and compare his or her current work with previous works. A related work section is often used for this purpose to show the differences and advantages of his or her work, compared with related research works. In this study, we attempt to automatically generate a related work section for a target academic paper with its reference papers. This kind of related work sections can be used as a basis to reduce the author's time and effort when he or she wants to complete his or her final related work section.

Automatic related work section generation is a very challenging task. It can be considered a topic-biased, multiple-document summarization problem. The input is a target academic paper, which has no related work section, along with its reference papers. The goal is to create a related work section that describes the related works and addresses the relationship between the target paper and the reference papers. Here we assume that the set of reference papers has been given as part of the input. Existing works in the NLP and recommendation systems communities have already focused on the task of finding reference papers. For example, citation prediction (Nallapati et al., 2008) aims at finding individual paper citation patterns.

Generally speaking, automatic related work section generation is a strikingly different problem and it is much more difficult in comparison with general multi-document summarization tasks. For example, multi-document summarization of news articles aims at synthesizing contents of similar news and removing the redundant information contained by the different news articles. However, each scientific paper has much specific content to state its own work and contribution. Even for the papers that investigate the same research topic, their contributions and contents can be totally different. The related work section generation task needs to find the specific contributions of individual papers and arrange them into one or several paragraphs.

In this study, we focus on the problem of automatic related work section generation and propose a novel system called ARWG to address the

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1624–1633,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

problem. For the target paper, we assume that the abstract and introduction sections have already been written by the author and they can be used to help generate the related work section. For the reference papers, we only consider and extract the abstract, introduction, related work and conclusion sections, because other sections like the method and evaluation sections always describe the extreme details of the specific work and they are not suitable for this task. Then we generate the related work section using both sentence sets which are extracted from the target paper and reference papers, respectively.

Firstly, we use a PLSA model to group both sentence sets of the target paper and its reference papers into different topic-biased clusters. Secondly, the importance of each sentence in the target paper and the reference papers is learned by using two different Support Vector Regression (SVR) models. At last, a global optimization framework is proposed to generate the related work section by selecting sentences from both the target paper and the reference papers. Meanwhile, the framework selects sentences from different topic-biased clusters globally.

Experimental results on a test set of 150 target papers show our method can generate related work sections with better quality than those of several baseline methods. With the ROUGE toolkit, the results indicate the related work sections generated by our system can get higher ROUGE scores. Moreover, our related work sections can get higher rating scores based on a user study. Therefore, our related work sections can be much more suitable for the authors to prepare their final related work sections.

2 Related Work

There are few studies to directly address automatic related work generation. Hoang and Kan (2010) proposed a related work summarization system given the set of keywords arranged in a hierarchical fashion that describes the paper's topic. They used two different rule-based strategies to extract sentences for general topics as well as detailed ones.

A few studies focus on multi-document scientific article summarization. Agarwal et al., (2011) introduced an unsupervised approach to the problem of multi-document summarization. The input is a list of papers cited together within the same source article. The key point of this approach is a topic based clustering of fragments extracted from each co-cited article. They rank all the clusters using a query generated from the context surrounding the co-cited list of papers. Yeloglu et al., (2011) compared four different approaches for multi-document scientific articles summarization: MEAD, MEAD with corpus specific vocabulary, LexRank and W3SS.

Other studies investigate mainly on the single-document scientific article summarization. Early works including (Luhn 1958; Baxendale 1958; Edumundson 1969) tried to use various features specific to scientific text (e.g., sentence position, or rhetorical clues features). They have proved that these features are effective for the scientific article summarization. Citation information has been already shown effective in summarize the scientific articles. Works including (Mei and Zhai 2008; Qazvinian and Radev 2008; Schwartz and Hearst 2006; Mohammad et al., 2009) employed citation information for the single scientific article summarization. Earlier work (Nakov et al., 2004) indicated that citation sentences may contain important concepts that can give useful descriptions of a paper.

Various methods have been proposed for news document summarization, including rule-based methods (Barzilay and Elhadad 1997; Marcu and Daniel 1997), graph-based methods (Mani and Bloedorn 2000; Erkan and Radev 2004; Michalcea and Tarau 2005), learning-based methods (Conroy et al., 2001; Shen et al., 2007; Ouyang et al., 2007; Galanis et al., 2008), optimization-based methods (McDonald 2007; Gillick et al., 2009; Xie et al., 2009; Berg-Kirkpatrick et al., 2011; Lei Huang et al., 2011; Woodsend et al., 2012; Galanis 2012), etc.

The most relevant work is (Hoang and Kan, 2010) as mentioned above. They also assumed the set of reference papers was given as part of the input. They also adopt the hierarchical topic tree that describes the topic structure in the target paper as an essential input for their system. However, it is non-trivial to build the hierarchical topic tree. Moreover, they do not consider the content of the target paper to construct the related work section, which is actually crucial in the related work section. To the best of our knowledge, no previous works have used supervised learning and optimization framework to deal with the multiple scientific article summarization tasks.

3 Problem Analysis and Corpus

3.1 Problem Analysis

We firstly analyze the structure of related work sections briefly. By using examples for illustration, we can gain insight on how to generate related work sections. A specific related work example is shown in Figure 1.

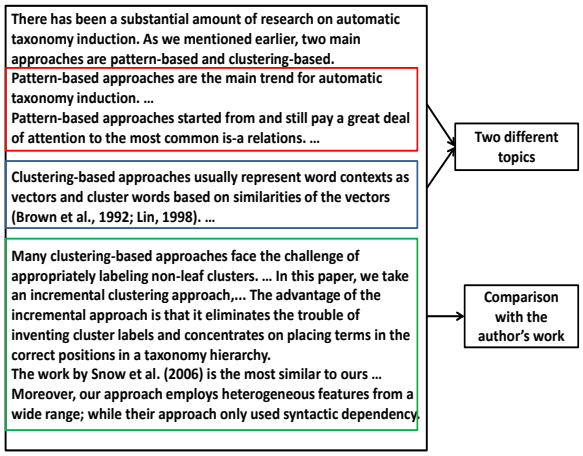

Figure 1: A sample related work section (Yang and Callan 2009)

This related work section introduces previous related works for a paper on Automatic Taxonomy Induction. From Figure 1, we can have a glance at the structure of related work sections. Related work sections usually discuss several different topics, such as "pattern-based" and "cluster-based" approaches shown in the Figure 1. Besides the knowledge of previous works, the author often compares his own work with the previous works. The differences and advantages are generally mentioned. The example in Figure 1 also indicates this phenomenon.

Therefore, we design our system to generate related work sections according to the related work section structure mentioned above. Our system takes the target paper for which a related work section needs to be drafted besides its reference papers as input. The goal of our system is to generate a related work section with the above structure. The generated related work section should have several topic-biased parts. The author's own work is also needed to be described and its difference with other works is needed to be emphasized on.

3.2 Corpus and Preprocessing

We build a corpus that contains academic papers and their corresponding reference papers. The academic papers are selected from the ACL Anthology[1]. The ACL Anthology currently hosts over 24,500 papers from major conferences such as ACL, EMNLP, COLING in the fields of computational linguistics and natural language processing. We remove the papers that contain related work sections with very short length, and randomly select 1050 target papers to construct our whole corpus.

The papers are all in PDF format. We extract their texts by using PDFlib[2] and detect their physical structures of paragraphs, subsections and sections by using ParsCit[3]. For the target papers, the related work sections are directly extracted as the gold summaries. The references are also extracted. For the references that can be found in the ACL Anthology, we download them from the ACL Anthology. The other reference papers are searched and downloaded by using Google Scholar. References to books and PhD theses are discarded, for their verbosity may change the problem drastically (Mihalcea and Ceylan, 2007).

The input of our system includes the abstract and introduction sections of the target paper, and the abstract, introduction, related work and conclusion sections of the reference papers. As mentioned above, the method and evaluation sections in the reference papers are not used as input because these sections usually describe extreme details of the methods and evaluation results and they are not suitable for related work generation. Note that it is reasonable to make use of the abstract and introduction sections of the target paper to help generate the related work section, because an author usually has already written the abstract and introduction sections before he or she wants to write the related work section for the target paper. Otherwise, we cannot get any information about the author's own work. All other sections in the target paper are not used.

4 Our Proposed System

4.1 Overview

In this paper, we propose a system called ARWG to automatically generate a related work section for a given target paper. The architecture of our system is shown in Figure 2. We take both the target paper and its reference papers as input and they are represented by several sections mentioned in Section 3.2. After preprocessing, we extract the feature vectors for sentences in the target paper and the reference papers, respective-

[1] http://aclweb.org/anthology/

[2] http://www.pdflib.com/

[3] http://aye.comp.nus.edu.sg/parsCit/

ly. The importance scores for sentences in the target paper and the reference papers are assigned by using two SVR based sentence scoring models. The two SVR models are trained for sentences in the target paper and the reference papers, respectively. Meanwhile, a topic model is applied to the whole set of sentences in both the target paper and reference papers. The sentences are grouped into several different topic-biased clusters. The sentences with importance scores and topic cluster information are taken as the input for the global optimization framework. The optimization framework extracts sentences to describe both the author's own work and background knowledge. More details of each part will be discussed in the following sections.

4.2 Topic Model Learning

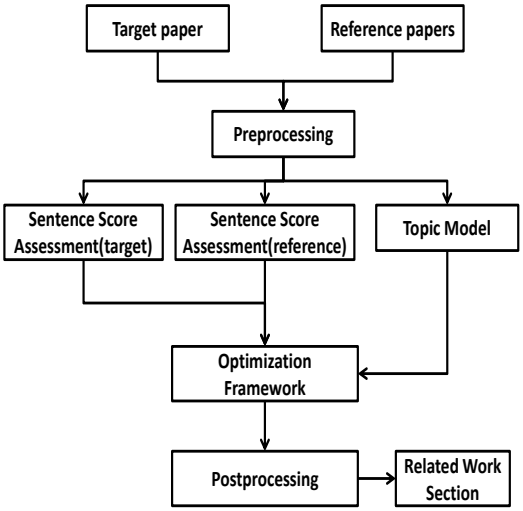

Figure 2: System Architecture

As mentioned in the previous section, the related work section usually addresses several different topics. The topics may be different research themes or different aspects of a broad research theme. The related work section should describe the specific details for each topic, respectively.

Therefore, we aim to discover the hidden topics of the input papers, and we use the Probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) to solve this problem.

The PLSA approach models each word in a document as a sample from a mixture model. The mixture components are multinomial random variables that can be viewed as representations of "topics". Different words in a document may be generated from different topics. Each document is represented a list of mixing proportions for these mixture components and can be reduced to a probability distribution on a fixed set of topics.

Considering that the sentences in one paper may relate to different topics, we treat each sentence as a "document" *d*. We treat the noun phases in the sentences as the "words" *w*. In order to extract the noun phrases, chunking implemented by the OpenNLP toolkit [4] is applied to the sentences. Noun phrases that contain words such as "paper" and "data" are discarded.

Then the sentences with their corresponding noun phrases are taken as input into the PLSA model. Here both the sentences in the target paper and the sentences in the reference papers are treated the same in the model. Finally, we can get the sentence set with topic information and use it in the subsequent steps. Each sentence has a topic weight *t* in each topic.

4.3 Sentence Important Assessment

In our proposed system, sentence importance assessment aims to assign an importance score to each sentence in the target paper and reference papers. The score of each sentence will be used in the subsequent optimization framework. We propose to use the support vector regression model to achieve this goal. In the above topic model learning process, we do not distinguish the sentences in the target paper and reference papers. In contrast, we train two different support vector regression models separately for the sentences in the target paper and the sentences in the reference papers. In the related work section, the sentences that describe the author's own work usually address the differences from the related works, while the sentences that describe the related works often focus on the specific details. We think the two kinds of sentences should be treated differently.

Scoring Method

To construct training data based on the papers collected, we apply a similarity scoring method to assign the importance scores to the sentences in the papers. The main hypothesis is that the sentences in the gold related work sections should summarize the target paper and reference papers as well. Thus the sentences in the papers which are more similar to the sentences in the gold related work sections should be considered more important and suitable to be selected. Our scoring method should assign higher scores to them.

[4] http://opennlp.apache.org/

We define the importance score of a sentence in the papers as below:

$$score(s) = \max_{s_i^* \in S^*}(sim(s, s_i^*)) \quad (1)$$

where s is a sentence in the papers, S^* is the set of the sentences in the corresponding gold related work section. The standard cosine measure is employed as the similarity function.

Considering the difference between the sentences that describe the author's work and the sentences that describe the related works, we split the set of sentences in the gold related work section into two parts: one discusses the author's own work and the other introduces the related works. We observe that sentences related to the author's own work often feature specific words or phrases (such as "we", "our work", "in this paper" etc.) in the related work section. So we check the sentences about whether they contain clue words or phrases (i.e., "in this paper", "our work" and 18 other phrases). If the clue phrase check fails, the sentence belongs to the related work part. If not, it belongs the own work part.

Thus for the sentences in the target paper, S^* is the set of sentences in the own work part of the gold related work section, while for the sentences in the reference papers, S^* is the set of sentences in the related work part of the gold related work section. Then we can use the scoring method to compute the target scores of the sentences in the training set. It is noteworthy that two SVR models can be trained on the two parts of the training data, respectively.

Feature

Each sentence is represented by a set of features. The common features used for the sentences of the target paper and reference papers are shown in Table 1. The additional features applied to the sentences of the target paper are introduced in Table 2.

Here, *s* is a sentence that needs to extract features. *th* is paper title, section headings and subsection headings set of the reference papers or target paper for the two SVR models, respectively. Each feature with "*" represent a feature set that contains similar features.

All the features are scaled into [0, 1]. Thus we can learn SVR models based on the features and importance scores of the sentences, and then use the models to predict an importance score for each sentence in the test set. The SVR models are trained and applied for the target paper and reference papers, respectively.

Table 1: Common features employed in the SVR models

Feature	Description
$Sim(s,th)^*$	The similarity between *s* and each title in *th*; Stop words are removed and stemming is employed.
WS(s,th)	Number of words shared by *s* and *th*.
$SP(s)^*$	The position of *s* in its section or subsection
$PTI(s)^*$	The parse tree information of *s*, including the number of noun phrase and verb phrases, the depth of the parse tree, etc.
$IsHead(s)^*$	Indicates whether *s* is the first sentence of the section or subsection
$IsEnd(s)^*$	Indicates whether *s* is the last sentence of the section or subsection
SWP(s)	The percentage of the stop words
Length(s)	The length of sentence *s*
Length_rw(s)	The length of *s* after removing stop words
SI(s)	The section index of *s* that indicates which section *s* is from.
$CluePhrase(s)^*$	Indicates whether a clue phrase appears in *s*. the clue phrases include "our work", "propose" and other 20 words. Each clue phrase corresponds to one feature.

Table 2: Additional features for sentences in the target paper

Feature	Description
HasCitation(s)	Indicates whether *s* contains a citation
$PhraseForCmp(s)^*$	Indicates whether *s* contains words or phrases used for comparison such as "in contrast", "instead" and other 26 words. Each word or phrase corresponds to one feature.

4.4 A Global Optimization Framework

In the above steps, we can get the predicted importance score and topic information for each sentence in the target paper and reference papers. Here, we introduce a global optimization framework to generate the related work section.

According to the structure of the related work section mentioned above, the related work section usually discusses several topics. In each topic, the related works and their details are introduced. Besides, the author often compares his own work with these previous works.

Therefore, we propose to formulate the generation as an optimization problem. Basically, we will be searching for a set of sentences to optimize the objective function.

Table 3: Notations used in this section

Symbol	Description
sr_i/st_i	the sentence in the reference/target paper
lr_i/lt_i	the length of sentence sr_i/ st_i
wr_i/wt_i	the importance score of sr_i/st_i
xr_{ij}/xt_{ij}	indicates whether sr_i/st_i is selected into the part of topic *j* in the generated related work section
nr/nt	the number of sentences in the reference/target papers
m	the topic count
t_{ij}	the topic weight of sr_i/st_i in topic j from the PLSA model
B	the set of unique bigrams
y_i	indicates whether bigram b_i is included in the result
c_{b_i}	the count of the occurrences of bigram b_i in the both target paper and reference papers
L_{max}	the maximum word count of the related work section
L_j	the maximum word count of the part of topic j which depends on the percentage of sentences belong to topic j
B^*	the total set of bigrams in the whole paper set
B_i	the set of bigrams that sentence sr_i/st_i contains
Sr_m/St_m	the set of sentences that include bigram b_m in the reference/target papers
$\lambda_1, \lambda_2, \lambda_3$	parameters for tuning

To design the objective function, three aspects should be considered:

1) First, the related work section we generate should introduce the previous works well. In our assumption, sentences with higher importance scores are better to be selected. In addition, very short sentences should be penalized. So we introduce the first part of our objective function below:

$$\sum_{i=1}^{nr}(lr_i wr_i \sum_{j=1}^{m} t_{ij} xr_{ij}) \quad (2)$$

We add the sentence length as a multiplication factor in order to penalize the very short sentences, or the objective function tends to select more and shorter sentences. At the same time, the objective function does not tend to select the very long sentences. The total length of the sentences selected is fixed. So if the objective function tends to select the longer sentences, the fewer sentences can be selected. A tradeoff needs to be made between the number and the average length of the sentences selected.

The constraints introduced below ensure that the sentence can only be selected into one topic and the topic weight is used to measure the degree that the sentence is relevant to the specific topic.

2) Second, similar to the first part, we should consider the own work part of the related work section. Thus the second part of our objective function is shown as follows:

$$\sum_{i=1}^{nt}(lt_i wt_i \sum_{j=1}^{m} t_{ij} xt_{ij}) \quad (3)$$

3) At last, redundancy reduction should be considered in the objective function. The last part of the objective function is shown below:

$$\sum_{i=1}^{|B|} c_{b_i} y_i \quad (4)$$

The intuition is that the more unique bigrams the related work section contains, the less redundancy the related work section has. We add c_{b_i} as the weight of the bigram in order to include more important bigrams.

By combing all the parts defined above, we have the following full objective function:

$$\max_{xr,xt} \lambda_1 \sum_{i=1}^{nr}(\frac{lr_i}{\alpha L_{max}} wr_i \sum_{j=1}^{m} t_{ij} xr_{ij}) + \lambda_2 \sum_{i=1}^{nt}(\frac{lt_i}{(1-\alpha)L_{max}} wt_i \sum_{j=1}^{m} t_{ij} xt_{ij}) + \lambda_3 \sum_{i=1}^{|B|} \frac{c_{b_i} y_i}{|B^*|} \quad (5)$$

Subject to:

$$\sum_{i=1}^{nr} lr_i xr_{ij} + \sum_{i=1}^{nt} lt_i xt_{ij} < L_j, for\ j = 1, \dots, m \quad (6)$$

$$\sum_{i=1}^{nr} \sum_{j=1}^{m} lr_i xr_{ij} < \alpha L_{max} \quad (7)$$

$$\sum_{i=1}^{nt} \sum_{j=1}^{m} lt_i xt_{ij} < (1-\alpha) L_{max} \quad (8)$$

$$\sum_{j=1}^{m} xr_{ij} \le 1, for\ i = 1, \dots, nr \quad (9)$$

$$\sum_{j=1}^{m} xt_{ij} \le 1, for\ i = 1, \dots, nt \quad (10)$$

$$\sum_{b_k \in B_i} y_k \ge |B_i| \sum_{j=1}^{m} xr_{ij}, for\ i = 1, \dots, nr \quad (11)$$

$$\sum_{b_k \in B_i} y_k \ge |B_i| \sum_{j=1}^{m} xt_{ij}, for\ i = 1, \dots, nt \quad (12)$$

$$\sum_{sr_i \in Sr_k} \sum_{j=1}^{m} xr_{ij} + \sum_{st_i \in St_k} \sum_{j=1}^{m} xt_{ij} \ge y_k, \quad k = 1, \dots |B| \quad (13)$$

$$xr_{ij}, xt_{ij}, y_i \in \{0,1\} \quad (14)$$

All the three parts in the objective function are normalized to [0, 1] by using the maximum length L_{max} and the total number of bigrams $|B^*|$. λ_1, λ_2 and λ_3 are parameters for tuning the three parts and we set $\lambda_1+\lambda_2+\lambda_3 = 1$.

We explain the constraints as follows:

Constraint (6): It ensures that the total word count of the part of topic *j* does not exceed L_j.

Constraints (7), (8): The two constraints try to balance the lengths of the previous works part and the own work part, respectively. α is set to 2/3.

Constraints (9), (10): These two constraints guarantee that the sentence can only be included into one topic.

Constraints (11), (12): When these two constraints hold, all bigrams that s_i has are selected if s_i is selected.

Constraint (13): This constraint makes sure that at least one sentence in Sr_m or St_m is selected if bigram b_m is selected.

Therefore, we transform our optimization problem into a linear programing problem. We solve this linear programming problem by using the IBM CPLEX optimizer[5]. It generally takes tens of seconds to solve the problem and it is very efficient.

Finally, ARWG post-processes sentences to improve readability, including replacing agentive forms with a citation to the specific article (e.g., "our work" → "(Hoang and Kan, 2010)") for the sentences extracted from reference papers. The sentences belonging to different topics are placed separately.

5 Evaluation

5.1 Evaluation Setup

To set up our experiments, we divide our dataset which contains 1050 target papers and their reference papers into two parts: 700 target papers for training, 150 papers for test and the other 200 papers for validation. The PLSA topic model is applied to the whole dataset. We train two SVR regression models based on the own work part and the previous work part of the training data and apply the models to the test data. The global optimization framework is used to generate the related work sections. We set the maximum word count of the generated related work section to be equal to that of the gold related work section. The parameter values of λ_1, λ_2 and λ_3 are set to 0.3, 0.1 and 0.6, respectively. The parameter values are tuned on the validation data.

We compare our system with five baseline systems: MEAD-WT, LexRank-WT, ARWG-WT, MEAD and LexRank. MEAD[6] (Radev et al., 2004) is an open-source extractive multi-document summarizer. LexRank[7] (Eran and Radev, 2004) is a multi-document summarization system which is based on a random walk on the similarity graph of sentences. We also implement the MEAD, LexRank baselines and our method with only the reference papers (i.e. the target paper's content is not considered). Those methods are signed by "-WT".

To evaluate the effectiveness of the SVR models we employ, we implement a baseline system RWGOF that uses the random walk scores as the important scores of the sentences and take the scores as inputs for the same global optimization framework as our system to generate the related work section. The random walk scores are computed for the sentences in the reference papers and the target paper, respectively.

We use the ROUGE toolkit to evaluate the content quality of the generated related work sections. ROUGE (Lin, 2004) is a widely used automatic summarization evaluation method based on n-gram comparison. Here, we use the F-Measure scores of ROUGE-1, ROUGE-2 and ROUGE-SU4. The model texts are set as the gold related work sections extracted from the target papers, and word stemming is utilized. ROUGE-N is an n-gram based measure between a candidate text and a reference text. The recall oriented score, the precision oriented score and the F-measure score for ROUGE-N are computed as follows:

$$ROUGE - N_{Recall} = \sum_{S\in\{Reference\ Text\}}\sum_{gram_n} Count_{match}(gram_n) \,/\, \sum_{S\in\{Reference\ Text\}}\sum_{gram_n} Count(gram_n) \quad (15)$$

$$ROUGE - N_{Precision} = \sum_{S\in\{Reference\ Text\}}\sum_{gram_n} Count_{match}(gram_n) \,/\, \sum_{S\in\{Candidate\ Text\}}\sum_{gram_n} Count(gram_n) \quad (16)$$

$$ROUGE - N_{F-measure} = 2 * ROUGE - N_{Recall} * ROUGE - N_{Precision} \,/\, ROUGE - N_{Recall} + ROUGE - N_{Precision} \quad (17)$$

where n stands for the length of the n-gram $gram_n$, and $Count_{match}(gram_n)$ is the maximum number of n-grams co-occurring in a candidate text and a reference text.

In addition, we conducted a user study to subjectively evaluate the related work sections to get more evidences. We selected the related work sections generated by different methods for 15 random target papers in the test set. We asked three human judges to follow an evaluation guideline we design and evaluate these related work sections. The human judges are graduate students in the computer science field and they did not know the identities of the evaluated related work sections. They were asked to give a rating on a scale of 1 (very poor) to 5 (very good) for the correctness, readability and usefulness of the related work sections, respectively:

[5] www-01.ibm.com/software/integration/optimization/cplex-optimizer/

[6] http://www.summarization.com/mead/

[7] In our experiments, LexRank performs much better than the more complex variant - C-LexRank (Qazvinian and Radev, 2008), and thus we choose LexRank, rather than C-LexRank, to represent graph-based summarization methods for comparison in this paper.

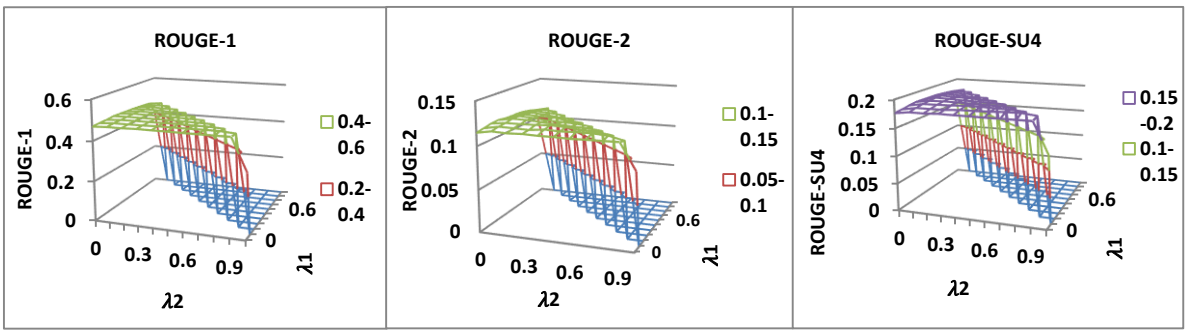

Figure 3: Parameter influences (horizontal, vertical axis are λ_1, λ_2 , respectively, $\lambda_3 = 1 - \lambda_1 - \lambda_2$)

1) Correctness: Is the related work section actually related to the target paper?
2) Readability: Is the related work section easy for the readers to read and grasp the key content?
3) Usefulness: Is the related work section useful for the author to prepare their final related work section?

Paired T-Tests are applied to both the ROUGE scores and rating scores for comparing ARWG and baselines and comparing the systems with WT and without WT.

5.2 Results and Discussion

Table 4: ROUGE F-measure comparison results

Method	ROUGE-1	ROUGE-2	ROUGE-SU4
Mead-WT	0.39720	0.08785	0.14694
LexRank-WT	0.43267	0.09228	0.16312
ARWG-WT	0.45077$^{*\{1,2\}}$	0.09987$^{*\{1,2\}}$	0.16731$^{*\{1\}\#\{2\}}$
Mead	0.41012$^{*\{1\}}$	0.09642$^{*\{1\}}$	0.15441$^{*\{1\}}$
LexRank	0.44235$^{*\{2\}}$	0.10090$^{*\{2\}}$	0.17067$^{*\{2\}}$
ARWG	**0.47940**$^{*\{1-5\}}$	**0.12176**$^{*\{1-5\}}$	**0.18618**$^{*\{1-5\}}$

(* represents pairwise t-test value $p < 0.01$; $^{\#}$ represents $p < 0.05$; the numbers in the brackets represent the indices of the methods compared, e.g. 1 for MEAD-WT, 2 for LexRank-WT, etc.)

Table 5: Average rating scores of judges

Method	Correctness	Readability	Usefulness
Mead	2.971	2.664	2.716
LexRank	2.958	2.847	2.784
ARWG	3.433$^{*\#}$	3.420$^{*\#}$	3.382$^{*\#}$

($^{*\#}$ represents pairwise t-test value $p < 0.01$, compared with Mead and LexRank, respectively.)

Table 6: ROUGE F-measure comparison of different sentence importance scores

Method	ROUGE-1	ROUGE-2	ROUGE-SU4
RWGOF	0.46932	0.11791	0.18426
ARWG	**0.47940**	**0.12176**	**0.18618**

The evaluation results over ROUGE metrics are presented in Table 4. It shows that our proposed system can get higher ROUGE scores, i.e., better content quality. In our system, we split the sentence set into different topic-biased parts, and the importance scores of sentences in the target paper and reference papers are learned differently. So the obtained importance scores of the sentences are more reliable.

The global optimization framework considers the extraction of both the previous work part and the own work part. We can see the importance of the own work part by comparing the results of the methods with or without considering the own work part. MEAD, LexRank and our method all get a significant improvement after considering the own work part by extracting sentences from the target paper. The results also prove our assumption about the related work section structure.

Figure 3 presents the fluctuation of ROUGE scores when tuning the parameters λ_1, λ_2 and λ_3. We can see our method generally performs better than the baselines. All the three parts in the objective function are useful to generate related work sections with good quality.

The average scores rated by human judges for each method are showed in Table 5. We can see that the related work sections generated by our system are more related to the target papers. Moreover, because of the good structure of our generated related work sections, our generated related work sections are considered more readable and more useful for the author to prepare the final related work sections.

T-test results show that the performance improvements of our method over baselines are statistically significant on both automatic and manual evaluations. Most of p-values for t-test are far smaller than 0.01.

Overall, the results indicate that our method can generate much better related work sections

than the baselines on both automatic and human evaluations.

Table 6 shows the comparison results between ARWG and RWGOF. We can see ARWG performs better than RWGOF. It proves that the SVR models can better estimate the importance scores of the sentences. For the SVR models are trained from the large dataset, the sentence scores predicted by the SVR models can be more reliable to be used in the global optimization framework.

6 Conclusion and Future Work

This paper proposes a novel system called ARWG to generate related work sections for academic papers. It first exploits a PLSA model to split the sentence set of the given papers into different topic-biased parts, and then applies regression models to learn the importance scores of the sentences. At last an optimization framework is proposed to generate the related work section. Evaluation results show that our system can generate much better related work sections than the baseline methods.

In future work, we will make use of citation sentences to improve our system. Citation sentences are the sentences that contains an explicit reference to another paper and they usually highlight the most important aspects of the cited papers. So citation sentences are likely to contain important and rich information for generating related work sections.

Abstract

There are several NLP systems whose accuracy depends crucially on finding misspellings fast. However, the classical approach is based on a quadratic time algorithm with 80% coverage. We present a novel algorithm for misspelling detection, which runs in constant time and improves the coverage to more than 96%. We use this algorithm together with a cross document coreference system in order to find proper name misspellings. The experiments confirmed significant improvement over the state of the art.

1 Introduction

The problem of finding the misspelled words in a corpus is an important issue for many NLP systems which have to process large collections of text documents, like news or tweets corpora, digitalized libraries etc. Any accurate systems, such as the ones developed for cross document coreference, text similarity, semantic search or digital humanities, should be able to handle the misspellings in corpora. However, the issue is not easy and the required processing time, memory or the dependence on external resources grow fast with the size of the analyzed corpus; consequently, most of the existing algorithms are inefficient. In this paper, we present a novel algorithm for misspelling detection which overcomes the drawbacks of the previous approaches and we show that this algorithm is instrumental in improving the state of the art of a cross document coreference system.

Many spelling errors in a corpus are accidental and usually just one or two letters in a word are affected, like *existnece* vs. the dictionary form *existence*. Such misspellings are rather a unique phenomenon occurring randomly in a text. For an automatic speller which has access to a dictionary, finding and compiling a list of correct candidates for the misspelled words like the one above is not very difficult. However, not all misspellings are in this category. To begin with, proper nouns, especially foreign proper names, are not present in the dictionary and their misspelling may affect more than one or two characters. Moreover, the misspelling of proper names may not be random, for example there might be different spellings of the same Chinese or Russian name in English, the incorrect ones occurring with some frequency. Also, especially if the corpus contains documents written by non native speakers, the number of characters varying between the correct and the actual written form may be more than two. In this case, finding and compiling the list of correct candidates is computationally challenging for traditional algorithms, as the distance between the source string and the words in the candidates list is high.

The Levenshtein distance has been used to compile a list of correct form candidates for a misspelled word. The Levenshtein distance between two strings counts the number of changes needed to transform one string into the other, where a change is one of the basic edit operations: deletion, insertion, substitution of a character and the transposition of two characters. The Edit Distance algorithm, (ED) computes the similarity between two strings according to the Levenshtein distance. Most of the random misspellings which are produced by a native speaker are within one or maximum two basic edit operations (Damerau, 1964). For this reason the ED algorithm is the most common way to detect and correct the misspellings. However, there is a major inconvenience associated with the use of ED, namely, ED

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1634–1642,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

runs in quadratic time considering the length of the strings, O(n^2). The computation time for more than a few thousands pairs is up to several tens of seconds, which is impracticably large for most of large scale applications. By comparison, the number of proper names occurring in a medium sized English news corpus is around 200, 000, which means that there are some 200, 000, 000 pairs.

In order to cope with the need for a lower computation time, on the basis of ED, a series of algorithms have been developed that run in linear time (Navaro 2001). Unfortunately, this improvement is not enough for practical applications which involve a large amount of data coming from large corpora. The reason is two-fold: firstly, the linear time is still too slow (Mihov and Schulz, 2004) and secondly, the required memory depends both on the strings' length and on the number of different characters between the source string and the correct word, and may well exceed several GBs. Another solution is to index the corpus using structures like trie trees, or large finite state automata. However, this solution may require large amounts of memory and is inefficient when the number of characters that differ between the source string and the candidate words is more than two characters (Boytsov, 2011).

We focus specifically on misspellings for which there is no dictionary containing the correct form and/or for which the Levenshtein distance to the correct word may be higher than two characters. For this purpose, we developed a novel approach to misspelling correction based on a non indexing algorithm, which we call the prime mapping algorithm, PM. PM runs in constant time, O(1), with insignificant memory consumption. The running time of the PM algorithm does not depend either on the strings' length or on the number of different characters between the source string and the candidate word. It requires a static amount of memory, ranging from a few KBs to a maximum of a few MBs, irrespective of the size of the corpus or the number of pairs for which the misspelling relationship is tested. We run a series of experiments using PM on various corpora in English and Italian. The results confirm that PM is practical for large corpora. It successfully finds the candidate words for misspellings even for large Levenshtein distances, being more than 30 times faster than a linear algorithm, and several hundred times faster than ED. The running time difference is due to the fact that PM maps the strings into numbers and performs only one arithmetic operation in order to decide whether the two strings may be in a misspelling relationship. Instead of a quadratic number of characters comparisons, PM executes only one arithmetic operation with integers.

We also report here the results obtained when using PM inside a cross document coreference system for proper nouns. Correcting a proper name misspelling is actually a more complex task than correcting a misspelled common word. Some misspellings may not be random and in order to cope with repetitive misspellings, as the ones resulting from the transliteration of foreign names, the PM is combined with a statistical learning algorithm which estimates the probability of a certain type of misspelling considering the surrounding characters in the source string. Unlike with common words, where a misspelling is obvious, in the case of proper names, *John* vs. *Jon* for example, it is unclear whether we are looking at two different names or a misspelling. The string similarity evidence is combined with contextual evidence provided by a CDC system to disambiguate.

To evaluate the PM algorithm we use publicly available misspelling annotated corpora containing documents created by both native and non-native speakers. The PM within a CDC system for proper names is evaluated using CRIPCO (Bentivogli et al., 2008). The experiments confirm that PM is a competitive algorithm and that the CDC system gains in accuracy by using a module of misspelling correction.

The rest of the paper is organized as follows. In Section 2 we review the relevant literature. In Section 3 we introduce the PM algorithm and compare it against other algorithms. In Section 4 we present the CDC system with misspelling correction for proper names. In Section 5 we present the results obtained on English and Italian corpora.

2 Related Work

In a seminal paper (Damerau, 1964) introduced the ED algorithm. The rationale for this algorithm was the empirical observation that about 80% of the misspelled words produced by native speakers have distance 1 to the correct word. ED cannot be extended to increase the accuracy, because for k = 2, k being the maximal admissible distance to the correct word, the running time is too high. Most of the techniques developed further use ED together with indexing methods and/or parallel processing.

In (San Segundo et al., 2001) an M-best can-

didate HMM recognizer for 10,000 Spanish city names is built for speech documents. An N-gram language model is incorporated to minimize the search spaces. A 90% recognition rate is reported. The model is not easily generalizable to the situation in which the names are unknown - as it is the case with the personal proper names in a large corpus. The N-gram model is memory demanding and for 200,000 different names the dimension of the requested memory is impracticably big.

The problem related to personal proper names was discussed in (Allan and Raghavan, 2002). However, the paper addresses only the problem of clustering together the names which "sound alike" and no cross document coreference check was carried out. The technique to find similar names is based on a noisy channel model. The conditional probabilities for each two names to be similarly spelled are computed. The time complexity is quadratic, which renders this technique unfeasible for big data. In fact, the results are reported for a 100 word set. A different approach comes from considering search queries databases (Bassil and Alwani, 2012). These techniques are similar to the model based on the noisy channel, as they compute the conditional probabilities of misspellings based on their frequencies in similar queries. Unfortunately, large numbers of queries for proper names are not available. A similar technique, but using morphological features, was presented in (Veronis, 1988). The method can manage complex combinations of typographical and phonographic errors.

It has been noted in many works dedicated to error correction, see among others (Mihov and Schulz, 2004), that the ED algorithm is impracticably slow when the number of pairs is large. A solution is to build a large tries tree. While this solution improves the searching time drastically, the memory consumption may be large. Automata indexing was used in (Oflazer, 1996). While the memory consumption is much less than for the tries tree approaches, it is still high. For Turkish, the author reported 28,825 states and 118,352 transitions labeled with surface symbols. The recovery error rate is 80%. In (Boytsov, 2011) a review of indexing methods is given. Testing on 5,000 strings for k=1,2,3 is reported and the paper shows the problem the systems run into for bigger values of k. In (Huldén, 2009) a solution employing approximations via an A* strategy with finite automata is presented. The method is much faster for k bigger than the one presented in (Chodorow and Leacock, 2000). However, the usage of A* for proper names may be less accurate than the one reported in the paper, because unlike the common words in a given language, the names may have unpredictable forms, especially the foreign names. The results reported show how the time and memory vary for indexing methods according to the length of the words for k=1,2,3.

A method that uses mapping from strings to numbers is presented in (Reynaert, 2004). This method uses sum of exponentials. The value of the exponential was empirically found. However, the mapping is only approximative. Our mapping is precise and does not use exponential operations which are time consuming.

The study in (Navarro, 2001) is focused on non indexing approximate string search methods, in particular on the simple ED distance. The non-indexing methods may reach linear running time, but it is not always the case that they are scalable to big data. In (Nagata et al., 2006) a study on the type of errors produced by non-native speakers of English is carried out, but the long distance misspellings are not considered.

3 Prime Mapping Misspeling Algorithm

The algorithms based on the Levenshtein distance use the dynamic programming technique to build a table of character to character comparisons. We present here a novel approach to misspelling which does not build this table, skipping the need to compare characters. In a nutshell, the prime mapping algorithm, PM, replaces the characters compare operations to a unique arithmetic operation.This can be done by associating to any letter of the alphabet a unique prime number. For example we can associate 2 to a, 3 to b, 5 to c ... 97 to z. Any string will be mapped into a unique number which is the product of the prime numbers corresponding to its letters. For example the name $abba$ is mapped to $2 \cdot 3 \cdot 3 \cdot 2 = 36$. By computing the ratio between any two words we can detect the different letters with just one operation. For example, the difference between $abba$ and aba is 36/12 = 3, which corresponds uniquely to b because the product/ratio of prime numbers is unique.

Unlike the ED algorithm, the prime mapping does not find the number of edit operations needed to transform one string into another. In fact, two words that have just one letter in the mutual difference set may be quite distinct: all the strings

aba, aab, baa differ by one letter when compared with $abba$. In order to be in a misspelling relationship, the two strings should also have a common part, like prefix or middle, or suffix. The complete Prime Mapping (PM) algorithm consists of two successive steps: (1) find all the candidate words that differ from the target word by at most *k* characters and (2) check weather the target word and the candidate word have a common part, suffix, prefix or middle part. Both steps above are executed in constant time, therefore they do not depend either on the length of the strings or on k, the maximal number of different characters. Normally, $k = 3$, because the probability of a misspelled word having more than three distinct letters is insignificant, but unlike in the case of ED, the choice of k has no influence on the running time. The first step takes an integer ratio and a hash table key check, both being O(1). The second step checks if the first k letters at the beginning or at the end of the word are the same, and it requires $2k$ character comparisons, which is also an O(1) process, as *k* is fixed. The pseudo code and detailed description of the PM algorithm are given below.

Algorithm 1 Prime Mapping

Require: $charList$ $wordsList$, $primeList$, k
Ensure: $misspList$
1: $misspList \leftarrow \emptyset$
2: **foreach** α **in** $charList$: p(α) $\leftarrow$ p_i, p_i **in** $primeList$
3: **foreach** w **in** $wordsList$: p(w) $\leftarrow \prod p(\alpha)$, α **in** w
4: $primeKTable \leftarrow \binom{n}{k}$ of prime arithmetics
5: **for** w **in** $wordsList$ **do**
6: **for** w' **in** $wordsList$, w $\neq$ w' **do**
7: r $\leftarrow \frac{p(w)}{p(w')}$
8: **if** r **in** $primeKTable$ **then**
9: **if** commonPart (w, w') $\neq \emptyset$ **then**
10: $misspList \leftarrow misspList$ + (w, w')
11: **end if**
12: **end if**
13: **end for**
14: **end for**

map letters to prime numbers. A helpful way to assign primes to letters is according to their frequency; on average, the numbers corresponding to names are smaller and the operation gets less time.

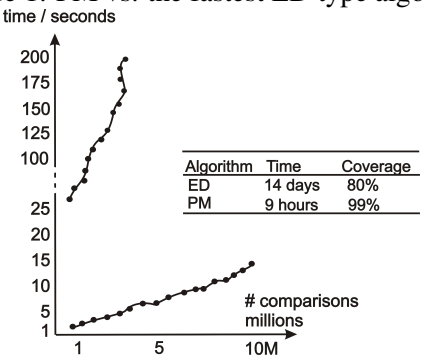
compute a hash table with prime arithmetics of K primes. In the hash table *primeKTable* we record all the combinations that can result from dividing two products which have less than *k* primes: $1/p_i$, p_i, p_i/p_j etc. If the ratio between two mappings is in the hash table, then the corresponding words have all the letters in common, except for at most *k*. The number of all the combination is $\binom{n}{k}$. The memory consumption for different values for *k* is given in Table 1. The figures compare extremely favorably with the ones of ED based approaches (gigs magnitude) . (line 7-8)

k letter difference	*#combination*	*Memory*
1	60	480B
2	435	8K
5	142,506	0.9MB
6	593, 775	3.8MB
10	30, 045, 015	180MB

Table 1: The PM algorithm memory needs

find misspelling candidates by ratio. By computing the ratio and by checking the hash table, we found the pairs which use the same letters, except for at most *k*. The procedure *commonpart* checks whether the two strings also have a common part by looking at the start and end *k*. If this is the case, the pair is in a misspelling relationship.

Figure 1: PM vs. the fastest ED type algorithm



The PM is much faster than ED. The fastest variant of ED, which does not compare strings having length difference bigger than 1, theoretically finds only 80% of the misspellings. In practice, only around 60% of the misspellings are found because of proper names and words misspelled by non-native speakers. The PM algorithm considers all possible pairs, finds more than 99% of misspellings and is 35 times faster. To obtain the same coverage, the ED algorithm must run for more than 100 days. The time comparison for millions of pairs is plotted in Figure 1. The experiments were performed on an i5, 2.8 GHz processor.

There is an immediate improvement we can bring to the basic variant of PM. The figures reported above are obtained by doing the whole set of possible pairs. By taking into account the fact that two words differing by $k + 1$ letters cannot be k similar, we can organize the number representing the names into an array which reduced drasti-

cally the number of comparisons. For example, all the words containing the letters *x, y, z* cannot be $k = 2$ similar with the words not containing any of these letters. By dividing the mapping of a word to the primes associated with the letters of an k-gram, we know if the words containing the k-gram can be misspelling candidates with at most k difference, and there is no more need to carry out all the ratios. We arrange the mappings of all words into an array such that on the first indexes we have the words containing the less frequent $k + 1$ gram, on the next indexes we have the words containing the second less frequent $k+1$ gram and do not contain the first $k + 1$ gram, on the next indexes the words containing the third less frequent $k + 1$ gram and do not contain the first two $k + 1$ gram, etc. In this way, even the most frequent $k + 1$ gram has only a few words assigned and consequently the number of direct comparisons is reduced to the minimum. The mapping corresponding to a $k+1$ gram are ordered in this array according to the length of the words. The number of trigrams is theoretically large, the $k + 1$ power of the size of the alphabet. However, the number of actually occurring k-trigrams is only a small fraction of it. For example, for $k = 2$, the number of trigrams is a few hundred, out of the 2, 700 possible ones. PM2gram runs in almost a quarter of the time needed by the basic PM. For the same set of names we obtained the results reported in Table 2. The last column indicates how many times the algorithm is slower than the PM in its basic form.

algorithm	*time*	*coverage*	*times slower*
basicED	132 days	99%	310
ED1	14 days	80%	35
PM	9 hours	99%	1
PM2gram	2 hours 42min	96%	0.26

Table 2: ED variants versus MP

4 Correcting Proper Names Misspellings

In this section we focus on a class of words which do not occur in a priorly given dictionary and for which the misspelled variants may not be random. Proper names are representative for this class. For example, the same Russian name occurs in corpus as *Berezovski*, *Berezovsky* or *Berezovschi* because of inaccurate transliteration. By convention, we consider the most frequent form as the canonical one, and all the other forms as misspelled variants.

Many times, the difference between a canonical form and a misspelled variant follows a pattern: a particular group of letters substitutes another one in the context created by the other characters in the name. A misspelling pattern specifies the context, as prefix or suffix of a string, where a particular group of characters is a misspelling of another. See Table 3 for examples of such patterns.

Pattern	*Context*	*Example*
dj→dji	ovic	djiukanovic djukanovic
k→kh	aler	kaler khaler, taler thaler
ki→ky	ovsk	berezovski berezovsky
n→ng	chan	chan-hee chang-hee
dl→del	abd	abdelkarim abdlkrim

Table 3: Name misspellings patterns

Finding and learning such patterns, along with their probability of indicating a true misspelling, bring an important gain to CDC systems both in running time and in alleviating the data-sparseness problem. The CDC system computes the probability of coreference for two mentions t and t' using a similarity metrics into a vectorial space, where vectors are made out of contextual features occurring with t and t' respectively (Grishman, 1994). However, the information extracted from documents is often too sparse to decide on coreference (Popescu, 2009). Coreference has a global effect, as the CDC systems generally improve the coverage creating new vectors by interpolating the information resulting from the documents which were coreferred (Hastie et al., 2005). This information is used to find further coreferences that no single pair of documents would allow. Thus, missing a coreference pair may result in losing the possibility of realizing further coreferences. However, for two mentions matching a misspelling pattern which is highly accurate, the threshold for contextual evidence is lowered. Thus, correcting a misspelling is not beneficial for a single mention only, but for the accuracy of the whole.

The strategy we adopt for finding patterns is to work in a bootstrapping manner, enlarging the valid patterns list while maintaining a high accuracy of the coreference, over 90%. Initially, we start with an empty base of patterns. Considering only the very high precision threshold for coreference, above 98% certainty, we obtain a set of misspelling pairs. This set is used to extract patterns of misspellings via a parameter estimation found using the EM-algorithm. The pattern is considered valid only if it also has more than a given number of occurrences. The recursion of the previous steps is carried out by lowering with an ε the threshold for accuracy of coreference for pat-

tern candidates. The details and the pseudo code are given below.

Algorithm 2 Misspelling Pattern Extraction

Require: $thCoref$, ε, $minO$, $thAcc$
Require: $thCDC$
Ensure: $pattList$
1: $pattList, candPattList \leftarrow \emptyset$
2: **while** there is a pair (t, t') to test for coreference **do**
3: **if** (t, t') *matches* p, p **in** $pattList$ **then**
4: prob ← corefProb(p)
5: **else**
6: use PM algorithm on pair (t, t')
7: prob ← $thCoref$
8: **end if**
9: **if** pair (t, t') coref with prob **then**
10: $candPattList \leftarrow candPattList$ + (t, t')
11: **end if**
12: extractPatterns from $candPattList$
13: **for** cp **in** $new\ extracted\ patterns$ **do**
14: **if** #cp>$minO$ **and** corefProb(cp)>$thAcc$ **then**
15: $pattList \leftarrow pattList$ + (t, t')
16: **end if**
17: **end for**
18: **if** prob>$thCDC$ **then**
19: corefer (t, t')
20: **end if**
21: **end while**
22: $thCoref \leftarrow thCoref$ - ε
23: **goto** line 2

1. Compile a list of misspelling candidates For each source string, t, try to match t against the list of patterns (initially empty). If there is a pattern matching (t, t') then their prior probability of coreference is the probability associated with that pattern (line 4).

2. CDC coreference evidence For each pair (t ,t') in the canonical candidates list use the CDC system to compute the probability of coreference between t and t'. If the probability of coreference of t and t' is higher than $thCoref$, the default value is 98%, then consider t as a misspelling of t' and put (t, t') in a candidate pattern list (line 10).

3. Extract misspelling patterns Find patterns in the candidate pattern list. Consider only patterns with more than $minO$ occurrences, whose default value is 10, and which have the probability of coreference higher than $thAcc$, whose default value is 90% (line 15).

4. CDC and pattern evidence For each (t,t') pair matching a pattern and the CDC probability of coreference more then $thCDC$, whose default value is 80%, then corefer t and t' (line 21). The fact that the pair (t,t') matches a pattern of misspelling is considered supporting evidence for coreference and in this way it plays a direct role in enhancing the system coverage. Decrease $thCoref$ by ε,whose default is value 0.5, and repeat the process of finding patterns (goto line 2).

To extract the pattern from a given list of pairs, procedure extractPatterns at line 12 above, we generate all the suffixes and prefixes of the strings. We compute the probability that a group of characters represents a spelling error, given a certain suffix and/or prefix. We use the EM algorithm to compute these probabilities. For a pair (P, S) of a prefix and a suffix, the tuples (p(P)=p, p(S)=s, π) are the quantities to be estimated via EM, with π being the coreference probability. A coreference event is directly observable, without knowing, however, which prefix or suffix contribute to the coreference. The EM equations are given below, where X is the observed data; Z are the hidden variable, p and s respectively; θ the parameters (p,s, π); Q(θ,$\theta^{(t)}$) the expected log likelihood at iteration t.

$\mathbf{E-step}$ $\mu_i^{(t)}$

$$\begin{aligned}\mu_i^{(t)} &= E[z_i|x_i,\theta^{(t)}] \\ &= \frac{p(x_i|z_i,\theta^{(t)})\ p(z_i=P|\theta^{(t)})}{p(x_i|\theta^{(t)})} \\ &= \frac{\pi^{(t)}[p^{(t)}]^{x_i}[(1-p^{(t)}]^{(1-x_i)}}{\pi^{(t)}[p^{(t)}]^{x_i}[(1-p^{(t)}]^{(1-x_i)}+(1-\pi^{(t)})[s^{(t)}]^{x_i}[(1-s^{(t)}]^{(1-x_i)}}\end{aligned} \quad (1)$$

$\mathbf{M-step}$ $\theta^{(t+1)}$

$$\begin{aligned}&\frac{\partial Q(\theta|\theta^t)}{\partial \pi}=0 \quad \pi^{(t+1)}=\frac{\sum_i \mu_i^{(t)}}{n} \\ &\frac{\partial Q(\theta|\theta^t)}{\partial p}=0 \quad p^{(t+1)}=\frac{\sum_i \mu_i^{(t)} x_i}{\sum_i \mu_i^{(t)}} \\ &\frac{\partial Q(\theta|\theta^t)}{\partial s}=0 \quad s^{(t+1)}=\frac{\sum_i (1-\mu_i^{(t)}) x_i}{\sum_i (1-\mu_i^{(t)})}\end{aligned} \quad (2)$$

5 Experiments

We performed a set of experiments on different corpora in order to evaluate: (1) the performances of the PM algorithm for misspelling detection, (2) the accuracy of proper name misspelling pattern acquisition from large corpora, and (3) the improvements of a CDC system, employing a correction module for proper name misspellings.

In Section 5.1 the accuracy of the PM algorithm is tested on various corpora containing annotated misspellings of English words. In particular, we were interested to see the results when the edit distance between the misspelled pair is bigger than 3, because handling bigger values for k is crucial for finding misspelling errors produced by non-native speakers. The evaluation is directly relevant for the correction of the spelling of foreign names.

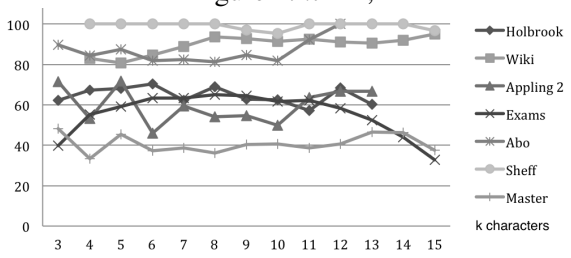
In Section 5.2 the proper name misspelling patterns were extracted from two large news corpora. One corpus is part of the English Gigawords, LDC2009T13 (Parker et al., 2009) and the second corpus is Adige500k in Italian (Magnini et al., 2006). We use a Named Entity Recognizer which has an accuracy above 90% for proper names. We evaluated the accuracy of the patterns by random sampling.

In Section 5.3 the accuracy of the CDC system with the correction module for proper name misspellings was tested against a gold standard.

5.1 PM Evaluation

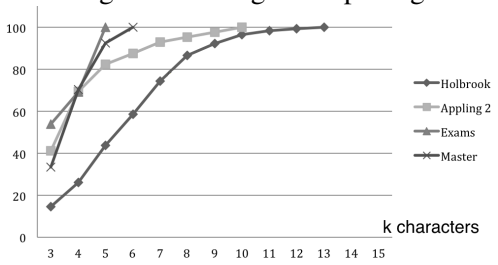
We consider the following publicly available English corpora containing the annotation of the misspelled words: Birkbeck, Aspell, Holbrook, Wikipidia. Birkbeck is a heterogeneous collection of documents, so in the experiments below we refer to each document separately. In particular we distinguish between misspellings of native speakers vs. misspelling of non-native speakers. Figure 2 shows that there are two types of corpora. For the first type, the misspellings found within two characters are between 80% and 100% of the whole number of misspellings. For the second type, less than 50% of the misspellings are within two characters.The second category is represented by the misspellings of non native speakers. The misspellings are far from the correct forms and they represent chunks of phonetically similar phonemes, like *boiz* vs. *boys*. The situation of the foreign name misspellings is likely to be similar to the misspellings found in the second type of corpora. For those cases, handling a k value bigger than 2 is crucial. Not only the

Figure 2: k = 1, 2



non-indexing methods, but also indexing ones are rather inefficient for k values bigger than 2 for large corpora. The PM algorithm does not have this drawback, and we tested the coverage of the errors we found for values of k ranging from 3 to 10. In Figure 3 we plot the distributions for the

Figure 3: Foreign Misspellings



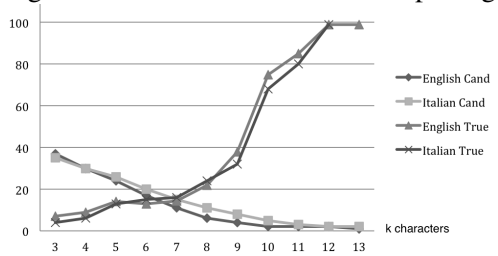
corpora which are problematic for k=2. Values of k are plotted on the OX axis, and the percentage of the misspellings within the respective k on the OY axis. The results showed PM is also able to find the phonemically similar misspellings. We can see that for k bigger than 9 the number of misspellings is not significant.

The PM algorithm performed very well, being able to find the misspellings even for large k values. There were 47, 837 words in Aspell, Holbrrok and Wikipedia, and 30, 671 in Birkbeck, and PM found all the misspelling pairs in a running time of 25 minutes. This is a very competitive time, even for indexing methods. For k above 8 the access to the hash table containing the prime combinations was slower, but not significantly so.

5.2 Pattern Extraction Evaluation

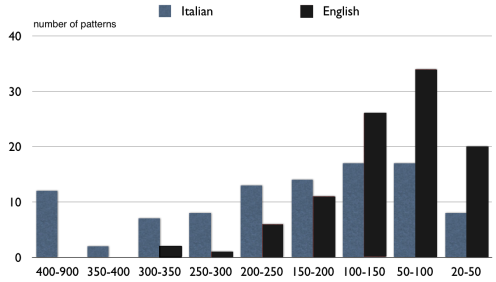
We extracted the set of names using a NER from the two corpora, LDC2009T13 and Adige500k. The set of proper names is rather large in both corpora - 160, 869 names from the English corpus and 185, 508 from the Italian corpus. Apparently, the quasi-similar names, which are considered as misspelled name candidates, is very high. In Figure 4 we plot this data. The *English Cand* and *Italian Cand* are absolute values, while the *English True* and *Italian True* represent percentages. For example, a name of length 5 is likely to have around 23 misspelling candidates, but only 17% of them are likely to be true misspellings, the rest being different names.

Figure 4: Candidates vs. True Misspellings



The numbers are estimated considering samples having the size between 30 and 50, for each name length. The percentages change rapidly with the length of the string. For names with the length bigger than 11, the probability that a misspelling candidate is a true misspelling is more than 98%. This fact suggests a strategy for pattern extraction: start from the higher name length towards the lower length names. The patterns found by the algorithm described in Section 4 have between 900 and 20 occurrences. There are 12 patterns having more than 400 occurrences, 20 having between 20 and 50 occurrences, see Fig. 5.

Figure 5: Distribution of the patterns:

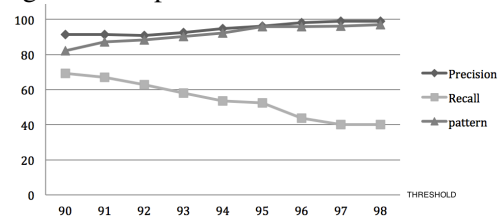


5.3 CDC and Misspelling correction

The CRIPCO corpus (Bentivogli et al., 2008) is a gold standard for CDC in Italian, containing pieces of news extracted from Adige500k. There are 107 names, the majority being Italian names. We scrambled the names to create misspelling candidates. For example the name $leonardo$ was scrambled like $teonardo$, $lionaldo$, $loenarod$ etc. We considered the top 15 frequency letters and maximum 4 letters for each scrambling. We randomly selected 70% of the original CRIPCO making no modifications, and called this corpus CRwCR. 30% of the original documents were assigned to the invented pseudo-names, and we called this corpus CRwSC (correct documents with scrambled names). From Adige500k we randomly chose 20, 000 documents and assigned them to the scrambled names as well, calling this corpus NCRwSC. From these pieces we created a new corpus: 70% of the initial CRIPCO documents with the original names, 30% of the CRIPCO documents with scrambled names and 20, 000 documents with the same scrambled names. For the names occurring in CRwCR, the scrambled names are valid name misspellings in the CRwSC corpus, and invalid in NCRwSC.

As expected, the PM algorithm found all the misspelling candidates and some others as well. We let the threshold confidence of coreference to vary from 90% to 98%. The number in Figure 6 refers to the precision and recall for the name misspellings in the CRIPCO corpus created via random scrambling. We were also interested to see how the pattern finding procedure works, but scrambling randomly produced too many contexts. Therefore, we chose to modify the names in a non random way, by replacing the final o to ino, ex. $paolo$ goes to $paolino$, and modifying one letter in the word for half of the occurrences, ex. $paorino$. The idea is that ino is a very common suffix for names in Italian. The system was able to learn the pseudo alternatives created in the context ino. The noise introduced was relatively low, see Fig. 6.

Figure 6: Proper Names CRIPCO Evaluation



6 Conclusion and Further Research

In this paper we described a system able to correct misspellings, including proper name misspellings, fast and accurately. The algorithm introduced, PM, overcomes the time/memory limitations of the approaches based on the edit distance.

The system is built on a novel string compare algorithm which runs in constant time independently of the length of the names or the number of different letters allowed, with no auxiliary memory request. As such, the algorithm is much faster than any other non-indexing algorithms. Because it is independent of k, it can be used even for large k, where even the indexing methods have limitations. We also used an EM based technique to find misspelling patterns. The results obtained are very accurate.

The system makes a first selection of the documents, drastically reducing the human work load. Another line of future research is to use the PM algorithm in other NLP tasks, where finding the pairs having some particular elements in common is necessary: for example, comparing parsing trees or dependency trees. We think that PM can be used in other NLP tasks as well and we hope the community can take advantage of it.

Abstract

Learning from errors is a crucial aspect of improving expertise. Based on this notion, we discuss a robust statistical framework for analysing the impact of different error types on machine translation (MT) output quality. Our approach is based on linear mixed-effects models, which allow the analysis of error-annotated MT output taking into account the variability inherent to the specific experimental setting from which the empirical observations are drawn. Our experiments are carried out on different language pairs involving Chinese, Arabic and Russian as target languages. Interesting findings are reported, concerning the impact of different error types both at the level of human perception of quality and with respect to performance results measured with automatic metrics.

1 Introduction

The dominant statistical approach to machine translation (MT) is based on learning from large amounts of parallel data and tuning the resulting models on reference-based metrics that can be computed automatically, such as BLEU (Papineni et al., 2001), METEOR (Banerjee and Lavie, 2005), TER (Snover et al., 2006), GTM (Turian et al., 2003). Despite the steady progress in the last two decades, especially for few well resourced translation directions having English as target language, this way to approach the problem is quickly reaching a performance plateau. One reason is that parallel data are a source of reliable information but, alone, limit systems knowledge to observed positive examples (*i.e.* how a sentence should be translated) without explicitly modelling any notion of error (*i.e.* how a sentence should *not* be translated). Another reason is that, as a development and evaluation criterion, automatic metrics provide a holistic view of systems' behaviour without identifying the specific issues of a translation. Indeed, the global scores returned by MT evaluation metrics depend on comparisons between translation hypotheses and reference translations, where the causes and the nature of the differences between them are not identified.

To cope with these issues and define system improvement priorities, the focus of MT evaluation research is gradually shifting towards profiling systems' behaviour with respect to various typologies of errors (Vilar et al., 2006; Popović and Ney, 2011; Farrús et al., 2012, *inter alia*). This shift has enriched the traditional MT evaluation framework with a new element, that is the actual errors done by a system. Until now, most of the research has focused on the relationship (*i.e.* the correlation) between two elements of the framework: humans and automatic evaluation metrics. As a new element of the framework, which becomes a sort of "evaluation triangle", the analysis of error annotations opens interesting research problems related to the relationships between: *i)* error types and human perception of MT quality and *ii)* error types and the sensitivity of automatic metrics.

Besides motivating further investigation on metrics featuring high correlation with human judgements (a well-established MT research sub-field, which is out of the scope of this paper), connecting the vertices of this triangle raises new challenging questions such as:

(1) Which types of MT errors have the highest impact on human perception of translation quality? Surprisingly, little prior work focused on this side of the triangle. Error annotations have been considered to highlight strengths and weaknesses of MT engines or to investigate the influence of different error types on post-editors' work. However, the direct connection between er-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1643–1653,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

rors and users' preferences has been only partially understood, mainly from a descriptive standpoint and through rudimentary techniques unsuitable to draw clear-cut conclusions or reliable inferences.
(2) To which types of errors are different MT evaluation metrics more sensitive? This side of the triangle has been even less explored. For instance, little has been done to understand which automatic metric is more suitable to assess system improvements with respect to a specific issue (*e.g.* word order or morphology) or to shed light on the joint impact of different error types on performance results calculated with different metrics.

To answer these questions, **we propose a robust statistical framework to analyse the impact of different error types**, alone and in combination, both on human perception of quality and on MT evaluation metrics' results. Our analysis is carried out **by employing linear mixed-effects models**, a generalization of linear regression models suited to model responses with fixed and random effects. Experiments are performed on data covering three translation directions (English to Chinese, Arabic and Russian). For each direction, two automatic translations were collected for around 400 sentences and were manually evaluated by expert translators through absolute quality judgements and error annotation.

Building on the advantages offered by linear mixed-effects models, our main contributions include:

- A rigorous method, novel to MT error analysis research, to relate MT issues to human preferences and MT metrics' results;
- The application of such method to three translation directions having English as source and different languages as target;
- A number of findings, specific to each language direction, which are out of the reach of the few simpler methods proposed so far.

Overall, our study has clear practical implications for MT systems' development and evaluation. Indeed, the proposed statistical analysis framework represents an ideal instrument to: *i)* identify translation issues having the highest impact on human perception of quality and *ii)* choose the most appropriate evaluation metric to measure progress towards their solution.

2 Related Work

Error analysis, as a way to identify systems' weaknesses and define priorities for their improvement, is gaining increasing interest in the MT community (Popović and Ney, 2011; Popovic et al., 2013). Along this direction, the initial efforts to develop error taxonomies covering different levels of granularity (Flanagan, 1994; Vilar et al., 2006; Farrús Cabeceran et al., 2010; Stymne and Ahrenberg, 2012; Lommel et al., 2014) have been recently complemented by investigations on how to exploit error annotations for diagnostic purposes. Error annotations of sentences produced by different MT systems, in different target languages and domains, have been used to determine the quality of translations according to the amount of errors encountered (Popovic et al., 2013), to design new automatic metrics that take into consideration human annotations (Popovic, 2012; Bojar et al., 2013), and to train classifiers that can automatic identify fine-grained errors in the MT output (Popović and Ney, 2011). The impact of edit operations on post-editors' productivity, which implicitly connects the severity of different errors to human activity, has also been studied (Temnikova, 2010; O'Brien, 2011; Blain et al., 2011), but few attempts have been made to explicitly model how fine-grained errors impact on human quality judgements and automatic metrics.

Recently, the relation between different error types, their frequency, and human quality judgements has been investigated from a descriptive standpoint in (Lommel et al., 2014; Popović et al., 2014). In both works, however, the underlying assumption that the most frequent error has also the largest impact on quality perception is not verified (in general and, least of all, across language pairs, domains, MT systems and post-editors). Another limitation of the proposed (univariate) analysis lies in the fact that it exclusively focuses on error types taken in isolation. This simplification excludes the possibility that humans, when assigning a global quality score to a translation, may be influenced not only by the error types but also by their interaction. The implications of such possibility call for a multivariate analysis capable to model also error interactions.

In (Kirchhoff et al., 2013), a statistically-grounded approach based on conjoint analysis has been used to investigate users' reactions to different types of translation errors. According to

their results, word order is the most dispreferred error type, and the count of the errors in a sentence is not a good predictor of users' preferences. Though more sophisticated than methods based on rough error counts, the conjoint model is bound to several constraints that limit its usability. In particular, the application of conjoint analysis in this context requires to: *i)* operate with semi-automatically created (hence artificial) data instead of real MT output, *ii)* manually define different levels of severity for each error type (*e.g.* high/medium/low), and *iii)* limit the number of error types considered to avoid the explosion of all possible combinations. Finally, the conjoint analysis framework is not able to explicitly model variance in the translated sentences, the human annotators, and the SMT systems used to translate the source sentences. Our claim is that avoiding any possible bias introduced by these factors should be a priority in the analysis of empirical observations in a given experimental setting.

So far, the relation between errors and automatic metrics has been analysed by measuring the correlation between single or total error frequencies and automatic scores (Popović and Ney, 2011; Farrús et al., 2012). Using two different error taxonomies, both works show that the sum of the errors has a high correlation with BLEU and TER scores. Similar to the aforementioned works addressing the impact of MT errors on human perception, these studies disregard error interactions, and their possible impact on automatic scores.

To overcome these issues, we propose a robust statistic analysis framework based on mixed-effects models, which have been successfully applied to several NLP problems such as sentiment analysis (Greene and Resnik, 2009), automatic speech recognition (Goldwater et al., 2010), and spoken language translation (Ruiz and Federico, 2014). Despite their effectiveness, the use of mixed-effects models in the MT field is rather recent and limited to the analysis of human post-editions (Green et al., 2013; Läubli et al., 2013). In both studies, the goal was to evaluate the impact of post-editing on the quality and productivity of human translation assuming an ANOVA mixed model for a between-subject design, in which human translators either post-edited or translated the same texts. Our scenario is rather different as we employ mixed models to measure the influence of different MT error types - expressed as continuous fixed effects - on quality judgements and automatic quality metrics. Mixed models, having the capability to absorb random variability due to the specific experimental set-up, provide a robust multivariate method to efficiently analyse the importance of error types.

Finally, differently from all previous works, our analysis is run on language pairs having English as source and languages distant from English (in term of morphology and word-order) as target.

3 Mixed-effects Models

Mixed-effects models - or simply mixed models - like any regression model, express the relationship between a *response variable* and some *covariates* and/or *contrast factors*. They enhance conventional models by complementing *fixed effects* with so-called *random effects*. Random effects are introduced to absorb random variability inherent to the specific experimental setting from which the observations are drawn. In general, random effects correspond to covariates that are not - or cannot be - exhaustively observed in an experiment, *e.g.* the human annotators and the evaluated systems. Hence, mixed models permit to elegantly cope with experimental design aspects that hinder the applicability of conventional regression models. These are, in particular, the use of repeated and/or clustered observations that introduce correlations in the response variable that clearly violate the independence and homoscedasticity assumptions of conventional linear, ANOVA, and logistic regression models. Significance testing with mixed models is in general more powerful, *i.e.* less prone to Type II Errors, and also permits to reduce the chance of Type I Errors in within-subject designs, which are prone to the "fallacy of language-as-a-fixed-effect" (Clark, 1973).

Random effects can be directly associated to the regression model parameters, as *random intercepts* and *random slopes*, and have the same form of the generic error component of the model, *i.e.* normally distributed with zero mean and unknown variance. As random effects introduce hidden variables, mixed models are trained with Expectation Maximization, while significance testing is performed via likelihood-ratio (LR) tests.

In this work we employ mixed *linear* models to measure the influence of different MT error types, expressed as continuous fixed effects, on quality

judgements or on automatic quality metrics.[1]

We illustrate mixed linear models (Baayen et al., 2008) by referring to our analysis, which addresses the relationships between a quality metric (y) and different types of errors (*e.g.* A, B, and C)[2] observed at the sentence level. For the sake of simplicity, we assume to have balanced repeated observations for one single crossed effect. That is, we have $i \in \{1, \ldots, I\}$ MT systems (our groups) each of which translated the same $j \in \{1, \ldots, J\}$ test sentences. Our response variable y_{ij} - a numeric quality score - is computed on each (sentence, system) pair, and we aim to investigate its relationship with error statistics available for each MT output, namely A_{ij}, B_{ij} and C_{ij}. A (possible) linear mixed model for our study would be:

$$\begin{aligned} y_{ij} &= \beta_0 + \beta_1\, A_{ij} + \beta_2\, B_{ij} + \beta_3\, C_{ij} + \\ &\quad b_{0,i} + b_{1,i} A_{ij} + b_{2,i} B_{ij} + b_{3,i} C_i + \epsilon_{ij} \end{aligned} \quad (1)$$

The model is split into two lines on purpose. The first line shows the fixed effect component, that is intercept (β_0) and slopes ($\beta_1, \beta_2, \beta_3$) for each error type. The second line specifies the random structure of the model, which includes random intercept and slopes for each MT system and the residual error. Borrowing the notation from (Green et al., 2013), we conveniently rewrite (1) in the group-wise arranged matrix notation:

$$y_i = x_i^T \beta + z_i^T b_i + \epsilon_i \quad (2)$$

where y_i is the $J \times 1$ vector of responses, x_i is the $J \times p$ design matrix of covariates (including the intercept) with fixed coefficients $\beta \in \mathcal{R}^{p \times 1}$, z is the random structure matrix defined by $J \times q$ covariates with random coefficients $b_i \in \mathcal{R}^{q \times 1}$, and ϵ_i is the vector of residuals (in our example, $p = 4$ and $q = 4$). By packing together vectors and matrices indexed over groups i, we can rewrite the model in a general form (Baayen et al., 2008), which can represent any possible crossed-effects and random structures defined over them allowing, at the same time, for a compact model specification:

$$\begin{aligned} y &= X^T \beta + Z^T b + \epsilon \\ &\quad \epsilon \sim \mathcal{N}(0, \sigma^2 I),\ b \sim \mathcal{N}(0, \sigma^2 \Sigma), b \perp \epsilon \end{aligned} \quad (3)$$

where Σ is the relative variance-covariance $q \times q$ matrix of the random effects (now $q = 4I$), σ^2 is the variance of the per-observation term ϵ, the symbol $\perp$ denotes independence of random variables, and $\mathcal{N}$ indicates the multivariate normal distribution. While b, σ, and Σ are estimated via maximum likelihood, the single random intercept and slope values for each group are calculated subsequently. They are referred to as Best Linear Unbiased Predictors (BLUPS) and, formally, are *not* parameters of the model.

The significance of the contribution of each single parameter (*e.g.* single entries of Σ) to the goodness of fit can be tested via likelihood ratio. In this way, both the fixed and random effect structure of the model can be investigated with respect to its actual necessity to the model.

4 Dataset

For our analysis we used a dataset that covers three translation directions, corresponding to English to Chinese, Arabic, and Russian. An international organization provided us a set of English sentences together with their translation produced by two anonymous MT systems. For each evaluation item (source sentence and two MT outputs) three experts were asked to assign quality scores to the MT outputs, and a fourth expert was asked to annotate translation errors. The four experts, who were all professional translators native in the examined target languages, were carefully trained to get acquainted with the evaluation guidelines and the annotation tool specifically developed for these evaluation tasks (Girardi et al., 2014). The annotation process was carried out in parallel by all annotators over one week, resulting in a final dataset composed of 312 evaluation items for the ENZH direction, 393 for ENAR, and 437 for ENRU.

4.1 Quality Judgements

Quality judgements were collected by asking the three experts to rate each automatic translation according to a 1-5 Likert scale, where 1 means "incomprehensible translation" and 5 means "perfect translation". The distribution of the collected annotations with respect to each quality score is shown in Figure 1. As we can see, this distribution reflects different levels of perceived quality across languages. ENZH, for instance, has the highest number of low quality scores (1 and 2), while ENRU has the highest number of high qual-

[1] Although mixed *ordinal* models (Tutz and Hennevogl, 1996) are in principle more appropriate to target quality judgements, in our preliminary investigations mixed linear models showed a significantly higher predictive power.

[2] Here, A, B and C represent three generic error classes. Their actual number in a given experimental setting will depend on the granularity of the reference error taxonomy.

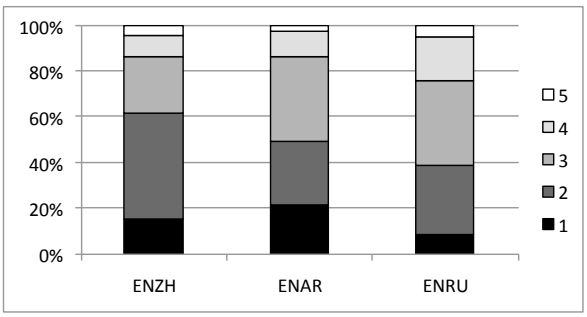

Figure 1: Distribution of quality scores.

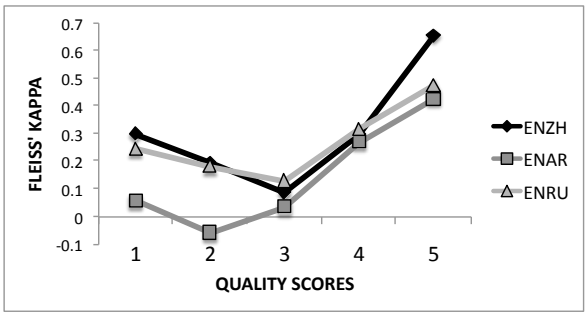

Figure 2: Class specific inter-annotator agreement.

ity scores (4 and 5).

Table 1 shows the average of all the quality scores assigned by each annototator as well as the average score obtained for each MT system. These values demonstrate the variability of annotators and systems. A particularly high variability among human judges is observed for the ENAR language direction (also reflected by the inter-annotator agreement scores discussed below), while ENZH shows the highest variability between systems. As we will see in §5.1, we successfully cope with this variability by considering systems and annotators as random effects, which allow the regression models to abstract from these differences.

	Ann1	Ann2	Ann3	Sys1	Sys2
ENZH	2.38	2.69	2.21	2.29	2.56
ENAR	2.76	2.77	1.84	2.39	2.53
ENRU	2.82	2.72	2.96	2.87	2.79

Table 1: Average quality scores per annotator and per system.

Inter-annotator agreement was computed using the *Fleiss' kappa coefficient* (Fleiss, 1971), and resulted in 22.70% for ENZH, 5.24% for ENAR, and 21.80% for ENRU. While for ENZH and ENRU the results fall in the range of "fair" agreement (Landis and Koch, 1977), for ENAR only "slight" agreement is reached, reflecting the higher annotators' variability evidenced in Table 1.

A more fine-grained agreement analysis is presented in Figure 2, where the *kappa* values are given for each score class. In general we notice a lower agreement on the intermediate quality scores, while annotators tend to agree on very bad and, even more, on good translations. In particular, we see that the agreement for ENAR is systematically lower than the values measured for the other languages on all the score classes.

4.2 Error Annotation

This evaluation task was carried out by one expert for each language direction, who was asked to identify the type of errors present in the MT output and to mark their position in the text. Since the focus of our work is the analysis method rather than the definition of an ideal error taxonomy, for the difficult language directions addressed we opted for the following general error classes, partially overlapping with (Vilar et al., 2006): *i)* reordering errors, *ii)* lexicon errors (including wrong lexical choices and extra words), *iii)* missing words, *iv)* morphology errors.

Figure 3 shows the distribution of the errors in terms of affected tokens (words) for each error type. Since token counts for Chinese are not word-based but character-based, for readability purposes the number of errors counted for Chinese translations have been divided by 2.5. Note also that morphological errors annotated for ENZH involve only 13 characters and thus are not visible in the plot. The total number of errors amounts to 16,320 characters for ENZH, 4,926 words for ENAR, and 5,965 words for ENRU.

This distribution highlights some differences between languages directions. For example, translations into Arabic and Russian present several morphology errors, while word reordering is the most frequent issue for translations into Chinese. As we will see in §5.1, error frequency does not give a direct indication of their impact on traslation quality judgements.

4.3 Automatic Metrics

In our investigation we consider three popular automatic metrics: sentence-level BLEU (Lin and Och, 2004), TER (Snover et al., 2006), and GTM (Turian et al., 2003). We compute all automatic scores by relying on a single reference and by

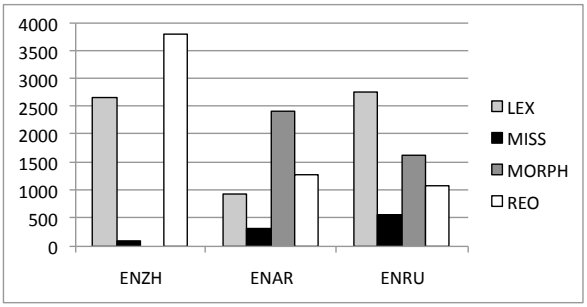

Figure 3: Distribution of error types.

means of standard packages. In particular, automatic scores on Chinese are computed at the character level. Moreover, as we use metrics as response variables for our regression models, we compute all metrics at the sentence level. The overall mean scores for all systems and languages are reported in Table 2. Differences in systems' performance can be observed for all language pairs; as we will observe in §5.2 such variability explains the effectiveness of considering the MT systems as a random effect.

	BLEU		TER		GTM	
	Sys1	Sys2	Sys1	Sys2	Sy1	Sys2
ENZH	27.95	44.11	64.52	48.13	62.15	72.30
ENAR	19.63	25.25	68.83	63.99	47.20	52.33
ENRU	27.10	31.07	60.89	54.41	53.74	56.41

Table 2: Overall automatic scores per system.

5 Experiments

To assess the impact of translation errors on MT quality we perform two sets of experiments. The first set (§5.1) addresses the relation between errors and human quality judgements. The second set (§5.2) focuses on the relation between errors and automatic metrics. In both cases, before measuring the impact of different errors on the response variable (respectively quality judgements and metrics), we validate the effectiveness of mixed linear models by comparing their prediction capability with other methods.

In all experiments, error counts of each category were normalized into percentages with respect to the sentence length and mapped in a logarithmic scale. In this way, we basically assume that the impact of errors tends to saturate above a given threshold, hypothesis that also results in better fits by our models.[3] Notice that while the chosen log-10 base is easy to interpret, linear models can implicitly adjust it. Our analysis makes use of mixed linear models incorporating, as fixed effects, the four types of errors (*lex*, *miss*, *morph* and *reo*) and their pairwise interactions (the product of the single error log counts), while their random structure depends on each specific experiment. For the experiments we rely on the R language (R Core Team, 2013) implementation of linear mixed model in the *lme4* library (Bates et al., 2014).

We assess the quality of our mixed linear models (*MLM*) by comparing their prediction capability with a sequence of simpler linear models including only fixed effects. In particular, we built five univariate models and two multivariate models. The univariate models use as covariates, respectively, the sum of all error types (*baseline*), and each of the four types of errors (*lex*, *miss*, *morph* and *reo*). The two multivariate models include all the four error types, considering them without interactions (*FLM w/o Interact.*) and with interactions (*FLM)*.

Prediction performance is computed in terms of Mean Absolute Error (MAE),[4] which we estimate by averaging over 1,000 random splits of the data in 90% training and 10% test. In particular, for the human quality classes we pick the integer between 1-5 that is closest to the predicted value.

5.1 Errors vs. Quality Judgements

The response variable we target in this experiment is the quality score produced by human annotators. Our measurements follow a typical within-subject design in which all the 3 annotators are exposed to the same conditions (levels of the independent variables), corresponding in our case to perfectly balanced observations from 2 MT systems and N sentences. This setting results in repeated or clustered observations (thus violating independence) corresponding to groups which naturally identify possible random effects,[5] namely the annotators (3 levels with 2xN observations each), the systems (2 levels and 3xN observations each), and the sen-

[3] In other words, we assume that human sensitivity to errors follows a log-scale law: *e.g.* more sensitive to variations in the interval [1-10] that in the interval [30-40].

[4] MAE is calculated as the average of the absolute errors $|f_i - y_i|$, where f_i is the prediction of the model and y_i the true value for the i^{th} instance. As it is a measure of error, lower MAE scores indicate that our predictions are closer to the true values of each test instance.

[5] In all our experiments, random effects are limited to random shifts since preliminary experiments also including random slopes did not provide consistent results.

Model	ENZH	ENAR	ENRU
baseline	0.58	0.73	0.67
lex	0.67	0.78	0.72
miss	0.72	0.89	0.74
morph	0.72	0.89	0.74
reo	0.70	0.82	0.76
FLM w/o Interact.	0.59	0.77	0.65
FLM	0.57	0.72	0.63
MLM	0.53	0.61	0.61

lex:reo	0.50	0.21	-
miss:morph	-	0.35	-
miss:reo	0.54	0.33	-
morph:reo	-	0.37	-

Table 4: Effect of translation errors on MT quality perception on all judged sentences. Reported coefficients (β) are all statistically significant with $p \leq 10^{-4}$, except those marked with $_\bullet$ ($p \leq 10^{-3}$), and $_\circ$ ($p \leq 10^{-2}$).

tences (N levels with 6 observations each). In principle, such random effects permit to remove systematic biases of individual annotators, single systems and even single sentences, which are modelled as random variables sampled from distinct populations.

Table 3 shows a comparison of the **prediction capability** of the mixed model[6] with simpler approaches. While the good performance achieved by our strong baseline cannot be outperformed by separately counting the number of errors of a single type, lower MAE results are obtained by methods based on multivariate analysis. Among them, FLM brings the first consistent improvements over the baseline by considering error interactions, while MLM leads to the lowest MAE due to the addition of random effects. The importance of random effects is particularly evidenced by ENAR (12 points below the baseline). Indeed, as discussed in §4.1, for this language combination human annotators show the lowest agreement score. This variability, which hides the smaller differences in systems' behaviour, demonstrates the importance of accounting for the erratic factors that might influence empirical observations in a given setting. The good performance achieved by MLM, combined with their high descriptive power,[7] motivates their adoption in our study.

Concerning the analysis of **error impact**, Table 4 shows the statistically significant coefficients for the full-fledged MLM models for each translation direction. By default, all reported coefficients have p-values $\leq 10^{-4}$, while those marked with $\bullet$ and $\circ$ have respectively p-values $\leq 10^{-3}$ and $\leq 10^{-2}$. Slope coefficients basically show the impact of different error types (alone and in combination) on human quality scores. Those that are not statistically significant are omitted as they do not increase the fitting capability of our model. As can be seen from the table, such impact varies across the different language combinations. While for ENZH and ENRU *miss* is the error having the highest impact (highest decrement with respect to the intercept), the most problematic error for ENAR is *lex*. It is interesting to observe that positive values for error combinations indicate that their combined impact is lower that the sum of the impact of the single errors. For instance, while for ENZH a one-step increment in *lex* and *miss* errors would respectively cause a reduction in the human judgement of 1.27 and 1.76, their occurrence in the same sentence would be discounted by 1.00. This would result in a global judgement of 2.26 (4.29 -1.27 -1.76 +1.00) instead of 1.26. While for ENAR this phenomenon can be observed for all error combinations, such discount effects are not always significant for the other two language pairs. The existence of discount effects of various magnitude associated to the different error combinations is a novel finding made possible by the adoption of mixed-effect models.

Another interesting observation is that, in contrast with the common belief that the most frequent errors have the highest impact on human quality judgements, our experiments do not reveal such strict correlation (at least for the examined language pairs). For instance, for ENZH and ENRU the impact of *miss* errors is higher than the impact of other more frequent issues.

[6]Note that the mixed model used in prediction does not include the random effect on sentences since the training samples do not guarantee sufficient observations for each test sentence.

[7]Note that the strong baseline used for comparison is not capable to describe the contribution of the different error types.

Model	BLEU score			TER			GTM		
	ENZH	ENAR	ENRU	ENZH	ENAR	ENRU	ENZH	ENAR	ENRU

Table 5: Prediction capability of BLEU score, TER and GTM (MAE).

5.2 Errors vs. Automatic Metrics

In this experiment, the response variable is an automatic metric which is computed on a sample of MT outputs (which are again perfectly balanced over systems and sentences) and a set of reference translations. As no subjects are involved in the experiment, random variability is assumed to come from the involved systems, the tested sentences, and the unknown missing link between the covariates (error types) and the response variable which is modelled by the residual noise. Notice that, in this case, the random effect on the sentences also incorporates in some sense the randomness of the corresponding reference translations, which are themselves representatives of larger samples.

The **prediction capability** of the mixed model, in comparison with the simpler ones, is reported in Table 5. Also in this case, the low MAE achieved by the baseline is out of the reach of univariate methods. Again, small improvements are brought by FLM when considering error interactions, whereas the most visible gains are achieved by MLM due to their control of random effects. This is more evident for some language combinations and can be explained by the differences in systems' performance, a variability factor easily absorbed by random effects. Indeed, the largest MAE decrements over the baseline are always observed for ENZH (for which the overall mean results reported in Table 2 show the largest differences) and the smallest decrements relate to language/metric combinations where systems' behaviour is more similar (*e.g.* ENRU/GTM).

Concerning the analysis of **error impact**, Table 6 shows how different error types (alone and in combination) influence performance results measured with automatic metrics. To ease interpretation of the reported figures we also show Pearson and Spearman correlations of each set of coefficients (excluding intercept estimates) with their corresponding coefficients reported in Table 4. In fact, our primary interest in this experiment is to see which metrics show a sensitivity to specific error types similar to human perception. As we can see, the coefficients for each metric significantly vary depending on the language, for the simple reason that also the distribution and co-occurrence of errors vary significantly across the different languages and MT systems. Remarkably, for some translation directions, some of the metrics show a sensitivity to errors that is very similar to that of human judges. In particular, BLEU for ENZH and ENAR, and GTM for ENZH show a very high correlation with the human sensitivity to translation errors, with Pearson correlation coefficient $\geq$ 0.97. For ENRU, the best Pearson correlation is instead achieved by TER (-0.78).

Besides these general observations, a closer look at the reported scores brings additional findings. In three cases (BLEU for ENZH, GTM for ENZH and ENAR) the analysed metrics are most sensitive to the same error type that has the highest influence on human judgements (according to Table 4, these are *miss* for ENZH and ENRU, *lex* for ENAR). On the contrary, in one case (TER for ENZH) the analysed metric is insensitive to the error type (*miss*) which has the highest impact on human quality scores. From a practical point of view, these remarks provide useful indications about the appropriateness of each metric to highlight the deficiencies of a specific system and to measure improvements targeting specific issues. As a rule of thumb, for instance, to measure improvements of an ENZH system with respect to *miss*ing words, it would be more advisable to use BLEU or GTM instead of TER.[8]

[8]Note that this conclusion holds for our data sample, in which different types of errors co-occur and only one reference translation is available. In such conditions, our regression model shows that TER is not influenced by *miss* errors in a statistically significant way. This does not mean that TER is insensitive to missing words when occurring in isolation,

Table 6: Effect of translation errors on BLEU score, TER and GTM on all judged sentences and correlation with their corresponding effects on human quality scores (from Table 4). Reported coefficients (β) are statistically significant with $p \leq 10^{-4}$, except those marked with $_{\bullet}$ ($p \leq 10^{-3}$), $_{\circ}$ ($p \leq 10^{-2}$) and $_{\square}$($p \leq 10^{-1}$).

Similar considerations also apply to the analysis of the impact of error combinations. The same discount effects that we noticed when analysing the impact of errors' co-occurrence on human perception (§5.1) are evidenced, with different degrees of sensitivity, by the automatic metrics. While some of them substantially reflect human response (*e.g.* BLEU and GTM for ENZH), in some cases we observe either the insensitivity to specific combinations (mostly for ENAR), or a higher sensitivity compared to the values measured for human assessors (mostly for ENRU, where the impact of *miss:reo* combinations is discounted - hence underestimated - by all the metrics).

Despite such small differences, the coherence of our results with previous findings (§5.1) suggests the reliability of the applied method. Completing the picture along the side of the MT evaluation triangle which connects error annotations and automatic metrics, our findings contribute to shed light on the existing relationships between translation errors, their interaction, and the sensitivity of widely used automatic metrics.

6 Conclusion

We investigated the MT evaluation triangle (having as corners *automatic metrics*, *human quality judgements* and *error annotations*) along the two less explored sides, namely: *i)* the relation between MT errors and human quality judgements and *ii)* the relation between MT errors and automatic metrics. To this aim we employed a robust statistical analysis framework based on linear mixed-effects models (the first contribution of the paper), which have a higher descriptive power than simpler methods based on the raw count of translation errors and are less artificial compared to previous statistically-grounded approaches.

Working on three translation directions having Chinese, Arabic and Russian as target (our second contribution), we analysed error-annotated translations considering the impact of specific errors (alone and in combination) and accounting for the variability of the experimental set-up that originated our empirical observations. This led us to interesting findings specific to each language pair (third contribution). Concerning the relation between MT errors and quality judgements, we have shown that: *i)* the frequency of errors of a given type does not correlate with human preferences, *ii)* errors having the highest impact can be precisely isolated and *iii)* the impact of error interactions is often subject to measurable and previously unknown "discount" effects. Concerning the relation between MT errors and automatic metrics (BLEU, TER and GTM), our analysis evidenced significant differences in the sensitivity of each metric to different error types. Such differences provide useful indications about the most appropriate metric to assess system improvements with respect to specific weaknesses. If learning from errors is a crucial aspect of improving expertise, our method and the resulting empirical findings represent a significant contribution towards a

but that TER becomes less sensitive to such errors when they co-occur with other types of errors. Overall, our experiments show that when MT outputs contain more than one error type, automatic metrics show different levels of sensitivity to each specific error type.

more informed approach to system development, improvement and evaluation.

Refining Word Segmentation Using a Manually Aligned Corpus for Statistical Machine Translation

Abstract

Languages that have no explicit word delimiters often have to be segmented for statistical machine translation (SMT). This is commonly performed by automated segmenters trained on manually annotated corpora. However, the word segmentation (WS) schemes of these annotated corpora are handcrafted for general usage, and may not be suitable for SMT. An analysis was performed to test this hypothesis using a manually annotated word alignment (WA) corpus for Chinese-English SMT. An analysis revealed that 74.60% of the sentences in the WA corpus if segmented using an automated segmenter trained on the Penn Chinese Treebank (CTB) will contain conflicts with the gold WA annotations. We formulated an approach based on word splitting with reference to the annotated WA to alleviate these conflicts. Experimental results show that the refined WS reduced word alignment error rate by 6.82% and achieved the highest BLEU improvement (0.63 on average) on the Chinese-English open machine translation (OpenMT) corpora compared to related work.

1 Introduction

Word segmentation is a prerequisite for many natural language processing (NLP) applications on those languages that have no explicit space between words, such as Arabic, Chinese and Japanese. As the first processing step, WS affects all successive steps, thus it has a large potential impact on the final performance. For SMT, the unsupervised WA, building translation models and reordering models, and decoding are all based on segmented words.

Automated word segmenters built through supervised-learning methods, after decades of intensive research, have emerged as effective solutions to WS tasks and become widely used in many NLP applications. For example, the Stanford word segmenter (Xue et al., 2002)[1] which is based on conditional random field (CRF) is employed to prepare the official corpus for NTCIR-9 Chinese-English patent translation task (Goto et al., 2011).

However, one problem with applying these supervised-learning word segmenters to SMT is that the WS scheme of annotating the training corpus may not be optimal for SMT. (Chang et al., 2008) noticed that the words in CTB are often too long for SMT. For example, a full Chinese personal name which consists of a family name and a given name is always taken as a single word, but its counterpart in English is usually two words.

Manually WA corpora are precious resources for SMT research, but they used to be only available in small volumes due to the production cost. For example, (Och and Ney, 2000) initially annotated 447 English-French sentence pairs, which later became the test data set in ACL 2003 shared task on word alignment (Mihalcea and Pedersen, 2003), and was used frequently thereafter (Liang et al., 2006; DeNero and Klein, 2007; Haghighi et al., 2009)

For Chinese and English, the shortage of manually WA corpora has recently been relieved by the linguistic data consortium (LDC) [2] GALE Chinese-English word alignment and tagging training corpus (the GALE WA corpus)[3]. The corpus is considerably large, containing 4,735 documents, 18,507 sentence pairs, 620,189 Chinese tokens, 518,137 English words, and 421,763

alignment annotations. The corpus carries no Chinese WS annotation, and the WA annotation was performed between Chinese characters and English words. The alignment identifies minimum translation units and relations [4], referred as atomic blocks and atomic edges, respectively, in this paper. Figure 1 shows an example that contains six atomic edges.

Visual inspection of the segmentation of an automatic segmenter with reference to a WA corpus revealed a number of inconsistencies. For example, consider the word "bao fa" in Figure 1. Empirically we observed that this word is segmented as a single token by an automatic segmenter trained on the CTB, however, this segmentation differs with the alignment in the WA corpus, since its two components are aligned to two different English words. Our hypothesis was that the removal of these inconsistencies would benefit machine translation performance (this is explained further in Section 2.3), and we explored this idea in this work.

This paper focuses on optimizing Chinese WS for Chinese-English SMT, but both the research method and the proposed solution are language-independent. They can be applied to other language pairs.

The major contributions of this paper include,

- analyze the CTB WS scheme for Chinese-English SMT;
- propose a lexical word splitter to refine the WS;
- achieve a BLEU improvement over a baseline Stanford word segmenter, and a state-of-the-art extension, on Chinese-English OpenMT corpora.

The rest of this paper is organized as follows: first, Section 2 analyzes WS using a WA corpus; next, Section 3 proposes a lexical word splitter to refine WS; then, Section 4 evaluates the proposed method on end-to-end SMT as well as word segmentation and alignment; after that, Section 5 compares this work to related work; finally, Section 6 concludes this paper.

[4]Guidelines for Chinese-English Word Alignment(Version 4.0)

2 Analysis of a General-purpose Automatic Word Segmenter

This section first briefly describes the GALE WA corpus, then presents an analysis of the WS arising from a CTB-standard word segmenter with reference to the segmentation of the atomic blocks in the GALE WA corpus, finally the impact of the findings on SMT is discussed.

2.1 GALE WA corpus

The GALE WA corpus was developed by the LDC, and was used as training data in the DARPA GALE global autonomous language exploitation program [5]. The corpus incorporates linguistic knowledge into word aligned text to help improve automatic WA and translation quality. It employs two annotation schemes: alignment and tagging (Li et al., 2010). Alignment identifies minimum translation units and translation relations; tagging adds contextual, syntactic and language-specific features to the alignment annotation. For example, the sample shown in Figure 1 carries tags on both alignment edges and tokens.

The GALE WA corpus contains 18,057 manually word aligned Chinese and English parallel sentences which are extracted from newswire and web blogs. Table 1 presents the statistics on the corpus. One third of the sentences are approximately newswire text, and the remainder consists of web blogs.

2.2 Analysis of WS

In order to produce a Chinese word segmentation consistent with the CTB standard we used the Stanford Chinese word segmenter with a model trained on the CTB corpus. We will refer to this as the 'CTB segmenter' in the rest of this paper.

The Chinese sentences in the GALE WA corpus were first segmented by the CTB segmenter, and the predicted words were compared against the atomic blocks with respect to the granularity of segmentation. The analysis falls into the following three categories, two of which may be potentially harmful to SMT:

- Fully consistent: the word locates within the block of one atomic alignment edge. For example, in Figure 2(a), the Chinese text has

[5]https://catalog.ldc.upenn.edu/LDC2012T16

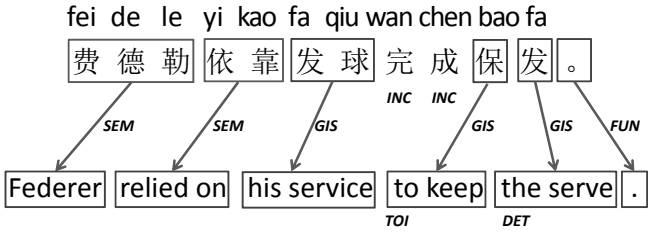

Figure 1: Example from the GALE WA corpus. Each line arrow represents an atomic edge, and each box represents an atomic block. SEM (semantic), GIS (grammatically inferred semantic) and FUN (function) are tags of edges. INC (not translated), TOI (to-infinitive) and DET (determiner) are tags of tokens.

Genre	# Files	# Sentences†	# CN tokens	# EN tokens	# Alignment edges
Newswire	2,175	6,218	246,371	205,281	164,033
Web blog	2,560	11,839	373,818	312,856	257,730
Total	4,735	18,057	620,189	518,137	421,763

Table 1: GALE WA corpus. † Sentences rejected by the annotators are excluded.

four atomic blocks; the CTB segmenter produces five words which all locate within the blocks, so they are all small enough.

- Alignment inconsistent: the word aligns to more than one atomic block, but the target expression is contiguous, allowing for correct phrase pair extraction (Zens et al., 2002). For example, in Figure 2(b), the characters in the word "shuang fang", which is produced by the CTB segmenter, contains two atomic blocks, but the span of the target "to both side" is continuous, therefore the phrase pair "shuang fang ||| to both sides" can be extracted.

- Alignment inconsistent and extraction hindered: the word aligned to more than one atomic block, and the target expression is not contiguous, which hinders correct phrase pair extractions. For example, in Figure 2(c), the word "zeng chan" has to be split in order to match the target language.

Table 2 shows the statistics of the three categories of CTB WS on the GALE WA corpus. 90.74% of the words are fully consistent, while the remaining 9.26% of the words have inconsistent alignments. 74.60% of the sentences contain this problem. The category with inconsistent alignment and extraction hindered only accounts for 0.46% of the words, affecting 9.06% of the sentences.

2.3 Impact of WS on SMT

The word alignment has a direct impact on the nature of both the translation model, and lexical reordering model in a phrase-base SMT system. The words in last two categories are all longer than an atomic block, which might lead to problems in the word alignment in two ways:

- First, longer words tend to be more sparse in the training corpus, thus the estimated distribution of their target phrases are less accurate.

- Second, the alignment from them to target sides are one-to-many, which is much more complicated and requires fertilized alignment models such as IBM model 4 – 6 (Och and Ney, 2000).

The words in the category of "fully consistent" can be aligned using simple models, because the alignment from them to the target side are one-to-one or many-to-one, and simple alignment models such as IBM model 1, IBM model 2 and HMM model are sufficient (Och and Ney, 2000).

3 Refining the Word Segmentation

In the last subsection, it was shown that 74.60% of parallel sentences were affected by issues related to under-segmentation of the corpus. Our hypothesis is that if these words are split into pieces that match English words, the accuracy of the unsupervised WA as well as the translation quality will be improved. To achieve this, we adopt a splitting

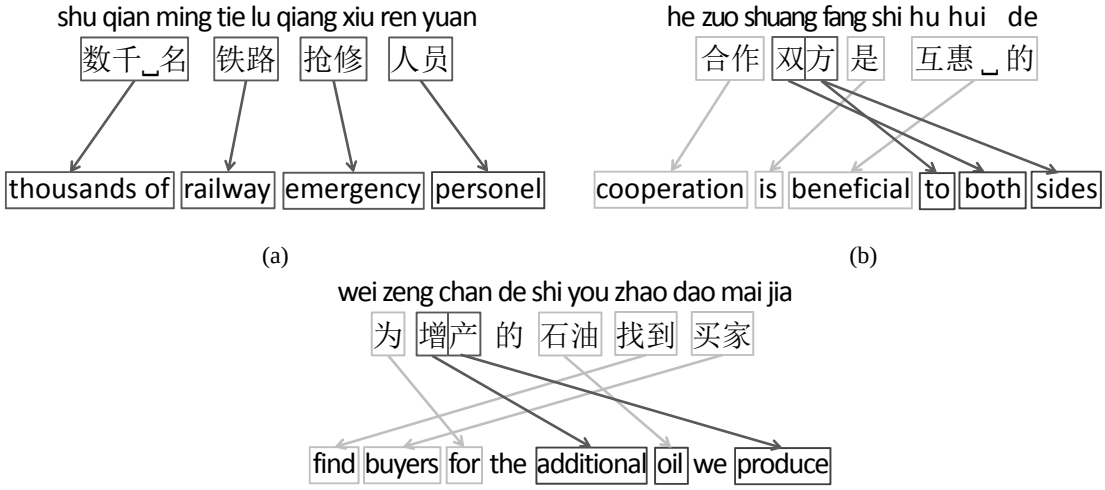

Figure 2: Examples of automated WS on manually WA corpus: (a) Fully consistent; (b) Alignment inconsistent; (c) Alignment inconsistent and extraction hindered. The Chinese words separated by white space are the output of the CTB segmenter. Arrows represent the alignment of atomic blocks. Note that "shuang fang" and "zeng chan" are words produced by the CTB segmenter, but consist of two atomic blocks.

Category	Count	Word Ratio	Sentence Ratio
Fully consistent	355,702	90.74%	25.40%†
Alignment inconsistent	34,464	8.81%	65.54%
Alignment inconsistent & extraction hindered	1,830	0.46%	9.06%
Sum of conflict ‡	36,294	9.26%	74.60%

Table 2: CTB WS on GALE WA corpus: † All words are fully consistent; ‡ Alignment inconsistent plus alignment inconsistent & extraction hindered

strategy, based on a supervised learning approach, to re-segment the corpus. This subsection first formalizes the task, and then presents the approach.

3.1 Word splitting task

The word splitting task is formalized as a sequence labeling task as follows: each word (represented by a sequence of characters $\mathbf{x} = x_1 \dots x_T$ where T is the length of sample) produced by the CTB segmenter is a sample, and a corresponding sequence of binary boundary labels $\mathbf{y} = y_1 \dots y_T$ is the learning target,

$$y_t = \begin{cases} 1 & \text{if there is a split point} \\ & \quad \text{between } c_t \text{ and } c_{t-1}; \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

The sequence of boundary labels is derived from the gold WA annotation as follows: for a sequence of two atomic blocks, where the first character of the second block is x_t, then the label $y_t = 1$. Figure 3 presents several samples extracted from the examples in Figure 2.

Input	*Target*	***y***
铁路	铁路	0 0
双方	双␣方	0 1
出版业	出版␣业	0 0 1
增 产	增␣产	0 1

Figure 3: Samples of word splitting task

Each word sample may have no split point, one split point or multiple split points, depending on the gold WA annotation. Table 3 shows the statistics of the word splitting data set which is built from the GALE manual WA corpus and the CTB segmenter's output, where 2000 randomly sampled sentences are taken as a held-out test set.

Set	# Sentences	# Samples	# Split points	# Split points per sample
Train.	16,057	348,086	32,337	0.0929
Test	2,000	43,910	3,929	0.0895

Table 3: Data set for learning the word splitting

3.2 CRF approach

This paper employs a condition random field (CRF) to solve this sequence labeling task (Lafferty et al., 2001). A linear-chain CRF defines the conditional probability of $\mathbf{y}$ given $\mathbf{x}$ as,

$$P_\Lambda(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_\mathbf{x}}(\sum_{t=1}^{T}\sum_k \lambda_k f_k(y_{t-1}, y_t, \mathbf{x}, t)), \tag{2}$$

where $\Lambda = \{\lambda_1, \ldots\}$ are parameters, $Z_\mathbf{x}$ is a per-input normalization that makes the probability of all state sequences sum to one; $f_k(y_{t-1}, y_t, \mathbf{x}, t)$ is a feature function which is often a binary-valued sparse feature. The training of CRF model is to maximize the likelihood of training data together with a regularization penalty to avoid over-fitting as (Peng et al., 2004; Peng and McCallum, 2006),

$$\Lambda^* = \underset{\Lambda}{argmax}(\sum_i logP_\Lambda(\mathbf{y}_i|\mathbf{x}_i) - \sum_k \frac{\lambda_k^2}{2\delta_k^2}), \tag{3}$$

where ($\mathbf{x}$,$\mathbf{y}$) are training samples; the hyperparameter δ_k can be understood as the variance of the prior distribution of λ_k. When predicting the labels of test samples, the CRF decoder searches for the optimal label sequence y^* that maximizes the conditional probability,

$$\mathbf{y}^* = \underset{\mathbf{y}}{argmax}\, P_\Lambda(\mathbf{y}|\mathbf{x}). \tag{4}$$

In (Chang et al., 2008) a method is proposed to select an appropriate level of segmentation granularity (in practical terms, to encourage smaller segments). We call their method "length tuner". The following artificial feature is introduced into the learned CRF model:

$$f_0(\mathbf{x}, y_{t-1}, y_t, 1) = \begin{cases} 1 & \text{if } y_t = +1 \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

The weight λ_0 of this feature is set by hand to bias the output of CRF model. By way of explanation, a very large positive λ_0 will cause every character to be segmented, or conversely a very large negative λ_0 will inhibit the output of segmentation boundaries. In their experiments, $\lambda_0 = 2$ was used to force a CRF segmenter to adopt an intermediate granularity between character and the CTB WS scheme. Compared to the length tuner, our proposed method exploits lexical knowledge about word splitting, and we will therefore refer to it as the "lexical word splitter" or "lexical splitter" for short.

3.3 Feature Set

The features $f_k(y_{t-1}, y_t, \mathbf{x}, t)$ we used include the WS features from the Chinese Stanford word segmenter and a set of extended features described below. The WS features are included because the target split points may share some common characteristics with the boundaries in the CTB WS scheme.

The extended features consists of four types – named entities, word frequency, word length and character-level unsupervised WA. For each type of the feature, the value and value concatenated with previous or current character are taken as sparse features (see Table 4 for details). The real values of word frequency, word length and character-level unsupervised WA are converted into sparse features due to the routine of CRF model.

The character-level unsupervised alignment feature is inspired by the related works of unsupervised bilingual WS (Xu et al., 2008; Chung and Gildea, 2009; Nguyen et al., 2010; Michael et al., 2011). The idea is that the character-level WA can approximately capture the counterpart English expression of each Chinese token, and source tokens aligned to different target expressions should be split into different words (see Figure 4 for an illustration).

The values of the character-level alignment features are obtained through building a dictionary. First, unsupervised WA is performed on the SMT training corpus where the Chinese sentences are treated as sequences of characters; then, the Chinese sentences are segmented by CTB segmenter and a dictionary of segmented words are built; finally, for each word in the dictionary, the relative frequency of being split at a certain position is cal-

Feature	Definition	Example
NE	NE tag of current word	Geography:NE
NE-C_{-1}	NE concatenated with previous character	Geo.-ding:NE-C_{-1}
NE-C_0	NE concatenated with current character	Geo.-mei:NE-C_0
Frequency	Nearest integer of negative logarithm of word frequency	5†:Freq
Freq.-C_{-1}	Frequency concatenated with previous character	5-ding:Freq-C_{-1}
Freq.-C_0	Frequency concatenated with current character	5-mei:Freq-C_0
Length	Length of current word (1,2,3,4,5,6,7 or $\geqslant$7)	4:Len
Len.-Position	Length concatenated with the position	4-2:Len-Pos
Len.-C_{-1}	Length concatenated with previous character	4-ding:Len-C_{-1}
Len.-C_0	Length concatenated with current character	4-mei:Len-C_0
Char. Align.	Five-level relative frequency of being split	0.4‡:CA
C.A.-C_{-1}	C.A. concatenated with previous character	0.4-ding:CA-C_{-1}
C.A.-C_0	C.A. concatenated with current character	0.4-mei:CA-C_0

Table 4: Extended features used in the CRF model for word splitting. The example shows the features used in the decision whether to split the Chinese word "la ding mei zhou" (Latin America, the first four Chinese characters in Figure 4) after the second Chinese character. † Round(-$\log_{10}$(0.00019)); ‡ Round(0.43 $\times$ 5) / 5

Figure 4: Illustration of character-level unsupervised alignment features. The dotted lines are word boundaries suggested by the alignment.

culated as,

$$f_{CA}(w,i) = \frac{n_i}{n_w} \quad (6)$$

where w is a word, i is a splitting position (from 1 to the length of w minus 1); n_i is the number of times the words as split at position i according to the character-level alignment, that is, the character before and after i are aligned to different English expressions; n_w is occurrence count of word w in the training corpus.

4 Experiments

In the last section we found that 9.26% of words produced by the CTB segmenter have the potential to cause problems for SMT, and propose a lexical word splitter to address this issue through segmentation refinement. This section contains experiments designed to empirically evaluate the proposed lexical word splitter in three aspects: first, whether the WS accuracy is improved; second, whether the accuracy of the unsupervised WA during training SMT systems is improved; third, whether the end-to-end translation quality is improved.

This section first describes the experimental methodology, then presents the experimental results, and finally illustrates the operation of our proposed method using a real example.

4.1 Experimental Methodology

4.1.1 Experimental Corpora

The GALE manual WA corpus and the Chinese to English corpus from the shared task of the NIST open machine translation (OpenMT) 2006 evaluation [6] were employed as the experimental corpus (Table 5).

The experimental corpus for WS was constructed by first segmenting 2000 held out sentences from the GALE manual WA corpus with the Stanford segmenter, and then refining the segmentation with the gold alignment annotation. For example, the gold segmentation for the examples in Figure 2 is presented in Figure 5. Note that this test corpus is intended to represent an oracle segmentation for our proposed method, and serves primarily to gauge the improvement of our method over the baseline Stanford segmenter, relative to an upper bound.

Table 5: NIST Open machine translation 2006 Corpora. † Number of sentence samples which contain one Chinese sentence and four English reference sentences.

The experimental corpus for unsupervised WA was the union set of the NIST OpenMT training set and the 2000 test sentence pairs from GALE WA corpus. We removed the United Nations corpus from the NIST OpenMT constraint training resources because it is out of domain.

The main result of this paper is the evaluation of the end-to-end performance of an SMT system. The experimental corpus for this task was the NIST OpenMT corpus. The data set of the NIST evaluation 2002 was used as a development set for MERT tuning (Och, 2003), and the remaining data sets of the NIST evaluation from 2003 to 2006 were used as test sets. The English sentences were tokenized by Stanford toolkit [7] and converted to lowercase.

4.1.2 Evaluation

The performance of WS was measured by precision, recall and F_1 of gold words (Sproat and Emerson, 2003),

The performance of unsupervised WA in the SMT training procedure was measured through alignment error rate (AER)(Och and Ney, 2000; Liang et al., 2006). Sure alignment edges and possible alignment edges were not distinguished in this paper as no such tags are found in GALE manual WA corpus.

The performance of SMT was measured using BLEU (Papineni et al., 2002).

[7] http://nlp.stanford.edu/software/corenlp.shtml

4.1.3 Baseline Methods

Two Chinese WS methods were taken as the baseline methods in this paper. One method was the CTB segmenter, that is, Stanford Chinese word segmenter with the model trained on CTB corpus. The other method was the length tuner in (Chang et al., 2008), which added a constant into the confidence scores of a trained CRF word segmenter to encourage it to output more word boundaries (see Section 3.2 for details).

4.1.4 Implementation and Parameter settings

The proposed lexical word splitter was implemented on the CRF model toolkit released with the Stanford segmenter (Tseng et al., 2005). The regularity parameters δ_k are set to be 3, the same as the Stanford segmenter, because no significant performance improvements were observed by tuning that parameter.

To extract features for the word splitter, the Stanford named entity recognizer (Finkel et al., 2005)[8] was employed to obtain the tags of named entities. Word frequencies were caculated from the source side of SMT training corpus. The character-level unsupervised alignment was conducted using GIZA++ (Och and Ney, 2003)[9].

The length tuner reused the CRF model of CTB segmenter. The parameter λ_0 was tuned through the grid search in (Chang et al., 2008), that is, observing the BLEU score on the SMT development set varing from $\lambda_0 = 0$ to $\lambda_0 = 32$. The grid search showed that $\lambda_0 = 2$ was optimal, agreeing with the value in (Chang et al., 2008).

Moses (Koehn et al., 2007)[10], a state-of-the-art phrase-based SMT system, was employed to perform end-to-end SMT experiments. GIZA++ was employed to perform unsupervised WA.

4.2 Experimental Results

4.2.1 Word Segmentation

The WS performance of CTB segmenter, length tuner and the proposed lexical splitter are presented in Table 6. The proposed method achieves the highest scores on all the criterion of F_1, precision and recall. The length tuner outperforms the CTB segmenter in terms of recall, but with lower precision.

WS	F_1	Prec.	Recall
CTB segmenter	0.878	0.917	0.842
Length tuner	0.873	0.894	0.852
Lexical splitter	**0.915**	**0.922**	**0.908**

Table 6: Performance of WS

WS	AER	Prec.	Recall
CTB segmenter	0.425	0.622	0.534
Length tuner	0.417	0.642	0.535
Lexical splitter	**0.396**	**0.674**	**0.547**

Table 7: Performance of unsupervised WA using different WS strategies

4.2.2 Word Alignment

The WA performance of the CTB segmenter, length tuner and the proposed lexical spliter is presented in Table 7. Both lexical splitter and length tuner outperform the CTB segmenter, indicating the splitting words into smaller pieces can improve the accuracy of unsupervised WA. This result supports the finding in (Chang et al., 2008) that the segment size from CTB WS is too large for SMT. In addition, the proposed lexical splitter significantly outperforms the length tuner.

4.2.3 Machine Translation

The end-to-end SMT performance of CTB segmenter, length tuner and the proposed lexical spliter are presented in Table 8. Each experiment was performed three times, and the average BLEU and standard derivation were calculated, because there is randomness in the results from MERT. The proposed lexical splitter outperformed the two baselines on all the test sets, and achieves an average improvement of 0.63 BLEU percentage points, indicating that the proposed method can effectively improve the translation quality. The length tuner also outperforms the CTB segmenter, but the average improvement is 0.15 BLEU percentage points, much less than the proposed methods.

4.3 Analysis

Figure 6 presents an example from the test corpus, which demonstrates how the proposed lexical splitter splits words more accurately than the baseline length tuner method. Two words in the segmentation result of the CTB segmenter are worthy of attention. The first one is “yang nian”(the year of goat), the lexical splitter split this word and got the right translation, while the length tuner did not split it. The second is “rong jing”(booming or prosperity), the length tuner split this word, which resulted in wrong translations, while the lexical splitter avoided this mistake.

5 Comparison to Related Work

The most similar work in the literature to the proposed method is the the length tuner method proposed by (Chang et al., 2008). This method also encourages the generation of more words during segmentation by using a single parameter that can be use to control segment length. Our method differs from theirs in that it is able to acquire vocabulary knowledge from word alignments that can be used to more accurately split words into segments suitable for machine translation.

There is large volume of research using bilingual unsupervised and semi-supervised WS to address the problem of optimizing WS for SMT (Xu et al., 2008; Chung and Gildea, 2009; Nguyen et al., 2010; Michael et al., 2011). The main difference with our approach is that they use automatic WA results, most often obtained using the same tools as are used in training SMT systems. One of the main problems of using unsupervised WA is that it is noisy, and therefore, employing iterative optimization methods to refine the results of unsupervised WA is a key issue in their research, for example boosting (Ma and Way, 2009; Michael et al., 2011), expectation maximization (Chung and Gildea, 2009), Bayesian sampling (Xu et al., 2008; Nguyen et al., 2010), or heuristic search (Zhao et al., 2013). Nevertheless, noisy WA makes both analyzing WS and improving SMT quality quite hard. In contrast, by using manual WA, we can clearly analyze the segmentation problems (Section 2), and train supervised models to solve the problem (Section 3).

As far as we are aware, among related work on WS, our method achieves the highest BLEU improvement relative to the start-of-the-art WS – the Stanford Chinese word segmenter – on the Chinese-English OpenMT corpora. The methods proposed in (Ma and Way, 2009; Chung and Gildea, 2009) fail to outperform the Stanford Chinese word segmenter on Chinese-English OpenMT corpora. The length tuner method proposed in (Chang et al., 2008) is less effective to ours according to the experimental results in this paper.

WS	eval03	eval04	eval05	eval06	improve
CTB segmenter	31.89 ± 0.09	32.73 ± 0.19	31.03 ± 0.16	31.38 ± 0.23	
Length tuner	32.06 ± 0.07	32.74 ± 0.10	31.34 ± 0.11	31.50 ± 0.11	0.15 ± 0.12
Lexical splitter	**32.55** ± **0.18**	**32.94** ± **0.11**	**31.87** ± **0.15**	**32.17** ± **0.35**	**0.63** ± **0.29**

The four gold references are: “ethnic chinese in asia celebrate year of goat and hope for economic prosperity in new year”, “ asian chinese celebrate the arrival of the year of sheep and wish a prosperous new year”, “ asian chinese happily welcome the year of goat , expecting economic prosperity in new year”,“asian chinese happily welcomed year of the goat , praying for prosperity in the new year”

6 Conclusion

This paper is concerned with the role of word segmentation in Chinese-to-English SMT. We explored the use of a manually annotated word alignment corpus to refine word segmentation for machine translation. Based on an initial finding that 74.60% of running sentences in the WA corpus have segmentation inconsistent with a gold WA annotation, we proposed a supervised lexical resegmentation model to modify the WS in order to relieve these issues.

Our main experimental results show that the proposed approach is capable of improving both alignment quality and end-to-end translation quality. The proposed method achieved the highest BLEU score relative to a number of respectable baseline systems that included the Stanford word segmenter, and an improved Stanford word segmenter that could be tuned for segment length. No language-specific techniques other than a manually aligned corpus were employed in this paper, thus the approach can applied to other SMT language pairs that require WS.

In the future, we plan to explore combining multiple source words which are aligned to the same target words. This is the symmetric topic of the post word splitting which is studied in this paper. The effect of this word combination oper-

ation on SMT is non-trivial. On one hand, it can reduce the ambiguity in the source side. On the other hand, it may cause sparseness problems.

Abstract

To overcome the scarceness of bilingual corpora for some language pairs in machine translation, pivot-based SMT uses pivot language as a "bridge" to generate source-target translation from source-pivot and pivot-target translation. One of the key issues is to estimate the probabilities for the generated phrase pairs. In this paper, we present a novel approach to calculate the translation probability by pivoting the co-occurrence count of source-pivot and pivot-target phrase pairs. Experimental results on Europarl data and web data show that our method leads to significant improvements over the baseline systems.

1 Introduction

Statistical Machine Translation (SMT) relies on large bilingual parallel data to produce high quality translation results. Unfortunately, for some language pairs, large bilingual corpora are not readily available. To alleviate the parallel data scarceness, a conventional solution is to introduce a “bridge” language (named pivot language) to connect the source and target language (de Gispert and Marino, 2006; Utiyama and Isahara, 2007; Wu and Wang, 2007; Bertoldi et al., 2008; Paul et al., 2011; El Kholy et al., 2013; Zahabi et al., 2013), where there are large amounts of source-pivot and pivot-target parallel corpora.

Among various pivot-based approaches, the triangulation method (Cohn and Lapata, 2007; Wu and Wang, 2007) is a representative work in pivot-based machine translation. The approach proposes to build a source-target phrase table by merging the source-pivot and pivot-target phrase table. One of the key issues in this method is to estimate the translation probabilities for the generated source-target phrase pairs. Conventionally, the probabilities are estimated by multiplying the posterior probabilities of source-pivot and pivot-target phrase pairs. However, it has been shown that the generated probabilities are not accurate enough (Cui et al., 2013). One possible reason may lie in the non-uniformity of the probability space. Through Figure 1. (a), we can see that the probability distributions of source-pivot and pivot-target language are calculated separately, and the source-target probability distributions are induced from the source-pivot and pivot-target probability distributions. Because of the absence of the pivot language (e.g., p2 is in source-pivot probability space but not in pivot-target one), the induced source-target probability distribution is not complete, which will result in inaccurate probabilities.

To solve this problem, we propose a novel approach that utilizes the co-occurrence count of source-target phrase pairs to estimate phrase translation probabilities more precisely. Different from the triangulation method, which merges the source-pivot and pivot-target phrase pairs after training the translation model, we propose to merge the source-pivot and pivot-target phrase pairs immediately after the phrase extraction step, and estimate the co-occurrence count of the source-pivot-target phrase pairs. Finally, we compute the translation probabilities according to the estimated co-occurrence counts, using the standard training method in phrase-based SMT (Koehn et al., 2003). As Figure 1. (b) shows, the

The shaded box in (c) denotes the difference between the interpolation model and the mixed model.

source-target probability distributions are calculated in a complete probability space. Thus, it will be more accurate than the traditional triangulation method. Figure 2. (a) and (b) show the difference between the triangulation method and our co-occurrence count method.

Furthermore, it is common that a small standard bilingual corpus can be available between the source and target language. The direct translation model trained with the standard bilingual corpus exceeds in translation performance, but its weakness lies in low phrase coverage. However, the pivot model has characteristics characters. Thus, it is important to combine the direct and pivot translation model to compensate mutually and further improve the translation performance. To deal with this problem, we propose a mixed model by merging the phrase pairs extracted by pivot-based method and the phrase pairs extracted from the standard bilingual corpus. Note that, this is different from the conventional interpolation method, which interpolates the direct and pivot translation model. See Figure 2. (b) and (c) for further illustration.

The remainder of this paper is organized as follows. In Section 2, we describe the related work. We introduce the co-occurrence count method in Section 3, and the mixed model in Section 4. In Section 5 and Section 6, we describe and analyze the experiments. Section 7 gives a conclusion of the paper.

2 Related Work

Several methods have been proposed for pivot-based translation. Typically, they can be classified into 3 kinds as follows:

Transfer Method: The transfer method (Utiyama and Isahara, 2007; Wang et al., 2008; Costa-jussà et al., 2011) connects two translation systems: a source-pivot MT system and a pivot-target MT system. Given a source sentence, (1) the source-pivot MT system translates it into the pivot language, (2) and the pivot-target MT system translates the pivot sentence into the target sentence. During each step (source to pivot and pivot to target), multiple translation outputs will be generated, thus a minimum Bayes-risk system combination method is often used to select the optimal sentence (González-Rubio et al., 2011; Duh et al., 2011). The problem with the transfer method is that it needs to decode twice. On one hand, the time cost is doubled; on the other hand, the translation error of the source-pivot translation system will be transferred to the pivot-target translation.

Synthetic Method: It aims to create a synthetic source-target corpus by: (1) translate the pivot part in source-pivot corpus into target language with a pivot-target model; (2) translate the pivot part in pivot-target corpus into source language with a pivot-source model; (3) combine the source sentences with translated target sentences or/and combine the target sentences with translated source sentences (Utiyama et al., 2008; Wu and Wang, 2009). However, it is difficult to build a high quality translation system with a corpus created by a machine translation system.

Triangulation Method: The triangulation method obtains source-target phrase table by merging source-pivot and pivot-target phrase table entries with identical pivot language phrases and multiplying corresponding posterior probabilities (Wu and Wang, 2007; Cohn and Lapata, 2007), which has been shown to work better than the other pivot approaches (Utiyama and Isahara, 2007). A problem of this approach is that the probability space of the source-target phrase pairs is non-uniformity due to the mismatching of the pivot phrase.

3 Our Approach

In this section, we will introduce our method for learning a source-target phrase translation model with a pivot language as a bridge. We extract the co-occurrence count of phrase pairs for each language pair with a source-pivot and a pivot-target corpus. Then we generate the source-target phrase pairs with induced co-occurrence information. Finally, we compute translation probabilities using the standard phrase-based SMT training method.

3.1 Phrase Translation Probabilities

Following the standard phrase extraction method (Koehn et al., 2003), we can extract phrase pairs $(\bar{s}, \bar{p})$ and $(\bar{p}, \bar{t})$ from the corresponding word-aligned source-pivot and pivot-target training corpus, where $\bar{s}$, $\bar{p}$ and $\bar{t}$ denotes the phrase in source, pivot and target language respectively.

Formally, given the co-occurrence count $c(\bar{s}, \bar{p})$ and $c(\bar{p}, \bar{t})$, we can estimate $c(\bar{s}, \bar{t})$ by Equation 1:

$$c(\bar{s}, \bar{t}) = \sum_{\bar{p}} g(c(\bar{s}, \bar{p}), c(\bar{p}, \bar{t})) \quad (1)$$

where $g(\cdot)$ is a function to merge the co-occurrences count $c(\bar{s}, \bar{p})$ and $c(\bar{p}, \bar{t})$. We propose four calculation methods for function $g(\cdot)$.

Given the co-occurrence count $c(\bar{s}, \bar{p})$ and $c(\bar{p}, \bar{t})$, we first need to induce the co-occurrence count $c(\bar{s}, \bar{p}, \bar{t})$. The $c(\bar{s}, \bar{p}, \bar{t})$ is counted when the source phrase, pivot phrase and target phrase occurred together, thus we can infer that $c(\bar{s}, \bar{p}, \bar{t})$ is smaller than $c(\bar{s}, \bar{p})$ and $c(\bar{p}, \bar{t})$. In this circumstance, we consider that $c(\bar{s}, \bar{p}, \bar{t})$ is approximately equal to the minimum value of $c(\bar{s}, \bar{p})$ and $c(\bar{p}, \bar{t})$, as shown in Equation 2.

$$c(\bar{s}, \bar{p}, \bar{t}) \approx \sum_{\bar{p}} \min(c(\bar{s}, \bar{p}), c(\bar{p}, \bar{t})) \quad (2)$$

Because the co-occurrence count of source-target phrase pairs needs the existence of pivot phrase $\bar{p}$, we intuitively believe that the co-occurrence count $c(\bar{s}, \bar{t})$ is equal to the co-occurrence count $c(\bar{s}, \bar{p}, \bar{t})$. Under this assumption, we can obtain the co-occurrence count $c(\bar{s}, \bar{t})$ as shown in Equation 3. Furthermore, to testify our assumption, we also try the *maximum* value (Equation 4) to infer the co-occurrence count of $(\bar{s}, \bar{t})$ phrase pair.

$$c(\bar{s},\bar{t}) = \sum_{\bar{p}} \min(c(\bar{s},\bar{p}), c(\bar{p},\bar{t})) \quad (3)$$

$$c(\bar{s},\bar{t}) = \sum_{\bar{p}} \max(c(\bar{s},\bar{p}), c(\bar{p},\bar{t})) \quad (4)$$

In addition, if source-pivot and pivot-target parallel corpus greatly differ in quantities, then the *minimum* function would likely just take the counts from the smaller corpus. To deal with the problem of the imbalance of the parallel corpora, we also try the *arithmetic mean* (Equation 5) and *geometric mean* (Equation 6) function to infer the co-occurrence count of source-target phrase pairs.

$$c(\bar{s},\bar{t}) = \sum_{\bar{p}} (c(\bar{s},\bar{p}) + c(\bar{p},\bar{t}))/2 \quad (5)$$

$$c(\bar{s},\bar{t}) = \sum_{\bar{p}} \sqrt{c(\bar{s},\bar{p}) \times c(\bar{p},\bar{t})} \quad (6)$$

When the co-occurrence count of source-target language is calculated, we can estimate the phrase translation probabilities with the following Equation 7 and Equation 8.

$$\phi(\bar{s}|\bar{t}) = \frac{c(\bar{s},\bar{t})}{\sum_{\bar{s}} c(\bar{s},\bar{t})} \quad (7)$$

$$\varphi(\bar{t}|\bar{s}) = \frac{c(\bar{s},\bar{t})}{\sum_{\bar{t}} c(\bar{s},\bar{t})} \quad (8)$$

3.2 Lexical Weight

Given a phrase pair $(\bar{s},\bar{t})$ and a word alignment a between the source word positions $i = 1,\cdots,n$ and the target word positions $j = 0,\cdots,m$, the lexical weight of phrase pair $(\bar{s},\bar{t})$ can be calculated by the following Equation 9 (Koehn et al., 2003).

$$p_\omega(\bar{s}|\bar{t},a) = \prod_{i=1}^{n} \frac{1}{|\{j|(i,j)\in a\}|} \sum_{\forall(i,j)\in a} \omega(s_i|t_j) \quad (9)$$

The lexical translation probability distribution $\omega(s|t)$ between source word *s* and target word *t* can be estimated with Equation 10.

$$\omega(s|t) = \frac{c(s,t)}{\sum_{s'} c(s',t)} \quad (10)$$

To compute the lexical weight for a phrase pair $(\bar{s},\bar{t})$ generated by $(\bar{s},\bar{p})$ and $(\bar{p},\bar{t})$, we need the alignment information a, which can be obtained as Equation 11 shows.

$$a = \{(s,t)|\exists p\colon (s,p)\in a_1 \& (p,t)\in a_2\} \quad (11)$$

where a_1 and a_2 indicate the word alignment information in the phrase pair $(\bar{s},\bar{p})$ and $(\bar{p},\bar{t})$ respectively.

4 Integrate with Direct Translation

If a standard source-target bilingual corpus is available, we can train a direct translation model. Thus we can integrate the direct model and the pivot model to obtain further improvements. We propose a mixed model by merging the co-occurrence count in direct translation and pivot translation. Besides, we also employ an interpolated model (Wu and Wang, 2007) by merging the direct translation model and pivot translation model using a linear interpolation.

4.1 Mixed Model

Given n pivot languages, the co-occurrence count can be estimated using the method described in Section 3.1. Then the co-occurrence count and the lexical weight of the mixed model can be estimated with the following Equation 12 and 13.

$$c(s,t) = \sum_{i=0}^{n} c_i(s,t) \quad (12)$$

$$p_\omega(\bar{s}|\bar{t},a) = \sum_{i=0}^{n} \alpha_i\, p_{\omega,i}(\bar{s}|\bar{t},a) \quad (13)$$

where $c_0(s,t)$ and $p_{\omega,0}(\bar{s}|\bar{t},a)$ are the co-occurrence count and lexical weight in the direct translation model respectively. $c_i(s,t)$ and $p_{\omega,i}(\bar{s}|\bar{t},a)$ denote the co-occurrence count and lexical weight in the pivot translation model. α_i is the interpolation coefficient, requiring $\sum_{i=0}^{n} \alpha_i = 1$.

4.2 Interpolated Model

Following Wu and Wang (2007), the interpolated model can be modelled with Equation 14.

$$\phi(\bar{s}|\bar{t}) = \sum_{i=0}^{n} \beta_i \phi_i(\bar{s}|\bar{t}) \quad (14)$$

where $\phi_0(\bar{s}|\bar{t})$ is the phrase translation probability in direct translation model; $\phi_i(\bar{s}|\bar{t})$ is the phrase translation probability in pivot translation model. The lexical weight is obtained with Equation 13. β_i is the interpolation coefficient, requiring $\sum_{i=0}^{n} \beta_i = 1$.

5 Experiments on Europarl Corpus

Our first experiment is carried out on Europarl[1] corpus, which is a multi-lingual corpus including 21 European languages (Koehn, 2005). In our work, we perform translations among French (fr), German (de) and Spanish (es). Due to the richness of available language resources, we choose English (en) as the pivot language. Table 1 summarized the statistics of training data. For the language model, the same monolingual data extracted from the Europarl are used.

The word alignment is obtained by GIZA++ (Och and Ney, 2000) and the heuristics "grow-diag-final" refinement rule (Koehn et al., 2003). Our translation system is an in-house phrase-based system analogous to Moses (Koehn et al., 2007). The baseline system is the triangulation method (Wu and Wang, 2007), including an interpolated model which linearly interpolate the direct and pivot translation model.

We use WMT08[2] as our test data, which contains 2000 in-domain sentences and 2051 out-of-domain sentences with single reference. The translation results are evaluated by case-insensitive BLEU-4 metric (Papineni et al., 2002). The statistical significance tests using 95% confidence interval are measured with paired bootstrap resampling (Koehn, 2004).

5.1 Results

We compare 4 merging methods with the baseline system. The results are shown in Table 2 and Table 3. We find that the *minimum* method outperforms the others, achieving significant improvements over the baseline on all translation directions. The absolute improvements range from 0.61 (fr-de) to 1.54 (es-fr) in BLEU% score on in-domain test data, and range from 0.36 (fr-de) to 2.05 (fr-es) in BLEU% score on out-of-domain test data. This indicates that our method is effective and robust in general.

[2] http://www.statmt.org/wmt08/shared-task.html

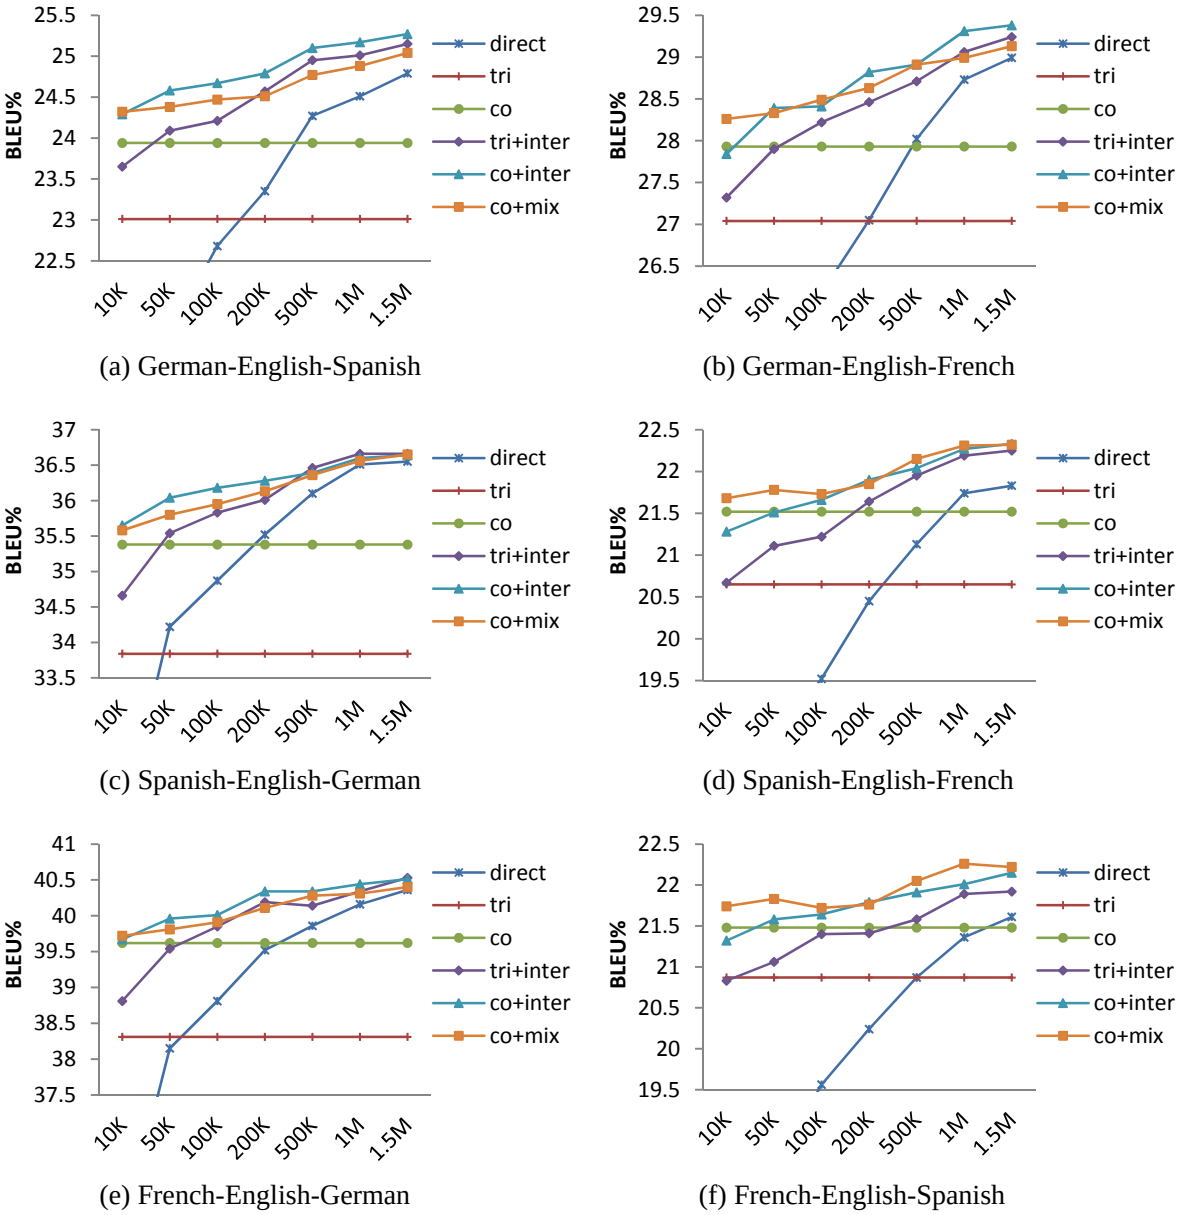

Figure 3: Comparisons of pivot-based methods on different scales of source-target standard corpora. (*direct*: direct model; *tri*: triangulation model; *co*: co-occurrence count model; *tri+inter*: triangulation model interpolated with direct model ; *co+inter*: co-occurrence count model interpolated with direct model; *co+mix*: mixed model). X-axis represents the scale of the standard training data.

The *geometric mean* method also achieves improvement, but not as significant as the *minimum* method. However, the *maximum* and the *arithmetic mean* methods show a decrement in BLEU scores. This reminds us that how to choose a proper merging function for the co-occurrence count is a key problem. In the future, we will explore more sophisticated method to merge co-occurrence count.

5.2 Analysis

The pivot-based translation is suitable for the scenario that there exists large amount of source-pivot and pivot-target bilingual corpora and only a little source-target bilingual data. Thus, we randomly select 10K, 50K, 100K, 200K, 500K, 1M, 1.5M sentence pairs from the source-target bilingual corpora to simulate the lack of source-target data. With these corpora, we train several direct translation models with different scales of bilingual data. We interpolate each direct translation model with the pivot model (both triangulation method and co-occurrence count method) to obtain the interpolated model respectively. We also mix the direct model and pivot model using the method described in Section 4.1. Following

Wu and Wang (2007), we set $\alpha_0 = 0.9$, $\alpha_1 = 0.1$, $\beta_0 = 0.9$ and $\beta_1 = 0.1$ empirically. The experiments are carried out on 6 translation directions: German-Spanish, German-French, Spanish-German, Spanish-French, French-German and French-Spanish. The results are shown in Figure 3. We only list the results on in-domain test sets. The trend of the results on out-of domain test sets is similar with in-domain test sets.

The results are explained as follows:

(1) Comparison of Pivot Translation and Direct Translation

The pivot translation models are better than the direct translation models trained on a small source-target bilingual corpus. With the increment of source-target corpus, the direct model first outperforms the triangulation model and then outperforms the co-occurrence count model consecutively.

Taking Spanish-English-French translation as an example, the co-occurrence count model achieves BLEU% scores of 35.38, which is close to the direct translation model trained with 200K source-target bilingual data. Compared with the co-occurrence count model, the triangulation model only achieves BLEU% scores of 33.84, which is close to the direct translation model trained with 50K source-target bilingual data.

(2) Comparison of Different Interpolated Models

For the pivot model trained by triangulation method and co-occurrence count method, we interpolate them with the direct translation model trained with different scales of bilingual data. Figure 3 shows the translation results of the different interpolated models. For all the translation directions, our co-occurrence count method interpolated with the direct model is better than the triangulation model interpolated with the direct model.

The two interpolated model are all better than the direct translation model. With the increment of the source-target training corpus, the gap becomes smaller. This indicates that the pivot model and its affiliated interpolated model are suitable for language pairs with small bilingual data. Even if the scale of source-pivot and pivot-target corpora is close to the scale of source-target bilingual corpora, the pivot translation model can help the direct translation model to improve the translation performance. Take Spanish-English-French translation as an issue, when the scale of Spanish-French parallel data is 1.5M sentences pairs, which is close to the Spanish-English and English-French parallel data, the performance of *co+mix* model is still outperforms the *direct* translation model.

(3) Comparison of Interpolated Model and Mixed Model

When only a small source-target bilingual corpus is available, the mix model outperforms the interpolated model. With the increasing of source-target corpus, the mix model is close to the interpolated model or worse than the interpolated model. This indicates that the mix model has a better performance when the source-target corpus is small which is close to the realistic scenario.

5.3 Integrate the Co-occurrence Count Model and Triangulation Model

Experimental results in the previous section show that, our co-occurrence count models generally outperform the baseline system. In this section, we carry out experiments that integrates co-occurrence count model into the triangulation model.

For French-English-German translation, we apply a linear interpolation method to integrate the co-occurrence count model into triangulation model following the method described in Section 4.2. We set α as the interpolation coefficient of triangulation model and $1 - \alpha$ as the interpolation coefficient of co-occurrence count model respectively. The experiments take 9 values for interpolation coefficient, from 0.1 to 0.9. The results are shown in Figure 4.

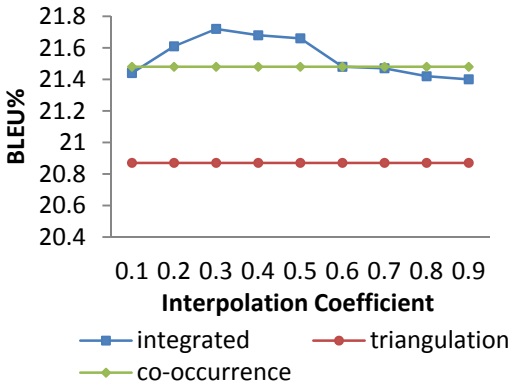

Figure 4: Results of integrating the co-occurrence count model and the triangulation model.

When using interpolation coefficient ranging from 0.2 to 0.7, the integrated models outperform the triangulation and the co-occurrence count model. However, for the other intervals, the inte-

Language Pairs	Sentence Pairs	Source Words	Target Words
zh-en-1	1M	18.1M	17.7M
zh-en-2	2M	36.2M	35.5M
zh-en-3	3M	54.2M	53.2M
zh-en-4	4M	72.3M	70.9M
zh-en-5	5M	90.4M	88.6M
en-jp	1M	9.2M	11.1M

Table 4: Training data of web corpus

System	BLEU%				
	zh-en-jp-1*	zh-en-jp-2	zh-en-jp-3	zh-en-jp-4	zh-en-jp-5
Baseline	29.07	29.39	29.44	29.67	29.80
Minimum	**31.13***	**31.28***	**31.43***	**31.62***	**32.02***
Maximum	28.88	29.01	29.12	29.37	29.59
Arithmetic mean	29.08	29.36	29.51	29.79	30.01
Geometric mean	**30.77***	**31.30***	**31.75***	**32.07***	**32.34***

Table 5: Comparison of different merging methods on the imbalanced web data. (zh-en-jp-1 means the translation system is trained with zh-en-1 as source-pivot corpus and en-jp as pivot-target corpus, and so on.)

grated models perform slightly lower than the co-occurrence count model, but still show better results than the triangulation model. The trend of the curve infers that the integrated model synthesizes the contributions of co-occurrence count model and triangulation model. Additionally, it also indicates that, the choice of the interpolation coefficient affects the translation performances.

6 Experiments on Web Data

The experimental on Europarl is artificial, as the training data for directly translating between source and target language actually exists in the original data sets. Thus, we conducted several experiments on a more realistic scenario: translating Chinese (zh) to Japanese (jp) via English (en) with web crawled data.

As mentioned in Section 3.1, the source-pivot and pivot-target parallel corpora can be imbalanced in quantities. If one parallel corpus was much larger than another, then *minimum* heuristic function would likely just take the counts from the smaller corpus.

In order to analyze this issue, we manually set up imbalanced corpora. For source-pivot parallel corpora, we randomly select 1M, 2M, 3M, 4M and 5M Chinese-English sentence pairs. On the other hand, we randomly select 1M English-Japanese sentence pairs as pivot-target parallel corpora. The training data of Chinese-English and English-Japanese language pairs are summarized in Table 4. For the Chinese-Japanese direct corpus, we randomly select 5K, 10K, 20K, 30K, 40K, 50K, 60K, 70K, 80K, 90K and 100K sentence pairs to simulate the lack of bilingual data. We built a 1K in-house test set with four references. For Japanese language model training, we used the monolingual part of English-Japanese corpus.

Table 5 shows the results of different co-occurrence count merging methods. First, the *minimum* method and the *geometric mean* method outperform the other two merging methods and the baseline system with different training corpus. When the scale of source-pivot and pivot-target corpus is roughly balanced (zh-en-jp-1), the *minimum* method achieves an absolute improvement of 2.06 percentages points on BLEU over the baseline, which is also better than the other merging methods. While, with the growth of source-pivot corpus, the gap between source-pivot corpus and pivot-target corpus becomes bigger. In this circumstance, the *geometric mean* method becomes better than the *minimum* method. Compared to the *minimum* method, the *geometric mean* method considers both the source-pivot and the pivot-target corpus, which may lead to a better result in the case of imbalanced training corpus.

Furthermore, with the imbalanced corpus zh-en-jp-5, we compared the translation performance of our co-occurrence count model (with *geometric mean* merging method), triangulation model, interpolated model, mixed model and the direct translation models. Figure 5 summarized the results.

The co-occurrence count model can achieve an absolute improvement of 2.54 percentages points on BLEU over the baseline. The triangulation method outperforms the direct translation when only 5K sentence pairs are available. Meanwhile, the number is 10K when using the co-occurrence count method. The co-occurrence count models interpolated with the direct model significantly outperform the other models.

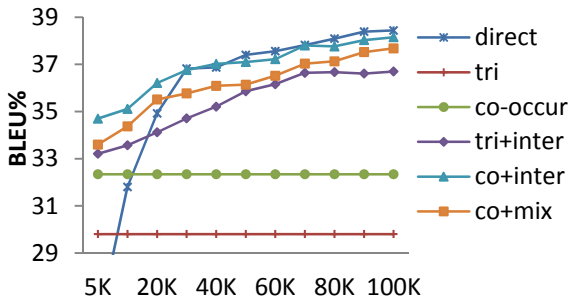

Figure 5: Results on Chinese-Japanese Web Data. X-axis represents the scale of the standard training data.

In this experiment, the training data contains parallel sentences on various domains. And the training corpora (Chinese-English and English-Japanese) are typically very different, since they are obtained on the web. It indicates that our co-occurrence count method is robust in the realistic scenario.

7 Conclusion

This paper proposed a novel approach for pivot-based SMT by pivoting the co-occurrence count of phrase pairs. Different from the triangulation method merging the source-pivot and pivot-target language after training the translation model, our method merges the source-pivot and pivot-target language after extracting the phrase pairs, thus the computing for phrase translation probabilities is under the uniform probability space. The experimental results on Europarl data and web data show significant improvements over the baseline systems. We also proposed a mixed model to combine the direct translation and pivot translation, and the experimental results show that the mixed model has a better performance when the source-target corpus is small which is close to the realistic scenario.

A key problem in the approach is how to learn the co-occurrence count. In this paper, we use the *minimum* function on balanced corpora and the *geometric mean* function on imbalanced corpora to estimate the co-occurrence count intuitively. In the future, we plan to explore more effective approaches.

Word Translation Prediction for Morphologically Rich Languages with Bilingual Neural Networks

Ke Tran Arianna Bisazza Christof Monz
Informatics Institute, University of Amsterdam
Science Park 904, 1098 XH Amsterdam, The Netherlands
{m.k.tran,a.bisazza,c.monz}@uva.nl

Abstract

Translating into morphologically rich languages is a particularly difficult problem in machine translation due to the high degree of inflectional ambiguity in the target language, often only poorly captured by existing word translation models. We present a general approach that exploits source-side contexts of foreign words to improve translation prediction accuracy. Our approach is based on a probabilistic neural network which does not require linguistic annotation nor manual feature engineering. We report significant improvements in word translation prediction accuracy for three morphologically rich target languages. In addition, preliminary results for integrating our approach into a large-scale English-Russian statistical machine translation system show small but statistically significant improvements in translation quality.

1 Introduction

The ability to make context-sensitive translation decisions is one of the major strengths of phrase-based SMT (PSMT). However, the way PSMT exploits source-language context has several limitations as pointed out, for instance, by Quirk and Menezes (2006) and Durrani et al. (2013). First, the amount of context used to translate a given input word depends on the phrase segmentation, with hypotheses resulting from different segmentations competing with one another. Another issue is that, given a phrase segmentation, each source phrase is translated independently from the others, which can be problematic especially for short phrases. As a result, the predictive translation of a source phrase does not access useful linguistic clues in the source sentence that are outside of the scope of the phrase.

Lexical weighting tackles the problem of unreliable phrase probabilities, typically associated with long phrases, but does not alleviate the problem of context segmentation. An important share of the translation selection task is then left to the language model (LM), which is certainly very effective but can only leverage *target* language context. Moreover, decisions that are taken at early decoding stages—such as the common practice of retaining only top n translation options for each source span—depend only on the translation models and on the target context available in the phrase.

Source context based translation models (Gimpel and Smith, 2008; Mauser et al., 2009; Jeong et al., 2010; Haque et al., 2011) naturally address these limitations. These models can exploit a boundless context of the input text, but they assume that target words can be predicted independently from each other, which makes them easy to integrate into state-of-the-art PSMT systems. Even though the independence assumption is made on the target side, these models have shown the benefits of utilizing source context, especially in translating into morphologically rich languages. One drawback of previous research on this topic, though, is that it relied on rich sets of manually designed features, which in turn required the availability of linguistic annotation tools like POS taggers and syntactic parsers.

In this paper, we specifically focus on improving the prediction accuracy for word translations. Achieving high levels of word translation accuracy is particularly challenging for language

pairs where the source language is morphologically poor, such as English, and the target language is morphologically rich, such as Russian, i.e., language pairs with a high degree of surface realization ambiguity (Minkov et al., 2007). To address this problem we propose a general approach based on bilingual neural networks (BNN) exploiting source-side contextual information.

This paper makes a number of contributions: Unlike previous approaches our models do not require any form of linguistic annotation (Minkov et al., 2007; Kholy and Habash, 2012; Chahuneau et al., 2013), nor do they require any feature engineering (Gimpel and Smith, 2008). Moreover, besides directly predicting fully inflected forms as Jeong et al. (2010), our approach can also model stem and suffix prediction explicitly. Prediction accuracy is evaluated with respect to three morphologically rich target languages (Bulgarian, Czech, and Russian) showing that our approach consistently yields substantial improvements over a competitive baseline. We also show that these improvements in prediction accuracy can be beneficial in an end-to-end machine translation scenario by integrating into a large-scale English-Russian PSMT system. Finally, a detailed analysis shows that our approach induces a positive bias on phrase translation probabilities leading to a better ranking of the translation options employed by the decoder.

2 Lexical coverage of SMT models

The first question we ask is whether translation can be improved by a more accurate selection of the translation options already existing in the SMT models, as opposed to generating new options. To answer this question we measure the lexical coverage of a baseline PSMT system trained on English-Russian.[1] We choose this language pair because of the morphological richness on the target side: Russian is characterized by a highly inflectional morphology with a particularly complex nominal declension (six core cases, three genders and two number categories). As suggested by Green and DeNero (2012), we compute the recall of reference tokens in the set of target tokens that the decoder could produce in a translation of the source, that is the target tokens of all phrase pairs that matched the input sentence and that were actually used for decoding.[2] We call this the decoder's *lexical search space*. Then, we compare the reference/space recall against the reference/MT-output recall: that is, the percentage of reference tokens that also appeared in the 1-best translation output by the SMT system. Results for the WMT12 benchmark are presented in Table 1. From the first two rows, we see that only a rather small part of the correct target tokens available to the decoder are actually produced in the 1-best MT output (50% against 86%). Although our word-level analysis does not directly estimate phrase-level coverage, these numbers suggest that a large potential for translation improvement lies in better lexical selection during decoding.

Token recall:	
reference/MT-search-space	86.0%
reference/MT-output	50.0%
stem-only reference/MT-output	12.3%
of which reachable	11.2%

Table 1: Lexical coverage analysis of the baseline SMT system (English-Russian wmt12).

To quantify the importance of morphology, we count how many reference tokens matched the MT output only at the stem level[3] and for how many of those the correct surface form existed in the search space (reachable matches). These two numbers represent the upper bound of the improvement achievable by a model only predicting suffixes given the target stems. As shown in Table 1, such a model could potentially increase the reference/MT-output recall by 12.3% with generation of new inflected forms, and by 11.2% without. Thus, also when it comes to morphology, generation seems to be of secondary importance compared to better selection in our experimental setup.

3 Predicting word translations in context

It is standard practice in PSMT to use word-to-word translation probabilities as an additional phrase score. More specifically, state-of-the-art PSMT systems employ the maximum-likelihood estimate of the context-independent probability of a target word given its aligned source word $P(t_j|s_i)$ for each word alignment link a_{ij}.

[1] Training data and SMT setup are described in Section 6.

[2] This corresponds to the top 30 phrases sorted by weighted phrase, lexical and LM probabilities, for each source span. Koehn (2004) and our own experience suggest that using more phrases has little or no impact on MT quality.

[3] Word segmentation for this analysis is performed by the Russian Snowball stemmer, see also Section 5.3.

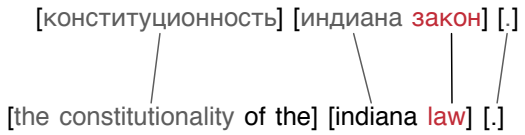

Figure 1: Fragment of English sentence and its incorrect Russian translation produced by the baseline SMT system. Square brackets indicate phrase boundaries.

The main goal of our work is to improve the estimation of such probabilities by exploiting the context of s_i, which in turn we expect will result in better phrase translation selection. Figure 1 illustrates this idea: the translation of "law" in this example has a wrong case—nominative instead of genitive. Due to the rare word "Indiana/индиана", the target LM must backoff to the bigram history and does not penalize this choice sufficiently. However, a model that has access to the word "of" in the near source context could bias the translation of "law" to the correct case.

We then model $P(t_j|\mathbf{c}_{s_i})$ with source context $\mathbf{c}_{s_i}$ defined as a fixed-length word sequence centered around s_i:

$$\mathbf{c}_{s_i} = s_{i-k}, ..., s_i, ..., s_{i+k}$$

Our definition of context is similar to the $n-1$ word history used in n-gram LMs. Similarly to previous work in source context-sensitive translation modeling (Jeong et al., 2010; Chahuneau et al., 2013), target words are predicted independently from each other, which allows for an efficient decoding integration. We are particularly interested in translating into morphologically rich languages where source context can provide useful information for the prediction of target translation, for example, the gender of the subject in a source sentence constrains the morphology of the translation of the source verb. Therefore, we integrate the notions of stem and suffix directly into the model. We assume the availability of a word segmentation function g that takes a target word t as input and returns its stem and suffix: $g(t) = (\sigma, \mu)$. Then, the conditional probability $p(t_j|\mathbf{c}_{s_i})$ can be decomposed into stem probability and suffix probability:

$$p(t_j|\mathbf{c}_{s_i}) = p(\sigma_j|\mathbf{c}_{s_i})p(\mu_j|\mathbf{c}_{s_i}, \sigma_j) \quad (1)$$

These two probabilities can be estimated separately, which yields the two subtasks:

1. predict target stem σ given source context $\mathbf{c}_s$;
2. predict target suffix μ given source context $\mathbf{c}_s$ and target stem σ.

Based on the results of our analysis, we focus on the selection of existing translation candidates. We then restrict our prediction on a set of possible target candidates depending on the task instead of considering all target words in the vocabulary. More specifically, for each source word s_i, our candidate generation function returns the set of target words $T_s = \{t_1, \ldots, t_m\}$ that were aligned to s_i in the parallel training corpus, which in turn corresponds to the set of target words that the SMT system can produce for a given source. In practice, we use a pruned version of T_s to speed up training and reduce noise (see details in Section 5).

As for the morphological models, given T_s and g, we can obtain $L_s = \{\sigma_1, \ldots, \sigma_k\}$, the set of possible target stem translations of s, and $M_\sigma = \{\mu_1, \ldots, \mu_l\}$, the set of possible suffixes for a target stem σ. The use of L_s, and M_σ is similar to stemming and inflection operations in (Toutanova et al., 2008) while the set T_s is similar to the GEN function in (Jeong et al., 2010).[4]

Our approach differs crucially from previous work (Minkov et al., 2007; Chahuneau et al., 2013) in that it does not require linguistic features such as part-of-speech and syntactic tree on the source side. The proposed models automatically learn features that are relevant for each of the modeled tasks, directly from word-aligned data. To make the approach completely language independent, the word segmentation function g can be trained with an unsupervised segmentation tool. The effects of using different word segmentation techniques are discussed in Section 5.

4 Bilingual neural networks for translation prediction

Probabilistic neural network (NN), or continuous space, language models have received increasing attention over the last few years and have been applied to several natural language processing tasks (Bengio et al., 2003; Collobert and Weston, 2008; Socher et al., 2011; Socher et al., 2012). Within statistical machine translation, they

[4]Note that our suffix generation function M_σ is restricted to the forms observed in the target monolingual data, but not to those aligned to a source word s, which opens the possibility of generating inflected forms that are missing from the translation models. We leave this possibility to future work.

have been used for monolingual target language modeling (Schwenk et al., 2006; Le et al., 2011; Duh et al., 2013; Vaswani et al., 2013), n-gram translation modeling (Son et al., 2012), phrase translation modeling (Schwenk, 2012; Zou et al., 2013; Gao et al., 2014) and minimal translation modeling (Hu et al., 2014). The recurrent neural network LMs of Auli et al. (2013) are primarily trained to predict target word sequences. However, they also experiment with an additional input layer representing source side context.

Our models differ from most previous work in neural language modeling in that we predict a target translation given a source context while previous models predict the next word given a target word history. Unlike previous work in phrase translation modeling with NNs, our models have the advantage of accessing source context that can fall outside the phrase boundaries.

We now describe our models in a general setting, predicting target translations given a source context, where target translations can be either words, stems or suffixes.[5]

4.1 Neural network architecture

Following a common approach in deep learning for NLP (Bengio et al., 2003; Collobert and Weston, 2008), we represent each source word s_i by a column vector $\mathbf{r}_{s_i} \in \mathbb{R}^d$. Given a source context $\mathbf{c}_{s_i} = s_{i-k}, ..., s_i, ..., s_{i+k}$ of k words on the left and k words on the right of s_i, the context representation $\mathbf{r}_{\mathbf{c}_{s_i}} \in \mathbb{R}^{(2k+1)\times d}$ is obtained by concatenating the vector representations of all words in $\mathbf{c}_{s_i}$:

$$\mathbf{r}_{\mathbf{c}_{s_i}} = \mathbf{r}_{s_{i-k}} \odot ... \odot \mathbf{r}_{s_{i+k}}$$

Our main BNN architecture for word or stem prediction (Figure 2a) is a feed-forward neural network (FFNN) with one hidden layer, a matrix $\mathbf{W}_1 \in \mathbb{R}^{n\times(2k+1)d}$ connecting the input layer to the hidden layer, a matrix $\mathbf{W}_2 \in \mathbb{R}^{|V_t|\times n}$ connecting the hidden layer to the output layer, and a bias vector $\mathbf{b}_2 \in \mathbb{R}^{|V_t|}$ where $|V_t|$ is the size of target translations vocabulary. The target translation distribution $P_{\text{BNN}}(t|\mathbf{c}_{s_i})$ for a given source context $\mathbf{c}_{s_i}$ is computed by a forward pass:

$$\text{softmax}\left(\mathbf{W}_2\, \phi(\mathbf{W}_1 \mathbf{r}_{\mathbf{c}_{s_i}}) + \mathbf{b}_2\right) \qquad (2)$$

where ϕ is a nonlinearity (tanh, sigmoid or rectified linear units). The parameters of the neural network are $\boldsymbol{\theta} = \{\mathbf{r}_{s_i}, \mathbf{W}_1, \mathbf{W}_2, \mathbf{b}_2\}$.

The suffix prediction BNN is obtained by adding the target stem representation $\mathbf{r}_\sigma$ to the input layer (see Figure 2b).

4.2 Model variants

We encounter two major issues with FFNNs: (i) They do not provide a natural mechanism to compute word surface conditional probability $p(t|\mathbf{c}_s)$ given individual stem probability $p(\sigma|\mathbf{c}_s)$ and suffix probability $p(\mu|\mathbf{c}_s, \sigma)$, and (ii) FFNNs do not provide the flexibility to capture long dependencies among words if they lie outside the source context window. Hence, we consider two BNN variants: a log-bilinear model (LBL) and a convolutional neural network model (ConvNet). LBL could potentially address (i) by factorizing target representations into target stem and suffix representations whereas ConvNets offer the advantage of modeling variable input length (ii) (Kalchbrenner et al., 2014).

Log-bilinear model. The FFNN models stem and suffix probabilities separately. A log-bilinear model instead could directly model word prediction through a factored representation of target words, similarly to Botha and Blunsom (2014). Thus, no probability mass would be wasted over stem-suffix combinations that are not in the candidate generation function. The LBL model specifies the conditional distribution for the word translation $t_j \in T_{s_i}$ given a source context $\mathbf{c}_{s_i}$:

$$P_{\boldsymbol{\theta}}(t_j|\mathbf{c}_{s_i}) = \frac{\exp(s_{\boldsymbol{\theta}}(t_j, \mathbf{c}_{s_i}))}{\sum_{t'_j \in T_{s_i}} \exp(s_{\boldsymbol{\theta}}(t'_j, \mathbf{c}_{s_i}))} \qquad (3)$$

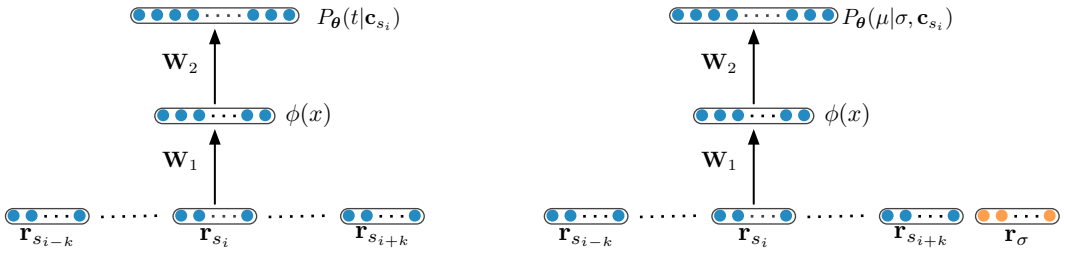
We use an additional set of word representations $\mathbf{q}_{t_j} \in \mathbb{R}^n$ for target translations t_j. The LBL model computes a predictive representation $\hat{\mathbf{q}}$ of a source context $\mathbf{c}_{s_i}$ by taking a linear combination of the source word representations $\mathbf{r}_{s_{i+m}}$ with the position-dependent weight matrices $\mathbf{C}_m \in \mathbb{R}^{n\times d}$:

$$\hat{\mathbf{q}} = \sum_{m=-k}^{k} \mathbf{C}_m \mathbf{r}_{s_{i+m}} \qquad (4)$$

The score function $s_{\boldsymbol{\theta}}(t_j, \mathbf{c}_{s_i})$ measures the similarity between the predictive representation $\hat{\mathbf{q}}$ and the target representation $\mathbf{q}_{t_j}$:

$$s_{\boldsymbol{\theta}}(t_j, \mathbf{c}_{s_i}) = \hat{\mathbf{q}}^\top \mathbf{q}_{t_j} + \mathbf{b}_h^\top \mathbf{q}_{t_j} + b_{t_j} \qquad (5)$$

[5] The source code of our models is available at `https://bitbucket.org/ketran`



(a) BNN for word prediction.

(b) BNN for suffix prediction.

Figure 2: Feed-forward BNN architectures for predicting target translations: (a) word model (similar to stem model), and (b) suffix model with an additional vector representation $\mathbf{r}_\sigma$ for target stems σ.

Here b_{t_j} is the bias term associated with target word t_j. $\mathbf{b}_h \in \mathbb{R}^n$ are the representation biases. $s_{\boldsymbol{\theta}}(t_j, \mathbf{c}_{s_i})$ can be seen as the negative energy function of the target translation t_j and its context $\mathbf{c}_{s_i}$. The parameters of the model thus are $\boldsymbol{\theta} = \{\mathbf{r}_{s_i}, \mathbf{C}_m, \mathbf{q}_{t_j}, \mathbf{b}_h, b_{t_j}\}$. Our log-bilinear model is a modification of the log-bilinear model proposed for n-gram language modeling in (Mnih and Hinton, 2007).

Convolutional neural network model. This model (Figure 3) computes the predictive representation $\hat{\mathbf{q}}$ by applying a sequence of $2k$ convolutional layers $\{\mathbf{L}_1, \ldots, \mathbf{L}_{2k}\}$. The source context $\mathbf{c}_{s_i}$ is represented as a matrix $\mathbf{m}_{c_{s_i}} \in \mathbb{R}^{d\times(2k+1)}$:

$$\mathbf{m}_{c_{s_i}} = \left[\mathbf{r}_{s_{i-k}}; \ldots; \mathbf{r}_{s_{i+k}}\right] \tag{6}$$

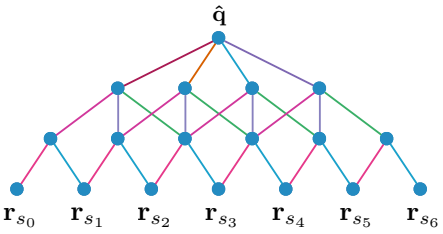


Figure 3: Convolutional neural network model. Edges with the same color indicate the same kernel weight matrix.

Each convolutional layer $\mathbf{L}_i$ consists of a one-dimensional filter $\mathbf{m}_i \in \mathbb{R}^{d\times 2}$. Each row of $\mathbf{m}_i$ is convolved with the corresponding row in the previous layer resulting in a weight matrix whose number of columns decreases by one. Thus after $2k$ convolutional layers, the network transforms the source context matrix $\mathbf{m}_{c_{s_i}}$ to a feature vector $\hat{\mathbf{q}} \in \mathbb{R}^d$. A fully connected layer with weight matrix $\mathbf{W}$ followed by a softmax layer are placed after the last convolutional layer $\mathbf{L}_{2k}$ to perform classification. The parameters of the convolutional neural network model are $\boldsymbol{\theta} = \{\mathbf{r}_{s_i}, \mathbf{m}_j, \mathbf{W}\}$. Here, we focus on a fixed length input, however convolutional neural networks may be used to model variable length input (Kalchbrenner et al., 2014; Kalchbrenner and Blunsom, 2013).

4.3 Training

In training, for each example $(t, \mathbf{c}_s)$, we maximize the conditional probability $P_{\boldsymbol{\theta}}(t|\mathbf{c}_s)$ of a correct target label t. The contribution of the training example $(t, \mathbf{c}_s)$ to the gradient of the log conditional probability is given by:

$$\frac{\partial}{\partial\boldsymbol{\theta}} \log P_{\boldsymbol{\theta}}(t|\mathbf{c}_s) = \frac{\partial}{\partial\boldsymbol{\theta}} s_{\boldsymbol{\theta}}(t|\mathbf{c}_s) - \sum_{t'\in T_s} P_{\boldsymbol{\theta}}(t'|\mathbf{c}_s) \frac{\partial}{\partial\boldsymbol{\theta}} s_{\boldsymbol{\theta}}(t', \mathbf{c}_s)$$

Note that in the gradient, we do not sum over all target translations T but a set of possible candidates T_s of a source word s. In practice $|T_s| \leq 200$ with our pruning settings (see Section 5.1), thus training time for one example does not depend on the vocabulary size. Our training criterion can be seen as a form of contrastive estimation (Smith and Eisner, 2005), however we explicitly move the probability mass from *competing* candidates to the correct translation candidate, thus obtaining more reliable estimates of the conditional probabilities.

The BNN parameters are initialized randomly according to a zero-mean Gaussian. We regularize the models with L_2. As an alternative to the L_2 regularizer, we also experiment with dropout (Hinton et al., 2012), where the neurons are randomly zeroed out with dropout rate p. This technique is known to be useful in computer vision tasks but has been rarely used in NLP tasks. In FFNN, we use dropout after the hidden layer, while in ConvNet, dropout applies after the last convolutional layer. The dropout rate p is set to 0.3 in our exper-

iments. We use rectified nonlinearities[6] in FFNN and after each convolutional layer in ConvNet. We train our BNN models with the standard stochastic gradient descent.

5 Evaluating word translation prediction

In this section, we assess the ability of our BNN models to predict the correct translation of a word in context. In addition to English-Russian, we also consider translation prediction for Czech and Bulgarian. As members of the Slavic language family, Czech and Bulgarian are also characterized by highly inflectional morphology. Czech, like Russian, displays a very rich nominal inflection with as many as 14 declension paradigms. Bulgarian, unlike Russian, is not affected by case distinctions but is characterized by a definiteness suffix.

5.1 Experimental setup

The following parallel corpora are used to train the BNN models:

- English-Russian: WMT13 data (News Commentary and Yandex corpora);
- English-Czech: CzEng 1.0 corpus (Bojar et al., 2012) (Web Pages and News sections);
- English-Bulgarian: a mix of crawled news data, TED talks and Europarl proceedings.

Detailed corpus statistics are given in Table 2. For each language pair, accuracies are measured on a held-out set of 10K parallel sentences.

To prepare the candidate generation function, each dataset is first word-aligned with GIZA++, then a bilingual lexicon with maximum-likelihood probabilities (P_{mle}) is built from the symmetrized alignment. After some frequency and significance pruning,[7] the top 200 translations sorted by $P_{\text{mle}}(t|s) \cdot P_{\text{mle}}(s|t)$ are kept as candidate word translations for each source word in the vocabulary. Word alignments are also used to train the BNN models: each alignment link constitutes a training sample, with no special treatment of unaligned words and 1-to-many alignments.

The context window size k is set to 3 (corresponding to 7-gram) and the dimensionality of source word representations to 100 in all experiments. The number of hidden units in our feedforward neural networks and the target translation embedding size in LBL models are set to 200. All models are trained for 10 iterations with learning rate set to 0.001.

	En-Ru	**En-Cs**	**En-Bg**
Sentences	1M	1M	0.8M
Src. tokens	26.5M	19.2M	19.3M

Trg. T/T	.0247	.0163	.0104

Table 2: BNN training corpora statistics: number of sentences, tokens, and type/token ratio (T/T).

5.2 Word, stem and suffix prediction accuracy

We measure accuracy at top-n, i. e. the number of times the correct translation was in the top n candidates sorted by a model. For each subtask—word, stem and suffix prediction—the BNN model is compared to the context-independent maximum-likelihood baseline $P_{\text{mle}}(t|s)$ on which the PSMT lexical weighting score is based. Note that this is a more realistic baseline than the uniform models sometimes reported in the literature. The oracle corresponds to the percentage of aligned source-target word pairs in the held-out set that are covered by the candidate generation function. Out of the missing links, about 4% is due to lexicon pruning. Results for all three language pairs are presented in Table 3. In this series of experiments, the morphological BNNs utilize unsupervised segmentation models trained on each target language following Lee et al. (2011).[8]

As shown in Table 3, the BNN models outperform the baseline by a large margin in all tasks and languages. In particular, word prediction accuracy at top-1 increases by +6.4%, +24.6% and +9.0% absolute in English-Russian, English-Czech and English-Bulgarian respectively, without the use of any features based on linguistic annotation. While the baseline and oracle differences among languages can be explained by different levels of overlap between training and held-out set, we cannot easily explain why the Czech BNN performance is so much higher. When comparing the

[6] We find that using rectified linear units gives better results than sigmoid and tanh.

[7] Each lexicon is pruned with minimum word frequency 5, minimum source-target word pair frequency 2, minimum log odds ratio 10.

[8] We use the C++ implementation available at `http://groups.csail.mit.edu/rbg/code/morphsyn`

Model	En-Ru	En-Cs	En-Bg
Word prediction (%):			
Baseline	33.0 / 50.1	42.0 / 59.9	47.9 / 66.0
Word BNN	39.4 / 56.6	66.6 / 81.4	56.9 / 74.0
	+6.4 / +6.5	+24.6/+21.5	+9.0 / +8.0
Oracle	79.5	90.2	86.9
Stem prediction (%):			
Baseline	40.7 / 58.2	46.1 / 64.3	51.9 / 70.1
Stem BNN	45.1 / 62.5	66.1 / 81.6	56.7 / 74.4
	+4.4 / +4.3	+20.0/+17.3	+4.8 / +4.3
Suffix prediction (%):			
Baseline	71.2 / 85.6	78.8 / 93.2	81.5 / 92.4
Suffix BNN	77.0 / 89.7	91.9 / 97.4	87.7 / 94.9
	+5.8 / +4.1	+13.1 /+4.2	+6.2 / +2.5

Table 3: BNN prediction accuracy (top-1/top-3) compared to a context-independent maximum-likelihood baseline.

three prediction subtasks, we find that word prediction is the hardest task as expected. Stem prediction accuracies are considerably higher than word prediction accuracies in Russian, but almost equal in the other two languages. Finally, baseline accuracies for suffix prediction are by far the highest, ranging between 71.2% and 81.5%, which is primarily explained by a smaller number of candidates to choose from. Also on this task, the BNN model achieves considerable gains of +5.8%, +13.1% and +6.2% at top-1, without the need of manual feature engineering.

From these figures, it is hard to predict whether word BNNs or morphological BNNs will have a better effect on SMT performance. On one hand, the word-level BNN achieves the highest gain over the MLE baseline. On the other, the stem- and suffix-level BNNs provide two separate scoring functions, whose weights can be directly tuned for translation quality. A preliminary answer to this question is given by the SMT experiments presented in Section 6.

5.3 Effect of word segmentation

This section analyzes the effect of using different segmentation techniques. We consider two supervised tagging methods that produce lemma and inflection tag for each token in a context-sensitive manner: TreeTagger (Sharoff et al., 2008) for Russian and the Morce tagger (Spoustová et al., 2007) for Czech.[9] Finally, we employ the Russian Snowball rule-based stemmer as a light-weight context-insensitive segmentation technique.[10]

[9] Annotation included in the CzEng 1.0 corpus release.

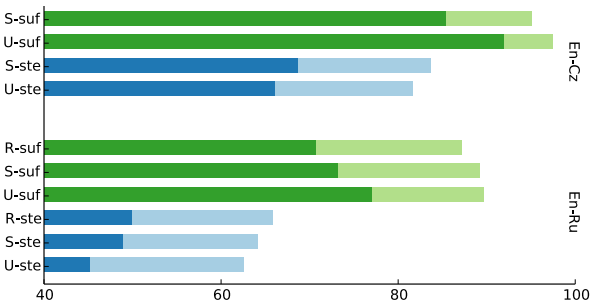

Figure 4: Effect of different word segmentation techniques (U: unsupervised, S: supervised, R: rule-based stemmer) on stem and suffix prediction accuracy. The dark part of each bar stands for top-1, the light one for top-3 accuracy.

As shown in Figure 4, accuracies for both stem and suffix prediction vary noticeably with the segmentation used. However, higher stem accuracies corresponds to lower suffix accuracies and vice versa, which can be mainly due to a general preference of a tool to segment more or less than another. In summary, the unsupervised segmentation methods and the light-weight stemmer appear to perform comparably to the supervised methods.

5.4 Effect of training data size

We examine the predictive power of our models with respect to the size of training data. Table 4 shows the accuracies of stem and suffix models trained on 200K and 1M English-Russian sentence pairs with unsupervised word segmentation. Surprisingly, we observe only a minor loss when we decrease the training data size, which suggests that our models are robust even on a small data set.

# Train sent.	Stem Acc.	Suffix Acc.
1M	45.1 / 62.5	77.0 / 89.7
200K	44.6 / 61.8	75.7 / 88.6

Table 4: Accuracy at top-1/top-3 (%) of stem and suffix BNNs with different training data sizes.

5.5 Fine-grained evaluation

We evaluate the suffix BNN model at the part-of-speech (POS) level. Table 5 provides suffix prediction accuracy per POS for En-Ru. For this analysis, Russian data is segmented by TreeTag-

[10] http://snowball.tartarus.org/algorithms/russian/stemmer.html

ger. Additionally, we report the average number of suffixes per stem given the part-of-speech.

Our results are consistent with the findings of Chahuneau et al. (2013):[11] the prediction of adjectives is more difficult than that of other POS while Russian verb prediction is relatively easier in spite of the higher number of suffixes per stem. These differences reflect the importance of source versus target context features in the prediction of the target inflection: For instance, adjectives agree in gender with the nouns they modify, but this may be only inferred from the target context.

POS	A	V	N	M	P
Acc. (%)	49.6	61.9	62.8	84.5	64.4
$\lvert M_\sigma \rvert$	18.2	18.4	9.2	7.1	13.3

Table 5: Suffix prediction accuracy at top-1 (%), breakdown by category (A: adjectives, V: verbs, N: nouns, M: numerals and P: pronouns). $|M_\sigma|$ denotes the average number of suffixes per stem.

5.6 Neural Network variants

Table 6 shows the stem and suffix accuracies of BNN variants on English-Czech. Although none of the variants outperform our main FFNN architecture, we observe similar performances by the LBL on stem prediction, and by the ConvNet on suffix prediction. This suggests that future work could exploit their additional flexibilities (see Section 4.2) to improve the BNN predictive power. As for the low suffix accuracy by the LBL, it can be explained by the absence of nonlinearity transformation. Nonlinearity is important for the suffix model where the prediction of target suffix μ_j often does not depend linearly on s_i and σ_j. The predictive representation of target stem in the LBL stem model, however, mainly depends on the source representation $\mathbf{r}_{s_i}$ through a position dependent weight matrix $\mathbf{C}_0$. Thus, we observe a smaller accuracy drop in the stem model than in the suffix model. Conversely, the ConvNet performs poorly on stem prediction because it captures the meaning of the whole source context instead of emphasizing the importance of the source word s_i as the main predictor of the target translation t_j.

[11] Chahuneau et al. (2013) report an average accuracy of 63.1% for the prediction of A, V, N, M suffixes. When we train our model on the same dataset (news-commentary) we obtain a comparable result (64.7% vs 63.1%).

Unexpectedly, no improvement is obtained by the use of dropout regularizer (see Section 4.3).

Model	Stem Acc	Suffix Acc
FFNN	66.1 / 81.6	91.9 / 97.4
FFNN+do	64.6 / 81.1	91.5 / 97.5
LBL	63.6 / 79.6	86.4 / 96.4
ConvNet+do	58.6 / 75.6	90.3 / 96.9

Table 6: Accuracies at top-1/top-3 (%) of stem and suffix models. +do indicates dropout instead of L_2 regularizer. FFNN is our main architecture.

6 SMT experiments

While the main objective of this paper is to improve prediction accuracy of word translations, see Section 5, we are also interested in knowing to which extent these improvements carry over within an end-to-end machine translation task. To this end, we integrate our translation prediction models described in Section 4 into our existing English-Russian SMT system.

For each phrase pair matching the input, the phrase BNN score $P_{\text{BNN-p}}$ is computed as follows:

$$P_{\text{BNN-p}}(\tilde{s}, \tilde{t}, a) = \prod_{i=1}^{|\tilde{s}|} \begin{cases} \frac{1}{|\{a_i\}|} \sum_{j \in \{a_i\}} P_{\text{BNN}}(t_j | \mathbf{c}_{s_i}) & \text{if } |\{a_i\}| > 0 \\ P_{\text{mle}}(\text{NULL} | s_i) & \text{otherwise} \end{cases}$$

where a is the word-level alignment of the phrase pair $(\tilde{s}, \tilde{t})$ and $\{a_i\}$ is the set of target positions aligned to s_i. If a source-target link cannot be scored by the BNN model, we give it a P_{BNN} probability of 1 and increment a separate count feature ε. Note that the same phrase pair can get different BNN scores if used in different source side contexts.

Our baseline is an in-house phrase-based (Koehn et al., 2003) statistical machine translation system very similar to Moses (Koehn et al., 2007). All system runs use hierarchical lexicalized reordering (Galley and Manning, 2008; Cherry et al., 2012), distinguishing between monotone, swap, and discontinuous reordering, all with respect to left-to-right and right-to-left decoding. Other features include linear distortion, bidirectional lexical weighting (Koehn et al., 2003), word and phrase penalties, and finally a word-level 5-gram target LM trained on all available monolingual data with modified Kneser-Ney smoothing (Chen and Goodman, 1999). The distortion

Corpus	Lang.	#Sent.	#Tok.

	RU		45.9M
Wiki dict.	EN/RU	508K	–
mono.train	RU	21.0M	390M
WMT2012	EN	3K	64K
WMT2013		3K	56K

Table 7: SMT training and test data statistics. All numbers refer to tokenized, lowercased data.

limit is set to 6 and for each source phrase the top 30 translation candidates are considered. When translating into a morphologically rich language, data sparsity issues in the target language become particularly apparent. To compensate for this we also experiment with a 5-gram suffix-based LM in addition to the surface-based LM (Müller et al., 2012; Bisazza and Monz, 2014).

The BNN models are integrated as additional log-probability feature functions ($\log P_{\text{BNN-p}}$): one feature for the word prediction model or two features for the stem and suffix models respectively, plus the penalty feature ε.

Table 7 shows the data used to train our English-Russian SMT system. The feature weights for all approaches were tuned by using pairwise ranking optimization (Hopkins and May, 2011) on the wmt12 benchmark (Callison-Burch et al., 2012). During tuning, 14 PRO parameter estimation runs are performed in parallel on different samples of the n-best list after each decoder iteration. The weights of the individual PRO runs are then averaged and passed on to the next decoding iteration. Performing weight estimation independently for a number of samples corrects for some of the instability that can be caused by individual samples. The wmt13 set (Bojar et al., 2013) was used for testing. We use approximate randomization (Noreen, 1989) to test for statistically significant differences between runs (Riezler and Maxwell, 2005).

Translation quality is measured with case-insensitive BLEU[%] using one reference translation. As shown in Table 8, statistically significant improvements over the respective baseline (Baseline and Base+suffLM) are marked ▲ at the $p < .01$ level. Integrating our bilingual neural network approach into our SMT system yields small but statistically significant improvements of 0.4 BLEU over a competitive baseline. We can also

SMT system	wmt12 (dev)	wmt13 (test)
Baseline	24.7	18.9
+ stem/suff. BNN	25.1	19.3▲
Base+suffLM	24.5	19.2
+ word BNN	24.5	19.3
+ stem/suff. BNN	24.7	19.6▲

Table 8: Effect of our BNN models on English-Russian translation quality (BLEU[%]).

see that it is beneficial to add a suffix-based language model to the baseline system. The biggest improvement is obtained by combining the suffix-based language model and our BNN approach, yielding 0.7 BLEU over a competitive, state-of-the-art baseline, of which 0.4 BLEU are due to our BNNs. Finally, one can see that the BNNs modeling stems and suffixes separately perform better than a BNN directly predicting fully inflected forms.

To better understand the BNN effect on the SMT system, we analyze the set of phrase pairs that are employed by the decoder to translate each sentence. This set is ranked by the weighted combination of phrase translation and lexical weighting scores, target language model score and, if available, phrase BNN scores. As shown in Table 9, the morphological BNN models have a positive effect on the decoder's lexical search space increasing the recall of reference tokens among the top 1 and 3 phrase translation candidates. The mean reciprocal rank (MRR) also improves from 0.655 to 0.662. Looking at the 1-best SMT output, we observe a slight increase of reference/output recall (50.0% to 50.7%), which is less than the increase we observe for the top 1 translation candidates (57.6% to 59.0%). One possible explanation is that the new, more accurate translation distributions are overruled by other SMT model scores,

Token recall (wmt12):	Baseline	+BNN
reference/MT-search-space [top-1]	57.6%	59.0%
reference/MT-search-space [top-3]	70.7%	70.9%
reference/MT-search-space [top-30]	86.0%	85.0%
reference/MT-search-space [MRR]	0.655	0.662
reference/MT-output	50.0%	50.7%
stem-only reference/MT-output	12.3%	11.5%
of which reachable	11.2%	10.3%

Table 9: Target word coverage analysis of the English-Russian SMT system before and after adding the morphological BNN models.

like the target LM, that are based on traditional maximum-likelihood estimates. While the suffix-based LMs proved beneficial in our experiments, we speculate that higher gains could be obtained by coupling our approach with a morphology-aware neural LM like the one recently presented by Botha and Blunsom (2014).

7 Related work

While most relevant literature has been discussed in earlier sections, the following approaches are particularly related to ours: Minkov et al. (2007) and Toutanova et al. (2008) address target inflection prediction with a log-linear model based on rich morphological and syntactic features. Their model exploits target context and is applied to inflect the output of a stem-based SMT system, whereas our models predict target words (or pairs of stem-suffix) independently and are integrated into decoding. Chahuneau et al. (2013) address the same problem with another feature-rich discriminative model that can be integrated in decoding, like ours, but they also use it to inflect on-the-fly stemmed phrases. It is not clear what part of their SMT improvements is due to the generation of new phrases or to better scoring. Jeong et al. (2010) predict surface word forms in context, similarly to our word BNN, and integrate the scores into the SMT system. Unlike us, they rely on linguistic feature-rich log-linear models to do that. Gimpel and Smith (2008) propose a similar approach to directly predict phrases in context, instead of words.

All those approaches employed features that capture the global structure of source sentences, like dependency relations. By contrast, our models access only local context in the source sentence but they achieve accuracy gains comparably to models that also use global sentence structure.

8 Conclusions

We have proposed a general approach to predict word translations in context using bilingual neural network architectures. Unlike previous NN approaches, we model word, stem and suffix distributions in the target language given context in the source language. Instead of relying on manually engineered features, our models automatically learn abstract word representations and features that are relevant for the modeled task directly from word-aligned parallel data. Our preliminary results with LBL and ConvNet architectures suggest that potential improvement may be achieved by factorizing target representations or by dynamically modeling source context size. Evaluated on three morphologically rich languages, our approach achieves considerable gains in word, stem and suffix accuracy over a context-independent maximum-likelihood baseline. Finally, we have shown that the proposed BNN models can be tightly integrated into a phrase-based SMT system, resulting in small but statistically significant BLEU improvement over a competitive, large-scale English-Russian baseline.

Our analysis shows that the number of correct target words occurring in highly scored phrase translation candidates increases after integrating the morphological BNNs. However, only few of these end up in the 1-best translation output. Future work will investigate the benefits of coupling our BNN models with target language models that also exploit abstract word representations, such as Botha and Blunsom (2014) and Auli et al. (2013).

Abstract

This paper presents a novel approach to improve reordering in phrase-based machine translation by using richer, syntactic representations of units of bilingual language models (BiLMs). Our method to include syntactic information is simple in implementation and requires minimal changes in the decoding algorithm. The approach is evaluated in a series of Arabic-English and Chinese-English translation experiments. The best models demonstrate significant improvements in BLEU and TER over the phrase-based baseline, as well as over the lexicalized BiLM by Niehues et al. (2011). Further improvements of up to 0.45 BLEU for Arabic-English and up to 0.59 BLEU for Chinese-English are obtained by combining our dependency BiLM with a lexicalized BiLM. An improvement of 0.98 BLEU is obtained for Chinese-English in the setting of an increased distortion limit.

1 Introduction

In statistical machine translation (SMT) reordering (also called distortion) refers to the order in which source words are translated to generate the translation in the target language. Word orders can differ significantly across languages. For instance, Arabic declarative sentences can be verb-initial, while the corresponding English translation should realize the verb after the subject, hence requiring a reordering. Determining the correct reordering during decoding is a major challenge for SMT. This problem has received a lot of attention in the literature (see, e.g., Tillmann (2004), Zens and Ney (2003), Al-Onaizan and Papineni (2006)), as choosing the correct reordering improves readability of the translation and can have a substantial impact on translation quality (Birch, 2011). In this paper, we only consider those approaches that include a reordering feature function into the log-linear interpolation used during decoding.

The simplest reordering model is linear distortion (Koehn et al., 2003) which scores the distance between phrases translated at steps t and $t+1$ of the derivation. This model ignores any contextual information, as the distance between translated phrases is its only parameter. Lexical distortion modeling (Tillmann, 2004) conditions reordering probabilities on the phrase pairs translated at the current and previous steps. Unlike linear distortion, it characterizes reordering not in terms of distance but type: monotone, swap, or discontinuous.

In this paper, we base our approach to reordering on bilingual language models (Marino et al., 2006; Niehues et al., 2011). Instead of directly characterizing reordering, they model sequences of elementary translation events as a Markov process.[1] Originally, Marino et al. (2006) used this kind of model as the translation model, while more recently it has been used as an additional model in PBSMT systems (Niehues et al., 2011). We adopt and generalize the approach of Niehues et al. (2011) to investigate several variations of bilingual language models. Our method consists of labeling elementary translation events (tokens of bilingual LMs) with their different contextual properties.

What kind of contextual information should be incorporated in a reordering model? Lexical information has been used by Tillmann (2004) but is known to suffer from data sparsity (Galley and Manning, 2008). Also previous contributions to bilingual language modeling (Marino et al., 2006; Niehues et al., 2011) have mostly used lexical information, although Crego and Yvon (2010a) and Crego and Yvon (2010b) label bilingual to-

[1] Note that the standard PBSMT translation model assumes that events of translating separate phrases in a sentence are independent.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1689–1700,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

kens with a rich set of POS tags. But in general, reordering is considered to be a syntactic phenomenon and thus the relevant features are syntactic (Fox, 2002; Cherry, 2008). Syntactic information is incorporated in tree-based approaches in SMT, allowing one to provide a more detailed definition of translation events and to redefine decoding as parsing of a source string (Liu et al., 2006; Huang et al., 2006; Marton and Resnik, 2008), of a target string (Shen et al., 2008), or both (Chiang, 2007; Chiang, 2010). Reordering is a result of a given derivation, and CYK-based decoding used in tree-based approaches is more syntax-aware than the simple PBSMT decoding algorithm. Although tree-based approaches potentially offer a more accurate model of translation, they are also a lot more complex and requiring more intricate optimization and estimation techniques (Huang and Mi, 2010).

Our idea is to keep the simplicity of PBSMT but move towards the expressiveness typical of tree-based models. We incrementally build up the syntactic representation of a translation during decoding by adding precomputed fragments from the source parse tree. The idea to combine the merits of the two SMT paradigms has been proposed before, where Huang and Mi (2010) introduce incremental decoding for a tree-based model. On a very general level, our approach is similar to theirs in that it keeps track of a sequence of source syntactic subtrees that are being translated at consecutive decoding steps. An important difference is that they keep track of whether the visited subtrees have been fully translated, while in our approach, once a syntactic structural unit has been added to the history, it is not updated anymore.

In this paper, we focus on source syntactic information. During decoding we have full access to the source sentence, which allows us to obtain a better syntactic analysis (than for a partial sentence) and to precompute the units that the model operates with. We investigate the following research questions: How well can we capture reordering regularities of a language pair by incorporating source syntactic parameters into the units of a bilingual language model? What kind of source syntactic parameters are necessary and sufficient?

Our contributions can be summarized as follows: We argue that the contextual information used in the original bilingual models (Niehues et al., 2011) is insufficient and introduce a simple model that exploits source-side syntax to improve reordering (Sections 2 and 3). We perform a thorough comparison between different variants of our general model and compare them to the original approach. We carry out translation experiments on multiple test sets, two language pairs (Arabic-English and Chinese-English), and with respect to two metrics (BLEU and TER). Finally, we present a preliminary analysis of the reorderings resulting from the proposed models (Section 4).

2 Motivation

In this section, we elaborate on our research questions and provide background for our approach. We also discuss existing bilingual n-gram models and argue that they are often not expressive enough to differentiate between alternative reorderings. We should first note that the most commonly used n-gram model to distinguish between reorderings is a target language model, which does not take translation correspondence into account and just models target-side fluency. Al-Onaizan and Papineni (2006) show that target language models by themselves are not sufficient to correctly characterize reordering. In what follows we only discuss bilingual models.

The word-aligned sentence pair in Figure 1.a[2] demonstrates a common Arabic-English reordering. As stated in the introduction, bilingual language models capture reordering regularities as a sequence of elementary translation events[3]. In the given example, one could decompose the sequential process of translation as follows: First translate the first word *Alwzyr* as *the minister*, then *ArjE* as *attributed*, then *ArtfAE* as *the increase* and so on. The sequence of elementary translation events is modeled as an n-gram model (Equation 1, where t_i is a translation event). There are numerous ways in which t_i can be defined. Below we first discuss how they have been defined within previous approaches, and then introduce our definition.

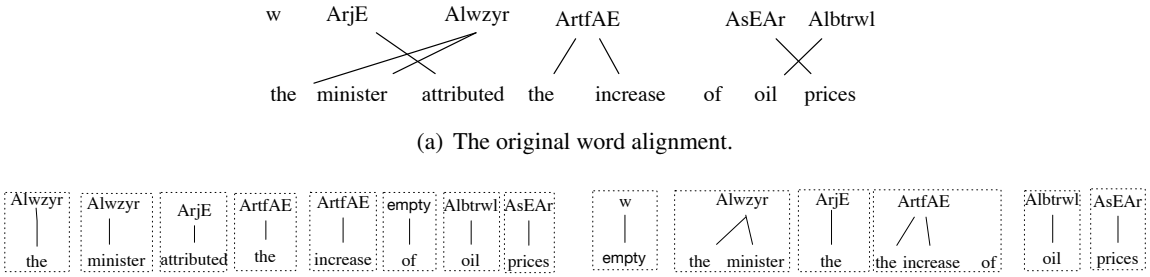
$$p(t_1, \ldots, t_m) = \prod_{i=1}^{m} p(t_i | t_{i-n+1} \ldots t_{i-1}) \quad (1)$$

2.1 Lexicalized bilingual LMs

By including both source and target information into the representation of translation events we ob-

[2]We used Buckwalter transliteration for Arabic words.

[3]By an *elementary* translation event we mean a translation of some substructure of a sentence.



(a) The original word alignment.

(b) BiLM tokens extracted from sentence (a).

(c) MTU tokens extracted from sentence (a).

Figure 1: Arabic-English parallel sentence, automatically word-aligned. The bilingual token sequences are produced according to two alternative definitions (BiLM and MTU).

tain a bilingual LM. The richer representation allows for a finer distinction between reorderings. For example, Arabic has a morphological marker of definiteness on both nouns and adjectives. If we first translate a definite adjective and then an indefinite noun, it will probably not be a likely sequence according to the translation model. This kind of intuition underlies the model of Niehues et al. (2011), a *bilingual LM* (BiLM), which defines elementary translation events $t_1, ..., t_n$ as follows:

$$t_i = \langle e_i, \{f | f \in A(e_i)\} \rangle, \quad (2)$$

where e_i is the i-th target word and $A : E \rightarrow \mathcal{P}(F)$ is an alignment function, E and F referring to target and source sentences, and $\mathcal{P}(\cdot)$ is the powerset function. In other words, the i-th translation event consists of the i-th target word and all source words aligned to it. Niehues et al. (2011) refer to the defined translation events t_i as *bilingual tokens* and we adopt this terminology.

There are alternative definitions of bilingual language models. Our choice of the above definition is supported by the fact that it produces an unambiguous segmentation of a parallel sentence into tokens. Ambiguous segmentation is undesirable because it increases the token vocabulary, and thus the model sparsity. Another disadvantage comes from the fact that we want to compare permutations of the same set of elements. For example, the two different segmentations of ba into $[ba]$ and $[b][a]$ still represent the same permutation of the sequence ab. In Figure 1 one can produce a segmentation of (*AsEAr Albtrwl*, *oil prices*) into (*Albtrwl*, *oil*) and (*AsEAr*, *prices*) or leave it as is. If we allow for both segmentations, the learnt probability parameters may be different for the sum of (*Albtrwl*, *oil*) and (*AsEAr*, *prices*) and for the unsegmented phrase.

Durrani et al. (2011) introduce an alternative method for unambiguous bilingual segmentation where tokens are defined as minimal phrases, called minimal translation units (MTUs). Figure 1 compares the BiLM and MTU tokenization for a specific example. Since Niehues et al. (2011) have shown their model to work successfully as an additional feature in combination with commonly used standard phrase-based features, we use their approach as the main point of reference and base our approach on their segmentation method. In the rest of the text we refer to Niehues et al. (2011) as the *original* BiLM.[4] At the same time, we do not see any specific obstacles for combining our work with MTUs.

2.2 Suitability of lexicalized BiLM to model reordering

As mentioned in the introduction, lexical information is not very well-suited to capture reordering regularities. Consider Figure 2.a. The extracted sequence of bilingual tokens is produced by aligning source words with respect to target words (so that they are in the same order), as demonstrated by the shaded part of the picture. If we substituted the Arabic translation of *Egyptian* for the Arabic translation of *Israeli*, the reordering should remain the same. What matters for reordering is the syntactic role or context of a word. By using unnecessarily fine-grained categories we risk running into sparsity issues.

Niehues et al. (2011) also described an alternative variant of the original BiLM, where words are substituted by their POS tags (Figure 2.a, shaded part). Also, however, POS information by itself may be insufficiently expressive to separate cor-

[4] Although, strictly speaking, it is not the original approach (see the references in Section 1).

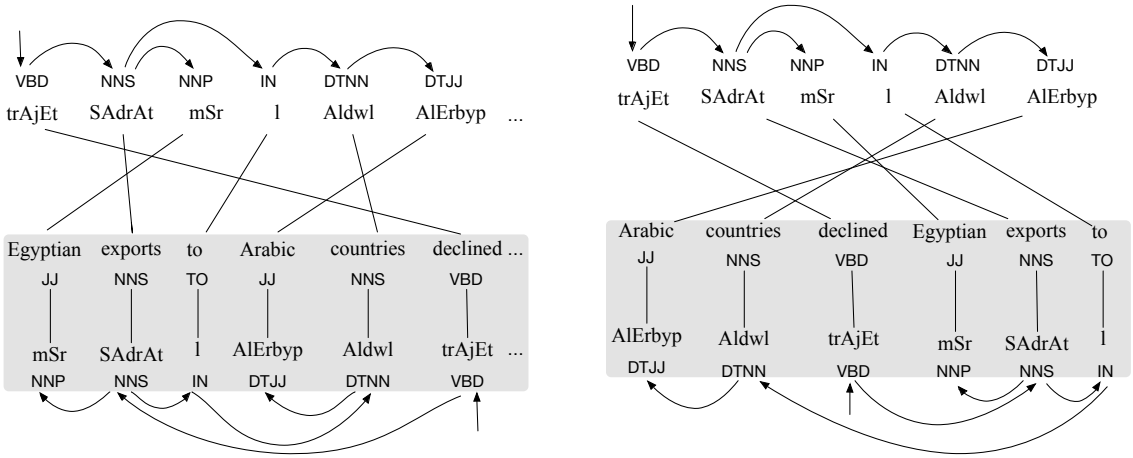


Figure 2: Arabic-English parallel sentence, automatically parsed and word-aligned, with corresponding sequences of bilingual tokens (in the shaded part). Comparison between translations produced via correct (a) and incorrect (b) reorderings.

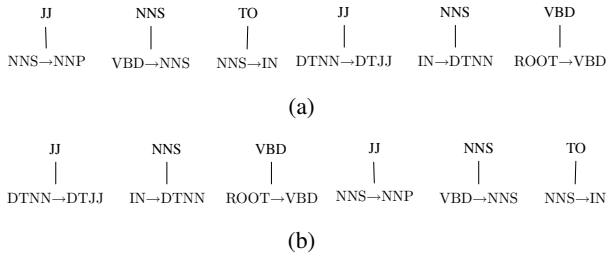

Figure 3: Sequences of bilingual tokens with source words substituted with their and their parents' POS tags: correct (a) and incorrect (b) reorderings.

rect and incorrect reorderings, see Figure 2.b. Although the corresponding sequence of POS-tag-substituted bilingual tokens is different from the correct sequence (Figure 2.b, shaded part), it still is a likely sequence. Indeed, the log-probabilities of the two sequences with respect to a 4-gram BiLM model[5] result in a higher probability of -10.25 for the incorrect reordering than for the correct one (-10.39).

Since fully lexicalized bilingual tokens suffer from data sparsity and POS-based bilingual tokens are insufficiently expressive, the question is which level of syntactic information strikes the right balance between expressiveness and generality.

[5]Section 4 contains details about data and software setup.

2.3 BiLM with dependency information

Dependency grammar is commonly used in NLP to formalize role-based relations between words. The intuitive notion of syntactic modification is captured by the primitive binary relation of dependence. Dependency relations do not change with the linear order of words (Figure 2) and therefore can provide a characterization of a word's syntactic class that invariant under reordering.

If we incorporate dependency relations into the representation of bilingual tokens, the incorrect reordering in Figure 2.b will produce a highly unlikely sequence. For example, we can substitute each source word with its POS tag and its parent's POS tag (Figure 3). Again, we computed 4-gram log-probabilities for the corresponding sequences: the correct reordering results in a substantially higher probability of -10.58 than the incorrect one (-13.48). We may consider situations where more fine-grained distinctions are required. In the next section, we explore different representations based on source dependency trees.

3 Dependency-based BiLM

In this section, we introduce our model which combines the BiLM from Niehues et al. (2011) with source dependency information. We further give details on how the proposed models are trained and integrated into a phrase-based decoder.

3.1 The general framework

In the previous section we outlined our framework as composed of two steps: First, a parallel sentence is tokenized according to the BiLM model (Niehues et al., 2011). Next, words in the bilingual tokens are substituted with their contextual properties. It is thus convenient to use the following generalized definition for a token sequence $t_1...t_n$ in our framework:

$$t_i = \langle ContE(e_i), \{ContF(f)|f \in A(e_i)\}\rangle, \quad (3)$$

where e_i is the i-th target word, $A : E \rightarrow \mathcal{P}(F)$ is an alignment function, F and E are source and target sentences, and $ContE$ and $ContF$ are target and source *contextual functions*, respectively. A contextual function returns a word's contextual property, based on its sentential context (source or target). See Figure 4 for an example of a sequence of BiLM tokens with a $ContF$ defined as returning the POS tag of the source word combined with the POS tags of its parent, grandparent and siblings, and $ContE$ defined as an identity function (see Section 3.2 for a detailed explanation of the functions and notation).

In this work we focus on source contextual functions ($ContF$). We also exploit some very simple target contextual functions, but do not go into an in-depth exploration.

3.2 Dependency-based contextual functions

In NLP approaches exploiting dependency structure, two kinds of relations are of special importance: the parent-child relation and the sibling relation. Shen et al. (2008) work with two well-formed dependency structures, both of which are defined in such a way that there is one common parent and a set of siblings. Li et al. (2012) characterize rules in hierarchical SMT by labeling them with the POS tags of the parents of the words inside the rule. Lerner and Petrov (2013) model reordering as a sequence of classification steps based on a dependency parse of a sentence. Their model first decides how a word is reordered with respect to its parent and then how it is reordered with respect to its siblings.

Based on these previous approaches, we propose to characterize contextual syntactic roles of a word in terms of POS tags of the words themselves and their relatives in a dependency tree. It is straightforward to incorporate parent information since each node has a unique parent. As for siblings information, we incorporate POS tags of the closest sibling to the left and the closest to the right. We do not include all of the siblings to avoid overfitting. In addition to these basic syntactic relations, we consider the grandparent relation.

The following list is a summary of the source contextual functions that we use. We describe a function with respect to the kind of contextual property of a word it returns: (i) the word itself (Lex); (ii) POS label of the word (Pos); (iii) POS label of the word's parent; (iv) POS of the word's closest sibling to the left, concatenated with the POS tag of the closest sibling to the right; (v) the POS label of the word's grandparent. We use target-side contextual functions returning: (i) an empty string, (ii) POS of the word, (iii) the word itself.

Notation. We do not use the above functions separately to define individual BiLM models, but use combinations of these functions. We use the following notation for function combinations: "•" horizontally connects source (on the left) and target (on the right) contextual functions for a given model. For example, Lex•Lex refers to the original (lexicalized) BiLM. We use arrows (→) to designate parental information (the arrow goes from parent to child). Pos→Pos refers to a combination of a function returning the POS of a word and the POS of its parent (as in Figure 3). Pos→Pos→Pos is a combination of the previous with the function returning the grandparent's POS. Finally, we use +sibl to indicate the use of the sibling function described above: For example, Pos→Pos+sibl is a source function that returns the word's POS, its parent's POS and the POS labels of the closest siblings to left and right.[6] Pos+sibl→Pos is a source function returning the word's own POS, the POS of a word's parent, and the POS tags of the parent's siblings (left- and right-adjacent).

Figure 4 represents the sentence from Figure 2 during decoding in a system with an integrated Pos→Pos→Pos+sibl•Lex feature. It shows the sequence of produced bilingual tokens and corresponding labels in the introduced notation.

3.3 Training

Training of dependency-based BiLMs consists of a sequence of extraction steps: After having produced word-alignments for a bitext (Section 4),

[6] In case there is no sibling on one of the sides, ϵ (empty word) is returned.

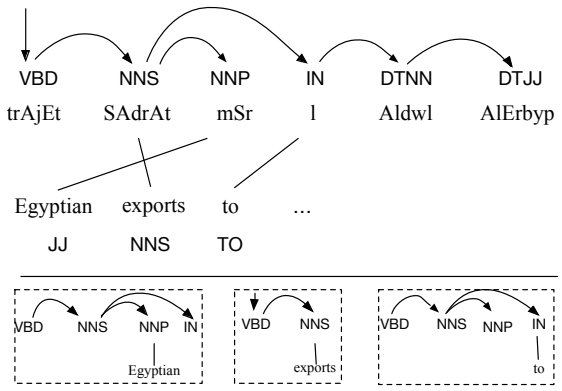

Figure 4: Sequence of bilingual tokens produced by a Pos→Pos→Pos+sibl•Lex after translating three words of the source sentence: VBD→NNS→ϵ+NNS+IN•Egyptian, ROOT→VBD→ϵ+NNS+ϵ•exports, VBD→NNS→NNP+IN+ϵ•to (if there is no sibling on either of the sides, ϵ is returned).

sentences are segmented according to Equation 3. We produce a dependency parse of a source sentence and a POS-tag labeling of a target sentence. For Chinese, we use the Stanford dependency parser (Chang et al., 2009). For Arabic a dependency parser is not available for public use, so we produce a constituency parse with the Stanford parser (Green and Manning, 2010) and extract dependencies based on the rules in Collins (1999). For English POS-tagging, we use the Stanford POS-tagger (Toutanova et al., 2003). After having produced a labeled sequence of tokens, we learn a 5-gram model using SRILM (Stolcke et al., 2011). Kneyser-Ney smoothing is used for all model variations except for Pos•Pos where Witten-Bell smoothing is used due to zero count-of-counts.

3.4 Decoder integration

Dependency-based BiLMs are integrated into our phrase-based SMT decoder as follows: Before translating a sentence, we produce its dependency parse. Phrase-internal word-alignments, needed to segment the translation hypothesis into tokens, are stored in the phrase table, based on the most frequent internal alignment observed during training. Likewise, we store the most likely target-side POS-labeling for each phrase pair.

The decoding algorithm is augmented with one additional feature function and one additional, corresponding feature weight. At each step of the derivation, as a new phrase pair is added to the partial translation hypothesis, this function segments the new phrase into bilingual tokens (given the internal alignment information) and substitutes the words in the phrase pair with syntactic labels (given the source parse and the target POS labeling associated with the phrase). The new syntactified bilingual tokens are added to the stack of preceding $n-1$ tokens, and the feature function computes the weighted updated model probability. During decoding, the probabilities of the BiLMs are computed in a stream-based fashion, with bilingual tokens as string tokens, and not in a class-based fashion, with syntactic source-side representations emitting the corresponding target words (Bisazza and Monz, 2014).

Training set	N. of lines	N. of tokens
Source side of Ar-En set	4,376,320	148M
Target side of Ar-En set	4,376,320	146M
Source side of Ch-En set	2,104,652	20M
Target side of Ch-En set	2,104,652	28M

Table 1: Training data for Arabic-English and Chinese-English experiments.

4 Experiments

4.1 Setup

We conduct translation experiments with a baseline PBSMT system with additionally one of the dependency-based BiLM feature functions specified in Section 3. We compare the translation performance to a baseline PBSMT system and to a baseline augmented with the original BiLMs from (Niehues et al., 2011).

Word-alignment is produced with GIZA++ (Och and Ney, 2003). We use an in-house implementation of a PBSMT system similar to Moses (Koehn et al., 2007). Our baseline contains all standard PBSMT features including language model, lexical weighting, and lexicalized reordering. The distortion limit is set to 5. A 5-gram LM is trained on the English Gigaword corpus (1.6B tokens) using SRILM with modified Kneyser-Ney smoothing and interpolation. The BiLMs were trained as described in Section 3.3. Information about the parallel data used for training the Arabic-English[7] and Chinese-English systems[8] is

[7]The following Arabic-English parallel corpora were used: LDC2006E25, LDC2004T18, several gale corpora, LDC2004T17, LDC2005E46, LDC2007T08, LDC2004E13.

[8]The following Chinese-English parallel corpora were used: LDC2002E18, LDC2002L27, LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10, LDC2005T34,

shown in Table 1.

The feature weights were tuned by using pairwise ranking optimization (Hopkins and May, 2011) on the MT04 benchmark (for both language pairs). During tuning, 14 PRO parameter estimation runs are performed in parallel on different samples of the n-best list after each decoder iteration. The weights of the individual PRO runs are then averaged and passed on to the next decoding iteration. Performing weight estimation independently for a number of samples corrects for some of the instability that can be caused by individual samples. For testing, we used MT08 and MT09 for Arabic, and MT06 and MT08 for Chinese. We use approximate randomization (Noreen, 1989; Riezler and Maxwell, 2005) to test for statistically significant differences.

In the next two subsections we discuss the general results for Arabic and Chinese, where we use case-insensitive BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) as evaluation metrics. This is followed by a preliminary analysis of observed reorderings where we compare 4-gram precision results and conduct experiments with an increased distortion limit.

4.2 Arabic-English translation experiments

We are interested in how a translation system with an integrated dependency-based BiLM feature performs as compared to the standard PBSMT baseline and, more importantly, to the original BiLM model. We consider two variants of BiLM discussed by Niehues et al. (2011): the standard one, Lex•Lex, and the simplest syntactic one, Pos•Pos. Results for the experiments can be found in Table 2. In the discussion below we mostly focus on the experimental results for the large, combined test set MT08+MT09.

Table 2.a–b compares the performance of the baseline and original BiLM systems. Lex•Lex yields strongly significant improvements over the baseline for BLEU and weakly significant improvements for TER. Therefore, for the rest of the experiments we are interested in obtaining further improvements over Lex•Lex.

Pos→Pos•Pos (Table 2.c) demonstrates the effect of adding minimal dependency information to a BiLM.[9] It results in strongly significant improvements over the baseline and weak improvements over Lex•Lex in terms of BLEU. We additionally ran experiments with the different target functions (Table 3). •Pos shows the highest results, and •ϵ the lowest ones: this implies that a rather expressive source syntactic representation alone still benefits from target-side syntactic information. Below, our dependency-based systems only use •Pos.

Next, we tested the effect of adding more source

and several gale corpora.

[9] Additional significance testing, which is not shown in Table 2, shows a strongly significant improvement over the original syntactic BiLM Pos•Pos.

Pos→Pos•Lex	$32.69^{\blacktriangle,-}$	$57.03^{\blacktriangle,\triangle}$	25.72	$60.17^{\blacktriangle,-}$	$29.52^{\blacktriangle,-}$	$58.49^{\blacktriangle,\triangle}$

Table 5: Different combinations of a target contextual function with the Pos→Pos source contextual function for Chinese-English. See Table 2 for the notation regarding statistical significance.

dependency information. Pos→Pos+sibl•Pos (Table 2.d) only improves over the PBSMT baseline (but also shows weak improvements over Lex•Lex for TER). It significantly degrades the performance with respect to the Pos→Pos•Pos system (Table 2.c). Pos→Pos→Pos•Pos (Table 2.e) shows the best results overall for BLEU, although it must be pointed out that the difference with Pos→Pos•Pos is very small. With respect to TER, Pos→Pos•Pos outperforms the grandparent variant.

So far, we can conclude that source parent information helps improve translation performance. Increased specificity of a parent (parent specified by a grandparent) tends to further improve performance. Up to now, we have only used syntactic information and obtained considerable improvements over Pos•Pos, surpassing the improvement provided by Lex•Lex. Can we gain further improvements by also adding lexical information? To this end, we conduct experiments combining the best performing dependency-based BiLM (Pos→Pos→Pos•Pos) and the lexicalized BiLM (Lex•Lex). We hypothesize that the two models improve different aspects of translation: Lex•Lex is biased towards improving lexical choice and Pos→Pos→Pos•Pos towards improving reordering. Combining these two models, we may improve both aspects. The metric results for the combined set indeed support this hypothesis (Table 2.f).

4.3 Chinese-English translation experiments

The results of the Chinese-English experiments are shown in Table 4. In the discussion below we mostly focus on the experimental results for the large, combined test set MT06+MT08. We observe the same general pattern for the Pos→Pos source function (Table 4.c) as for Arabic-English: the system with the •Pos target function has the highest scores (Table 5). All of the Pos→Pos• configurations show statistically significant improvements over the PBSMT baseline. For TER, two of the three Pos→Pos• variants significantly outperform Lex•Lex. The system with sibling information (Table 4.d) obtains quite low BLEU results, just as in the Arabic experiments. On the other hand, its TER results are the highest overall. The system with the Pos→Pos→Pos•Pos function (Table 4.e) achieves the best results among dependency-based BiLMs for BLEU. Finally, combining Pos→Pos→Pos•Pos and Lex•Lex results in the largest and significant improvements over all competing systems for BLEU.

4.4 Preliminary analysis of reordering in translation experiments

In general, the experimental results show that using source dependency information yields consistent improvements for translating from Arabic and Chinese into English. On the other hand, we have pointed out some discrepancies between the two metrics employed, suggesting that different system configurations may improve different aspects

of translation. To this end, we conducted some additional evaluations to understand how reordering is affected by the proposed features.

We use 4-gram precision as a metric of how much of the reference set word order is preserved. Table 6 shows the corresponding results for both languages. Just as in the previous two sections, configurations with parental information produce the best results. For Arabic, all of the dependency configurations outperform Lex•Lex. But the system with two feature functions, one of which is Lex•Lex, still obtains the best results, which may suggest that the lexicalized BiLM also helps to differentiate between word orders. For Chinese, Pos→Pos→Pos•Pos and the system combining the latter and Lex•Lex also obtain the best results. However, other dependency-based configurations do not outperform Lex•Lex.

All the experiments so far were run with a distortion limit of 5. But both of the languages, especially Chinese, often require reorderings over a longer distance. We performed additional experiments with a distortion limit of 10 for the Lex•Lex and Pos→Pos→Pos•Pos systems (Tables 7 and 8). It is more difficult to translate with a higher distortion limit (Green et al., 2010) as the set of permutations grows larger thereby making it more difficult to differentiate between correct and incorrect continuations of the current hypothesis. It has also been noted that higher distortion limits are more likely to result in improvements for Chinese rather than Arabic to English translation (Chiang, 2007; Green et al., 2010).

We compared performance of fixed BiLM models at distortion lengths of 5 and 10. Arabic-English results did not reveal statistically significant differences between the two distortion limits for Pos→Pos→Pos•Pos. On the other hand, for Lex•Lex BLEU decreases when using a distortion limit of 10 compared to a limit of 5. This implies that the dependency BiLM is more robust in the more challenging reordering setting than the lexicalized BiLM. Chinese-English results for Pos→Pos→Pos•Pos do show significant improvements over the distortion limit of 5 (up to 0.49 BLEU higher than the best result in Table 4). This indicates that the dependency-based BiLM is better capable to take advantage of the increased distortion limit and discriminate between correct and incorrect reordering choices.

Comparing the results for Pos→Pos→Pos•Pos and Lex•Lex at a distortion limit of 10, we obtain strongly significant improvements for all metrics. For Chinese, a larger distortion limit helps for both configurations, but more so for our dependency BiLM, yielding an improvement of 0.98 BLEU

over the original, lexicalized BiLM (Table 8).

5 Conclusions

In this paper, we have introduced a simple, yet effective way to include syntactic information into phrase-based SMT. Our method consists of enriching the representation of units of a bilingual language model (BiLM). We argued that the very limited contextual information used in the original bilingual models (Niehues et al., 2011) can capture reorderings only to a limited degree and proposed a method to incorporate information from a source dependency tree in bilingual units. In a series of translation experiments we performed a thorough comparison between various syntactically-enriched BiLMs and competing models. The results demonstrated that adding syntactic information from a source dependency tree to the representations of bilingual tokens in an n-gram model can yield statistically significant improvements over the competing systems.

A number of additional evaluations provided an indication for better modeling of reordering phenomena. The proposed dependency-based BiLMs resulted in an increase in 4-gram precision and provided further significant improvements over all considered metrics in experiments with an increased distortion limit.

In this paper, we have focused on rather elementary dependency relations, which we are planning to expand on in future work. Our current approach is still strictly tied to the number of target tokens. In particular, we are interested in exploring ways to better capture the notion of syntactic cohesion in translation (Fox, 2002; Cherry, 2008) within our framework.

Abstract

Automatically compiling bilingual dictionaries of technical terms from comparable corpora is a challenging problem, yet with many potential applications. In this paper, we exploit two independent observations about term translations: (a) terms are often formed by corresponding sub-lexical units across languages and (b) a term and its translation tend to appear in similar lexical context. Based on the first observation, we develop a new character n-gram compositional method, a logistic regression classifier, for learning a string similarity measure of term translations. According to the second observation, we use an existing context-based approach. For evaluation, we investigate the performance of compositional and context-based methods on: (a) similar and unrelated languages, (b) corpora of different degree of comparability and (c) the translation of frequent and rare terms. Finally, we combine the two translation clues, namely string and contextual similarity, in a linear model and we show substantial improvements over the two translation signals.

1 Introduction

Bilingual dictionaries of technical terms are resources useful for various tasks, such as computer-aided human translation (Dagan and Church, 1994; Fung and McKeown, 1997), *Statistical Machine Translation* (Och and Ney, 2003) and *Cross-Language Information Retrieval* (Ballesteros and Croft, 1997). In the last two decades, researchers have focused on automatically compiling bilingual term dictionaries either from *parallel* (Smadja et al., 1996; Van der Eijk, 1993) or *comparable* corpora (Rapp, 1999; Fung and Yee, 1998). While parallel corpora contain the same sentences in two languages, comparable corpora consist of bilingual pieces of text that share some features, only, such as topic, domain, or time period. Comparable corpora can be constructed more easily than parallel corpora. Freely available, up-to-date, on-line resources (e.g., Wikipedia) can be employed.

In this paper, we exploit two different sources of information to extract bilingual terminology from comparable corpora: the *compositional* and the *contextual clue*. The *compositional clue* is the hypothesis that the representations of a term in any pair of languages tend to consist of corresponding lexical or sub-lexical units, e.g., prefixes, suffices and morphemes. In order to capture associations of textual units across languages, we investigate three different character n-gram approaches, namely a *Random Forest* (RF) classifier (Kontonatsios et al., 2014), *Support Vector Machines* with an RBF kernel (SVM-RBF) and a *Logistic Regression* (LogReg) classifier. Whilst the previous approaches take as an input monolingual features and then try to find cross-lingual mappings, our proposed method (LogReg classifier) considers multilingual features, i.e., tuples of co-occurring n-grams.

The *contextual* clue is the hypothesis that mutual translations of a term tend to occur in similar lexical context. Context-based approaches are unsupervised methods that compare the context distributions of a source and a target term. A bilingual seed dictionary is used to map context vector dimensions of two languages. Li and Gaussier (2010) suggested that the seed dictionary can be used to estimate the degree of comparability of a bilingual corpus. Given a seed dictionary, the *corpus comparability* is the expectation of finding for each word of the source corpus, its translation in the target part of the corpus. The performance of context-based methods has been shown to depend on the frequency of terms to be translated and the

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

corpus comparability. In this work, we use an existing distributional semantics approach to locate term translations.

Furthermore, we hypothesise that the compositional and contextual clue are orthogonal, since the former considers the internal structure of terms while the latter exploits the surrounding lexical context. Based on the above hypothesis, we combine the two translation clues in a linear model.

For experimentation, we construct comparable corpora for four language pairs (English-Spanish, English-French, English-Greek and English-Japanese) of the biomedical domain.

We choose this domain because a large proportion of the medical terms tends to compositionally translate across languages (Lovis et al., 1997; Namer and Baud, 2007). Additionally, given the vast amount of newly introduced terms (neologisms) in the medical domain (Pustejovsky et al., 2001), term alignment methods are needed in order to automatically update existing resources.

We investigate the following aspects of term alignment: (a) the performance of compositional methods on closely related and on distant languages, (b) the performance of context vectors and compositional methods when translating frequent or rare terms, (c) the degree to which the corpus comparability affects the performance of context-based and compositional methods (d) the improvements that we can achieve when we combine the compositional and context clue.

Our experiments show that the performance of compositional methods largely depends on the distance between the two languages. The performance of the context-based approach is greatly affected by corpus-specific parameters (the frequency of occurrence of the terms to be translated and the degree of corpora comparability). It is also shown that the combination of compositional and contextual methods performs better than each of the clues, separately. Combined systems can be deployed in application environments with different language pairs, comparable corpora and seeds dictionaries.

The LogReg, dictionary extraction method described in this paper is freely available [1].

2 Related Work

Context-based methods (Fung and Yee, 1998; Rapp, 1999) adapt the *Distributional Hypothesis* (Harris, 1954), i.e., words that occur in similar lexical context tend to have the same meaning, in a multilingual environment. They represent the context of each term t as a context vector, usually following the *bag-of-words* model. Each dimension of the vector corresponds to a context word occurring within a predefined window, while the corresponding value is computed by a correlation metric, e.g., Log-Likelihood Ratio (Morin et al., 2007; Chiao and Zweigenbaum, 2002) or Point-wise Mutual Information (Andrade et al., 2010). A general bilingual dictionary is then used to translate/project the target context vectors into the source language. As a result, the source and target context vectors become directly comparable. In a final step, candidate translations are being ranked according to a distance metric, e.g., cosine similarity (Tamura et al., 2012) or Jaccard index (Zanzotto et al., 2010; Apidianaki et al., 2012).

Whilst context-based methods have become a common practise for bilingual dictionary extraction from comparable corpora, nonetheless, their performance is subject to various factors, one of which is the quality of the comparable corpus. Li and Gaussier (2010) introduced the corpus comparability metric and showed that it is related to the performance of context vectors. The higher the corpus comparability is, the higher the performance of context vectors is. Furthermore, context vector approaches are sensitive to the frequency of terms. For frequent terms, distributional semantics methods exhibit robust performance since the corresponding context is more informative. Chiao and Zweigenbaum (2002) reported an accuracy of 91% for the top 20 candidates when translating terms that occur 100 times or more. However, the performance of context vectors drastically decreases for lower frequency terms (Kontonatsios et al., 2014; Morin and Daille, 2010).

Our work is more closely related to a second class of term alignment methods that exploits the internal structure of terms between a source and a target language. Compositional translation algorithms are based on the *principal of compositionality* (Keenan and Faltz, 1985), which claims that the translation of the whole is a function of the translation of its parts. Lexical (Morin and Daille, 2010; Daille, 2012; Robitaille et al., 2006;

Tanaka, 2002) and sub-lexical (Delpech et al., 2012) compositional algorithms are knowledge-rich approaches that proceed in two steps, namely generation and selection. In the generation step, an input source term is segmented into basic translation units: words (lexical compositional methods) or morphemes (sub-lexical methods). Then a pre-compiled, seed dictionary of words or morphemes is used to translate the components of the source term. Finally, a permutation function generates candidate translations using the list of the translated segments. In the selection step, candidate translations are ranked according to their frequency (Morin and Daille, 2010; Robitaille et al., 2006) or their context similarity with the source term (Tanaka, 2002). The performance of the compositional translation algorithms is bound to the coverage of the seed dictionary (Daille, 2012). Delpech et al. (2012) noted that 30% of untranslated terms were due to the low coverage of the seed dictionary.

Kontonatsios et al. (2014) introduced a Random Forest (RF) classifier that learns correspondences of character n-grams between a source and target language. Unlike lexical and sub-lexical compositional methods, a RF classifier does not require a bilingual dictionary of translation units. The model is able to automatically build correlation paths between source and target sub-lexical segments that best discriminate translation from non-translation pairs. However, being a supervised method, it still requires a seed bilingual dictionary of technical terms for training. The RF classifier was previously applied on an English-Spanish comparable corpus and it was shown to significantly outperform context-based approaches.

3 Methods

In this section we describe the character n-gram models, the context vector method and the hybrid system. The lexicon induction task is formalised as a two-class classification problem. Given a pair of terms in a source and a target language, the output is a prediction of whether the terms are mutual translations are not. Furthermore, each term alignment method implements a ranking function that calculates a similarity score between a source and a target term. The methods rank target terms according to the similarity score and select the top N ranked terms as candidate translations. The ranking functions will be discussed in the following subsections.

3.1 Character n-gram models

Let s be a source term containing p character n-grams (s=$\{s_1, s_2, ..., s_p\}$ $s_i \in S$, $\forall i \in [1, p]$) and t a target term of q n-grams (t=$\{t_1, t_2, ..., t_q\}$ $t_i \in T$, $\forall i \in [1, q]$). We extract character n-grams by considering any contiguous, non-linguistically motivated sequence of characters that occurs within a window size of $[2-5]$ [2]) for English, French and Greek. For Japanese, unigrams are included (window size of $[1-5]$ because Japanese terms often contain Kanji (Chinese) characters.

Given the two lists of source and target n-grams, our objective is to find an underlying relationship between S and T that best discriminates translation from non-translation pairs. The RF classifier was previously shown to exhibit such behaviour (Kontonatsios et al., 2014). An RF classifier (Breiman, 2001) is a collection of decision trees voting for the most popular class. For a pair of source and target terms $\langle s, t \rangle$, the RF method creates feature vectors of a fixed size $2r$, i.e., *first order* feature space. The first r features are extracted from the source term, while the last r features from the target term. Each feature has a boolean value (0 or 1) that designates the presence/absence of the corresponding n-gram in the input instance.

The ability of the RF to detect latent associations between S and T relies on the decision trees. The internal nodes of a decision tree represent the n-gram features that are linked together in the tree-hierarchy. Each leaf node of the trees is labelled as *translation* or *non-translation* indicating whether the parent path of n-gram features is positively or negatively associated. The classification margin that we use to rank the candidate translations is given by a margin function (Breiman, 2001):

$$mg(X, Y) = av(I(x) = 1) - av(I(x)) = 0) \quad (1)$$

where x is an instance $\langle s, t \rangle$, $y \in Y = \{0, 1\}$ the class label, $I(\cdot) : (s, t) \longrightarrow \{0, 1\}$ is the indicator function of a decision tree and $av(I(\cdot))$ the average number of trees voting for the same class label. In our experiments, we used the same settings as the ones reported in Kontonatsios et al. (2014).

[2] we have experiments with larger and narrower window sizes but this setting resulted in better translation accuracy

We used 140 decision trees and $\log_2 |2q| + 1$ random features. For training an RF model, we used the WEKA platform (Hall et al., 2009).

The second class of machine learning algorithms that we investigate is Support Vector Machines (SVMs). The simplest version of SVMs is a linear classifier (linear-SVM) that tries to place a hyperplane, a decision boundary, that separates translation from non-translation instances. A linear-SVM is a feature agnostic method since the model only exploits the position of the vectors in the hyperspace to achieve class separation (Hastie et al., 2009).

The first order feature representation used with the RF classifier does not model associations between S and T. Hence, intuitively, a first order feature space is not linearly separable, i.e., there exists no decision boundary that divides the data points into translations and non-translations. [3]. To solve non-linear classification problems, SVMs employ non-linear kernels. A kernel function projects input instances into a higher dimensional space to discover non-linear associations between the initial features. In this new, projected feature space, the SVM attempts to define a separating plane. For training an non-linear SVM on the first order feature space, we used the LIBSVM package (Chang and Lin, 2011) with a *radial basis function* (RBF) kernel. For ranking candidate translations, we used the decision value given by LIBSVM which represents the distance between an instance and the hyperplane. To translate a source term, the method ranks candidate translations by decision value and suggests as best translation the candidate with the maximum distance (*maximum margin*).

While the first order models try to find cross-lingual mappings between monolingual features, our proposed method follows a different approach. It models cross-lingual links between the source and target character n-grams and uses them as *second order* features to train a linear classifier. A second order feature is a tuple of n-grams in S and T, respectively, that co-occur in a training, translation instance. Second order feature values are boolean. Given a translation instance $\langle s, t \rangle$ of p source and q target n-grams, there are $p \times q$ second order features. For dimensionality reduction, we consider as second order features the most frequent out of all possible first order feature combinations, only. Experiments indicate that a large number of features needs to be considered to achieve robust performance. To cope with the high dimensional second order space, we use LIBLINEAR (Fan et al., 2008), which is designed to solve large-scale, linear classifications problems. LIBLINEAR implements two linear classification algorithms: LogReg and linear-SVM. Both models solve the same optimisation problem, i.e., determine the optimal separating plane, but they adopt different loss functions. Since LIBLINEAR does not support decision value estimations for the linear-SVM, we only experimented with LogReg. Similarly to SVM-RBF, LogReg ranks candidate translations by classification margin.

3.2 Context vectors

We follow a standard approach to calculate context similarity of source and target terms (Rapp, 1999; Morin and Daille, 2010; Morin and Prochasson, 2011a; Delpech et al., 2012). Context vectors of candidate terms in the source and target language are populated after normalising each bilingual corpus, separately. Normalisation consists of stop-word filtering, tokenisation, lemmatisation and Part-of-Speech (PoS) tagging. For English, Spanish and French we used the TreeTagger (Schmid, 1994) while for Greek we used the ILSP toolkit (Papageorgiou et al., 2000). The Japanese corpus was segmented and PoS-tagged using Juman (Kurohashi and Kawahara, 2005).

In succession, monolingual context vectors are compiled by considering all lexical units that occur within a window of 3 words before or after a term (a seven-word window). Only lexical units (seeds) that occur in a bilingual dictionary are retained The values in context vectors are Log-Likelihood Ratio associations (Dunning, 1993) of the term and a seed lexical unit occurring in it. In a second step, we use the translations in the seed dictionary to map target context vectors into the source vector space. If there are several translations for a term, they are all considered with equal weights. Finally, candidate translations are ranked in descending order of the cosine of the angle between the mapped target vectors and the source

[3] We applied a linear-SVM with the first order feature representation on the four comparable corpora for English-French, English-Spanish, English-Greek and English-Japanese. In all cases, the best accuracies achieved were close to zero. Additionally, the ranked list of candidate translations was the same for all source terms. Hence, we can empirically suggest that the linear-SVM cannot exploit a first order feature space.

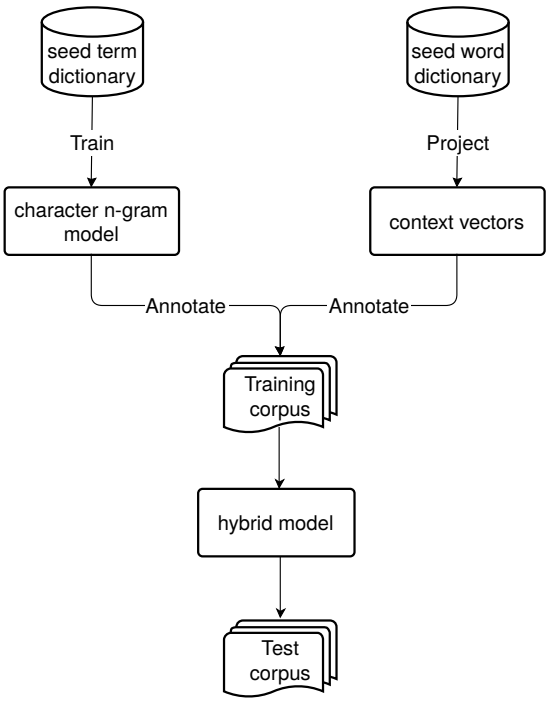

Figure 1: Architecture of the hybrid term alignment system.

vector.

3.3 Hybrid term alignment system

Figure 1 illustrates a block diagram of our term alignment system. We use two bilingual seed dictionaries: (a) a dictionary of term translation pairs to train the n-gram models and (b) a dictionary of word-to-word correspondences to translate target context vectors. The n-gram and context vector methods are used separately to score term pairs. The n-gram model computes the value of the *compositional clue* while the context vector estimates the score of the *contextual clue*. The hybrid model combines both methods by using the corresponding scores as features to train a linear classifier. For this, we used a linear-SVM of the LIBSVM package with default values for all parameters.

4 Data

Following previous research (Prochasson and Fung, 2011; Irvine and Callison-Burch, 2013; Klementiev et al., 2012), we construct comparable biomedical corpora using Wikipedia as a freely available resource.

Starting with a list of 4K biomedical English terms (query-terms), we collected 4K English Wikipedia articles, by matching query-terms to the topic signatures of articles. Then, we followed the Wikipedia interlingual links to retrieve thematically related articles in each target language. Since not all English articles contain links for all four target languages (Spanish, French, Greek and Japanese), we used a different list of query-terms for each language pair. Corpora were randomly divided into training and testing parts. For training we used 3K documents and for testing the remaining 1K. Table 1 shows the size of corpora in terms of numbers of source (SW) and target words (TW).

4.1 Seed dictionaries

As shown in Figure 1, the term alignment methods require two seed bilingual dictionaries: a term and a word dictionary. The character n-gram models rely on a bilingual term dictionary to learn associations of n-grams that appear often in technical terms. The dictionary may contain both single-word and multi-word terms. For English-Spanish and English-French we used UMLS (Bodenreider, 2004) while for English-Japanese we used an electronic dictionary of medical terms (Denshika and Kenkyukai, 1991).

An English-Greek biomedical dictionary was not available at the time of conducting these experiments, thus we automatically compiled a dictionary from a parallel corpus. For this, we trained a standard Statistical Machine Translation system (Koehn et al., 2007) on *EMEA* (Tiedemann, 2009), a biomedical parallel corpus containing sentence-aligned documents from the European Medicines Agency. Then, we extracted all English-Greek pairs for which: (a) the English sequence was listed in UMLS and (b) the translation probability was equal or higher to 0.7.

The sizes of the seed term dictionaries vary significantly, e.g., 500K entries for English-French but only 20K entries for English-Greek. However, the character n-gram models require a relatively small portion of the corresponding dictionary to converge. In the reported experiments, we used 10K translation pairs as positive, training instances. In addition, we generated an equal number of *pseudo-negative* instances by randomly matching non-translation terms.

Morin and Prochasson (2011b) showed that the translation accuracy of context vectors is higher when using bilingual dictionaries that contain both general language entries and technical terms rather than general or domain-specific dictionaries, sep-

en-el	0.68	22K
en-jpn	0.49	57K

Table 2: Corpus comparability and number of features of the seed word dictionaries

arately. In a mixed dictionary, lexical units are either single-word technical terms, such as "disease" and "patient", or general language words, such as "occur" and "high". Note that we have already compiled a seed term dictionary for each pair of languages. Following the suggestion of Morin and Prochasson (2011b), we attempt to enrich the seed term dictionaries with general language entries. For this, we extracted bilingual word dictionaries for English-Spanish, English-French and English-Greek by applying GIZA++ (Och and Ney, 2003) on the EMEA corpus. We then concatenated the word with the term dictionaries to obtain enhanced seeds for the three language pairs. For English-Japanese, we only used the term dictionary to translate the target context vectors.

Once the word dictionaries have been compiled, we compute the *corpus comparability* measure. Li and Gaussier (2010) define corpus comparability as the percentage of words that can be translated bi-directionally, given a seed dictionary.

Table 2 shows corpus comparability scores of the four corpora accompanied with the number of English, single words in the seed dictionaries. It can be observed that seed dictionary sizes are not necessarily proportional to the corresponding corpus comparability scores. As expected, for English-Japanese, corpus comparability is low because the dictionary contains single-word terms, only. The English-Spanish dictionary is smaller than the English-French but achieved higher corpus comparability, i.e., a higher percentage of words can be bi-directionally translated using the corresponding seed dictionary. A possible explanation is that the comparable corpora were constructed using different lists of query-terms. Hence, the query-terms used for English-Spanish retrieved a more coherent corpus. The resulting values of corpus comparability indicate that the context vectors will perform the best for English-Spanish while for English-Japanese the performance is expected to be substantially lower.

4.2 Training and evaluation datasets

For evaluation, we construct a test dataset of single-word terms, in particular nouns or adjectives. The dataset contains $1K$ terms that occur more frequently than 20 but not more than 200 times and are listed in the English part of the UMLS. In order to extract candidate translations, we considered all nouns or adjectives that occur at least 5 times in the target part of the corpus. Furthermore, we do not constraint the evaluation datasets only to those terms whose corresponding translation occurs in the corpus.

The hybrid model that combines the compositional and context clue, is based on a two-feature model. Therefore, the model converges using only a few hundred instances. For training a hybrid model, we used $1K$ translation instances that occurred in the training comparable corpora. Similarly, to the character n-gram models, *pseudo-negative* instances were generated by randomly coupling non-translation terms. The ratio of positive to negative instances is $1:1$.

5 Experiments

In this section, we present three experiments conducted to evaluate the *character n-gram*, *context vector* and *hybrid* methods. Firstly, we examine the performance of the n-gram models on closely related language pairs (English-French, English-Spanish), on a distant language pair (English-Greek) and on an unrelated language pair (English-Japanese). English and Greek are not unrelated because they are members of the same language family, but also not closely related because they use different scripts. Secondly,

we compare the character n-gram methods against context vectors when translating frequent or rare terms and on comparable corpora of similar language pairs (English-French, English-Spanish) but of different corpus comparability scores. Thirdly, we evaluate the hybrid method on all four comparable corpora and investigate the improvement margin of combining the *contextual* with the *compositional* clue.

As evaluation metrics, we adopt the top-N translation accuracy, following most previous approaches (Rapp, 1999; Chiao and Zweigenbaum, 2002; Morin et al., 2007; Tamura et al., 2012). The top-N translation accuracy is defined as the percentage of source terms for which a given method has output the correct translation among the top N candidate translations.

5.1 Character n-gram models

In the first experiment, we investigate the performance of the character n-gram models considering an increasing number of features. The features were sorted in order of decreasing frequency of occurrence. Starting from the top of the list, more features were incrementally added and translation accuracy was recorded.

Figure 2 shows the top-20 translation accuracy of single-word terms on an increasing number of first and second order features. With regards to the first order models (Subfigure 2a), the Random Forest (RF) classifier outperforms our baseline method (SVM-RBF) for all four language pairs. The largest margin between RF and SVM-RBF can be observed for the English-Greek dataset while for closely related language pairs, i.e., English-French and English-Spanish, the margin is smaller. Furthermore, it can be noted that using only a small number of first order features, $1K$ features (500 for the source and 500 for the target language, both n-gram models reach a stable performance.

In contrast to the first order models, the LogReg classifier requires a large number of second order features to achieve a robust performance (Subfigure 2b). Starting from $100K$ features, the translation accuracy continuously increases. The best performance is observed for a total number of $4M$ second order features when considering the English-French, English-Spanish and English-Greek datasets. For English-Japanese, the best performance is achieved for $2M$ features. Beyond this point, translation accuracy decreases slightly.

After feature selection is performed, we directly compare all the character n-gram models. Table 3 summarises performance achieved by the LogReg, RF and SVM-RBF models. It can be noted that LogReg and RF performed similarly for closely related languages (no statistically significant differences were observed) while both methods outperformed the SVM-RBF. However, for English-Greek and English-Japanese, LogReg achieved a statistically significant improvement over the translation accuracy of RF and SVM-RBF. LogReg outperformed RF by 7% for English-Greek, while for English-Japanese the improvement was 10% and 17% percent for top-1 and top-20 accuracy, respectively. Finally, it can be observed that the more distant the language pair is, the lower the performance.

5.2 N-gram methods and context vectors

In this experiment, we compare the n-gram methods against context vectors with regards to two parameters: (a) the frequency of source terms to be translated and (b) corpus comparability. English-French and English-Spanish are similar language pairs but the corresponding corpora are of different corpus comparability scores. To investigate how performance is affected by term occurrence frequency, we compiled an additional test dataset of $1K$ rare English terms in the frequency range $[10, 20]$. Our intuition is, that character n-gram methods will perform similarly for all settings since character n-grams are corpus independent features.

We compare (a) the character n-gram models (LogReg, RF and SVM-RBF) with (b) the context vector method (context) and (c) an upper bound. The latter represents the percentage of source terms for which a reference translation actually occurs in the target corpus. Hence, the upper bound is the maximum performance achievable according to the reference evaluation.

Figure 3a shows the top-20 translation accuracy for high and medium frequency terms, within the frequency range $[20, 200]$. Context vectors achieved a robust performance of 52% and 45% for English-Spanish and English-French, respectively. The difference in corpus comparability can explain this 7% margin between these performances. As shown in Table 2, the corpus comparability scores for English-Spanish and English-

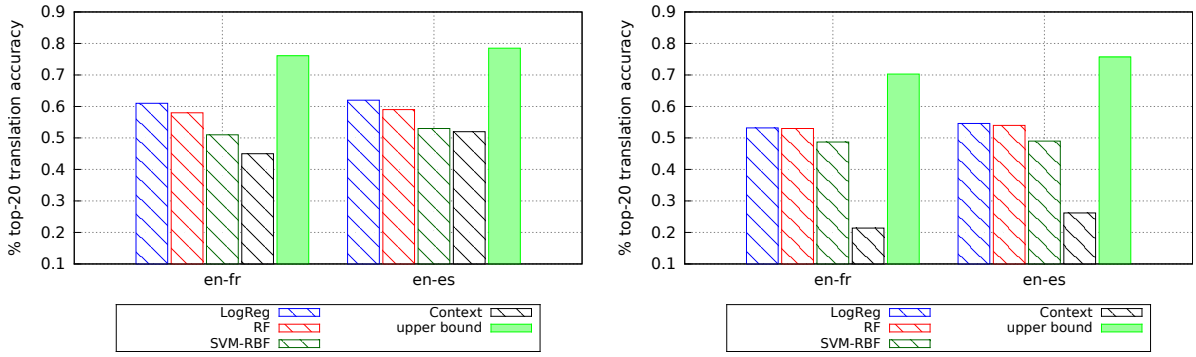
Table 3: Top-1 (acc@1) and top-20 (acc@20) translation accuracy of LogReg, RF and SVM-RBF



(a) Test terms with frequency $[20, 200]$

(b) Test terms with frequency $[10, 20]$

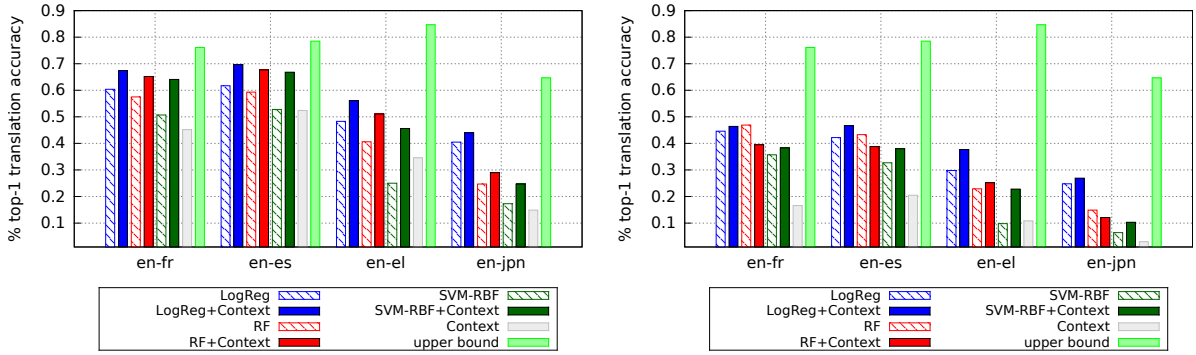
Figure 3: Top-20 translation accuracy of terms in the frequency range of $[10, 200]$ and $[10, 20]$

French are 0.75 and 0.71, respectively. In contrast to context vectors, the character n-gram methods performed comparably.

A second factor that affects the performance of context vectors, is the frequency of the terms to be translated. The translation of rare terms has been shown to be a challenging case for context vectors. For example, Morin and Daille (2010) reported low accuracy (21% for the top-20 candidates) of context vectors for terms occurring 20 times or less. In our experiments, Figure 3b illustrates accuracies achieved for less frequent terms ($[10, 20]$). The performance of context vectors is significantly lower, 26% for English-Spanish and 21% for English-French. Furthermore, the translation accuracy of the n-gram methods decreases slightly ($\sim$ 5% to 8%). This can be explained by the decrease of the upper bound for lower frequency terms ($\sim$ 3% to 6%).

5.3 Combining internal and contextual similarity

We have hypothesised that the *compositional* and *contextual* clue are orthogonal, i.e., they convey



(a) Top-20 accuracy (acc@20)

(b) Top-1 accuracy (acc@1)

Figure 4: Overall performance. Top-20 and top-1 translation accuracy

different and possibly complimentary information. To investigate this intuition, we evaluate the hybrid model on all four comparable corpora, for term occurrence frequencies in $[20, 200]$.

Figure 4a illustrates top-20 translation accuracy scores for (a) the character n-gram models, (b) the context vector method and (c) the hybrid models, i.e., LogReg+Context, RF+Context, SVM-RBF+Context. We observe that the combination of the *compositional* and *contextual* clue improved the performance of all methods. The hybrid model largely improved the performance of the SVM-RBF ($\sim$ 14% to 20%). With regards to the combined signals the translation accuracy of LogReg and RF increased by $\sim$ 4% for the English-Japanese corpus and $\sim$ 8% for all other corpora.

For the top 1 candidate translation, we observe in Figure 4 smaller improvements achieved by the hybrid model in comparison to the top-20 accuracy. Interestingly, the RF classifier performed slightly better on its own for English-French, English-Spanish and English-Japanese. This indicates that the hybrid method ranks more correct translations in the top 20 candidates but it does not always assign the best score to the correct answer.

6 Discusion and Future work

In this paper, we investigated a compositional and a context-based approach useful for compiling bilingual dictionaries of terms automatically from comparable corpora. Compositional translation methods exploit the internal structure of terms across languages while context-based approaches investigate the surrounding lexical context.

We proposed a character n-gram compositional method, i.e., a *Logistic Regression* classifier, which uses a multilingual representation, i.e., source and target terms. Experimental evidence showed that the LogReg classifier significantly outperformed the baseline methods on distant languages. For closely related languages, LogReg performed comparably to an existing n-gram method based on a *Random Forest* classifier.

Furthermore, we compared the n-gram models against a context-based approach under different corpus-specific parameters: (a) corpus comparability, which is relevant to the seed dictionary, and (b) the occurrence frequency of the terms to be translated. It was shown that the performance of n-gram methods was not affected by different parameter settings. Only small fluctuations were observed, since the n-gram methods are based on corpus-independent features, only. In contrast, the context-based method was affected by corpus comparability scores. The corresponding translation accuracy declined significantly for rare terms.

Finally, we hypothesised that the n-gram and context-based methods provide complimentary information. To test this hypothesis, we developed a hybrid method that combines compositional and contextual similarity scores as features in a linear classifier. The hybrid model achieved significantly better top-20 translation accuracy than the two methods separately but minor improvements were observed in terms of top-1 accuracy.

As future work, we plan to improve the quality of the extracted dictionary further by exploiting additional translation signals. For example, previous works (Schafer and Yarowsky, 2002; Klementiev et al., 2012) have reported that the *temporal* and *topic* similarity are clues that indicate translation equivalence. It would be interesting to investigate the contribution of different clues for various

experimental parameters, e.g., domain, distance of languages, types of comparable corpora.

Abstract

Vector space models (VSMs) are mathematically well-defined frameworks that have been widely used in the distributional approaches to semantics. In VSMs, high-dimensional vectors represent linguistic entities. In an application, the similarity of vectors—and thus the entities that they represent—is computed by a distance formula. The high dimensionality of vectors, however, is a barrier to the performance of methods that employ VSMs. Consequently, a dimensionality reduction technique is employed to alleviate this problem. This paper introduces a novel technique called Random Manhattan Indexing (RMI) for the construction of ℓ_1 normed VSMs at reduced dimensionality. RMI combines the construction of a VSM and dimension reduction into an incremental and thus scalable two-step procedure. In order to attain its goal, RMI employs the sparse Cauchy random projections. We further introduce Random Manhattan Integer Indexing (RMII): a computationally enhanced version of RMI. As shown in the reported experiments, RMI and RMII can be used reliably to estimate the ℓ_1 distances between vectors in a vector space of low dimensionality.

1 Introduction

Distributional semantics embraces a set of methods that decipher the meaning of linguistic entities using their usages in large corpora (Lenci, 2008). In these methods, the distributional properties of linguistic entities in various contexts, which are collected from their observations in corpora, are compared to quantify their meaning. Vector spaces are intuitive, mathematically well-defined frameworks to represent and process such information.[1] In a vector space model (VSM), linguistic entities are represented by vectors and a distance formula is employed to measure their distributional similarities (Turney and Pantel, 2010).

In a VSM, each element $\vec{s}_i$ of the standard basis of the vector space (informally, each dimension of the VSM) represents a context element. Given n context elements, an entity whose meaning is being analyzed is expressed by a vector $\vec{v}$ as a linear combination of $\vec{s}_i$ and scalars $\alpha_i \in \mathbb{R}$ such that $\vec{v} = \alpha_1\vec{s}_1 + \cdots + \alpha_n\vec{s}_n$. The value of α_i is derived from the frequency of the occurrences of the entity that $\vec{v}$ represents in/with the context element that $\vec{s}_i$ represents. As a result, the values assigned to the coordinates of a vector (i.e. α_i) exhibit the correlation of entities and context elements in an n-dimensional real vector space $\mathbb{R}^n$. Each vector can be written as a $1 \times n$ row matrix, e.g. $(\alpha_1, \cdots, \alpha_n)$. Therefore, a group of m vectors in a vector space is often represented by a matrix $\mathbf{M}_{m\times n}$.

Latent semantic analysis (LSA) is a familiar technique that employs a *word-by-document* VSM (Deerwester et al., 1990).[2] In this word-by-document model, the meaning of words (i.e. the linguistic entities) is described by their occurrences in documents (i.e. the context elements). Given m words and n distinct documents, each word is represented by an n-dimensional vector $\vec{v_i} = (\alpha_{i1}, \cdots, \alpha_{in})$, where α_{ij} is a numeric value that associates the word $\vec{v_i}$ represents to the document d_j, for $1 < j < n$. For instance, the value of α_{ij} may correspond to the frequency of the word in the document. It is hypothesized that the relevance of words can be assessed by counting the documents in which they co-occur. Therefore, words with similar vectors are assumed to have the same meaning (Figure 1).

[1] Amongst other representation frameworks.

[2] See Martin and Berry (2007) for an overview of the mathematical foundation of LSA.

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

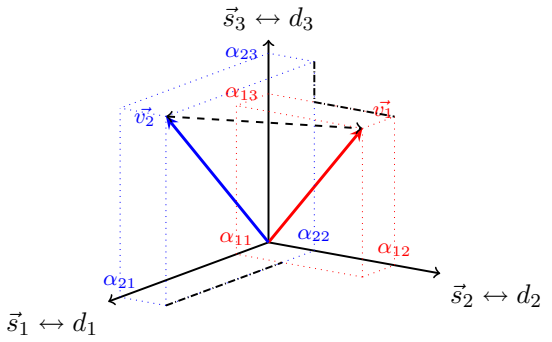

Figure 1: Illustration of a *word-by-document* model consisting of 2 words and 3 documents. The words are represented in a 3-dimensional vector space, in which each $\vec{s_i}$ (each dimension) represents each of the 3 documents in the model. $\vec{v_1} = (\alpha_{11}, \alpha_{12}, \alpha_{13})$ and $\vec{v_2} = (\alpha_{21}, \alpha_{22}, \alpha_{23})$ represent the two words in the model. The dashed line shows the Euclidean distance between the two vectors that represent words, while the sum of dash-dotted lines is the Manhattan distance between them.

In order to assess the similarity between vectors, a vector space V is endowed with a *norm* structure. A norm $\|.\|$ is a function that maps vectors from V to the set of non-negative real numbers, i.e. $V \mapsto [0, \infty)$. The pair of $(V, \|.\|)$ is then called a *normed* space. In a normed space, the similarity between vectors is assessed by their distances. The distance between vectors is defined by a function that satisfies certain axioms and assigns a real value to each pair of vectors, i.e.

$$dist : V \times V \mapsto \mathbb{R}, \quad d(\vec{v}, \vec{t}) = \|\vec{v} - \vec{u}\|. \quad (1)$$

The smaller the distance between two vectors, the more similar they are.

Euclidean space is the most familiar example of a normed space. It is a vector space that is endowed by the ℓ_2 norm. In Euclidean space, the ℓ_2 norm—which is also called the Euclidean norm—of a vector $\vec{v} = (v_1, \cdots, v_n)$ is defined as

$$\|\vec{v}\|_2 = \sqrt{\sum_{i=1}^{n} v_i^2}. \quad (2)$$

Using the definition of distance given in Equation 1 and the ℓ_2 norm, the Euclidean distance is measured as

$$dist_2(\vec{v}, \vec{u}) = \|\vec{v} - \vec{u}\|_2 = \sqrt{\sum_{i=1}^{n} (v_i - u_i)^2}. \quad (3)$$

In Figure 1, the dashed line shows the Euclidean distance between the two vectors. In ℓ_2 normed vector spaces, various similarity metrics are defined using different normalization of the Euclidean distance between vectors, e.g. the *cosine similarity*.

The similarity between vectors, however, can also be computed in ℓ_1 normed spaces.[3] The ℓ_1 norm for $\vec{v}$ is given by

$$\|\vec{v}\|_1 = \sum_{i=1}^{n} |v_i|, \quad (4)$$

where $|.|$ signifies the modulus. The distance in an ℓ_1 normed vector space is often called the *Manhattan* or the *city block* distance. According to the definition given in Equation 1, the Manhattan distance between two vectors $\vec{v}$ and $\vec{u}$ is given by

$$dist_1(\vec{v}, \vec{u}) = \|\vec{v} - \vec{u}\|_1 = \sum_{k=1}^{n} |v_i - u_j|. \quad (5)$$

In Figure 1, the collection of the dash-dotted lines is the ℓ_1 distance between the two vectors. Similar to the ℓ_2 spaces, various normalizations of the ℓ_1 distance[4] define a family of ℓ_1 normed similarity metrics.

As the number of text units that are being modelled in a VSM increases, the number of context elements that are required to be utilized to capture their meaning escalates. This phenomenon is explained using power-law distributions of text units in context elements (e.g. the familiar Zipfian distribution of words). As a result, extremely high-dimensional vectors, which are also sparse—i.e. most of the elements of the vectors are zero—represent text units. The high dimensionality of the vectors results in setbacks, which are colloquially known as *the curse of dimensionality*. For instance, in a word-by-document model that consists of a large number of documents, a word appears only in a few documents, and the rest of the documents are irrelevant to the meaning of the word. Few common documents between words results in sparsity of the vectors; and the presence of irrelevant documents introduces noise.

Dimension reduction, which usually follows the construction of a VSM, alleviates the problems

[3] The definition of the norm is generalized to ℓ_p spaces with $\|\vec{v}\|_p = \left(\sum_i |v_i|^p\right)^{1/p}$, which is beyond the scope of this paper.

[4] As long as the axioms in the distance definition hold.

listed above by reducing the number of context elements that are employed for the construction of the VSM. In its simple form, dimensionality reduction can be performed using a *selection process*: choose a subset of contexts and eliminate the rest using a heuristic. Alternatively, *transformation* methods can be employed. A transformation method maps a vector space V_n onto a V_m of lowered dimension, i.e. $\tau : V_n \mapsto V_m, m \ll n$. The vector space at reduced dimension, i.e. V_m, is often the best approximation of the original V_n in a *sense*. LSA employs a dimension reduction technique called truncated singular value decomposition (SVD). In a standard truncated SVD, the transformation guarantees the least distortion in the ℓ_2 distances.[5]

Besides the problem of high computational complexity of SVD computation,[6] which can be addressed by incremental techniques (see e.g. Brand (2006)), matrix factorization methods such as truncated SVD are *data-sensitive*: if the structure of the data being analyzed changes, i.e. when either the linguistic entities or context elements are updated, e.g. some are removed or new ones are added, the transformation should be recomputed and reapplied to the whole VSM to reflect the updates. In addition, a VSM at the original high dimension must be first constructed. Following the construction of the VSM, the dimension of the VSM is reduced in an independent process. Therefore, the VSM at reduced dimension is available for processing only after the whole sequence of these processes. Construction of the VSM at its original dimension is computationally expensive and a delay in access to the VSM at reduced dimension is not desirable. Hence, the application of truncated SVD is not suitable in several applications, particularly when dealing with frequently updated big text–data such as applications in the web context.

Random indexing (RI) is an alternative method that solves the problems stated above by combining the construction of a vector space and the dimensionality reduction process. RI, which is introduced in Kanerva et al. (2000), constructs a VSM directly at reduced dimension. Unlike methods that first construct a VSM at its original high dimension and conduct a dimensionality reduction afterwards, the RI method avoids the construction of the original high-dimensional VSM. Instead, it merges the vector space construction and the dimensionality reduction process. RI, thus, significantly enhances the computational complexity of deriving a VSM from text. However, the application of the RI technique (likewise the standard truncated SVD in LSA) is limited to ℓ_2 normed spaces, i.e. when similarities are assessed using a measure based on the ℓ_2 distance. It can be verified that using RI causes large distortions in the ℓ_1 distances between vectors (Brinkman and Charikar, 2005). Hence, if the similarities are computed using the ℓ_1 distance, then the RI technique is not suitable for the VSM construction.

Depending on the distribution of vectors in a VSM, the performance of similarity measures based on the ℓ_1 and the ℓ_2 norms varies from one task to another. For instance, it is known that the ℓ_1 distance is more robust to the presence of outliers and non-Gaussian noise than the ℓ_2 distance (e.g. see the problem description in Ke and Kanade (2003)). Hence, the ℓ_1 distance can be more reliable than the ℓ_2 distance in certain applications. For instance, Weeds et al. (2005) suggest that the ℓ_1 distance outperforms other similarity metrics in a term classification task. In another experiment, Lee (1999) observed that the ℓ_1 distance gives more desirable results than the Cosine and the ℓ_2 measures.

In this paper, we introduce a novel method called *Random Manhattan Indexing* (RMI). RMI constructs a vector space model directly at reduced dimension while it preserves the pairwise ℓ_1 distances between vectors in the original high-dimensional VSM. We then introduced a computationally enhanced version of RMI called *Random Manhattan Integer Indexing* (RMII). RMI and RMII, similar to RI, merge the construction of a VSM and dimension reduction into an incremental and thus efficient and scalable process.

In Section 2, we explain and evaluate the RMI method. In Section 3, the RMII method is explained. We compare the proposed method with RI in Section 4. We conclude in Section 5.

2 Random Manhattan Indexing

We propose the RMI method: a novel technique that adapts an incremental procedure for the construction of ℓ_1 normed vector spaces at a reduced dimension. The RMI method employs a two-step

[5] Please note that there are matrix factorization techniques that guarantee the least distortion in the ℓ_1 distances, see e.g. Kwak (2008).

[6] Matrix factorization techniques, in general.

procedure: (a) the creation of *index vectors* and (b) the construction of *context vectors* .

In the first step, each context element is assigned exactly to one *index vector* $\vec{r_i}$. Index vectors are high-dimensional and generated randomly such that entries r_j of index vectors have the following distribution:

$$r_i = \begin{cases} \frac{-1}{U_1} & \text{with probability } \frac{s}{2} \\ 0 & \text{with probability } 1-s \\ \frac{1}{U_2} & \text{with probability } \frac{s}{2} \end{cases}, \quad (6)$$

where U_1 and U_2 are independent uniform random variables in $(0, 1)$. In the second step, each target linguistic entity that is being analyzed in the model is assigned to a context vector $\vec{v_c}$ in which all the elements are initially set to 0. For each encountered occurrence of a linguistic entity and a context element—e.g. through a sequential scan of an input text collection—$\vec{v_c}$ that represents the linguistic entity is accumulated by the index vector $\vec{r_i}$ that represents the context element, i.e. $\vec{v_c} = \vec{v_c} + \vec{r_i}$. This process results in a VSM of a reduced dimensionality that can be used to estimate the ℓ_1 distances between linguistic entities. In the constructed VSM by RMI, the ℓ_1 distance between vectors is given by the *sample median* (Indyk, 2000). For given vectors $\vec{v}$ and $\vec{u}$, the approximate ℓ_1 distance between vectors is estimated by

$$\hat{L}_1(\vec{u}, \vec{v}) = \text{median}\{|v_i - u_i|, i = 1, \cdots, m\}, \quad (7)$$

where m is the dimension of the VSM constructed by RMI, and $|.|$ denotes the modulus.

RMI is based on the random projection (RP) technique for dimensionality reduction. In RP, a high-dimensional vector space is mapped onto a random subspace of lowered dimension expecting that—with a high probability—relative distances between vectors are approximately preserved. Using the matrix notation, this projection is given by

$$\mathbf{M}'_{p\times m} = \mathbf{M}_{p\times n}\mathbf{R}_{n\times m}, \quad m \ll p, n, \quad (8)$$

where $\mathbf{R}$ is often called the *random projection matrix*, and $\mathbf{M}$ and $\mathbf{M}'$ denote p vectors in the original n-dimensional and reduced m-dimensional vector spaces, respectively.

In RMI, the stated mapping in Equation 8 is given by *Cauchy random projections*. Indyk (2000) suggests that vectors in a high-dimensional space $\mathbb{R}^n$ can be mapped onto a vector space of lowered dimension $\mathbb{R}^m$ while the relative pairwise ℓ_1 distances between vectors are preserved with a high probability. In Indyk (2000, Theorem 3) and Indyk (2006, Theorem 5), it is shown that for an $m \geq m_0 = \log(1/\delta)^{O(1/\epsilon)}$, where $\delta > 0$ and $\epsilon \leq 1/2$, there exists a mapping from $\mathbb{R}^n$ onto $\mathbb{R}^m$ that guarantees the ℓ_1 distances between any pair of vectors $\vec{u}$ and $\vec{v}$ in $\mathbb{R}^n$ after the mapping does not increase by a factor more than $1+\epsilon$ with constant probability δ, and it does not decrease by more than $1-\epsilon$ with probability $1-\delta$.

In Indyk (2000), this projection is proved to be obtained using a random projection matrix $\mathbf{R}$ that has *Cauchy distribution*—i.e. for r_{ij} in $\mathbf{R}$, $r_{ij} \sim C(0, 1)$. Since $\mathbf{R}$ has a Cauchy distribution, for every two vectors $\vec{u}$ and $\vec{v}$ in the high-dimensional space $\mathbb{R}^n$, the projected differences $x = \hat{\vec{u}} - \hat{\vec{v}}$ also have Cauchy distribution, with the scale parameter being the ℓ_1 distances, i.e. $x \sim C(0, \sum_{i=1}^{n} |u_i - v_i|)$. As a result, in Cauchy random projections, estimating the ℓ_1 distances boils down to the estimation of the Cauchy scale parameter from independent and identically distributed (i.i.d.) samples x. Because the expectation value of x is infinite,[7] the sample mean cannot be employed to estimate the Cauchy scale parameter. Instead, using the 1-stability of Cauchy distribution, Indyk (2000) proves that the median can be employed to estimate the Cauchy scale parameter, and thus the ℓ_1 distances at the projected space $\mathbb{R}^m$.

Subsequent studies simplified the method proposed by Indyk (2000). Li (2007) shows that $\mathbf{R}$ with Cauchy distribution can be substituted by a *sparse* $\mathbf{R}$ that has a mixture of symmetric 1-Pareto distribution. A 1-Pareto distribution can be sampled by $1/U$, where U is an independent uniform random variable in $(0, 1)$. This results in a random matrix $\mathbf{R}$ that has the same distribution as described by Equation 6.

The RMI's two-step procedure is explained using the basic properties of matrix arithmetic and the descriptions given above. Given the projection in Equation 8, the first step of RMI refers to the construction of $\mathbf{R}$: index vectors are the row vectors of $\mathbf{R}$. The second step of the process refers to the construction of $\mathbf{M}'$: context vectors are the row vectors of $\mathbf{M}'$. Using the distributive property of multiplication over addition in matrices,[8]

[7] That is $E(x) = \infty$, since x has a Cauchy distribution.

[8] That is, $(\mathbf{A} + \mathbf{B})\mathbf{C} = \mathbf{AC} + \mathbf{BC}$.

it can be verified that the explicit construction of $\mathbf{M}$ and its multiplication to $\mathbf{R}$ can be substituted by a number of summation operations. $\mathbf{M}$ can be represented by the sum of unit vectors in which a unit vector corresponds to the co-occurrence of a linguistic entity and a context element. The result of the multiplication of each unit vector and $\mathbf{R}$ is the row vector that represents the context element in $\mathbf{R}$—i.e. the index vector. Therefore, $\mathbf{M}'$ can be computed by the accumulation of the row vectors of $\mathbf{R}$ that represent encountered context elements, as stated in the second step of the RMI procedure.

2.1 Alternative Distance Estimators

As stated above, Indyk (2000) suggests using the sample median for the estimation of the ℓ_1 distances. However, Li (2008) argues that sample median estimator can be biased and inaccurate, specifically if m—i.e. the targeted (reduced) dimensionality—is small. Hence, Li (2008) suggests using the geometric mean estimator instead of the median sample:[9]

$$\hat{L}_1(\vec{u},\vec{v}) = \Big(\prod_{i=1}^{m} |u_i - v_i|\Big)^{\frac{1}{m}}. \qquad (9)$$

We suggest computing the $\hat{L}_1(\vec{u},\vec{v})$ in Equation 9 using arithmetic mean of logarithm-transformed values of $|u_i - v_i|$. Therefore, using the logarithmic identities, the multiplications and the power in Equation 9 are, respectively, transformed to a sum and a multiplication:

$$\hat{L}_1(\vec{u},\vec{v}) = \exp\Big(\frac{1}{m}\sum_{i=1}^{m} \ln(|u_i - v_i|)\Big). \qquad (10)$$

Equation 10 for computing $\hat{L}_1$ is more plausible for computational implementation than Equation 9 (e.g. the overflow is less likely to happen during the process). Moreover, calculating the median involves sorting an array of real numbers. Thus, computation of the geometric mean in logarithmic scales can be faster than computation of the median sample, especially when the value of m is large.

2.2 RMI's Parameters

In order to employ the RMI method for the construction of a VSM at reduced dimension and the estimation of the ℓ_1 distance between vectors, two model parameters should be decided: (a) the targeted (reduced) dimensionality of the VSM, which is indicated by m in Equation 8 and (b) the number of non-zero elements in index vectors, which is determined by s in Equation 6. In contrast to the classic *one-dimension-per-context-element* methods of VSM construction,[10] the value of m in RPs and thus in RMI is chosen independently of the number of context elements in the model (n in Equation 8).

In RMI, m determines the probability and the maximum expected amount of distortions ϵ in the pairwise distance between vectors. Based on the proposed refinements of Indyk (2000, Theorem 3) by Li et al. (2007), it is verified that the pairwise ℓ_1 distance between any p vectors is approximated within a factor $1 \pm \epsilon$, if $m = \mathrm{O}(\log p/\epsilon^2)$, with a constant probability. Therefore, the value of ϵ in RMI is subject to the number of vectors p in the model. For a fixed p, a larger m yields to lower bounds on the distortion with a higher probability. Because a small m is desirable from the computational complexity outlook, the choice of m is often a trade-off between accuracy and efficiency. According to our experiment, $m > 400$ is suitable for most applications.

The number of non-zero elements in index vectors, however, is decided by the number of context elements n and the sparseness of the VSM β at its original dimension. Li (2007) suggests $\frac{1}{\mathrm{O}(\sqrt{\beta n})}$ as the value of s in Equation 6. VSMs employed in distributional semantics are highly sparse. The sparsity of a VSM in its original dimension β is often considered to be around 0.0001–0.01. As the original dimension of VSM n is very large—otherwise there would be no need for dimensionality reduction—the index vectors are often very sparse. Similar to m, larger s produces smaller errors; however, it imposes more processes during the construction of a VSM.

2.3 Experimental Evaluation of RMI

We report the performance of the RMI method with respect to its ability to preserve the relative ℓ_1 distance between linguistic entities in a VSM. Therefore, instead of a task-specific evaluation, we show that the relative ℓ_1 distance between a set of words in a high-dimensional *word-by-document* model remains intact when the model

[9] See also Li et al. (2007, Lemma 5–9).

[10] That is, n context elements are modelled in an n-dimensional VSM.

is constructed at reduced dimensionality using the RMI technique. We further explore the effect of the RMI's parameter setting in the observed results.

Depending on the structure of the data that is being analyzed and the objective of the task in hand, the performance of the ℓ_1 distance for similarity measurement varies from one application to another.[11] The purpose of our reported evaluation, thus, is not to show the superiority of the ℓ_1 distance (thus RMI) to another similarity measure (e.g. the ℓ_2 distance or the cosine similarity) and employed techniques for dimensionality reduction (e.g. RI or truncated SVD) in a specific task. If, in a task, the ℓ_1 distance shows higher performance than the ℓ_2 distance, then the RMI technique is preferable to the RI technique or truncated SVD. Contrariwise, if the ℓ_2 norm shows higher performance than the ℓ_1, then RI or truncated SVD are more desirable than the RMI method.

In our experiment, a word-by-document model is first constructed from the UKWaC corpus at its original high dimension. UKWaC is a freely available corpus of 2,692,692 web documents, nearly 2 billion tokens and 4 million types (Baroni et al., 2009).[12] Therefore, a word-by-document model constructed from this corpus using the classic one-dimension-per-context-element method has a dimension of 2.69 million. In order to keep the experiments computationally tractable, the reported results are limited to 31 words from this model, which are listed in Table 1.

In the designed experiment, a word from the list is taken as the reference and its ℓ_1 distance to the remaining 30 words is calculated using the vector representations in the high-dimensional VSM. These 30 words are then sorted in ascending order by the calculated ℓ_1 distance. The procedure is repeated for all the 31 words in the list, one by one. Therefore, the procedure results in 31 sorted lists, each containing 30 words. Figure 2 shows an example of the obtained sorted list, in which the reference is the word 'research'.[13]

The procedure described above is replicated to obtain the lists of sorted words from VSMs that are constructed by the RMI method at reduced

dimensionality, when the method's parameters—i.e. the dimensionality of VSM and the number of non-zero elements in index vectors—are set differently. We expect the obtained relative ℓ_1 distances between each reference word and the 30 other words in an RMI-constructed VSM to be the same as the obtained relative distances in the original high-dimensional VSM. Therefore, for each VSM that is constructed by the RMI technique, the resulting sorted lists of words are compared by the sorted lists that are obtained from the original high-dimensional VSM.

We employ the *Spearman's rank correlation coefficient* (ρ) to compare the sorted lists of words and thus the degree of distance preservation in the RMI-constructed VSMs at reduced dimensionality. The Spearman's rank correlation measures the strength of association between two ranked variables, i.e. two lists of sorted words in our experiments. Given a list of sorted words obtained from the original high-dimensional VSM (list_o) and its corresponding list obtained from a VSM of reduced dimensionality (list_{RMI}), the Spearman's rank correlation for the two lists is calculated by

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2-1)}, \qquad (11)$$

where d_i is the difference in paired ranks of words in list_o and list_{RMI}, and $n = 30$ is the number of words in each list. We report the average of ρ over the 31 lists of sorted words, denoted by $\bar{\rho}$, to

[11] E.g. see the experiments in Bullinaria and Levy (2007).

[12] UkWaC can be obtained from http://goo.gl/3isfIE.

[13] Please note that the number of possible arrangements of 30 words without repetition in a list in which the order is important (i.e. all permutations of 30 words) is 30!.

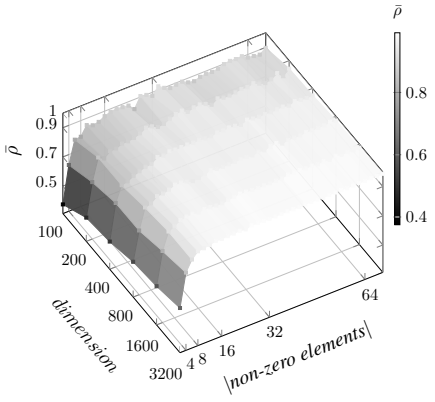

Figure 3: The $\bar{\rho}$ axis shows the observed average Spearman' rank correlation between the order of the words in the lists that are sorted by the ℓ_1 distance obtained from the original high-dimensional VSM and the VSMs that are constructed by RMI at reduced dimensionality using index vectors of various numbers of non-zero elements.

indicate the performance of RMI with respect to its ability for distance preservation. The closer $\bar{\rho}$ is to 1, the better the performance of RMI.

Figure 3 shows the observed results at a glance when the distances are estimated using the median (Equation 7). As shown in the figure, when the dimension of the VSM is above 400 and the number of non-zero elements is more than 12, the obtained relative distances from the VSMs constructed by the RMI technique start to be analogous to the relative distances that are obtained from the original high-dimensional VSM, i.e. a high correlation ($\bar{\rho} > 0.90$). For the baseline, we report the average correlation of $\bar{\rho}_{random} = -0.004$ between the sorted lists of words obtained from the high-dimensional VSM and 31×1000 lists of sorted words that are obtained by randomly assigned distances.

Figure 4 shows the same results as Figure 3, however, in minute detail and only for VSMs of dimension $m \in \{100, 400, 800, 3200\}$. In these plots, squares (■) indicate the $\bar{\rho}$ while the error bars show the best and the worst observed ρ amongst all the sorted lists of words. The minimum value of ρ-axis is set to 0.611, which is the worst observed correlation in the baseline (i.e. randomly generated distances). The dotted line ($\rho = .591$) shows the best observed correlation in the baseline and the dashed-dotted line shows the average correlation in the baseline ($\rho = -0.004$). As suggested in Section 2.2, it can be verified that an increase in the dimension of VSMs (i.e. m) increases the stability of the obtained results (i.e. the probability of preserving distances increases). Therefore, for large values of m (i.e. $m > 400$), the difference between the best and the worst observed ρ decreases; average correlation $\bar{\rho} \to 1$ and the observed relative distances in RMI-constructed VSMs tend to be identical to those in the original high-dimensional VSM.

Figure 5 represents the obtained results in the same setting as above, however, when the distances are approximated using the geometric mean (Equation 10). The obtained average correlations $\bar{\rho}$ from the geometric mean estimations are almost identical to the median estimations. However, as expected, the geometric mean estimations are more reliable for small values of m; particularly, the worst observed correlations when using the geometric mean are higher than those observed when using the median estimator.

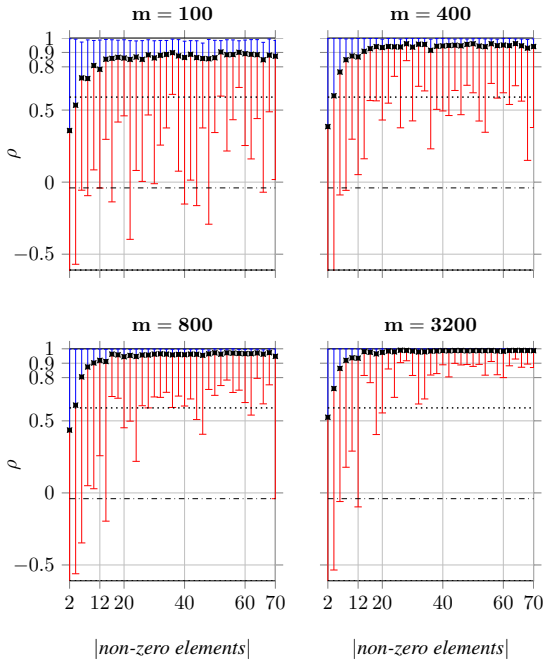

Figure 4: Detailed observation of the obtained correlation between relative distances in RMI-constructed VSMs and the original high-dimensional VSM. The ℓ_1 distance is estimated using the median. The squares denote $\bar{\rho}$ and the error bars show the best and the worst observed correlations. The dashed-dotted line shows the random baseline.

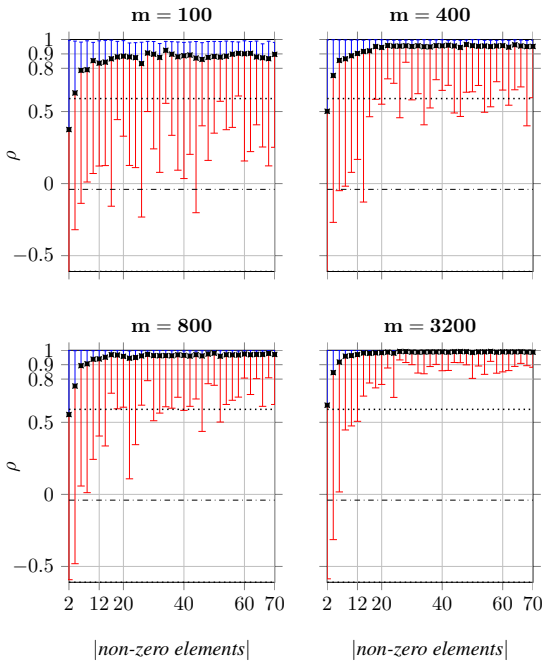

Figure 5: The observed results when the ℓ_1 distance in RMI-constructed VSMs is estimated using the geometric mean.

3 Random Manhattan Integer Indexing

The application of the RMI method is hindered by two obstacles: float arithmetic operations required for the construction and processing of the RMI-constructed VSMs and the calculation of the product of large numbers when ℓ_1 distances are estimated using the geometric mean.

The proposed method for the generation of index vectors in RMI results in index vectors of non-zero elements that are real numbers. Consequently, index vectors and thus context vectors are arrays of floating point numbers. These vectors must be stored and accessed efficiently when using the RMI technique. However, resources that are required for the storage and processing of floating numbers is high. Even if the requirement for the storage of index vectors is alleviated, e.g., using a derandomization technique for their generation, context vectors that are derived from these index vectors are still arrays of float numbers. To tackle this problem, we suggest substituting the value of non-zero elements of RMI's index vectors (given in Equation 6) from $\frac{1}{U}$ to integer values of $\lfloor \frac{1}{U} \rfloor$, where $\lfloor \frac{1}{U} \rfloor \neq 0$. We argue that the resulting random projection matrix still has a Cauchy distribution. Therefore, the proposed methodology to estimate the ℓ_1 distance between vectors is also valid.

The ℓ_1 distance between context vectors must be estimated using either the median or the geometric mean. The use of the median estimator—for the reasons stated in Section 2.1—is not plausible. On the other hand, the computation of the geometric mean can be laborious as the overflow is highly likely to happen during its computation. Using the value of $\lfloor \frac{1}{U} \rfloor$ for non-zero elements of index vectors, we know that for any pair of context vectors $\vec{u} = (u_1, \cdots, u_m)$ and $\vec{v} = (v_1, \cdots, v_m)$, if $u_i \neq v_i$ then $|u_i - v_i| \geq 1$. Therefore, for $u_i \neq v_i$, $\ln |u_i - v_i| \geq 0$ and thus $\sum_{i=1}^{m} \ln(|u_i - v_i|) \geq 0$. In this case, the exponent in Equation 10 is a scale factor that can be discarded without a change in the relative distances between vectors.[14] Based on the intuition that the distance between a vector and itself is zero and the explanation given above, inspired by smoothing techniques and without being able to provide mathematical proofs, we suggest estimating the relative distances between vectors using

$$\hat{L}_1(\vec{u}, \vec{v}) = \sum_{\substack{i=1 \\ u_i \neq v_i}}^{m} \ln(|u_i - v_i|). \qquad (12)$$

In order to distinguish the above changes in RMI, we name the resulting technique random Manhattan integer indexing (RMII). The experiment described in Section 2.2 is repeated using the RMII method. As shown in Figure 6, the obtained results are almost identical to the observed results when using the RMI technique. While RMI performs slightly better than RMII in lower dimensions, e.g. $m = 400$, RMII shows more stable behaviour than RMI at higher dimensions, e.g. $m = 800$.

4 Comparison of RMI and RI

RMI and RI utilize a similar two-step procedure consisting of the creation of index vectors and the construction of context vectors. Both methods are incremental techniques that construct a VSM at reduced dimensionality directly, without requiring the VSM to be constructed at its original high dimension. Despite these similarities, RMI and RI are motivated by different applications and math-

[14] Please note that according to the axioms in the distance definition, the distance between two numbers is always a non-negative value. When index vectors consist of non-zero elements of real numbers, the value of $|u_i - v_i|$ can be between 0 and 1, i.e. $0 < |u_i - v_i| < 1$. Therefore, $\ln(|u_i - v_i|)$ can be a negative number and thus the exponent scale is required to make sure that the result is a non-negative number.

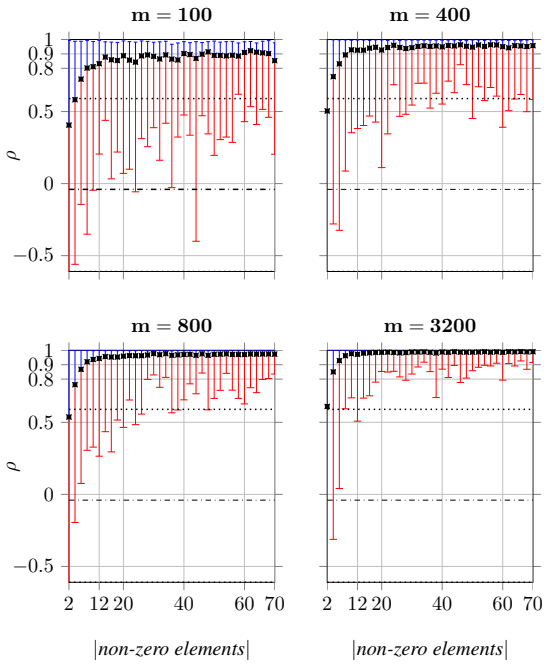

Figure 6: The observed results when using the RMII method for the construction and estimation of the ℓ_1 distances between vectors. The method is evaluated in the same setup as the RMI technique.

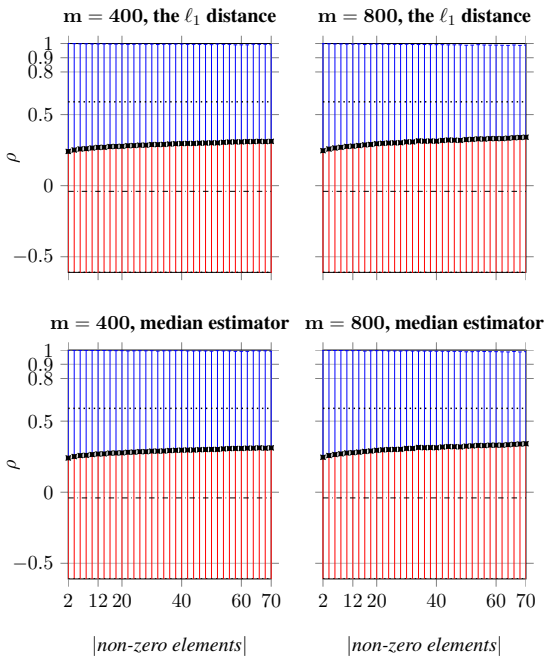

Figure 7: Evaluation of RI for the ℓ_1 distance estimation for $m = 400$ and $m = 800$ when the distances are calculated using the standard definition of distance in ℓ_1 normed spaces and the median estimator. The obtained results using RI do not show correlation to the ℓ_1 distances in the original high-dimensional VSM.

ematical theorems. As described above, RMI approximates the ℓ_1 distance using a *non-linear estimator*, which has not yet been employed for the construction of VSMs and the calculation of ℓ_1 distances in distributional approaches to semantics. Moreover, RMI is justified using Cauchy random projections.

In contrast, RI approximates the ℓ_2 distance using a linear estimator. RI has initially been justified using the mathematical model of the sparse distributed memory (SDM)[15]. Later, Sahlgren (2005) delineates the RI method using the lemma proposed by Johnson and Lindenstrauss (1984)—which elucidates random projections in Euclidean spaces—and the reported refinement in Achlioptas (2001) for the projections employed in the lemma. Although both the RMI and RI methods can be established as α-stable random projections—respectively for $\alpha = 1$ and $\alpha = 2$—the methods cannot be compared as they address different goals. If, for a given task, the ℓ_1 norm outperforms the ℓ_2 norm, then RMI is preferable to RI. Contrariwise, if the ℓ_2 norm outperforms the ℓ_1 norm, then RI is preferable to RMI.

To support the earlier claim that RI-constructed VSMs cannot be used for the ℓ_1 distance estimation, we evaluate the RI method in the experimental setup that has been used for the evaluation of RMI and RMII. In these experiments, however, we use RI to construct vector spaces at reduced dimensionality and estimate the ℓ_1 distance using Equation 5 (the standard ℓ_1 distance definition) and Equation 7 (the median estimator) for $m \in 400, 800$. As shown in Figure 7, the experiments support the theoretical claims.

5 Conclusion

In this paper, we introduce a novel technique, named Random Manhattan Indexing (RMI), for the construction of ℓ_1 normed VSMs directly at reduced dimensionality. We further suggest the Random Manhattan Integer Indexing (RMII) technique, a computationally enhanced version of the RMI technique. We demonstrated the ℓ_1 distance preservation ability of the proposed technique in an experimental setup using a word-by-document model. In these experiments, we showed how the variable parameters of the methods, i.e. the number of non-zero elements in index vectors and the

[15] See Kanerva (1993) for an overview of the SDM model.

dimensionality of the VSM, influence the obtained results. The proposed incremental (and thus efficient and scalable) methods significantly enhance the computation of the ℓ_1 distances in VSMs.

Abstract

In this paper, we propose a novel neural network model called RNN Encoder–Decoder that consists of two recurrent neural networks (RNN). One RNN encodes a sequence of symbols into a fixed-length vector representation, and the other decodes the representation into another sequence of symbols. The encoder and decoder of the proposed model are jointly trained to maximize the conditional probability of a target sequence given a source sequence. The performance of a statistical machine translation system is empirically found to improve by using the conditional probabilities of phrase pairs computed by the RNN Encoder–Decoder as an additional feature in the existing log-linear model. Qualitatively, we show that the proposed model learns a semantically and syntactically meaningful representation of linguistic phrases.

1 Introduction

Deep neural networks have shown great success in various applications such as objection recognition (see, e.g., (Krizhevsky et al., 2012)) and speech recognition (see, e.g., (Dahl et al., 2012)). Furthermore, many recent works showed that neural networks can be successfully used in a number of tasks in natural language processing (NLP). These include, but are not limited to, language modeling (Bengio et al., 2003), paraphrase detection (Socher et al., 2011) and word embedding extraction (Mikolov et al., 2013). In the field of statistical machine translation (SMT), deep neural networks have begun to show promising results. (Schwenk, 2012) summarizes a successful usage of feedforward neural networks in the framework of phrase-based SMT system.

Along this line of research on using neural networks for SMT, this paper focuses on a novel neural network architecture that can be used as a part of the conventional phrase-based SMT system. The proposed neural network architecture, which we will refer to as an *RNN Encoder–Decoder*, consists of two recurrent neural networks (RNN) that act as an encoder and a decoder pair. The encoder maps a variable-length source sequence to a fixed-length vector, and the decoder maps the vector representation back to a variable-length target sequence. The two networks are trained jointly to maximize the conditional probability of the target sequence given a source sequence. Additionally, we propose to use a rather sophisticated hidden unit in order to improve both the memory capacity and the ease of training.

The proposed RNN Encoder–Decoder with a novel hidden unit is empirically evaluated on the task of translating from English to French. We train the model to learn the translation probability of an English phrase to a corresponding French phrase. The model is then used as a part of a standard phrase-based SMT system by scoring each phrase pair in the phrase table. The empirical evaluation reveals that this approach of scoring phrase pairs with an RNN Encoder–Decoder improves the translation performance.

We qualitatively analyze the trained RNN Encoder–Decoder by comparing its phrase scores with those given by the existing translation model. The qualitative analysis shows that the RNN Encoder–Decoder is better at capturing the linguistic regularities in the phrase table, indirectly explaining the quantitative improvements in the overall translation performance. The further analysis of the model reveals that the RNN Encoder–Decoder learns a continuous space representation of a phrase that preserves both the semantic and syntactic structure of the phrase.

2 RNN Encoder–Decoder

2.1 Preliminary: Recurrent Neural Networks

A recurrent neural network (RNN) is a neural network that consists of a hidden state $\mathbf{h}$ and an optional output $\mathbf{y}$ which operates on a variable-length sequence $\mathbf{x} = (x_1, \ldots, x_T)$. At each time step t, the hidden state $\mathbf{h}_{\langle t \rangle}$ of the RNN is updated by

$$\mathbf{h}_{\langle t \rangle} = f\left(\mathbf{h}_{\langle t-1 \rangle}, x_t\right), \tag{1}$$

where f is a non-linear activation function. f may be as simple as an element-wise logistic sigmoid function and as complex as a long short-term memory (LSTM) unit (Hochreiter and Schmidhuber, 1997).

An RNN can learn a probability distribution over a sequence by being trained to predict the next symbol in a sequence. In that case, the output at each timestep t is the conditional distribution $p(x_t \mid x_{t-1}, \ldots, x_1)$. For example, a multinomial distribution (1-of-K coding) can be output using a softmax activation function

$$p(x_{t,j} = 1 \mid x_{t-1}, \ldots, x_1) = \frac{\exp\left(\mathbf{w}_j \mathbf{h}_{\langle t \rangle}\right)}{\sum_{j'=1}^{K} \exp\left(\mathbf{w}_{j'} \mathbf{h}_{\langle t \rangle}\right)}, \tag{2}$$

for all possible symbols $j = 1, \ldots, K$, where $\mathbf{w}_j$ are the rows of a weight matrix $\mathbf{W}$. By combining these probabilities, we can compute the probability of the sequence $\mathbf{x}$ using

$$p(\mathbf{x}) = \prod_{t=1}^{T} p(x_t \mid x_{t-1}, \ldots, x_1). \tag{3}$$

From this learned distribution, it is straightforward to sample a new sequence by iteratively sampling a symbol at each time step.

2.2 RNN Encoder–Decoder

In this paper, we propose a novel neural network architecture that learns to *encode* a variable-length sequence into a fixed-length vector representation and to *decode* a given fixed-length vector representation back into a variable-length sequence. From a probabilistic perspective, this new model is a general method to learn the conditional distribution over a variable-length sequence conditioned on yet another variable-length sequence, e.g. $p(y_1, \ldots, y_{T'} \mid x_1, \ldots, x_T)$, where one should note that the input and output sequence lengths T and T' may differ.

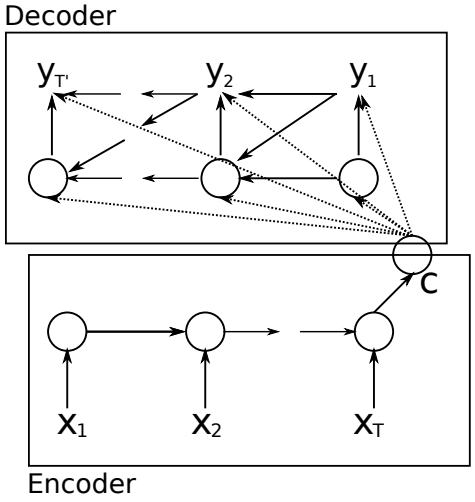

Figure 1: An illustration of the proposed RNN Encoder–Decoder.

The encoder is an RNN that reads each symbol of an input sequence $\mathbf{x}$ sequentially. As it reads each symbol, the hidden state of the RNN changes according to Eq. (1). After reading the end of the sequence (marked by an end-of-sequence symbol), the hidden state of the RNN is a summary $\mathbf{c}$ of the whole input sequence.

The decoder of the proposed model is another RNN which is trained to *generate* the output sequence by predicting the next symbol y_t given the hidden state $\mathbf{h}_{\langle t \rangle}$. However, unlike the RNN described in Sec. 2.1, both y_t and $\mathbf{h}_{\langle t \rangle}$ are also conditioned on y_{t-1} and on the summary $\mathbf{c}$ of the input sequence. Hence, the hidden state of the decoder at time t is computed by,

$$\mathbf{h}_{\langle t \rangle} = f\left(\mathbf{h}_{\langle t-1 \rangle}, y_{t-1}, \mathbf{c}\right),$$

and similarly, the conditional distribution of the next symbol is

$$P(y_t | y_{t-1}, y_{t-2}, \ldots, y_1, \mathbf{c}) = g\left(\mathbf{h}_{\langle t \rangle}, y_{t-1}, \mathbf{c}\right).$$

for given activation functions f and g (the latter must produce valid probabilities, e.g. with a softmax).

See Fig. 1 for a graphical depiction of the proposed model architecture.

The two components of the proposed *RNN Encoder–Decoder* are jointly trained to maximize the conditional log-likelihood

$$\max_{\boldsymbol{\theta}} \frac{1}{N} \sum_{n=1}^{N} \log p_{\boldsymbol{\theta}}(\mathbf{y}_n \mid \mathbf{x}_n), \tag{4}$$

where $\boldsymbol{\theta}$ is the set of the model parameters and each $(\mathbf{x}_n, \mathbf{y}_n)$ is an (input sequence, output sequence) pair from the training set. In our case, as the output of the decoder, starting from the input, is differentiable, we can use a gradient-based algorithm to estimate the model parameters.

Once the RNN Encoder–Decoder is trained, the model can be used in two ways. One way is to use the model to generate a target sequence given an input sequence. On the other hand, the model can be used to *score* a given pair of input and output sequences, where the score is simply a probability $p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$ from Eqs. (3) and (4).

2.3 Hidden Unit that Adaptively Remembers and Forgets

In addition to a novel model architecture, we also propose a new type of hidden unit (f in Eq. (1)) that has been motivated by the LSTM unit but is much simpler to compute and implement.[1] Fig. 2 shows the graphical depiction of the proposed hidden unit.

Let us describe how the activation of the j-th hidden unit is computed. First, the *reset* gate r_j is computed by

$$r_j = \sigma\left(\left[\mathbf{W}_r\mathbf{x}\right]_j + \left[\mathbf{U}_r\mathbf{h}_{\langle t-1\rangle}\right]_j\right), \quad (5)$$

where σ is the logistic sigmoid function, and $[.]_j$ denotes the j-th element of a vector. $\mathbf{x}$ and $\mathbf{h}_{t-1}$ are the input and the previous hidden state, respectively. $\mathbf{W}_r$ and $\mathbf{U}_r$ are weight matrices which are learned.

Similarly, the *update* gate z_j is computed by

$$z_j = \sigma\left(\left[\mathbf{W}_z\mathbf{x}\right]_j + \left[\mathbf{U}_z\mathbf{h}_{\langle t-1\rangle}\right]_j\right). \quad (6)$$

The actual activation of the proposed unit h_j is then computed by

$$h_j^{\langle t\rangle} = z_j h_j^{\langle t-1\rangle} + (1 - z_j)\tilde{h}_j^{\langle t\rangle}, \quad (7)$$

where

$$\tilde{h}_j^{\langle t\rangle} = \phi\left(\left[\mathbf{W}\mathbf{x}\right]_j + \left[\mathbf{U}\left(\mathbf{r} \odot \mathbf{h}_{\langle t-1\rangle}\right)\right]_j\right). \quad (8)$$

In this formulation, when the reset gate is close to 0, the hidden state is forced to ignore the previous hidden state and reset with the current input only. This effectively allows the hidden state to *drop* any information that is found to be irrelevant later in the future, thus, allowing a more compact representation.

On the other hand, the update gate controls how much information from the previous hidden state will carry over to the current hidden state. This acts similarly to the memory cell in the LSTM network and helps the RNN to remember long-term information. Furthermore, this may be considered an adaptive variant of a leaky-integration unit (Bengio et al., 2013).

As each hidden unit has separate reset and update gates, each hidden unit will learn to capture dependencies over different time scales. Those units that learn to capture short-term dependencies will tend to have reset gates that are frequently active, but those that capture longer-term dependencies will have update gates that are mostly active.

In our preliminary experiments, we found that it is crucial to use this new unit with gating units. We were not able to get meaningful result with an oft-used $\tanh$ unit without any gating.

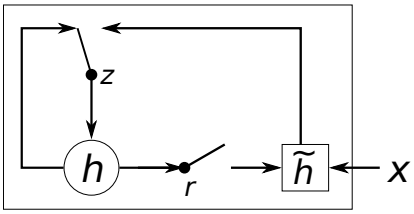

Figure 2: An illustration of the proposed hidden activation function. The update gate z selects whether the hidden state is to be updated with a new hidden state $\tilde{h}$. The reset gate r decides whether the previous hidden state is ignored. See Eqs. (5)–(8) for the detailed equations of r, z, h and $\tilde{h}$.

3 Statistical Machine Translation

In a commonly used statistical machine translation system (SMT), the goal of the system (decoder, specifically) is to find a translation $\mathbf{f}$ given a source sentence $\mathbf{e}$, which maximizes

$$p(\mathbf{f} \mid \mathbf{e}) \propto p(\mathbf{e} \mid \mathbf{f})p(\mathbf{f}),$$

where the first term at the right hand side is called *translation model* and the latter *language model* (see, e.g., (Koehn, 2005)). In practice, however, most SMT systems model $\log p(\mathbf{f} \mid \mathbf{e})$ as a log-linear model with additional features and corre-

[1] The LSTM unit, which has shown impressive results in several applications such as speech recognition, has a memory cell and four gating units that adaptively control the information flow inside the unit, compared to only two gating units in the proposed hidden unit. For details on LSTM networks, see, e.g., (Graves, 2012).

sponding weights:

$$\log p(\mathbf{f} \mid \mathbf{e}) = \sum_{n=1}^{N} w_n f_n(\mathbf{f}, \mathbf{e}) + \log Z(\mathbf{e}), \quad (9)$$

where f_n and w_n are the n-th feature and weight, respectively. $Z(\mathbf{e})$ is a normalization constant that does not depend on the weights. The weights are often optimized to maximize the BLEU score on a development set.

In the phrase-based SMT framework introduced in (Koehn et al., 2003) and (Marcu and Wong, 2002), the translation model $\log p(\mathbf{e} \mid \mathbf{f})$ is factorized into the translation probabilities of matching phrases in the source and target sentences.[2] These probabilities are once again considered additional features in the log-linear model (see Eq. (9)) and are weighted accordingly to maximize the BLEU score.

Since the neural net language model was proposed in (Bengio et al., 2003), neural networks have been used widely in SMT systems. In many cases, neural networks have been used to *rescore* translation hypotheses (n-best lists) (see, e.g., (Schwenk et al., 2006)). Recently, however, there has been interest in training neural networks to score the translated sentence (or phrase pairs) using a representation of the source sentence as an additional input. See, e.g., (Schwenk, 2012), (Son et al., 2012) and (Zou et al., 2013).

3.1 Scoring Phrase Pairs with RNN Encoder–Decoder

Here we propose to train the RNN Encoder–Decoder (see Sec. 2.2) on a table of phrase pairs and use its scores as additional features in the log-linear model in Eq. (9) when tuning the SMT decoder.

When we train the RNN Encoder–Decoder, we ignore the (normalized) frequencies of each phrase pair in the original corpora. This measure was taken in order (1) to reduce the computational expense of randomly selecting phrase pairs from a large phrase table according to the normalized frequencies and (2) to ensure that the RNN Encoder–Decoder does not simply learn to rank the phrase pairs according to their numbers of occurrences. One underlying reason for this choice was that the existing translation probability in the phrase table already reflects the frequencies of the phrase pairs in the original corpus. With a fixed capacity of the RNN Encoder–Decoder, we try to ensure that most of the capacity of the model is focused toward learning linguistic regularities, i.e., distinguishing between plausible and implausible translations, or learning the "manifold" (region of probability concentration) of plausible translations.

Once the RNN Encoder–Decoder is trained, we add a new score for each phrase pair to the existing phrase table. This allows the new scores to enter into the existing tuning algorithm with minimal additional overhead in computation.

As Schwenk pointed out in (Schwenk, 2012), it is possible to completely replace the existing phrase table with the proposed RNN Encoder–Decoder. In that case, for a given source phrase, the RNN Encoder–Decoder will need to generate a list of (good) target phrases. This requires, however, an expensive sampling procedure to be performed repeatedly. In this paper, thus, we only consider rescoring the phrase pairs in the phrase table.

3.2 Related Approaches: Neural Networks in Machine Translation

Before presenting the empirical results, we discuss a number of recent works that have proposed to use neural networks in the context of SMT.

Schwenk in (Schwenk, 2012) proposed a similar approach of scoring phrase pairs. Instead of the RNN-based neural network, he used a feedforward neural network that has fixed-size inputs (7 words in his case, with zero-padding for shorter phrases) and fixed-size outputs (7 words in the target language). When it is used specifically for scoring phrases for the SMT system, the maximum phrase length is often chosen to be small. However, as the length of phrases increases or as we apply neural networks to other variable-length sequence data, it is important that the neural network can handle variable-length input and output. The proposed RNN Encoder–Decoder is well-suited for these applications.

Similar to (Schwenk, 2012), Devlin et al. (Devlin et al., 2014) proposed to use a feedforward neural network to model a translation model, however, by predicting one word in a target phrase at a time. They reported an impressive improvement, but their approach still requires the maximum length of the input phrase (or context words) to be fixed a priori.

[2] Without loss of generality, from here on, we refer to $p(\mathbf{e} \mid \mathbf{f})$ for each phrase pair as a translation model as well

Although it is not exactly a neural network they train, the authors of (Zou et al., 2013) proposed to learn a bilingual embedding of words/phrases. They use the learned embedding to compute the distance between a pair of phrases which is used as an additional score of the phrase pair in an SMT system.

In (Chandar et al., 2014), a feedforward neural network was trained to learn a mapping from a bag-of-words representation of an input phrase to an output phrase. This is closely related to both the proposed RNN Encoder–Decoder and the model proposed in (Schwenk, 2012), except that their input representation of a phrase is a bag-of-words. A similar approach of using bag-of-words representations was proposed in (Gao et al., 2013) as well. Earlier, a similar encoder–decoder model using two recursive neural networks was proposed in (Socher et al., 2011), but their model was restricted to a monolingual setting, i.e. the model reconstructs an input sentence. More recently, another encoder–decoder model using an RNN was proposed in (Auli et al., 2013), where the decoder is conditioned on a representation of either a source sentence or a source context.

One important difference between the proposed RNN Encoder–Decoder and the approaches in (Zou et al., 2013) and (Chandar et al., 2014) is that the order of the words in source and target phrases is taken into account. The RNN Encoder–Decoder naturally distinguishes between sequences that have the same words but in a different order, whereas the aforementioned approaches effectively ignore order information.

The closest approach related to the proposed RNN Encoder–Decoder is the Recurrent Continuous Translation Model (Model 2) proposed in (Kalchbrenner and Blunsom, 2013). In their paper, they proposed a similar model that consists of an encoder and decoder. The difference with our model is that they used a convolutional n-gram model (CGM) for the encoder and the hybrid of an inverse CGM and a recurrent neural network for the decoder. They, however, evaluated their model on rescoring the n-best list proposed by the conventional SMT system and computing the perplexity of the gold standard translations.

4 Experiments

We evaluate our approach on the English/French translation task of the WMT'14 workshop.

4.1 Data and Baseline System

Large amounts of resources are available to build an English/French SMT system in the framework of the WMT'14 translation task. The bilingual corpora include Europarl (61M words), news commentary (5.5M), UN (421M), and two crawled corpora of 90M and 780M words respectively. The last two corpora are quite noisy. To train the French language model, about 712M words of crawled newspaper material is available in addition to the target side of the bitexts. All the word counts refer to French words after tokenization.

It is commonly acknowledged that training statistical models on the concatenation of all this data does not necessarily lead to optimal performance, and results in extremely large models which are difficult to handle. Instead, one should focus on the most relevant subset of the data for a given task. We have done so by applying the data selection method proposed in (Moore and Lewis, 2010), and its extension to bitexts (Axelrod et al., 2011). By these means we selected a subset of 418M words out of more than 2G words for language modeling and a subset of 348M out of 850M words for training the RNN Encoder–Decoder. We used the test set `newstest2012 and 2013` for data selection and weight tuning with MERT, and `newstest2014` as our test set. Each set has more than 70 thousand words and a single reference translation.

For training the neural networks, including the proposed RNN Encoder–Decoder, we limited the source and target vocabulary to the most frequent 15,000 words for both English and French. This covers approximately 93% of the dataset. All the out-of-vocabulary words were mapped to a special token ([UNK]).

The baseline phrase-based SMT system was built using Moses with default settings. This system achieves a BLEU score of 30.64 and 33.3 on the development and test sets, respectively (see Table 1).

4.1.1 RNN Encoder–Decoder

The RNN Encoder–Decoder used in the experiment had 1000 hidden units with the proposed gates at the encoder and at the decoder. The input matrix between each input symbol $x_{\langle t \rangle}$ and the hidden unit is approximated with two lower-rank matrices, and the output matrix is approximated

Models	BLEU	
	dev	test
Baseline	30.64	33.30
RNN	31.20	33.87
CSLM + RNN	31.48	34.64
CSLM + RNN + WP	31.50	34.54

Table 1: BLEU scores computed on the development and test sets using different combinations of approaches. WP denotes a *word penalty*, where we penalizes the number of unknown words to neural networks.

similarly. We used rank-100 matrices, equivalent to learning an embedding of dimension 100 for each word. The activation function used for $\tilde{h}$ in Eq. (8) is a hyperbolic tangent function. The computation from the hidden state in the decoder to the output is implemented as a deep neural network (Pascanu et al., 2014) with a single intermediate layer having 500 maxout units each pooling 2 inputs (Goodfellow et al., 2013).

All the weight parameters in the RNN Encoder–Decoder were initialized by sampling from an isotropic zero-mean (white) Gaussian distribution with its standard deviation fixed to 0.01, except for the recurrent weight parameters. For the recurrent weight matrices, we first sampled from a white Gaussian distribution and used its left singular vectors matrix, following (Saxe et al., 2014).

We used Adadelta and stochastic gradient descent to train the RNN Encoder–Decoder with hyperparameters $\epsilon = 10^{-6}$ and $\rho = 0.95$ (Zeiler, 2012). At each update, we used 64 randomly selected phrase pairs from a phrase table (which was created from 348M words). The model was trained for approximately three days.

Details of the architecture used in the experiments are explained in more depth in the supplementary material.

4.1.2 Neural Language Model

In order to assess the effectiveness of scoring phrase pairs with the proposed RNN Encoder–Decoder, we also tried a more traditional approach of using a neural network for learning a target language model (CSLM) (Schwenk, 2007). Especially, the comparison between the SMT system using CSLM and that using the proposed approach of phrase scoring by RNN Encoder–Decoder will clarify whether the contributions from multiple neural networks in different parts of the SMT system add up or are redundant.

We trained the CSLM model on 7-grams from the target corpus. Each input word was projected into the embedding space $\mathbb{R}^{512}$, and they were concatenated to form a 3072-dimensional vector. The concatenated vector was fed through two rectified layers (of size 1536 and 1024) (Glorot et al., 2011). The output layer was a simple softmax layer (see Eq. (2)). All the weight parameters were initialized uniformly between -0.01 and 0.01, and the model was trained until the validation perplexity did not improve for 10 epochs. After training, the language model achieved a perplexity of 45.80. The validation set was a random selection of 0.1% of the corpus. The model was used to score partial translations during the decoding process, which generally leads to higher gains in BLEU score than n-best list rescoring (Vaswani et al., 2013).

To address the computational complexity of using a CSLM in the decoder a buffer was used to aggregate n-grams during the stack-search performed by the decoder. Only when the buffer is full, or a stack is about to be pruned, the n-grams are scored by the CSLM. This allows us to perform fast matrix-matrix multiplication on GPU using Theano (Bergstra et al., 2010; Bastien et al., 2012).

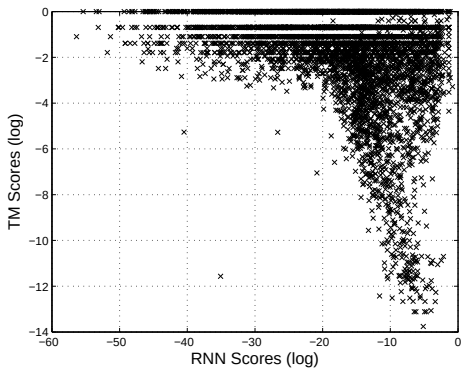

Figure 3: The visualization of phrase pairs according to their scores (log-probabilities) by the RNN Encoder–Decoder and the translation model.

4.2 Quantitative Analysis

We tried the following combinations:

1. Baseline configuration
2. Baseline + RNN
3. Baseline + CSLM + RNN
4. Baseline + CSLM + RNN + Word penalty

(b) Long, rare source phrases

Table 2: The top scoring target phrases for a small set of source phrases according to the translation model (direct translation probability) and by the RNN Encoder–Decoder. Source phrases were randomly selected from phrases with 4 or more words. **?** denotes an incomplete (partial) character. **r** is a Cyrillic letter *ghe*.

The results are presented in Table 1. As expected, adding features computed by neural networks consistently improves the performance over the baseline performance.

The best performance was achieved when we used both CSLM and the phrase scores from the RNN Encoder–Decoder. This suggests that the contributions of the CSLM and the RNN Encoder–Decoder are not too correlated and that one can expect better results by improving each method independently. Furthermore, we tried penalizing the number of words that are unknown to the neural networks (i.e. words which are not in the shortlist). We do so by simply adding the number of unknown words as an additional feature the log-linear model in Eq. (9).[3] However, in this case we were not able to achieve better performance on the test set, but only on the development set.

4.3 Qualitative Analysis

In order to understand where the performance improvement comes from, we analyze the phrase pair scores computed by the RNN Encoder–Decoder against the corresponding $p(\mathbf{f} \mid \mathbf{e})$ from the translation model. Since the existing translation model relies solely on the statistics of the phrase pairs in the corpus, we expect its scores to be better estimated for the frequent phrases but badly estimated for rare phrases. Also, as we mentioned earlier in Sec. 3.1, we further expect the RNN Encoder–Decoder which was trained without any frequency information to score the phrase pairs based rather on the linguistic regularities than on the statistics of their occurrences in the corpus.

We focus on those pairs whose source phrase is *long* (more than 3 words per source phrase) and

[3] To understand the effect of the penalty, consider the set of all words in the 15,000 large shortlist, SL. All words $x^i \notin$ SL are replaced by a special token [UNK] before being scored by the neural networks. Hence, the conditional probability of any $x_t^i \notin$ SL is actually given by the model as

$$p(x_t = [\text{UNK}] \mid x_{<t}) = p(x_t \notin \text{SL} \mid x_{<t}) = \sum_{x_t^j \notin SL} p\left(x_t^j \mid x_{<t}\right) \geq p\left(x_t^i \mid x_{<t}\right),$$

where $x_{<t}$ is a shorthand notation for $x_{t-1}, \ldots, x_1$.

As a result, the probability of words not in the shortlist is always overestimated. It is possible to address this issue by backing off to an existing model that contain non-shortlisted words (see (Schwenk, 2007)) In this paper, however, we opt for introducing a word penalty instead, which counteracts the word probability overestimation.

frequent. For each such source phrase, we look at the target phrases that have been scored high either by the translation probability $p(\mathbf{f} \mid \mathbf{e})$ or by the RNN Encoder–Decoder. Similarly, we perform the same procedure with those pairs whose source phrase is *long* but *rare* in the corpus.

Table 2 lists the top-3 target phrases per source phrase favored either by the translation model or by the RNN Encoder–Decoder. The source phrases were randomly chosen among long ones having more than 4 or 5 words.

In most cases, the choices of the target phrases by the RNN Encoder–Decoder are closer to actual or literal translations. We can observe that the RNN Encoder–Decoder prefers shorter phrases in general.

Interestingly, many phrase pairs were scored similarly by both the translation model and the RNN Encoder–Decoder, but there were as many other phrase pairs that were scored radically different (see Fig. 3). This could arise from the proposed approach of training the RNN Encoder–Decoder on a set of unique phrase pairs, discouraging the RNN Encoder–Decoder from learning simply the frequencies of the phrase pairs from the corpus, as explained earlier.

Furthermore, in Table 3, we show for each of the source phrases in Table 2, the generated samples from the RNN Encoder–Decoder. For each source phrase, we generated 50 samples and show the top-five phrases accordingly to their scores. We can see that the RNN Encoder–Decoder is able to propose well-formed target phrases without looking at the actual phrase table. Importantly, the generated phrases do not overlap completely with the target phrases from the phrase table. This encourages us to further investigate the possibility of replacing the whole or a part of the phrase table

with the proposed RNN Encoder–Decoder in the future.

4.4 Word and Phrase Representations

Since the proposed RNN Encoder–Decoder is not specifically designed only for the task of machine translation, here we briefly look at the properties of the trained model.

It has been known for some time that continuous space language models using neural networks are able to learn semantically meaningful embeddings (See, e.g., (Bengio et al., 2003; Mikolov et al., 2013)). Since the proposed RNN Encoder–Decoder also projects to and maps back from a sequence of words into a continuous space vector, we expect to see a similar property with the proposed model as well.

The left plot in Fig. 4 shows the 2–D embedding of the words using the word embedding matrix learned by the RNN Encoder–Decoder. The projection was done by the recently proposed Barnes-Hut-SNE (van der Maaten, 2013). We can clearly see that semantically similar words are clustered with each other (see the zoomed-in plots in Fig. 4).

The proposed RNN Encoder–Decoder naturally generates a continuous-space representation of a phrase. The representation ($\mathbf{c}$ in Fig. 1) in this case is a 1000-dimensional vector. Similarly to the word representations, we visualize the representations of the phrases that consists of four or more words using the Barnes-Hut-SNE in Fig. 5.

From the visualization, it is clear that the RNN Encoder–Decoder captures *both semantic and syntactic* structures of the phrases. For instance, in the bottom-left plot, most of the phrases are about the duration of time, while those phrases that are syntactically similar are clustered together. The bottom-right plot shows the cluster of phrases that are semantically similar (countries or regions). On the other hand, the top-right plot shows the phrases that are syntactically similar.

5 Conclusion

In this paper, we proposed a new neural network architecture, called an *RNN Encoder–Decoder* that is able to learn the mapping from a sequence

of an arbitrary length to another sequence, possibly from a different set, of an arbitrary length. The proposed RNN Encoder–Decoder is able to either score a pair of sequences (in terms of a conditional probability) or generate a target sequence given a source sequence. Along with the new architecture, we proposed a novel hidden unit that includes a reset gate and an update gate that adaptively control how much each hidden unit remembers or forgets while reading/generating a sequence.

We evaluated the proposed model with the task of statistical machine translation, where we used the RNN Encoder–Decoder to score each phrase pair in the phrase table. Qualitatively, we were able to show that the new model is able to capture linguistic regularities in the phrase pairs well and also that the RNN Encoder–Decoder is able to propose well-formed target phrases.

The scores by the RNN Encoder–Decoder were found to improve the overall translation performance in terms of BLEU scores. Also, we found that the contribution by the RNN Encoder–Decoder is rather orthogonal to the existing approach of using neural networks in the SMT system, so that we can improve further the performance by using, for instance, the RNN Encoder–Decoder and the neural net language model together.

Our qualitative analysis of the trained model shows that it indeed captures the linguistic regularities in multiple levels i.e. at the word level as well as phrase level. This suggests that there may be more natural language related applications that may benefit from the proposed RNN Encoder–Decoder.

The proposed architecture has large potential for further improvement and analysis. One approach that was not investigated here is to replace the whole, or a part of the phrase table by letting the RNN Encoder–Decoder propose target phrases. Also, noting that the proposed model is not limited to being used with written language, it will be an important future research to apply the proposed architecture to other applications such as speech transcription.

Type-based MCMC for Sampling Tree Fragments from Forests

Xiaochang Peng and **Daniel Gildea**
Department of Computer Science
University of Rochester
Rochester, NY 14627

Abstract

This paper applies type-based Markov Chain Monte Carlo (MCMC) algorithms to the problem of learning Synchronous Context-Free Grammar (SCFG) rules from a forest that represents all possible rules consistent with a fixed word alignment. While type-based MCMC has been shown to be effective in a number of NLP applications, our setting, where the tree structure of the sentence is itself a hidden variable, presents a number of challenges to type-based inference. We describe methods for defining variable types and efficiently indexing variables in order to overcome these challenges. These methods lead to improvements in both log likelihood and BLEU score in our experiments.

1 Introduction

In previous work, sampling methods have been used to learn Tree Substitution Grammar (TSG) rules from derivation trees (Post and Gildea, 2009; Cohn et al., 2009) for TSG learning. Here, at each node in the derivation tree, there is a binary variable indicating whether the node is internal to a TSG rule or is a split point, which we refer to as a **cut**, between two rules. The problem of extracting machine translation rules from word-aligned bitext is a similar problem in that we wish to automatically learn the best granularity for the rules with which to analyze each sentence. The problem of rule extraction is more complex, however, because the tree structure of the sentence is also unknown.

In machine translation applications, most previous work on joint alignment and rule extraction models uses heuristic methods to extract rules from learned word alignment or bracketing structures (Zhang et al., 2008; Blunsom et al., 2009; DeNero et al., 2008; Levenberg et al., 2012). Chung et al. (2014) present a MCMC algorithm schedule to learn Hiero-style SCFG rules (Chiang, 2007) by sampling tree fragments from phrase decomposition forests, which represent all possible rules that are consistent with a set of fixed word alignments. Assuming fixed word alignments reduces the complexity of the sampling problem, and has generally been effective in most state-of-the-art machine translation systems. The algorithm for sampling rules from a forest is as follows: from the root of the phrase decomposition forest, one samples a cut variable, denoting whether the current node is a cut, and an edge variable, denoting which incoming hyperedge is chosen, at each node of the current tree in a top-down manner. This sampling schedule is efficient in that it only samples the current tree and will not waste time on updating variables that are unlikely to be used in any tree.

As with many other token-based Gibbs Sampling applications, sampling one node at a time can result in slow mixing due to the strong coupling between variables. One general remedy is to sample blocks of coupled variables. Cohn and Blunsom (2010) and Yamangil and Shieber (2013) used blocked sampling algorithms that sample the whole tree structure associated with one sentence at a time for TSG and TAG learning. However, this kind of blocking does not deal with the coupling of variables correlated with the same type of structure across sentences. Liang et al. (2010) introduced a type-based sampling schedule which updates a block of variables of the same type jointly. The **type** of a variable is defined as the combination of new structural choices added when assigning different values to the variable. Type-based MCMC tackles the coupling issue by assigning the same type to variables that are strongly coupled.

In this paper, we follow the phrase decomposition forest construction procedures of Chung et

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1735–1745,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

al. (2014) and present a type-based MCMC algorithm for sampling tree fragments from phrase decomposition forests which samples the variables of the same type jointly. We define the type of the cut variable for each node in our sampling schedule. While type-based MCMC has been proven to be effective in a number of NLP applications, our sample-edge, sample-cut setting is more complicated as our tree structure is unknown. We need additional steps to maintain the cut type information when the tree structure is changed as we sample the edge variable. Like other type-based MCMC applications, we need bookkeeping of node sites to be sampled in order to loop through sites of the same type efficiently. As noted by Liang et al. (2010), indexing by the complete type information is too expensive in some applications like TSG learning. Our setting is different from TSG learning in that the internal structure of each SCFG rule is abstracted away when deriving the rule type from the tree fragment sampled.

We make the following contributions:

1. We apply type-based MCMC to the setting of SCFG learning and have achieved better log likelihood and BLEU score result.

2. We present an innovative way of storing the type information by indexing on partial type information and then filtering the retrieved nodes according to the full type information, which enables efficient updates to maintain the type information while the amount of bookkeeping is reduced significantly.

3. We replace the two-stage sampling schedule of Liang et al. (2010) with a simpler and faster one-stage method.

4. We use parallel programming to do inexact type-based MCMC, which leads to a speed up of four times in comparison with non-parallel type-based MCMC, while the likelihood result of the Markov Chain does not change. This strategy should also work with other type-based MCMC applications.

2 MCMC for Sampling Tree Fragments from Forests

2.1 Phrase Decomposition Forest

The phrase decomposition forest provides a compact representation of all machine translation rules

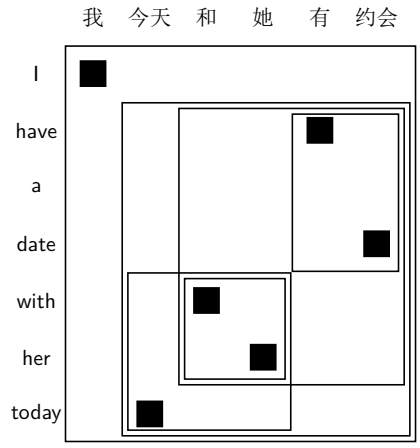

Figure 1: Example word alignment, with boxes showing valid phrase pairs. In this example, all individual alignment points are also valid phrase pairs.

that are consistent with our fixed input word alignment (Chung et al., 2014), and our sampling algorithm selects trees from this forest.

As in Hiero, our grammars will make use of a single nonterminal X, and will contain rules with a mixture of nonterminals and terminals on the righthand side (r.h.s.), with at most two nonterminal occurrences on the r.h.s. Under this restriction, the maximum number of rules that can be extracted from an input sentence pair is $O(n^{12})$ with respect to the length of the sentence pair, as the left and right boundaries of the lefthand side (l.h.s.) nonterminal and each of the two r.h.s. nonterminals can take $O(n)$ positions in each of the two languages. This complexity leads us to explore sampling algorithms instead of using dynamic programming.

A **span** $[i, j]$ is a set of contiguous word indices $\{i, i+1, \ldots, j-1\}$. Given an aligned Chinese-English sentence pair, a **phrase** n is a pair of spans $n = ([i_1, j_1], [i_2, j_2])$ such that Chinese words in positions $[i_1, j_1]$ are aligned only to English words in positions $[i_2, j_2]$, and vice versa. A **phrase forest** $H = \langle V, E \rangle$ is a hypergraph made of a set of hypernodes V and a set of hyperedges E. Each node $n = ([i_1, j_1], [i_2, j_2]) \in V$ is a **tight** phrase as defined by Koehn et al. (2003), i.e., a phrase containing no unaligned words at its boundaries. A phrase $n = ([i_1, j_1], [i_2, j_2])$ **covers** $n' = ([i'_1, j'_1], [i'_2, j'_2])$ if

$$i_1 \leq i'_1 \wedge j'_1 \leq j_1 \wedge i_2 \leq i'_2 \wedge j'_2 \leq j_2$$

Each edge in E, written as $T \rightarrow n$, is made of a

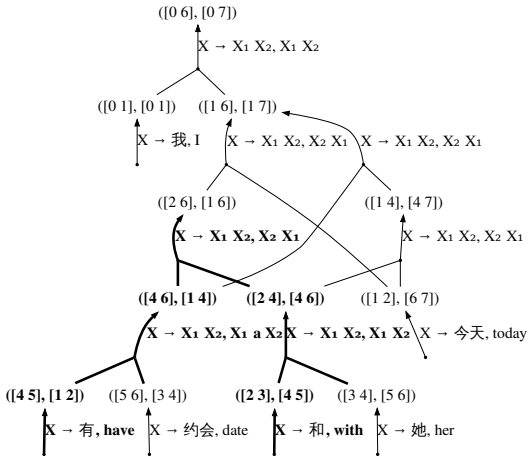

Figure 2: A phrase decomposition forest extracted from the sentence pair ⟨我 今天 和 她 有 约会, I have a date with her today⟩. Each edge is a minimal SCFG rule, and the rules at the bottom level are phrase pairs. Unaligned word "a" shows up in the rule $X \rightarrow X_1X_2, X_1aX_2$ after unaligned words are put back into the alignment matrix. The highlighted portion of the forest shows an SCFG rule built by composing minimal rules.

set of non-intersecting tail nodes $T \subset V$, and a single head node $n \in V$ that covers each tail node. We say an edge $T \rightarrow n$ is **minimal** if there does not exist another edge $T' \rightarrow n$ such that T' covers T. A **minimal edge** is an SCFG rule that cannot be decomposed by factoring out some part of its r.h.s. as a separate rule. We define a **phrase decomposition forest** to be made of all phrases from a sentence pair, connected by all minimal SCFG rules. A phrase decomposition forest compactly represents all possible SCFG rules that are consistent with word alignments. For the example word alignment shown in Figure 1, the phrase decomposition forest is shown in Figure 2. Each boxed phrase in Figure 1 corresponds to a node in the forest of Figure 2, while hyperedges in Figure 2 represent ways of building phrases out of shorter phrases.

A phrase decomposition forest has the important property that any SCFG rule consistent with the word alignment corresponds to a contiguous fragment of some complete tree found in the forest. For example, the highlighted tree fragment of the forest in Figure 2 corresponds to the SCFG rule:

$$X \rightarrow \text{和 } X_2 \text{ 有 } X_1, \text{ have a } X_1 \text{ with } X_2$$

Thus any valid SCFG rule can be formed by selecting a set of adjacent hyperedges from the forest and composing the minimal SCFG rules specified by each hyperedge. Therefore, the problem of SCFG rules extraction can be solved by sampling tree fragments from the phrase decomposition forest. We use a bottom-up algorithm to construct the phrase decomposition forest from the word alignments.

2.2 Sampling Tree Fragments From Forest

We formulate the rule sampling procedure into two phases: first we select a tree from a forest, then we select the cuts in the tree to denote the split points between fragments, with each fragment corresponding to a SCFG rule. A tree can be specified by attaching a variable e_n to each node n in the forest, indicating which hyperedge is turned on at the current node. Thus each assignment will specify a unique tree by tracing the edge variables from the root down to the leaves. We also attach a cut variable z_n to each node, indicating whether the node is a split point between two adjacent fragments.

Let all the edge variables form the random vector Y and all the cut variables form the random vector Z. Given an assignment y to the edge variables and assignment z to the cut variables, our desired distribution is proportional to the product of weights of the rules specified by the assignment:

$$P_t(Y = y, Z = z) \propto \prod_{r \in \tau(y,z)} w(r) \qquad (1)$$

where $\tau(y, z)$ is the set of rules identified by the assignment. We use a generative model based on a Dirichlet Process (DP) defined over composed rules. We draw a distribution G over rules from a DP, and then rules from G.

$$G \mid \alpha, P_0 \sim Dir(\alpha, P_0)$$
$$r \mid G \sim G$$

For the base distribution P_0, we use a uniform distribution where all rules of the same size have equal probability:

$$P_0(r) = V_f^{-|r_f|} V_e^{-|r_e|} \qquad (2)$$

where V_f and V_e are the vocabulary sizes of the source language and the target language, and $|r_f|$ and $|r_e|$ are the lengths of the source side and target side of rule r. By marginalizing out G we get a simple posterior distribution over rules which can be described using the Chinese Restaurant Process (CRP). For this analogy, we imagine a restaurant has infinite number of tables that represent rule types and customers that represent translation rule instances. Each customer enters the restaurant and chooses a table to sit at. Let z_i be the table chosen by the i-th customer, then the customer chooses a table k either having been seated or a new table with probability:

$$P(z_i = k|z_{-i}) = \begin{cases} \frac{n_k}{i-1+\alpha} & 1 \leq k \leq K \\ \frac{\alpha}{i-1+\alpha} & k = K+1 \end{cases} \quad (3)$$

where z_{-i} is the current seating arrangement, n_k is the number of customers at the table k, K is the total number of occupied tables. If the customer sits at a new table, the new table will be assigned a rule label r with probability $P_0(r)$. We can see from Equation 3 that the only history related to the current table assignment is the counts in z_{-i}. Therefore, we define a table of counts $N = \{N_C\}_{C \in I}$ which memorizes different categories of counts in z_{-i}. I is an index set for different categories of counts. Each N_C is a vector of counts for category C. We have $P(r_i = r|z_{-i}) = P(r_i = r|N)$. If we marginalize over tables labeled with the same rule, we get the following probability over rule r given the previous count table N:

$$P(r_i = r|N) = \frac{N_R(r) + \alpha P_0(r)}{n + \alpha} \quad (4)$$

here in the case of DP, $I = \{R\}$, where R is the index for the category of rule counts. $N_R(r)$ is the number of times that rule r has been observed in z_{-i}, $n = \sum_r N_R(r)$ is the total number of rules observed.

We also define a Pitman-Yor Process (PYP) (Pitman and Yor, 1997) over rules of each length l. We draw the rule distribution G from a PYP, and then rules of length l are drawn from G.

$$G|\alpha, d, P_0 \sim PY(\alpha, d, P_0)$$

$$r|G \sim G$$

The first two parameters, a concentration parameter α and a discount parameter d, control the shape of distribution G by controlling the size and the number of clusters. Integrating over G, we have the following PYP posterior probability:

$$P(r_i = r|N) = \frac{N_R(r) - T_r d + (T_l d + \alpha) P_0(r)}{N_L(l) + \alpha} \quad (5)$$

here for the case of PYP, $I = \{R, L\}$. We have an additional index L for the category of rule length counts, and $N_L(l)$ is the total number of rules of length l observed in z_{-i}. T_r is the number of tables labeled with r in z_{-i}. The length of the rule is drawn from a Poisson distribution, so a rule length probability $P(l; \lambda) = \frac{\lambda^l e^{-\lambda}}{l!}$ is multiplied by this probability to calculate the real posterior probability for each rule. In order to simplify the tedious book-keeping, we estimate the number of tables using the following equations (Huang and Renals, 2010):

$$T_r = N_R(r)^d \quad (6)$$

$$T_l = \sum_{r:|r|=l} N_R(r)^d \quad (7)$$

We use the *top-down* sampling algorithm of Chung et al. (2014) (see Algorithm 1). Starting from the root of the forest, we sample a value for the edge variable denoting which incoming hyperedge of the node is turned on in the current tree, and then we sample a cut value for the node denoting whether the node is a split point between two fragments in the tree. For each node n, we denote the composed rule type that we get when we set the cut of node n to 0 as r_1 and the two split rule types that we get when we set the cut to 1 as r_2, r_3. We sample the cut value z_i of the current node according to the posterior probability:

$$P(z_i = z|N) = \begin{cases} \frac{P(r_1|N)}{P(r_1|N)+P(r_2|N)P(r_3|N')} & \text{if } z = 0 \\ \frac{P(r_2|N)P(r_3|N')}{P(r_1|N)+P(r_2|N)P(r_3|N')} & \text{otherwise} \end{cases} \quad (8)$$

where the posterior probability $P(r_i|N)$ is according to either a DP or a PYP, and N, N' are tables of counts. In the case of DP, N, N' differ only in the rule counts of r_2, where $N'_R(r_2) = N_R(r_2) + 1$. In the case of PYP, there is an extra difference that

        queue.push(c)
    end for
end while
```

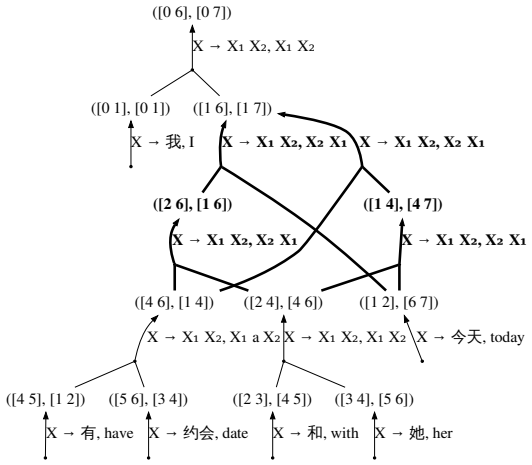

Figure 3: An example of cut type: Consider the two nodes marked in bold, $([2\,6],[1\,6])$, $([1\,4],[4\,7])$. These two non-split nodes are internal to the same composed rule: $X \rightarrow X_1X_2X_3, X_3X_2X_1$. We keep these two sites with the same index. However, when we set the cut value of these two nodes to 1, as the rules immediately above and immediately below are different for these two sites, they are not of the same type.

$N'_L(l) = N_L(l) + 1$, where l is the rule length of r_2.

As for edge variables e_i, we refer to the set of composed rules turned on below n including the composed rule fragments having n as an internal or root node as $\{r_1, \ldots, r_m\}$. We have the following posterior probability over the edge variable e_i:

$$P(e_i = e|N) \propto \prod_{i=1}^{m} P(r_i|N^{i-1}) \prod_{v \in \tau(e) \cap \text{in}(n)} \deg(v) \quad (9)$$

where $\deg(v)$ is the number of incoming edges for node v, $\text{in}(n)$ is the set of nodes in all subtrees under n, and $\tau(e)$ is the tree specified when we set $e_i = e$. N^0 to N^m are tables of counts where $N^0 = N$, $N^i_R(r_i) = N^{i-1}_R(r_i) + 1$ in the case of DP and additionally $N^i_L(l_i) = N^{i-1}_L(l_i) + 1$ in the case of PYP, where l_i is the rule length of r_i.

3 Type-based MCMC Sampling

Our goal in this paper is to organize blocks of variables that are strongly coupled into types and sample variables of each type jointly. One major property of type-based MCMC is that the joint probability of variables of the same type should be exchangeable so that the order of the variables does not matter. Also, the choices of the variables to be sampled jointly should not interfere with each other, which we define as a *conflict*. In this section, we define the type of cut variables in our sampling schedule and explain that with the two priors we introduced before, the joint probability of the variables will satisfy the exchangeability property. We will also discuss how to check conflict sites in our application.

In type-based MCMC, we need bookkeeping of sites as we need to loop through them to search for sites having the same type efficiently. In our two-stage sample-edge, sample-cut schedule, updating the edge variable would change the tree structure and trigger updates for the cut variable types in both the old and the new subtree. We come up with an efficient bookkeeping strategy to index on partial type information which significantly reduces the bookkeeping size, while updates are quite efficient when the tree structure is changed. The detail will become clear below.

3.1 Type-based MCMC

We refer to each node site to be sampled as a pair (t, n), indicating node n of forest t. For each site (t, n) and the corresponding composed rule types r_1 obtained when we set n's cut value to 0 and r_2, r_3 obtained when we set the cut value to 1, the cut variable type of site (t, n) is:

$$type(t, n) \stackrel{\text{def}}{=} (r_1, r_2, r_3)$$

We say that the cut variables of two sites are of the same type if the composed rule types r_1, r_2 and r_3 are exactly the same. For example, in Figure 3, assume that all the nodes in the hypergraph are currently set to be split points except for the two nodes marked in bold, $([2\,6],[1\,6]),([1\,4],[4\,7])$. Considering these two non-split nodes, the composed rule types they are internal to (r_1) are exactly the same. However, the situation changes if we set the cut variables of these two nodes to be 1, i.e., all of the nodes in the hypergraph are now split points. As the rule type immediately above and the rule type immediately below the two nodes (r_2 and r_3) are now different, they are not of the same type.

We sample the cut value z_i according to Equation 8. As each rule is sampled according to a DP or PYP posterior and the joint probabilities according to both posteriors are exchangeable, we can see from Equation 8 that the joint prob-

ability of a sequence of cut variables is also exchangeable. Consider a set of sites S containing n cut variables $z_S = (z_1, ..., z_n)$ of the same type. This exchangeability property leads to the fact that any sequence containing same number of cuts (cut value of 1) would have same probability. We have the following probability distribution:

$$P(z_S|N) \propto \prod_{i=1}^{n-m} P(r_1|N^{i-1}) \prod_{i=1}^{m} P(r_2|\bar{N}^{i-1})P(r_3|\hat{N}^{i-1}) \stackrel{\text{def}}{=} g(m) \quad (10)$$

where N is the count table for all the other variables except for S. $m = \sum_{i=1}^{n} z_i$ is the number of cut sites. The variables N, $\bar{N}$, and $\hat{N}$ keep track of the counts as the derivation proceeds step by step:

$$\begin{aligned} N^0 &= N \\ N_R^i(r_1) &= N_R^{i-1}(r_1) + 1 \\ \bar{N}^0 &= N^{n-m} \\ \hat{N}_R^{i-1}(r_2) &= \bar{N}_R^{i-1}(r_2) + 1 \\ \bar{N}_R^i(r_3) &= \hat{N}_R^{i-1}(r_3) + 1 \end{aligned}$$

For PYP, we add extra count indices for rule length counts similarly.

Given the exchangeability property of the cut variables, we can calculate the posterior probability of $m = \sum_{i=1}^{n} z_i$ by summing over all $\binom{n}{m}$ combinations of the cut sites:

$$p(m|N) \propto \sum_{z_S: m=\sum_i z_i} p(z_S|N) = \binom{n}{m} g(m) \quad (11)$$

3.2 Sampling Cut-types

Given Equation 11 and the exchangeability property, our sampling strategy falls out naturally: first we sample m according to Equation 11, then conditioned on m, we pick m sites of z_S as cut sites out of the $\binom{n}{m}$ combinations with uniform probability.

Now we proceed to define **conflict** sites. In addition to exchangeability, another important property of type-based MCMC is that the type of each site to be sampled should be independent of the assignment of the other sites sampled at the same time. That is, in our case, setting the cut value of each site should not change the (r_1, r_2, r_3) triple of another site. We can see that the cut value of the current site would have effect on and only on the nodes in the r_1 fragment. We denote $nodes(r)$ as the node set for all nodes within fragment r. Then for $\forall z, z' \in S$, z is not in conflict with z' if and only if $nodes(r_1) \cap nodes(r_1') = \emptyset$, where r_1 and r_1' are the corresponding composed rule types when we set z, z' to 0.

Another crucial issue in type-based sampling is the bookkeeping of sampling sites, as we need to loop through all sites having the same type with the current node. We only maintain the type information of nodes that are currently turned on in the chosen tree of the forest, as we only sample these nodes. It is common practice to directly use the type value of each variable as an index and maintain a set of sites for each type. However, maintaining a (r_1, r_2, r_3) triple for each node in the chosen tree is too memory heavy in our appli-

Algorithm 2 Type-based MCMC Algorithm for Sampling One Site

```
sample one type of sites, currently sample site (node, parent)
if parent is None or node is sampled then
    return
end if
old = node.cut
node.cut = 0
r_1 = composed_rule(parent)
node.cut = 1
r_2 = composed_rule(parent)
r_3 = composed_rule(node)
node.cut = old
sites =
for sites s ∈ index[r_1] do
    for sites s' in rule rooted at s do
        if s' of type (r_1, r_2, r_3) and no conflict then
            add s' to sites
        end if
    end for
end for
for sites s ∈ index[r_3] do
    if s of type (r_1, r_2, r_3) and no conflict then
        add s to sites
    end if
end for
sample m according to Equation 11
remove sites from index
uniformly choose m in sites to be cut sites.
add new cut sites to index
mark all nodes in sites as sampled
```

cation.

In our two-stage sample-edge, sample-cut schedule, there is an additional issue that we must deal with efficiently: when we have chosen a new incoming edge for the current node, we also have to update the bookkeeping index as the current tree structure is changed. Cut variable types in the old subtree will be turned off and a new subtree of variable types will be turned on. In the extreme case, when we have chosen a new incoming edge at the root node, we have chosen a new tree in the forest. So, we need to remove appearances of cut variable types in the old tree and add all cut variable types in the newly chosen tree.

Our strategy to deal with these two issues is to build a small, simple index, at the cost of some additional computation when retrieving nodes of a specified type. To be precise, we build an index from (single) rule types r to all occurrences of r in the data, where each occurrence is represented as a pointer to the root of r in the forest. Our strategy has two important differences from the standard strategy of building an index having the complete type (r_1, r_2, r_3) as the key and having every node as an entry. Specifically:

1. We index only the roots of the current rules, rather than every node, and

2. We key on a single rule type, rather than a triple of rule types.

Differences (1) and (2) both serve to keep the index small, and the dramatic savings in memory is essential to making our algorithm practical. Furthermore, difference (1) reduces the amount of work that needs to be done when an edge variable is resampled. While we must still re-index the entire subtree under the changed edge variable, we need only to re-index the roots of the current tree fragments, rather than all nodes in the subtree.

Given this indexing strategy, we now proceed to describe the process for retrieving nodes of a specified type (r_1, r_2, r_3). These nodes fall into one of two cases:

1. Internal nodes, i.e., nodes whose cut variable is currently set to 0. These nodes must be contained in a fragment of rule type r_1, and must furthermore have r_2 above them, and r_3 below them. We retrieve these nodes by looking up r_1 in the index, iterating over all nodes in each fragment retrieved, and retaining only those with r_2 above and r_3 below. (Lines 13–19 in Algorithm 2.)

2. Boundary nodes, i.e., nodes whose cut variable is currently set to 1. These nodes must form the root of a fragment r_3, and have a fragment r_2 above them. We retrieve these nodes by looking up r_3 in the index, and then checking each node retrieved to retain only those nodes with r_2 above them in the current tree. (Lines 20–24 in Algorithm 2.)

This process of winnowing down the nodes retrieved by the index adds some computational overhead to our algorithm, but we find that it is minimal in practice.

We still use the top-down sampling schedule of Algorithm 1, except that in the *sample-edge* step, when we choose a new incoming edge, we add additional steps to update the bookkeeping index. Furthermore, in the *sample-cut* step, we sample all non-conflict sites having the same type with n jointly. Our full algorithm for sampling one cut-type is shown in Algorithm 2. When sampling each site, we record a $parent$ node of the nearest cut ancestor of the current node so that we can build r_1 and r_2 more quickly, as they are both rooted at $parent$. We first identify the type of the current site. Then we search the bookkeeping index to find possible candidate sites of the same type, as described above. As for conflict checking, we keep a set of nodes that includes all nodes in the r_1 fragment of previous non-conflict sites. If the r_1 fragment of the current site has any node in common with this node set, we arrive at a conflict site.

4 Methods of Further Optimization

4.1 One-stage Sampling Schedule

Instead of calculating the posterior of each m according to Equation 11 and then sampling m, we can build our real m more greedily.

$$P(z_S|N) = \prod_{i=1}^{n} P(z_i|N^{i-1}) \qquad (12)$$

where $N, N^0, \ldots, N^n$ are count tables, and $N^0 = N$. N^i is the new count table after we update N^{i-1} according to the assignment of z_i. This equation gives us a hint to sample each z_i according to $P(z_i|N^{i-1})$ and then update the count table N^{i-1} according to the assignment of z_i. This greedy

sampling saves us the effort to calculate each m by multiplying over each posterior of cut variables but directly samples the real m. In our experiment, this one-stage sampling strategy gives us a 1.5 times overall speed up in comparison with the two-stage sampling schedule of Liang et al. (2010).

4.2 Parallel Implementation

As our type-based sampler involves tedious bookkeeping and frequent conflict checking and mismatch of cut types, one iteration of the type-based sampler is slower than an iteration of the token-based sampler when run on a single processor. In order to speed up our sampling procedure, we used a parallel sampling strategy similar to that of Blunsom et al. (2009) and Feng and Cohn (2013), who use multiple processors to perform inexact Gibbs Sampling, and find equivalent performance in comparison with an exact Gibbs Sampler with significant speed up. In our application, we split the data into several subsets and assign each subset to a processor. Each processor performs type-based sampling on its subset using local counts and local bookkeeping, and communicates the update of the local counts after each iteration. All the updates are then aggregated to generate global counts and then we refresh the local counts of each processor. We do not communicate the update on the bookkeeping of each processor. In this implementation, we have a slightly "out-of-date" counts at each processor and a smaller bookkeeping of sites of the same type, but we can perform type-based sampling independently on each processor. Our experiments show that, with proper division of the dataset, the final performance does not change, while the speed up is significant.

5 Experiments

We used the same LDC Chinese-English parallel corpus as Chung et al. (2014),[1] which is composed of newswire text. The corpus consists of 41K sentence pairs, which has 1M words on the English side. The corpus has a 392-sentence development set with four references for parameter tuning, and a 428-sentence test set with four references for testing.[2] The development set and the test set have sentences with less than 30 words. A trigram language model was used for all experiments. We plotted the log likelihood graph to compare the convergence property of each sampling schedule and calculated BLEU (Papineni et al., 2002) for evaluation.

5.1 Experiment Settings

We use the top-down token-based sampling algorithm of Chung et al. (2014) as our baseline. We use the same SCFG decoder for translation with both the baseline and the grammars sampled using our type-based MCMC sampler. The features included in our experiments are differently normalized rule counts and lexical weightings (Koehn et al., 2003) of each rule. Weights are tuned using Pairwise Ranking Optimization (Hopkins and May, 2011) using a grammar extracted by the standard heuristic method (Chiang, 2007) and the development set. The same weights are used throughout our experiments.

First we want to compare the DP likelihood of the baseline with our type-based MCMC sampler to see if type-based sampling would converge to a better sampling result. In order to verify if type-based MCMC really converges to a good optimum point, we use simulated annealing (Kirkpatrick et al., 1983) to search possible better optimum points. We sample from the real distribution modified by an annealing parameter β:

$$z \sim P(z)^{\beta}$$

We increase our β from 0.1 to 1.3, and then decrease from 1.3 to 1.0, changing by 0.1 every 3 iterations. We also run an inexact parallel approximation of type-based MCMC in comparison with the non-parallel sampling to find out if parallel programming is feasible to speed up type-based MCMC sampling without affecting the performance greatly. We do not compare the PYP likelihood because the approximation renders it impossible to calculate the real PYP likelihood. We also calculate the BLEU score to compare the grammars extracted using each sampling schedule. We just report the BLEU result of grammars sampled using PYP as for all our schedules, since PYP always performs better than DP.

[1] The data are randomly sampled from various different sources (LDC2006E86, LDC2006E93, LDC2002E18, LDC2002L27, LDC2003E07, LDC2003E14, LDC2004T08, LDC2005T06, LDC2005T10, LDC2005T34, LDC2006E26, LDC2005E83, LDC2006E34, LDC2006E85, LDC2006E92, LDC2006E24, LDC2006E92, LDC2006E24) The language model is trained on the English side of entire data (1.65M sentences, which is 39.3M words.)

[2] They are from newswire portion of NIST MT evaluation data from 2004, 2005, and 2006.

As for parameter settings, we used $d = 0.5$ for the Pitman-Yor discount parameter. Though we have a separate PYP for each rule length, we used same $\alpha = 5$ for all rule sizes in all experiments, including experiments using DP. For rule length probability, a Poisson distribution where $\lambda = 2$ was used for all experiments.[3]

For each sentence sample, we initialize all the nodes in the forest to be cut sites and choose an incoming edge for each node uniformly. For each experiment, we run for 160 iterations. For each DP experiment, we draw the log likelihood graph for each sampling schedule before it finally converges. For each PYP experiment, we tried averaging the grammars from every 10th iteration to construct a single grammar and use this grammar for decoding. We tune the number of grammars included for averaging by comparing the BLEU score on the dev set and report the BLEU score result on the test with the same averaging of grammars.

As each tree fragment sampled from the forest represents a unique translation rule, we do not need to explicitly extract the rules; we merely need to collect them and count them. However, the fragments sampled include purely non-lexical rules that do not conform to the rule constraints of Hiero, and rules that are not useful for translation. In order to get rid of this type of rule, we prune every rule that has **scope** (Hopkins and Langmead, 2010) greater than two. Whereas Hiero does not allow two adjacent nonterminals in the source side, our pruning criterion allows some rules of scope two that are not allowed by Hiero. For example, the following rule (only source side shown) has scope two but is not allowed by Hiero:

$$X \rightarrow w_1 X_1 X_2 w_2 X_3$$

5.2 Experiment Results

Figure 4 shows the log likelihood result of our type-based MCMC sampling schedule and the baseline top-down sampling. We can see that type-based sampling converges to a much better result than non-type-based top-down sampling. This shows that type-based MCMC escapes some local optima that are hard for token-based methods to escape. This further strengthens the idea that sampling a block of strongly coupled variables jointly

[3]The priors are the same as the work of Chung et al. (2014). The priors are set to be the same because other priors turn out not to affect much of the final performance and add additional difficulty for tuning.

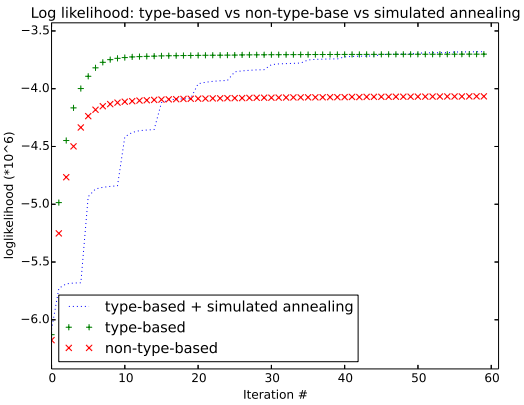

Figure 4: Log likelihood result of type-based MCMC sampling against non-type-based MCMC sampling, simulated annealing is used to verify if type-based MCMC converges to a good likelihood

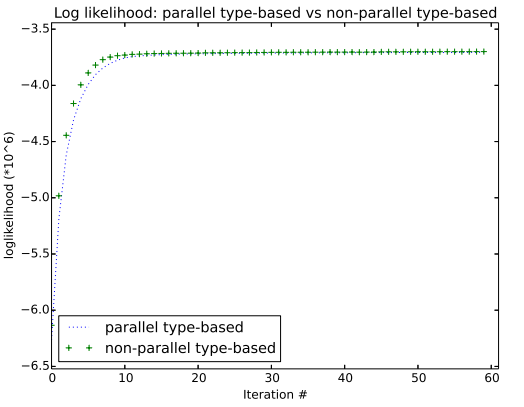

Figure 5: parallelization result for type-based MCMC

helps solve the slow mixing problem of token-based sampling methods. Another interesting observation is that, even though theoretically these two sampling methods should finally converge to the same point, in practice a worse sampling algorithm is prone to get trapped at local optima, and it will be hard for its Markov chain to escape it. We can also see from Figure 4 that the log likelihood result only improves slightly using simulated annealing. One possible explanation is that the Markov chain has already converged to a very good optimum point with type-based sampling and it is hard to search for a better optimum.

Figure 5 shows the parallelization result of type-based MCMC sampling when we run the program on five processors. We can see from the graph that when running on five processors, the likelihood fi-

Sampling Schedule	iteration	dev	test
Non-type-based	averaged (0-90)	25.62	24.98
Type-based	averaged (0-100)	25.88	25.20
Parallel Type-based	averaged (0-90)	25.75	25.04

Table 1: Comparisons of BLEU score results

nally converges to the same likelihood result as non-parallel type-based MCMC sampling. However, when we use more processors, the likelihood eventually becomes lower than with non-parallel sampling. This is because when we increase the number of processors, we split the dataset into very small subsets. As we maintain the bookkeeping for each subset separately and do not communicate the updates to each subset, the power of type-based sampling is weakened with bookkeeping for very few sites of each type. In the extreme case, when we use too many processors in parallel, the bookkeeping would have a singleton site for each type. In this case, the approximation would degrade to the scenario of approximating token-based sampling. By choosing a proper size of division of the dataset and by maintaining local bookkeeping for each subset, the parallel approximation can converge to almost the same point as non-parallel sampling. As shown in our experimental results, the speed up is very significant with the running time decreasing from thirty minutes per iteration to just seven minutes when running on five processors. Part of the speed up comes from the smaller bookkeeping since with fewer sites for each index, there is less mismatch or conflict of sites.

Table 1 shows the BLEU score results for type-based MCMC and the baseline. For non-type-based top-down sampling, the best BLEU score result on dev is achieved when averaging the grammars of every 10th iteration from the 0th to the 90th iteration, while our type-based method gets the best result by averaging over every 10th iteration from the 0th to the 100th iteration. We can see that the BLEU score on dev for type-based MCMC and the corresponding BLEU score on test are both better than the result for the non-type-based method, though not significantly. This shows that the better likelihood of our Markov Chain using type-based MCMC does result in better translation.

We have also done experiments calculating the BLEU score result of the inexact parallel implementation. We can see from Table 1 that, while the likelihood of the approximation does not change in comparison with the exact type-based MCMC, there is a gap between the BLEU score results. We think this difference might come from the inconsistency of the grammars sampled by each processor within each iteration, as they do not communicate the update within each iteration.

6 Conclusion

We presented a novel type-based MCMC algorithm for sampling tree fragments from phrase decomposition forests. While the hidden tree structure in our settings makes it difficult to maintain the constantly changing type information, we have come up with a compact way to store the type information of variables and proposed efficient ways to update the bookkeeping index. Under the additional hidden structure limitation, we have shown that type-based MCMC sampling still works and results in both better likelihood and BLEU score. We also came with techniques to speed up the type-based MCMC sampling schedule while not affecting the final sampling likelihood result. A remaining issue with parallelization is the inconsistency of the grammar within an iteration between processors. One possible solution would be using better averaging methods instead of simply averaging over every few iterations. Another interesting extension for our methods would be to also define types for the edge variables, and then sample both cut and edge types jointly.

Abstract

We report on a series of experiments with convolutional neural networks (CNN) trained on top of pre-trained word vectors for sentence-level classification tasks. We show that a simple CNN with little hyperparameter tuning and static vectors achieves excellent results on multiple benchmarks. Learning task-specific vectors through fine-tuning offers further gains in performance. We additionally propose a simple modification to the architecture to allow for the use of both task-specific and static vectors. The CNN models discussed herein improve upon the state of the art on 4 out of 7 tasks, which include sentiment analysis and question classification.

1 Introduction

Deep learning models have achieved remarkable results in computer vision (Krizhevsky et al., 2012) and speech recognition (Graves et al., 2013) in recent years. Within natural language processing, much of the work with deep learning methods has involved learning word vector representations through neural language models (Bengio et al., 2003; Yih et al., 2011; Mikolov et al., 2013) and performing composition over the learned word vectors for classification (Collobert et al., 2011). Word vectors, wherein words are projected from a sparse, 1-of-V encoding (here V is the vocabulary size) onto a lower dimensional vector space via a hidden layer, are essentially feature extractors that encode semantic features of words in their dimensions. In such dense representations, semantically close words are likewise close—in euclidean or cosine distance—in the lower dimensional vector space.

Convolutional neural networks (CNN) utilize layers with convolving filters that are applied to local features (LeCun et al., 1998). Originally invented for computer vision, CNN models have subsequently been shown to be effective for NLP and have achieved excellent results in semantic parsing (Yih et al., 2014), search query retrieval (Shen et al., 2014), sentence modeling (Kalchbrenner et al., 2014), and other traditional NLP tasks (Collobert et al., 2011).

In the present work, we train a simple CNN with one layer of convolution on top of word vectors obtained from an unsupervised neural language model. These vectors were trained by Mikolov et al. (2013) on 100 billion words of Google News, and are publicly available.[1] We initially keep the word vectors static and learn only the other parameters of the model. Despite little tuning of hyperparameters, this simple model achieves excellent results on multiple benchmarks, suggesting that the pre-trained vectors are 'universal' feature extractors that can be utilized for various classification tasks. Learning task-specific vectors through fine-tuning results in further improvements. We finally describe a simple modification to the architecture to allow for the use of both pre-trained and task-specific vectors by having multiple channels.

Our work is philosophically similar to Razavian et al. (2014) which showed that for image classification, feature extractors obtained from a pre-trained deep learning model perform well on a variety of tasks—including tasks that are very different from the original task for which the feature extractors were trained.

2 Model

The model architecture, shown in figure 1, is a slight variant of the CNN architecture of Collobert et al. (2011). Let $\mathbf{x}_i \in \mathbb{R}^k$ be the k-dimensional word vector corresponding to the i-th word in the sentence. A sentence of length n (padded where

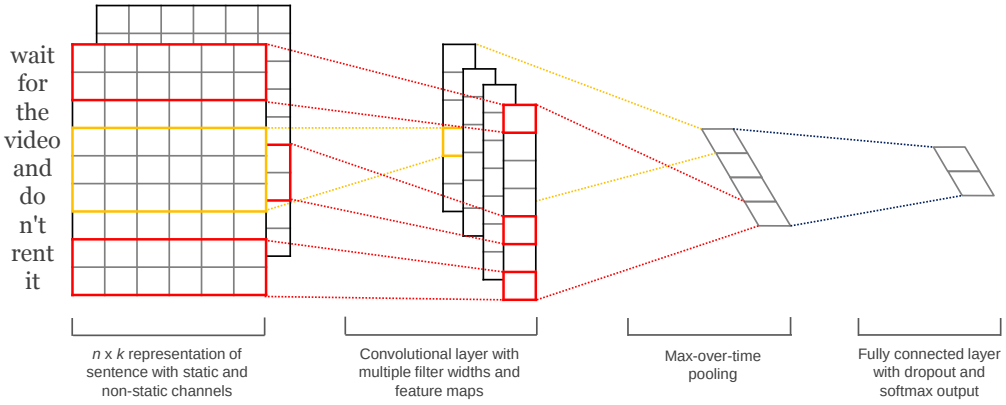

Figure 1: Model architecture with two channels for an example sentence.

necessary) is represented as

$$\mathbf{x}_{1:n} = \mathbf{x}_1 \oplus \mathbf{x}_2 \oplus \ldots \oplus \mathbf{x}_n, \quad (1)$$

where $\oplus$ is the concatenation operator. In general, let $\mathbf{x}_{i:i+j}$ refer to the concatenation of words $\mathbf{x}_i, \mathbf{x}_{i+1}, \ldots, \mathbf{x}_{i+j}$. A convolution operation involves a *filter* $\mathbf{w} \in \mathbb{R}^{hk}$, which is applied to a window of h words to produce a new feature. For example, a feature c_i is generated from a window of words $\mathbf{x}_{i:i+h-1}$ by

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b). \quad (2)$$

Here $b \in \mathbb{R}$ is a bias term and f is a non-linear function such as the hyperbolic tangent. This filter is applied to each possible window of words in the sentence $\{\mathbf{x}_{1:h}, \mathbf{x}_{2:h+1}, \ldots, \mathbf{x}_{n-h+1:n}\}$ to produce a *feature map*

$$\mathbf{c} = [c_1, c_2, \ldots, c_{n-h+1}], \quad (3)$$

with $\mathbf{c} \in \mathbb{R}^{n-h+1}$. We then apply a max-over-time pooling operation (Collobert et al., 2011) over the feature map and take the maximum value $\hat{c} = \max\{\mathbf{c}\}$ as the feature corresponding to this particular filter. The idea is to capture the most important feature—one with the highest value—for each feature map. This pooling scheme naturally deals with variable sentence lengths.

We have described the process by which *one* feature is extracted from *one* filter. The model uses multiple filters (with varying window sizes) to obtain multiple features. These features form the penultimate layer and are passed to a fully connected softmax layer whose output is the probability distribution over labels.

In one of the model variants, we experiment with having two 'channels' of word vectors—one that is kept static throughout training and one that is fine-tuned via backpropagation (section 3.2).[2] In the multichannel architecture, illustrated in figure 1, each filter is applied to both channels and the results are added to calculate c_i in equation (2). The model is otherwise equivalent to the single channel architecture.

2.1 Regularization

For regularization we employ dropout on the penultimate layer with a constraint on l_2-norms of the weight vectors (Hinton et al., 2012). Dropout prevents co-adaptation of hidden units by randomly dropping out—i.e., setting to zero—a proportion p of the hidden units during foward-backpropagation. That is, given the penultimate layer $\mathbf{z} = [\hat{c}_1, \ldots, \hat{c}_m]$ (note that here we have m filters), instead of using

$$y = \mathbf{w} \cdot \mathbf{z} + b \quad (4)$$

for output unit y in forward propagation, dropout uses

$$y = \mathbf{w} \cdot (\mathbf{z} \circ \mathbf{r}) + b, \quad (5)$$

where $\circ$ is the element-wise multiplication operator and $\mathbf{r} \in \mathbb{R}^m$ is a 'masking' vector of Bernoulli random variables with probability p of being 1. Gradients are backpropagated only through the unmasked units. At test time, the learned weight vectors are scaled by p such that $\hat{\mathbf{w}} = p\mathbf{w}$, and $\hat{\mathbf{w}}$ is used (without dropout) to score unseen sentences. We additionally constrain l_2-norms of the weight vectors by rescaling $\mathbf{w}$ to have $||\mathbf{w}||_2 = s$ whenever $||\mathbf{w}||_2 > s$ after a gradient descent step.

[2] We employ language from computer vision where a color image has red, green, and blue channels.

Data	c	l	N	$\|V\|$	$\|V_{pre}\|$	*Test*
MR	2	20	10662	18765	16448	CV

Subj	2	23	10000	21323	17913	CV
TREC	6	10	5952	9592	9125	500
CR	2	19	3775	5340	5046	CV
MPQA	2	3	10606	6246	6083	CV

Table 1: Summary statistics for the datasets after tokenization. c: Number of target classes. l: Average sentence length. N: Dataset size. $|V|$: Vocabulary size. $|V_{pre}|$: Number of words present in the set of pre-trained word vectors. *Test*: Test set size (CV means there was no standard train/test split and thus 10-fold CV was used).

3 Datasets and Experimental Setup

We test our model on various benchmarks. Summary statistics of the datasets are in table 1.

- **MR**: Movie reviews with one sentence per review. Classification involves detecting positive/negative reviews (Pang and Lee, 2005).[3]
- **SST-1**: Stanford Sentiment Treebank—an extension of MR but with train/dev/test splits provided and fine-grained labels (very positive, positive, neutral, negative, very negative), re-labeled by Socher et al. (2013).[4]
- **SST-2**: Same as SST-1 but with neutral reviews removed and binary labels.
- **Subj**: Subjectivity dataset where the task is to classify a sentence as being subjective or objective (Pang and Lee, 2004).
- **TREC**: TREC question dataset—task involves classifying a question into 6 question types (whether the question is about person, location, numeric information, etc.) (Li and Roth, 2002).[5]
- **CR**: Customer reviews of various products (cameras, MP3s etc.). Task is to predict positive/negative reviews (Hu and Liu, 2004).[6]
- **MPQA**: Opinion polarity detection subtask of the MPQA dataset (Wiebe et al., 2005).[7]

3.1 Hyperparameters and Training

For all datasets we use: rectified linear units, filter windows (h) of 3, 4, 5 with 100 feature maps each, dropout rate (p) of 0.5, l_2 constraint (s) of 3, and mini-batch size of 50. These values were chosen via a grid search on the SST-2 dev set.

We do not otherwise perform any dataset-specific tuning other than early stopping on dev sets. For datasets without a standard dev set we randomly select 10% of the training data as the dev set. Training is done through stochastic gradient descent over shuffled mini-batches with the Adadelta update rule (Zeiler, 2012).

3.2 Pre-trained Word Vectors

Initializing word vectors with those obtained from an unsupervised neural language model is a popular method to improve performance in the absence of a large supervised training set (Collobert et al., 2011; Socher et al., 2011; Iyyer et al., 2014). We use the publicly available `word2vec` vectors that were trained on 100 billion words from Google News. The vectors have dimensionality of 300 and were trained using the continuous bag-of-words architecture (Mikolov et al., 2013). Words not present in the set of pre-trained words are initialized randomly.

3.3 Model Variations

We experiment with several variants of the model.

- **CNN-rand**: Our baseline model where all words are randomly initialized and then modified during training.
- **CNN-static**: A model with pre-trained vectors from `word2vec`. All words—including the unknown ones that are randomly initialized—are kept static and only the other parameters of the model are learned.
- **CNN-non-static**: Same as above but the pre-trained vectors are fine-tuned for each task.
- **CNN-multichannel**: A model with two sets of word vectors. Each set of vectors is treated as a 'channel' and each filter is applied

[3] https://www.cs.cornell.edu/people/pabo/movie-review-data/

[4] http://nlp.stanford.edu/sentiment/ Data is actually provided at the phrase-level and hence we train the model on both phrases and sentences but only score on sentences at test time, as in Socher et al. (2013), Kalchbrenner et al. (2014), and Le and Mikolov (2014). Thus the training set is an order of magnitude larger than listed in table 1.

(2011).

to both channels, but gradients are back-propagated only through one of the channels. Hence the model is able to fine-tune one set of vectors while keeping the other static. Both channels are initialized with `word2vec`.

In order to disentangle the effect of the above variations versus other random factors, we eliminate other sources of randomness—CV-fold assignment, initialization of unknown word vectors, initialization of CNN parameters—by keeping them uniform within each dataset.

4 Results and Discussion

Results of our models against other methods are listed in table 2. Our baseline model with all randomly initialized words (CNN-rand) does not perform well on its own. While we had expected performance gains through the use of pre-trained vectors, we were surprised at the magnitude of the gains. Even a simple model with static vectors (CNN-static) performs remarkably well, giving competitive results against the more sophisticated deep learning models that utilize complex pooling schemes (Kalchbrenner et al., 2014) or require parse trees to be computed beforehand (Socher et al., 2013). These results suggest that the pre-trained vectors are good, 'universal' feature extractors and can be utilized across datasets. Fine-tuning the pre-trained vectors for each task gives still further improvements (CNN-non-static).

4.1 Multichannel vs. Single Channel Models

We had initially hoped that the multichannel architecture would prevent overfitting (by ensuring that the learned vectors do not deviate too far from the original values) and thus work better than the single channel model, especially on smaller datasets. The results, however, are mixed, and further work on regularizing the fine-tuning process is warranted. For instance, instead of using an additional channel for the non-static portion, one could maintain a single channel but employ extra dimensions that are allowed to be modified during training.

	Most Similar Words for	
	Static Channel	Non-static Channel
bad	*good*	*terrible*
	terrible	*horrible*
	horrible	*lousy*
	lousy	*stupid*
good	*great*	*nice*
	bad	*decent*
	terrific	*solid*
	decent	*terrific*
n't	*os*	*not*
	ca	*never*
	ireland	*nothing*
	wo	*neither*
!	*2,500*	*2,500*
	entire	*lush*
	jez	*beautiful*
	changer	*terrific*
,	*decasia*	*but*
	abysmally	*dragon*
	demise	*a*
	valiant	*and*

Table 3: Top 4 neighboring words—based on cosine similarity—for vectors in the static channel (left) and fine-tuned vectors in the non-static channel (right) from the multichannel model on the SST-2 dataset after training.

4.2 Static vs. Non-static Representations

As is the case with the single channel non-static model, the multichannel model is able to fine-tune the non-static channel to make it more specific to the task-at-hand. For example, *good* is most similar to *bad* in `word2vec`, presumably because they are (almost) syntactically equivalent. But for vectors in the non-static channel that were fine-tuned on the SST-2 dataset, this is no longer the case (table 3). Similarly, *good* is arguably closer to *nice* than it is to *great* for expressing sentiment, and this is indeed reflected in the learned vectors.

For (randomly initialized) tokens not in the set of pre-trained vectors, fine-tuning allows them to learn more meaningful representations: the network learns that exclamation marks are associated with effusive expressions and that commas are conjunctive (table 3).

4.3 Further Observations

We report on some further experiments and observations:

- Kalchbrenner et al. (2014) report much worse results with a CNN that has essentially the same architecture as our single channel model. For example, their Max-TDNN (Time Delay Neural Network) with randomly initialized words obtains 37.4% on the SST-1 dataset, compared to 45.0% for our model. We attribute such discrepancy to our CNN having much more capacity (multiple filter widths and feature maps).
- Dropout proved to be such a good regularizer that it was fine to use a larger than necessary network and simply let dropout regularize it. Dropout consistently added 2%–4% relative performance.
- When randomly initializing words not in `word2vec`, we obtained slight improvements by sampling each dimension from $U[-a, a]$ where a was chosen such that the randomly initialized vectors have the same variance as the pre-trained ones. It would be interesting to see if employing more sophisticated methods to mirror the distribution of pre-trained vectors in the initialization process gives further improvements.
- We briefly experimented with another set of publicly available word vectors trained by Collobert et al. (2011) on Wikipedia,[8] and found that `word2vec` gave far superior performance. It is not clear whether this is due to Mikolov et al. (2013)'s architecture or the 100 billion word Google News dataset.
- Adadelta (Zeiler, 2012) gave similar results to Adagrad (Duchi et al., 2011) but required fewer epochs.

5 Conclusion

In the present work we have described a series of experiments with convolutional neural networks built on top of `word2vec`. Despite little tuning of hyperparameters, a simple CNN with one layer of convolution performs remarkably well. Our results add to the well-established evidence that unsupervised pre-training of word vectors is an important ingredient in deep learning for NLP.

Abstract

Markov chain Monte Carlo (MCMC) approximates the posterior distribution of latent variable models by generating many samples and averaging over them. In practice, however, it is often more convenient to cut corners, using only a single sample or following a suboptimal averaging strategy. We systematically study different strategies for averaging MCMC samples and show empirically that averaging properly leads to significant improvements in prediction.

1 Introduction

Probabilistic topic models are powerful methods to uncover hidden thematic structures in text by projecting each document into a low dimensional space spanned by a set of *topics*, each of which is a distribution over words. Topic models such as latent Dirichlet allocation (Blei et al., 2003, LDA) and its extensions discover these topics from text, which allows for effective exploration, analysis, and summarization of the otherwise unstructured corpora (Blei, 2012; Blei, 2014).

In addition to exploratory data analysis, a typical goal of topic models is prediction. Given a set of unannotated training data, *unsupervised topic models* try to learn good topics that can generalize to unseen text. *Supervised topic models* jointly capture both the text and associated *metadata* such as a continuous response variable (Blei and McAuliffe, 2007; Zhu et al., 2009; Nguyen et al., 2013), single label (Rosen-Zvi et al., 2004; Lacoste-Julien et al., 2008; Wang et al., 2009) or multiple labels (Ramage et al., 2009; Ramage et al., 2011) to predict metadata from text.

Probabilistic topic modeling requires estimating the posterior distribution. Exact computation of the posterior is often intractable, which motivates approximate inference techniques (Asuncion et al., 2009). One popular approach is Markov chain Monte Carlo (MCMC), a class of inference algorithms to approximate the target posterior distribution. To make prediction, MCMC algorithms generate samples on training data to estimate corpus-level latent variables, and use them to generate samples to estimate document-level latent variables for test data. The underlying theory requires averaging on both training and test samples, but in practice it is often convenient to cut corners: either skip averaging entirely by using just the values of the last sample or use a single training sample and average over test samples.

We systematically study non-averaging and averaging strategies when performing predictions using MCMC in topic modeling (Section 2). Using popular unsupervised (LDA in Section 3) and supervised (SLDA in Section 4) topic models via thorough experimentation, we show empirically that cutting corners on averaging leads to consistently poorer prediction.

2 Learning and Predicting with MCMC

While reviewing all of MCMC is beyond the scope of this paper, we need to briefly review key concepts.[1] To estimate a target density $p(x)$ in a high-dimensional space $\mathcal{X}$, MCMC generates samples $\{x_t\}_{t=1}^{T}$ while exploring $\mathcal{X}$ using the Markov assumption. Under this assumption, sample x_{t+1} depends on sample x_t only, forming a *Markov chain*, which allows the sampler to spend more time in the most important regions of the density. Two concepts control sample collection:

Burn-in B: Depending on the initial value of the Markov chain, MCMC algorithms take time to reach the target distribution. Thus, in practice, samples before a burn-in period B are often discarded.

Sample-lag L: Averaging over samples to estimate the target distribution requires i.i.d. samples. However, future samples depend on the current samples (i.e., the Markov assumption). To avoid autocorrelation, we discard all but every L samples.

2.1 MCMC in Topic Modeling

As generative probabilistic models, topic models define a joint distribution over latent variables and observable evidence. In our setting, the latent variables consist of corpus-level *global* variables $\boldsymbol{g}$ and document-level *local* variables $\boldsymbol{l}$; while the evidence consists of words $\boldsymbol{w}$ and additional metadata $\boldsymbol{y}$—the latter omitted in unsupervised models.

During training, MCMC estimates the posterior $p(\boldsymbol{g}, \boldsymbol{l}^{\text{TR}} \mid \boldsymbol{w}^{\text{TR}}, \boldsymbol{y}^{\text{TR}})$ by generating a *training Markov chain* of T_{TR} samples.[2] Each training sample i provides a set of fully realized global latent variables $\hat{\boldsymbol{g}}(i)$, which can generate test data. During test time, given a

[1] For more details please refer to Neal (1993), Andrieu et al. (2003), Resnik and Hardisty (2010).

[2] We omit hyperparameters for clarity. We split data into training (TR) and testing (TE) folds, and denote the training iteration i and the testing iteration j within the corresponding Markov chains.

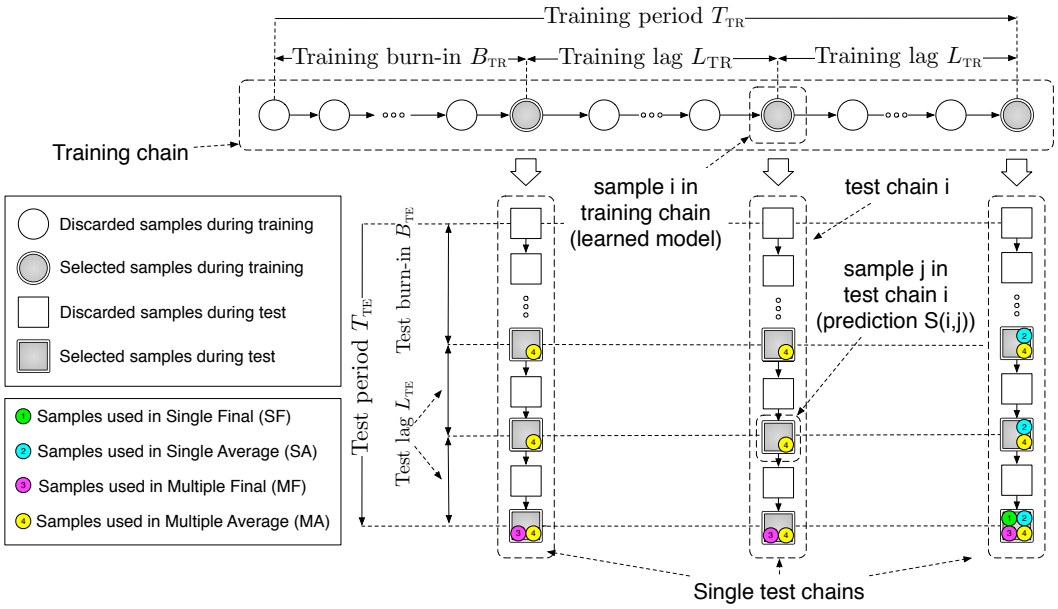

Figure 1: Illustration of training and test chains in MCMC, showing samples used in four prediction strategies studied in this paper: Single Final (SF), Single Average (SA), Multiple Final (MF), and Multiple Average (MA).

learned model from training sample i, we generate a *test Markov chain* of T_{TE} samples to estimate the local latent variables $p(\boldsymbol{l}^{\text{TE}} \mid \boldsymbol{w}^{\text{TE}}, \hat{\boldsymbol{g}}(i))$ of test data. Each sample j of test chain i provides a fully estimated local latent variables $\hat{\boldsymbol{l}}^{\text{TE}}(i,j)$ to make a prediction.

Figure 1 shows an overview. To reduce the effects of unconverged and autocorrelated samples, during training we use a burn-in period of B_{TR} and a sample-lag of L_{TR} iterations. We use $\mathcal{T}_{\text{TR}} = \{i \mid i \in (B_{\text{TR}}, T_{\text{TR}}] \wedge (i - B_{\text{TR}}) \mod L_{\text{TR}} = 0\}$ to denote the set of indices of the selected models. Similarly, B_{TE} and L_{TE} are the test burn-in and sample-lag. The set of indices of selected samples in test chains is $\mathcal{T}_{\text{TE}} = \{j \mid j \in (B_{\text{TE}}, T_{\text{TE}}] \wedge (j - B_{\text{TE}}) \mod L_{\text{TE}} = 0\}$.

2.2 Averaging Strategies

We use $S(i,j)$ to denote the prediction obtained from sample j of the test chain i. We now discuss different strategies to obtain the final prediction:

- **Single Final (SF)** uses the last sample of last test chain to obtain the predicted value,

$$S_{\text{SF}} = S(T_{\text{TR}}, T_{\text{TE}}). \tag{1}$$

- **Single Average (SA)** averages over multiple samples in the last test chain

$$S_{\text{SA}} = \frac{1}{|\mathcal{T}_{\text{TE}}|} \sum_{j \in \mathcal{T}_{\text{TE}}} S(T_{\text{TR}}, j). \tag{2}$$

This is a common averaging strategy in which we obtain a point estimate of the global latent variables at the end of the training chain. Then, a single test chain is generated on the test data and multiple samples of this test chain are averaged to obtain the final prediction (Chang, 2012; Singh et al., 2012; Jiang et al., 2012; Zhu et al., 2014).

- **Multiple Final (MF)** averages over the last samples of multiple test chains from multiple models

$$S_{\text{MF}} = \frac{1}{|\mathcal{T}_{\text{TR}}|} \sum_{i \in \mathcal{T}_{\text{TR}}} S(i, T_{\text{TE}}). \tag{3}$$

- **Multiple Average (MA)** averages over all samples of multiple test chains for distinct models,

$$S_{\text{MA}} = \frac{1}{|\mathcal{T}_{\text{TR}}|} \frac{1}{|\mathcal{T}_{\text{TE}}|} \sum_{i \in \mathcal{T}_{\text{TR}}} \sum_{j \in \mathcal{T}_{\text{TE}}} S(i,j), \tag{4}$$

3 Unsupervised Topic Models

We evaluate the predictive performance of the unsupervised topic model LDA using different averaging strategies in Section 2.

LDA: Proposed by Blei et al. in 2003, LDA posits that each document d is a multinomial distribution θ_d over K topics, each of which is a multinomial distribution ϕ_k over the vocabulary. LDA's generative process is:

1. For each topic $k \in [1, K]$
   (a) Draw word distribution $\phi_k \sim \text{Dir}(\beta)$
2. For each document $d \in [1, D]$
   (a) Draw topic distribution $\theta_d \sim \text{Dir}(\alpha)$
   (b) For each word $n \in [1, N_d]$
      i. Draw topic $z_{d,n} \sim \text{Mult}(\theta_d)$
      ii. Draw word $w_{d,n} \sim \text{Mult}(\phi_{z_{d,n}})$

In LDA, the global latent variables are topics $\{\phi_k\}_{k=1}^K$ and the local latent variables for each document d are topic proportions θ_d.

Train: During training, we use collapsed Gibbs sampling to assign each token in the training data with a topic (Steyvers and Griffiths, 2006). The probability of

assigning token n of training document d to topic k is $p(z^{\text{TR}}_{d,n} = k \mid \boldsymbol{z}^{\text{TR}}_{-d,n}, \boldsymbol{w}^{\text{TR}}_{-d,n}, w^{\text{TR}}_{d,n} = v) \propto$

$$\frac{N^{-d,n}_{\text{TR},d,k} + \alpha}{N^{-d,n}_{\text{TR},d,\cdot} + K\alpha} \cdot \frac{N^{-d,n}_{\text{TR},k,v} + \beta}{N^{-d,n}_{\text{TR},k,\cdot} + V\beta}, \tag{5}$$

where $N_{\text{TR},d,k}$ is the number of tokens in the training document d assigned to topic k, and $N_{\text{TR},k,v}$ is the number of times word type v assigned to topic k. Marginal counts are denoted by $\cdot$, and $^{-d,n}$ denotes the count excluding the assignment of token n in document d.

At each training iteration i, we estimate the distribution over words $\hat{\phi}_k(i)$ of topic k as

$$\hat{\phi}_{k,v}(i) = \frac{N_{\text{TR},k,v}(i) + \beta}{N_{\text{TR},k,\cdot}(i) + V\beta} \tag{6}$$

where the counts $N_{\text{TR},k,v}(i)$ and $N_{\text{TR},k,\cdot}(i)$ are taken at training iteration i.

Test: Because we lack explicit topic annotations for these data (c.f. Nguyen et al. (2012)), we use *perplexity*– a widely-used metric to measure the predictive power of topic models on held-old documents. To compute perplexity, we follow the *estimating* θ method (Wallach et al., 2009, Section 5.1) and evenly split each test document d into $\boldsymbol{w}^{\text{TE}_1}_d$ and $\boldsymbol{w}^{\text{TE}_2}_d$. We first run Gibbs sampling on $\boldsymbol{w}^{\text{TE}_1}_d$ to estimate the topic proportion $\hat{\theta}^{\text{TE}}_d$ of test document d. The probability of assigning topic k to token n in $\boldsymbol{w}^{\text{TE}_1}_d$ is $p(z^{\text{TE}_1}_{d,n} = k \mid \boldsymbol{z}^{\text{TE}_1}_{-d,n}, \boldsymbol{w}^{\text{TE}_1}, \hat{\phi}(i)) \propto$

$$\frac{N^{-d,n}_{\text{TE}_1,d,k} + \alpha}{N^{-d,n}_{\text{TE}_1,d,\cdot} + K\alpha} \cdot \hat{\phi}_{k,w^{\text{TE}_1}_{d,n}(i)} \tag{7}$$

where $N_{\text{TE}_1,d,k}$ is the number of tokens in $\boldsymbol{w}^{\text{TE}_1}_d$ assigned to topic k. At each iteration j in test chain i, we can estimate the topic proportion vector $\hat{\theta}^{\text{TE}}_d(i,j)$ for test document d as

$$\hat{\theta}^{\text{TE}}_{d,k}(i,j) = \frac{N_{\text{TE}_1,d,k}(i,j) + \alpha}{N_{\text{TE}_1,d,\cdot}(i,j) + K\alpha} \tag{8}$$

where both the counts $N_{\text{TE}_1,d,k}(i,j)$ and $N_{\text{TE}_1,d,\cdot}(i,j)$ are taken using sample j of test chain i.

Prediction: Given $\hat{\theta}^{\text{TE}}_d(i,j)$ and $\hat{\phi}(i)$ at sample j of test chain i, we compute the predicted likelihood for each unseen token $w^{\text{TE}_2}_{d,n}$ as $S(i,j) \equiv p(w^{\text{TE}_2}_{d,n} \mid \hat{\theta}^{\text{TE}}_d(i,j), \hat{\phi}(i)) = \sum_{k=1}^{K} \hat{\theta}^{\text{TE}}_{d,k}(i,j) \cdot \hat{\phi}_{k,w^{\text{TE}_2}_{d,n}}(i)$.

Using different strategies described in Section 2, we obtain the final predicted likelihood for each unseen token $p(w^{\text{TE}_2}_{d,n} \mid \hat{\theta}^{\text{TE}}_d, \hat{\phi})$ and compute the perplexity as $\exp\left(-(\sum_d \sum_n \log(p(w^{\text{TE}_2}_{d,n} \mid \hat{\theta}^{\text{TE}}_d, \hat{\phi})))/N^{\text{TE}_2}\right)$ where N^{TE_2} is the number of tokens in $\boldsymbol{w}^{\text{TE}_2}$.

Setup: We use three Internet review datasets in our experiment. For all datasets, we preprocess by tokenizing, removing stopwords, stemming, adding bigrams to the vocabulary, and we filter using TF-IDF to obtain a vocabulary of 10,000 words.[3] The three datasets are:

- HOTEL: 240,060 reviews of hotels from TripAdvisor (Wang et al., 2010).
- RESTAURANT: 25,459 reviews of restaurants from Yelp (Jo and Oh, 2011).
- MOVIE: 5,006 reviews of movies from Rotten Tomatoes (Pang and Lee, 2005)

We report cross-validated average performance over five folds, and use $K = 50$ topics for all datasets. To update the hyperparameters, we use slice sampling (Wallach, 2008, p. 62).[4]

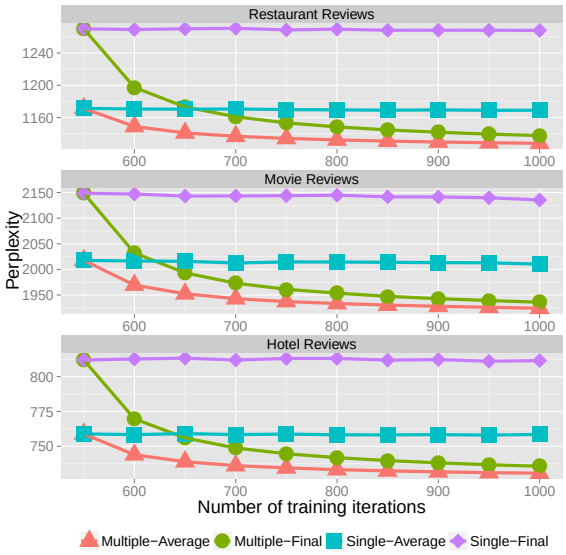

Figure 2: Perplexity of LDA using different averaging strategies with different number of training iterations T_{TR}. Perplexity generally decreases with additional training iterations, but the drop is more pronounced with multiple test chains.

Results: Figure 2 shows the perplexity of the four averaging methods, computed with different number of training iterations T_{TR}. SA outperforms SF, showing the benefits of averaging over multiple test samples from a single test chain. However, both multiple chain methods (MF and MA) significantly outperform these two methods.

This result is consistent with Asuncion et al. (2009), who run multiple training chains but a single test chain for each training chain and average over them. This is more costly since training chains are usually significantly longer than test chains. In addition, multiple training chains are sensitive to their initialization.

[3] To find bigrams, we begin with bigram candidates that occur at least 10 times in the corpus and use a χ^2 test to filter out those having a χ^2 value less than 5. We then treat selected bigrams as single word types and add them to the vocabulary.

[4] MCMC setup: $T_{\text{TR}} = 1,000$, $B_{\text{TR}} = 500$, $L_{\text{TR}} = 50$, $T_{\text{TE}} = 100$, $B_{\text{TE}} = 50$ and $L_{\text{TE}} = 5$.

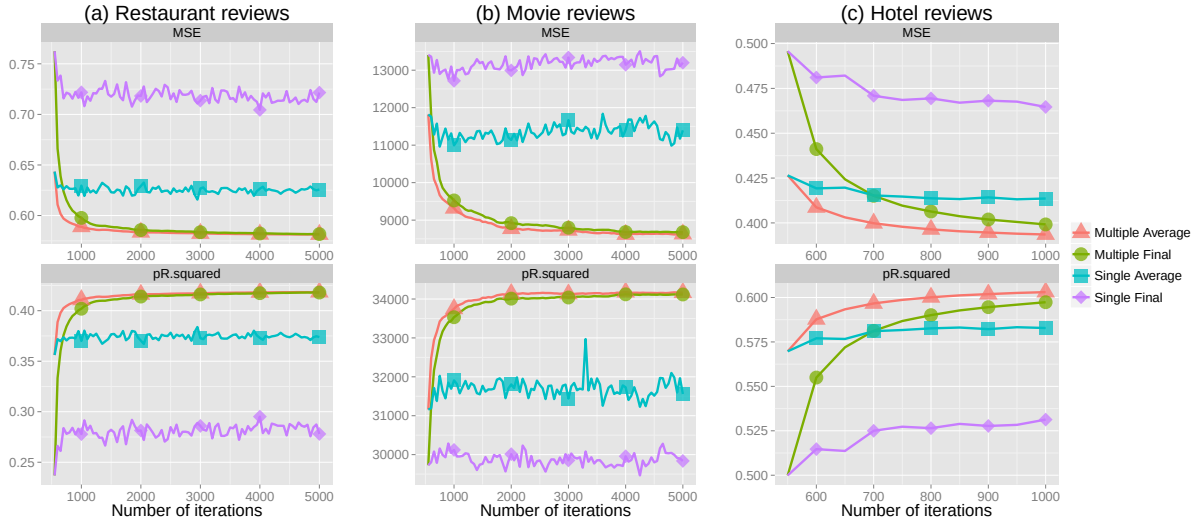

Figure 3: Performance of SLDA using different averaging strategies computed at each training iteration.

4 Supervised Topic Models

We evaluate the performance of different prediction methods using supervised latent Dirichlet allocation (SLDA) (Blei and McAuliffe, 2007) for sentiment analysis: predicting review ratings given review text. Each review text is the document $\boldsymbol{w}_d$ and the metadata $\boldsymbol{y}_d$ is the associated rating.

SLDA: Going beyond LDA, SLDA captures the relationship between latent topics and metadata by modeling each document's continuous response variable using a normal linear model, whose covariates are the document's empirical distribution of topics: $y_d \sim \mathcal{N}(\boldsymbol{\eta}^T \bar{\boldsymbol{z}}_d, \rho)$ where $\boldsymbol{\eta}$ is the regression parameter vector and $\bar{\boldsymbol{z}}_d$ is the empirical distribution over topics of document d. The generative process of SLDA is:

1. For each topic $k \in [1, K]$
   (a) Draw word distribution $\phi_k \sim \text{Dir}(\beta)$
   (b) Draw parameter $\eta_k \sim \mathcal{N}(\mu, \sigma)$
2. For each document $d \in [1, D]$
   (a) Draw topic distribution $\theta_d \sim \text{Dir}(\alpha)$
   (b) For each word $n \in [1, N_d]$
      i. Draw topic $z_{d,n} \sim \text{Mult}(\theta_d)$
      ii. Draw word $w_{d,n} \sim \text{Mult}(\phi_{z_{d,n}})$
   (c) Draw response $y_d \sim \mathcal{N}(\boldsymbol{\eta}^T \bar{\boldsymbol{z}}_d, \rho)$ where $\bar{z}_{d,k} = \frac{1}{N_d} \sum_{n=1}^{N_d} \mathbb{I}[z_{d,n} = k]$

where $\mathbb{I}[x] = 1$ if x is true, and 0 otherwise.

In SLDA, in addition to the K multinomials $\{\phi_k\}_{k=1}^K$, the global latent variables also contain the regression parameter η_k for each topic k. The local latent variables of SLDA resembles LDA's: the topic proportion vector θ_d for each document d.

Train: For posterior inference during training, following Boyd-Graber and Resnik (2010), we use stochastic EM, which alternates between (1) a Gibbs sampling step to assign a topic to each token, and (2) optimizing the regression parameters. The probability of assigning topic k to token n in the training document d is

$$p(z^{\text{TR}}_{d,n} = k \mid \boldsymbol{z}^{\text{TR}}_{-d,n}, \boldsymbol{w}^{\text{TR}}_{-d,n}, w^{\text{TR}}_{d,n} = v) \propto$$

$$\mathcal{N}(y_d; \mu_{d,n}, \rho) \cdot \frac{N^{-d,n}_{\text{TR},d,k} + \alpha}{N^{-d,n}_{\text{TR},d,\cdot} + K\alpha} \cdot \frac{N^{-d,n}_{\text{TR},k,v} + \beta}{N^{-d,n}_{\text{TR},k,\cdot} + V\beta} \quad (9)$$

where $\mu_{d,n} = (\sum_{k'=1}^K \eta_{k'} N^{-d,n}_{\text{TR},d,k'} + \eta_k)/N_{\text{TR},d}$ is the mean of the Gaussian generating y_d if $z^{\text{TR}}_{d,n} = k$. Here, $N_{\text{TR},d,k}$ is the number of times topic k is assigned to tokens in the training document d; $N_{\text{TR},k,v}$ is the number of times word type v is assigned to topic k; $\cdot$ represents marginal counts and $^{-d,n}$ indicates counts excluding the assignment of token n in document d.

We optimize the regression parameters $\boldsymbol{\eta}$ using L-BFGS (Liu and Nocedal, 1989) via the likelihood

$$\mathcal{L}(\boldsymbol{\eta}) = -\frac{1}{2\rho} \sum_{d=1}^{D} (y^{\text{TR}}_d - \boldsymbol{\eta}^T \bar{\boldsymbol{z}}^{\text{TR}}_d)^2 - \frac{1}{2\sigma} \sum_{k=1}^{K} (\eta_k - \mu)^2 \quad (10)$$

At each iteration i in the training chain, the estimated global latent variables include the a multinomial $\hat{\phi}_k(i)$ and a regression parameter $\hat{\eta}_k(i)$ for each topic k.

Test: Like LDA, at test time we sample the topic assignments for all tokens in the test data

$$p(z^{\text{TE}}_{d,n} = k \mid \boldsymbol{z}^{\text{TE}}_{-d,n}, \boldsymbol{w}^{\text{TE}}) \propto \frac{N^{-d,n}_{\text{TE},d,k} + \alpha}{N^{-d,n}_{\text{TE},d,\cdot} + K\alpha} \cdot \hat{\phi}_{k,w^{\text{TE}}_{d,n}} \quad (11)$$

Prediction: The predicted value $S(i, j)$ in this case is the estimated value of the metadata review rating

$$S(i,j) \equiv \hat{y}^{\text{TE}}_d(i,j) = \hat{\boldsymbol{\eta}}(i)^T \bar{z}^{\text{TE}}_d(i,j), \quad (12)$$

where the empirical topic distribution of test document d is $\bar{z}^{\text{TE}}_{d,k}(i,j) \equiv \frac{1}{N_{\text{TE},d}} \sum_{n=1}^{N_{\text{TE},d}} \mathbb{I}\left[z^{\text{TE}}_{d,n}(i,j) = k\right]$.

Figure 4: Performance of SLDA using different averaging strategies computed at the final training iteration T_{TR}, compared with two baselines MLR and SVR. Methods using multiple test chains (MF and MA) perform as well as or better than the two baselines, whereas methods using a single test chain (SF and SA) perform significantly worse.

Experimental setup: We use the same data as in Section 3. For all datasets, the metadata are the review rating, ranging from 1 to 5 stars, which is standardized using z-normalization. We use two evaluation metrics: mean squared error (MSE) and predictive R-squared (Blei and McAuliffe, 2007).

For comparison, we consider two baselines: (1) multiple linear regression (MLR), which models the metadata as a linear function of the features, and (2) support vector regression (Joachims, 1999, SVR). Both baselines use the normalized frequencies of unigrams and bigrams as features. As in the unsupervised case, we report average performance over five cross-validated folds. For all models, we use a development set to tune their parameter(s) and use the set of parameters that gives best results on the development data at test.[5]

Results: Figure 3 shows SLDA prediction results with different averaging strategies, computed at different training iterations.[6] Consistent with the unsupervised results in Section 3, SA outperforms SF, but both are outperformed significantly by the two methods using multiple test chains (MF and MA).

We also compare the performance of the four prediction methods obtained at the final iteration T_{TR} of the training chain with the two baselines. The results in Figure 4 show that the two baselines (MLR and SVR) outperform significantly the SLDA using only a single test chains (SF and SA). Methods using multiple test chains (MF and MA), on the other hand, match the baseline [7] (HOTEL) or do better (RESTAURANT and MOVIE).

5 Discussion and Conclusion

MCMC relies on averaging multiple samples to approximate target densities. When used for prediction, MCMC needs to generate and average over both training samples to learn from training data and test samples to make prediction. We have shown that simple averaging—not more aggressive, *ad hoc* approximations like taking the final sample (either training or test)—is not just a question of theoretical aesthetics, but an important factor in obtaining good prediction performance.

Compared with SVR and MLR baselines, SLDA using multiple test chains (MF and MA) performs as well as or better, while SLDA using a single test chain (SF and SA) falters. This simple experimental setup choice can determine whether a model improves over reasonable baselines. In addition, better prediction with shorter training is possible with multiple test chains. Thus, we conclude that averaging using multiple chains produces above-average results.

Acknowledgments

This research was supported in part by NSF under grant #1211153 (Resnik) and #1018625 (Boyd-Graber and Resnik). Any opinions, findings, conclusions, or recommendations expressed here are those of the authors and do not necessarily reflect the view of the sponsor.

[5] For MLR we use a Gaussian prior $\mathcal{N}(0, 1/\lambda)$ with $\lambda = a \cdot 10^b$ where $a \in [1, 9]$ and $b \in [1, 4]$; for SVR, we use SVM^{light} (Joachims, 1999) and vary $C \in [1, 50]$, which trades off between training error and margin; for SLDA, we fix $\sigma = 10$ and vary $\rho \in \{0.1, 0.5, 1.0, 1.5, 2.0\}$, which trades off between the likelihood of words and response variable.

[6] MCMC setup: $T_{\text{TR}} = 5,000$ for RESTAURANT and MOVIE and $1,000$ for HOTEL; for all datasets $B_{\text{TR}} = 500$, $L_{\text{TR}} = 50$, $T_{\text{TE}} = 100$, $B_{\text{TE}} = 20$ and $L_{\text{TE}} = 5$.

[7] This gap is because SLDA has not converged after 1,000 training iterations (Figure 3).

Large-scale Reordering Model for Statistical Machine Translation using Dual Multinomial Logistic Regression

Abstract

Phrase reordering is a challenge for statistical machine translation systems. Posing phrase movements as a prediction problem using contextual features modeled by maximum entropy-based classifier is superior to the commonly used lexicalized reordering model. However, Training this discriminative model using large-scale parallel corpus might be computationally expensive. In this paper, we explore recent advancements in solving large-scale classification problems. Using the dual problem to multinomial logistic regression, we managed to shrink the training data while iterating and produce significant saving in computation and memory while preserving the accuracy.

1 Introduction

Phrase reordering is a common problem when translating between two grammatically different languages. Analogous to speech recognition systems, statistical machine translation (SMT) systems relied on language models to produce more fluent output. While early work penalized phrase movements without considering reorderings arising from vastly differing grammatical structures across language pairs like Arabic-English (Koehn, 2004a), many researchers considered lexicalized reordering models that attempted to learn orientation based on the training corpus (Tillmann, 2004; Kumar and Byrne, 2005; Koehn et al., 2005).

Building on this, some researchers have borrowed powerful ideas from the machine learning literature, to pose the phrase movement problem as a prediction problem using contextual input features whose importance is modeled as weights of a linear classifier trained by entropic criteria. The approach (so called maximum entropy classifier or simply MaxEnt) is a popular choice (Zens and Ney, 2006; Xiong et al., 2006; Nguyen et al., 2009; Xiang et al., 2011). Max-margin structure classifiers were also proposed (Ni et al., 2011). Alternatively, Cherry (2013) proposed recently using sparse features optimize the translation quality with the decoder instead of training a classifier independently.

While large-scale parallel corpus is advantageous for improving such reordering model, this improvement comes at a price of computational complexity. This issue is particularly pronounced when discriminative models are considered such as maximum entropy-based model due to the required iterative learning.

Advancements in solving large-scale classification problems have been shown to be effective such as dual coordinate descent method for linear support vector machines (Hsieh et al., 2008). Similarly, Yu et al. (2011) proposed a two-level dual coordinate descent method for maximum entropy classifier.

In this work we explore the dual problem to multinomial logistic regression for building large-scale reordering model (section 3). One of the main advantages of solving the dual problem is providing a mechanism to shrink the training data which is a serious issue in building such large-scale system. We present empirical results comparing between the primal and the dual problems (section 4). Our approach is shown to be fast and memory-efficient.

2 Baseline System

In statistical machine translation, the most likely translation $\mathbf{e}_{\text{best}}$ of an input sentence $\mathbf{f}$ can be found by maximizing the probability $p(\mathbf{e}|\mathbf{f})$, as follows:

$$\mathbf{e}_{\text{best}} = \arg\max_{\mathbf{e}} p(\mathbf{e}|\mathbf{f}). \quad (1)$$

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1758–1763,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

A log-linear combination of different models (features) is used for direct modeling of the posterior probability $p(\mathbf{e}|\mathbf{f})$ (Papineni et al., 1998; Och and Ney, 2002):

$$\mathbf{e}_{\text{best}} = \arg\max_{\mathbf{e}} \sum_{i=1}^{n} \lambda_i h_i(\mathbf{f}, \mathbf{e}) \qquad (2)$$

where the feature $h_i(\mathbf{f}, \mathbf{e})$ is a score function over sentence pairs. The translation model and the language model are the main features in any system although additional features $h(.)$ can be integrated easily (such as word penalty). State-of-the-art systems usually have around ten features.

The language model, which ensures fluent translation, plays an important role in reordering; however, it has a bias towards short translations (Koehn, 2010). Therefore, a need for developing a specific model for the reordering problem.

2.1 Lexicalized Reordering Model

Adding a lexicalized reordering model consistently improved the translation quality for several language pairs (Koehn et al., 2005). Reordering modeling involves formulating phrase movements as a classification problem where each phrase position considered as a class (Tillmann, 2004). Some researchers classified phrase movements into three categories (monotone, swap, and discontinuous) but the classes can be extended to any arbitrary number (Koehn and Monz, 2005). In general, the distribution of phrase orientation is:

$$p(o_k|\bar{f}_i, \bar{e}_i) = \frac{1}{Z}\, h(\bar{f}_i, \bar{e}_i, o_k)\,. \qquad (3)$$

This lexicalized reordering model is estimated by relative frequency where each phrase pair $(\bar{f}_i, \bar{e}_i)$ with such an orientation (o_k) is counted and then normalized to yield the probability as follows:

$$p(o_k|\bar{f}_i, \bar{e}_i) = \frac{\text{count}(\bar{f}_i, \bar{e}_i, o_k)}{\sum_o \text{count}(\bar{f}_i, \bar{e}_i, o)}. \qquad (4)$$

The orientation of a current phrase pair is defined with respect to the previous target phrase. Galley and Manning (2008) extended the model to tackle long-distance reorderings. Their hierarchical model enables phrase movements that are more complex than swaps between adjacent phrases.

3 Multinomial Logistic Regression

Multinomial logistic regression (MLR), also known as maximum entropy classifier (Zens and Ney, 2006), is a probabilistic model for the multiclass problem. The class probability is given by:

$$p(o_k|\bar{f}_i, \bar{e}_i) = \frac{\exp(\mathbf{w}_k^\top \phi(\bar{f}_i, \bar{e}_i))}{\sum_{k'} \exp(\mathbf{w}_{k'}^\top \phi(\bar{f}_i, \bar{e}_i))}, \qquad (5)$$

where $\phi(\bar{f}_i, \bar{e}_i)$ is the feature vector of the i-th phrase pair. An equivalent notation to $\mathbf{w}_k^\top \phi(\bar{f}_i, \bar{e}_i)$ is $\mathbf{w}^\top f(\phi(\bar{f}_i, \bar{e}_i), o_k)$ where $\mathbf{w}$ is a long vector composed of all classes parameters (i.e. $\mathbf{w}^\top = [\mathbf{w}_1^\top \dots \mathbf{w}_K^\top]$) and $f(.,.)$ is a joint feature vector decomposed via the orthogonal feature representation (Rousu et al., 2006). This representation simply means there is no crosstalk between two different feature vectors. For example, $f(\phi(\bar{f}_i, \bar{e}_i), o_1)^\top = [\phi(\bar{f}_i, \bar{e}_i)^\top\, 0 \dots 0]$.

The model's parameters can be estimated by minimizing the following regularized negative log-likelihood $\mathcal{P}(\mathbf{w})$ as follows (Bishop, 2006):

$$\min_{\mathbf{w}} \; \frac{1}{2\sigma^2} \sum_{k=1}^{K} \|\mathbf{w}_k\|^2 - \sum_{i=1}^{N} \sum_{k=1}^{K} \tilde{p}_{ik} \log p(o_k|\bar{f}_i, \bar{e}_i) \qquad (6)$$

Here σ is a penalty parameter and $\tilde{p}$ is the empirical distribution where $\tilde{p}_{ik}$ equals zero for all $o_k \neq o_i$.

Solving the primal optimization problem (6) using the gradient:

$$\frac{\partial \mathcal{P}(\mathbf{w})}{\partial \mathbf{w}_k} = \frac{\mathbf{w}_k}{\sigma^2} - \sum_{i=1}^{N} \big(\tilde{p}_{ik} - p(o_k|\bar{f}_i, \bar{e}_i)\big)\, \phi(\bar{f}_i, \bar{e}_i), \qquad (7)$$

do not constitute a closed-form solution. In our experiments, we used stochastic gradient decent method (i.e. online learning) to estimate $\mathbf{w}$ which is shown to be fast and effictive for large-scale problems (Bottou, 2010). The method approximates (7) by a gradient at a single randomly picked phrase pair. The update rule is:

$$\mathbf{w}'_k = \mathbf{w}_k - \eta_i \nabla_k \mathcal{P}_i(\mathbf{w}), \qquad (8)$$

where η_i is a positive learning rate.

3.1 The Dual Problem

Lebanon and Lafferty (2002) derived an equivalent dual problem to (6). Introducing Lagrange multipliers $\boldsymbol{\alpha}$, the dual becomes

$$\begin{aligned} \min_{\mathbf{w}} \quad & \frac{1}{2\sigma^2}\sum_{k=1}^{K}\|\mathbf{w}_k(\boldsymbol{\alpha})\|^2 + \sum_{i=1}^{N}\sum_{k=1}^{K}\alpha_{ik}\log\alpha_{ik}, \\ \text{s.t.} \quad & \sum_{k=1}^{K}\alpha_{ik} = 1 \ \text{ and } \ \alpha_{\text{ik}} \geq 0\,, \forall \text{i}, \text{k}, \end{aligned} \tag{9}$$

where

$$\mathbf{w}_k(\boldsymbol{\alpha}) = \sigma^2\sum_{i=1}^{N}(\tilde{p}_{ik} - \alpha_{ik})\phi(\bar{f}_i, \bar{e}_i) \tag{10}$$

As mentioned in the introduction, Yu et al. (2011) proposed a two-level dual coordinate descent method to minimize $\mathcal{D}(\boldsymbol{\alpha})$ in (9) but it has some numerical difficulties. Collins et al. (2008) proposed simple exponentiated gradient (EG) algorithm for Conditional Random Feild (CRF). The algorithm is applicable to our problem, a special case of CRF. The rule update is:

$$\alpha'_{ik} = \frac{\alpha_{ik}\exp(-\eta_i\,\nabla_{ik}\mathcal{D}(\boldsymbol{\alpha}))}{\sum_{k'}\alpha_{ik'}\exp(-\eta_i\,\nabla_{ik'}\mathcal{D}(\boldsymbol{\alpha}))} \tag{11}$$

where

$$\begin{aligned} \nabla_{ik}\mathcal{D}(\boldsymbol{\alpha}) &\equiv \frac{\partial\mathcal{D}(\boldsymbol{\alpha})}{\partial\alpha_{ik}} = 1 + \log\alpha_{ik} \\ &+ \left(\mathbf{w}_y(\boldsymbol{\alpha})^\top\phi(\bar{f}_i, \bar{e}_i) - \mathbf{w}_k(\boldsymbol{\alpha})^\top\phi(\bar{f}_i, \bar{e}_i)\right). \end{aligned} \tag{12}$$

Here y represents the true class (i.e. $o_y = o_i$). To improve the convergence, η_i is adaptively adjusted for each example. If the objective function (9) did not decrease, η_i is halved for number of trials (Collins et al., 2008). Calculating the function difference below is the main cost in EG algorithm,

$$\begin{aligned} \mathcal{D}(\boldsymbol{\alpha}') - \mathcal{D}(\boldsymbol{\alpha}) &= \sum_{k=1}^{K}\left(\alpha'_{ik}\log\alpha'_{ik} - \alpha_{ik}\log\alpha_{ik}\right) \\ &- \sum_{k=1}^{K}(\alpha'_{ik} - \alpha_{ik})\mathbf{w}_k(\boldsymbol{\alpha})^\top\phi(\bar{f}_i, \bar{e}_i) \\ &+ \frac{\sigma^2}{2}\|\phi(\bar{f}_i, \bar{e}_i)\|^2\sum_{k=1}^{K}(\alpha'_{ik} - \alpha_{ik})^2. \end{aligned} \tag{13}$$

Clearly, the cost is affordable because $\mathbf{w}_k(\boldsymbol{\alpha})$ is maintained throughout the algorithm as follows:

$$\mathbf{w}_k(\boldsymbol{\alpha}') = \mathbf{w}_k(\boldsymbol{\alpha}) - \sigma^2(\alpha'_{ik} - \alpha_{ik})\phi(\bar{f}_i, \bar{e}_i) \tag{14}$$

Following Yu et al. (2011), we initialize α_{ik} as follows:

$$\alpha_{ik} = \begin{cases} (1-\epsilon) & \text{if } o_k = o_i; \\ \frac{\epsilon}{K-1} & \text{else.} \end{cases} \tag{15}$$

where ϵ is a small positive value. This is because the objective function (9) is not well defined at $\alpha_{ik} = 0$ due to the logarithm appearance.

Finally, the optimal dual variables are achieved when the following condition is satisfied for all examples (Yu et al., 2011):

$$\max_k \nabla_{ik}\mathcal{D}(\boldsymbol{\alpha}) = \min_k \nabla_{ik}\mathcal{D}(\boldsymbol{\alpha}) \tag{16}$$

This condition is the key to accelerate EG algorithm. Unlike the primal problem (6), the dual variables α_{ik} are associated with each example (i.e. phrase pair) therefore a training example can be disregarded once its optimal dual variables obtained. More data shrinking can be achieved by tolerating a small difference between the two values in (16). Algorithm 1 presents the overall procedure (shrinking step is from line 6 to 9).

Algorithm 1 Shrinking stochastic exponentiated gradient method for training the dual problem

Require: training set $S = \{\phi(\bar{f}_i, \bar{e}_i), o_i\}_{i=1}^N$

1: Given $\boldsymbol{\alpha}$ and the corresponding $\mathbf{w}(\boldsymbol{\alpha})$
2: **repeat**
3: Randomly pick i from S
4: Claculate $\nabla_{ik}\mathcal{D}(\boldsymbol{\alpha})\ \forall k$ by (12)
5: $v_i = \max_k \nabla_{ik}\mathcal{D}(\boldsymbol{\alpha}) - \min_k \nabla_{ik}\mathcal{D}(\boldsymbol{\alpha})$
6: **if** $v_i \leq \epsilon$ **then**
7: Remove i from S
8: Continue from line 3
9: **end if**
10: $\eta = 0.5$
11: **for** $t = 1$ **to** maxTrial **do**
12: Calculate $\alpha'_{ik}\ \forall k$ by (11)
13: **if** $\mathcal{D}(\boldsymbol{\alpha}') - \mathcal{D}(\boldsymbol{\alpha}) \leq 0$ **then**
14: Update $\boldsymbol{\alpha}$ and $\mathbf{w}(\boldsymbol{\alpha})$ by (14)
15: Break
16: **end if**
17: $\eta = 0.5\,\eta$
18: **end for**
19: **until** $v_i \leq \epsilon \quad \forall i$

4 Experiments

We used MultiUN which is a large-scale parallel corpus extracted from the United Nations website (Eisele and Chen, 2010). We have used Arabic and English portion of MultiUN where the English side is about 300 million words.

We simplify the problem by classifying phrase movements into three categories (monotone, swap, discontinuous). To train the reordering models, we used GIZA++ to produce word alignments (Och and Ney, 2000). Then, we used the `extract` tool that comes with the Moses toolkit (Koehn et al., 2007) in order to extract phrase pairs along with their orientation classes.

As shown in Table 1, each extracted phrase pair is represented by linguistic features as follows:

- Aligned source and target words in a phrase pair. Each word alignment is a feature.
- Words within a window around the source phrase to capture the context. We choose adjacent words of the phrase boundary.

The extracted phrase pairs after filtering are 47,227,789. The features that occur more than 10 times are 670,154.

Sentence pair:

$\mathbf{f}$: $f_1\ f_2\ {}_1\ f_3\ f_4\ f_5\ {}_2\ f_6\ {}_3$.

$\mathbf{e}$: $e_1\ {}_1\ e_2\ e_3\ {}_3\ e_4\ e_5\ {}_2$.

Extracted phrase pairs $(\bar{\mathbf{f}}, \bar{\mathbf{e}})$:

$\bar{f}_i$	$\bar{e}_i$	o_i	alignment	context
$f_1\ f_2$	e_1	mono	0-0 1-0	f_3
$f_3\ f_4\ f_5$	$e_4\ e_5$	swap	0-1 2-0	$f_2\ f_6$
f_6	$e_2\ e_3$	other	0-0 0-1	f_5

All linguistic features:

1. f_1&e_1 2. f_2&e_1 3. f_3 4. f_3&e_5 5. f_5&e_4
6. f_2 7. f_6 8. f_6&e_2 9. f_6&e_3 10. f_5

Bag-of-words representation:

a phrase pair is represented as a vector where each feature is a discrete number (0=not exist).

$\phi(\bar{f}_i, \bar{e}_i)$	1	2	3	4	5	6	7	8	9	10
$\phi(\bar{f}_1, \bar{e}_1) =$	1	1	1	0	0	0	0	0	0	0
$\phi(\bar{f}_2, \bar{e}_2) =$	0	0	0	1	1	1	1	0	0	0
$\phi(\bar{f}_3, \bar{e}_3) =$	0	0	0	0	0	0	1	1	1	1

Table 1: A generic example of the process of phrase pair extraction and representation.

4.1 Classification

We trained our reordering models by both primal and dual classifiers for 100 iterations. For the dual MLR, different shrinking levels have been tried by varying the parameter (ϵ) in Algorithm 1. Table 2 reports the training time and classification error rate of these models.

Training the dual MLR with moderate shrinking level (i.e. $\epsilon = 0.1$) is almost four times faster than training the primal one. Choosing larger value for (ϵ) leads to faster training but might harm the performance as shown below.

Classifier	Training Time	Error Rate
Primal MLR	1 hour 9 mins	17.81%
Dual MLR ϵ:0.1	18 minutes	17.95%
Dual MLR ϵ:1.0	13 minutes	21.13%
Dual MLR ϵ:0.01	22 minutes	17.89%

Table 2: Performance of the primal and dual MLR based on held-out data.

Figure 1 shows the percentage of active set during training dual MLR with various shrinking levels. Interestingly, the dual MLR could disregard more than 99% of the data after a couple of iterations. For very large corpus, the data might not fit in memory and training primal MLR will take long time due to severe disk-swapping. In this situation, using dual MLR is very beneficial.

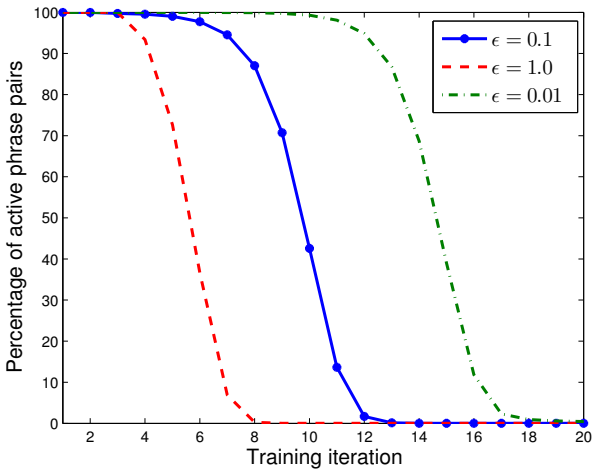

Figure 1: Percentage of active set in dual MLR. As the data size decreases, each iteration takes far less computation time (see Table 2 for total time).

4.2 Translation

We used the Moses toolkit (Koehn et al., 2007) with its default settings to build three phrase-based translation systems. They differ in how their reordering models were estimated. The language model is a 5-gram with interpolation and Kneser-Ney smoothing (Kneser and Ney, 1995). We tuned the system by using MERT technique (Och, 2003).

As commonly used in statistical machine translation, we evaluated the translation performance by BLEU score (Papineni et al., 2002). The test sets are NIST MT06 and MT08 where the English sides are 35,481 words (1056 sentences) and 116,840 words (3252 sentences), respectively. Table 3 shows the BLEU scores for the translation systems. We also computed statistical significance for the models using the *paired bootstrap resampling* method (Koehn, 2004b).

Translation System	MT06	MT08
Baseline + Lexical. model	30.86	34.22
Baseline + Primal MLR	31.37*	34.85*
Baseline + Dual MLR ϵ:0.1	31.36*	34.87*

Table 3: BLEU scores for Arabic-English translation systems with different reordering models (*: better than the lexicalized model with at least 95% statistical significance).

5 Conclusion

In training such system with large data sizes and big dimensionality, computational complexity become a serious issue. In SMT, maximum entropy-based reordering model is often introduced as a better alternative to the commonly used lexicalized one. However, training this discriminative model using large-scale corpus might be computationally expensive due to the iterative learning.

In this paper, we propose training the model using the dual MLR with shrinking method. It is almost four times faster than the primal MLR (also know as MaxEnt) and much more memory-efficient. For very large corpus, the data might not fit in memory and training primal MLR will take long time due to severe disk-swapping. In this situation, using dual MLR is very beneficial. The proposed method is also useful for many classification problems in natural language processing that require large-scale data.

Abstract

In this paper, we present two improvements to the beam search approach for solving homophonic substitution ciphers presented in Nuhn et al. (2013): An improved rest cost estimation together with an optimized strategy for obtaining the order in which the symbols of the cipher are deciphered reduces the beam size needed to successfully decipher the Zodiac-408 cipher from several million down to less than one hundred: The search effort is reduced from several hours of computation time to just a few seconds on a single CPU. These improvements allow us to successfully decipher the second part of the famous Beale cipher (see (Ward et al., 1885) and e.g. (King, 1993)): Having 182 different cipher symbols while having a length of just 762 symbols, the decipherment is way more challenging than the decipherment of the previously deciphered Zodiac-408 cipher (length 408, 54 different symbols). To the best of our knowledge, this cipher has not been deciphered automatically before.

1 Introduction

State-of-the-art statistical machine translation systems use large amounts of parallel data to estimate translation models. However, parallel corpora are expensive and not available for every domain.

Decipherment uses only monolingual data to train a translation model: Improving the core decipherment algorithms is an important step for making decipherment techniques useful for training practical machine translation systems.

In this paper we present improvements to the beam search algorithm for deciphering homophonic substitution ciphers as presented in Nuhn et al. (2013). We show significant improvements in computation time on the Zodiac-408 cipher and show the first decipherment of part two of the Beale ciphers.

2 Related Work

Regarding the decipherment of 1:1 substitution ciphers, various works have been published: Most older papers do not use a statistical approach and instead define some heuristic measures for scoring candidate decipherments. Approaches like Hart (1994) and Olson (2007) use a dictionary to check if a decipherment is useful. Clark (1998) defines other suitability measures based on n-gram counts and presents a variety of optimization techniques like simulated annealing, genetic algorithms and tabu search. On the other hand, statistical approaches for 1:1 substitution ciphers are published in the natural language processing community: Ravi and Knight (2008) solve 1:1 substitution ciphers optimally by formulating the decipherment problem as an integer linear program (ILP) while Corlett and Penn (2010) solve the problem using A^* search. Ravi and Knight (2011) report the first automatic decipherment of the Zodiac-408 cipher. They use a combination of a 3-gram language model and a word dictionary. As stated in the previous section, this work can be seen as an extension of Nuhn et al. (2013). We will therefore make heavy use of their definitions and approaches, which we will summarize in Section 3.

3 General Framework

In this Section we recap the beam search framework introduced in Nuhn et al. (2013).

3.1 Notation

We denote the ciphertext with $f_1^N = f_1 \dots f_j \dots f_N$ which consists of cipher

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1764–1768,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

tokens $f_j \in V_f$. We denote the plaintext with $e_1^N = e_1 \dots e_i \dots e_N$ (and its vocabulary V_e respectively). We define $e_0 = f_0 = e_{N+1} = f_{N+1} = \$$ with "$" being a special sentence boundary token. Homophonic substitutions are formalized with a general function $\phi : V_f \rightarrow V_e$. Following (Corlett and Penn, 2010), cipher functions ϕ, for which not all $\phi(f)$'s are fixed, are called partial cipher functions. Further, ϕ' is said to extend ϕ, if for all $f \in V_f$ that are fixed in ϕ, it holds that f is also fixed in ϕ' with $\phi'(f) = \phi(f)$. The cardinality of ϕ counts the number of fixed f's in ϕ. When talking about partial cipher functions we use the notation for relations, in which $\phi \subseteq V_f \times V_e$.

3.2 Beam Search

The main idea of (Nuhn et al., 2013) is to structure all partial ϕ's into a search tree: If a cipher contains N unique symbols, then the search tree is of height N. At each level a decision about the n-th symbol is made. The leaves of the tree form full hypotheses. Instead of traversing the whole search tree, beam search descents the tree top to bottom and only keeps the most promising candidates at each level. Practically, this is done by keeping track of all partial hypotheses in two arrays H_s and H_t. During search all allowed extensions of the partial hypotheses in H_s are generated, scored and put into H_t. Here, the function EXT_ORDER (see Section 5) chooses which cipher symbol is used next for extension, EXT_LIMITS decides which extensions are allowed, and SCORE (see Section 4) scores the new partial hypotheses. PRUNE then selects a subset of these hypotheses. Afterwards the array H_t is copied to H_s and the search process continues with the updated array H_s. Figure 1 shows the general algorithm.

```

```

Figure 1: The general structure of the beam search algorithm for decipherment of substitution ciphers as presented in Nuhn et al. (2013). This paper improves the functions SCORE and EXT_ORDER.

4 Score Estimation

The score estimation function is crucial to the search procedure: It predicts how good or bad a partial cipher function ϕ might become, and therefore, whether it's worth to keep it or not.

To illustrate how we can calculate these scores, we will use the following example with vocabularies $V_f = \{A, B, C, D\}$, $V_e = \{a, b, c, d\}$, extension order (B, C, A, D), and cipher text[1]

$$f_1^N = \texttt{\$ ABDD CABC DADC ABDC \$}$$

[1]We include blanks only for clarity reasons.

and partial hypothesis $\phi = \{(A, a), (B, b)\}$. This yields the following partial decipherment

$$\phi(f_1^N) = \texttt{\$ ab.. .ab. .a.. ab.. \$}$$

The score estimation function can only use this partial decipherment to calculate the hypothesis' score, since there are not yet any decisions made about the other positions.

4.1 Baseline

Nuhn et al. (2013) present a very simple rest cost estimator, which calculates the hypothesis' score based only on fully deciphered n-grams, i.e. those parts of the partial decipherment that form a contiguous chunk of n deciphered symbols. For all other n-grams containing not yet deciphered symbols, a trivial estimate of probability 1 is assumed, making it an admissible heuristic. For the above example, this baseline yields the probability $p(a|\$) \cdot p(b|a) \cdot 1^4 \cdot p(b|a) \cdot 1^6 \cdot p(b|a) \cdot 1^2$. The more symbols are fixed, the more contiguous n-grams become available. While being easy and efficient to compute, it can be seen that for example the single "a" is not involved in the computation of

the score at all. In practical decipherment, like e.g. the Zodiac-408 cipher, this forms a real problem: While making the first decisions—i.e. traversing the first levels of the search tree—only very few terms actually contribute to the score estimation, and thus only give a very coarse score. This makes the beam search "blind" when not many symbols are deciphered yet. This is the reason, why Nuhn et al. (2013) need a large beam size of several million hypotheses in order to not lose the right hypothesis during the first steps of the search.

4.2 Improved Rest Cost Estimation

The rest cost estimator we present in this paper solves the problem mentioned in the previous section by also including lower order n-grams: In the example mentioned before, we would also include unigram scores into the rest cost estimate, yielding a score of $p(a|\$) \cdot p(b|a) \cdot 1^3 \cdot p(a) \cdot p(b|a) \cdot 1^2 \cdot p(a) 1^2 \cdot p(a) \cdot p(b|a) \cdot 1^2$. Note that this is not a simple linear interpolation of different n-gram trivial scores: Each symbol is scored only using the maximum amount of context available. This heuristic is non-admissible, since an increased amount of context can always lower the probabilty of some symbols. However, experiments show that this score estimation function works great.

5 Extension Order

Besides having a generally good scoring function, also the order in which decisions about the cipher symbols are made is important for obtaining reliable cost estimates. Generally speaking we want an extension order that produces partial decipherments that contain useful information to decide whether a hypothesis is worth being kept or not as early as possible.

It is also clear that the choice of a good extension order is dependent on the score estimation function SCORE. After presenting the previous state of the art, we introduce a new extension order optimized to work together with our previously introduced rest cost estimator.

5.1 Baseline

In (Nuhn et al., 2013), two strategies are presented: One which at each step chooses the most frequent remaining cipher symbol, and another, which greedily chooses the next symbol to maximize the number of contiguously fixed n-grams in the ciphertext.

LM order	Perplexity	
	Zodiac-408	Beale Pt. 2
1	19.49	18.35
2	14.09	13.96
3	12.62	11.81
4	11.38	10.76
5	11.19	9.33
6	10.13	8.49
7	10.15	8.27
8	9.98	8.27

Table 1: Perplexities of the correct decipherment of Zodiac-408 and part two of the Beale ciphers using the character based language model used in beam search. The language model was trained on the English Gigaword corpus.

5.2 Improved Extension Order

Each partial mapping ϕ defines a partial decipherment. We want to choose an extension order such that *all possible* partial decipherments following this extension order are as informative as possible: Due to that, we can only use information about *which* symbols will be deciphered, not their actual decipherment. Since our heuristic is based on n-grams of different orders, it seems natural to evaluate an extension order by counting how many contiguously deciphered n-grams are available: Our new strategy tries to find an extension order optimizing the weighted sum of contiguously deciphered n-gram counts[2]

$$\sum_{n=1}^{N} w_n \cdot \#_n.$$

Here n is the n-gram order, w_n the weight for order n, and $\#_n$ the number of positions whose maximum context is of size n.

We perform a beam search over all possible enumerations of the cipher vocabulary: We start with fixing only the first symbol to decipher. We then continue with the second symbol and evaluate all resulting extension orders of length 2. In our experiments, we prune these candidates to the 100 best ones and continue with length 3, and so on.

Suitable values for the weights w_n have to be chosen. We try different weights for the different

[2]If two partial extension orders have the same score after fixing n symbols, we fall back to comparing the scores of the partial extension orders after fixing only the first $n-1$ symbols.

Table 2: Beginning and end of part two of the Beale cipher. Here we show a relabeled version of the cipher, which encodes knowledge of the gold decipherment to assign reasonable names to all homophones. The original cipher just consists of numbers.

orders on the Zodiac-408 cipher with just a beam size of 26. With such a small beam size, the extension order plays a crucial role for a successful decipherment: Depending on the choice of the different weights w_n we can observe decipherment runs with 3 out of 54 correct mappings, up to 52 out of 54 mappings correct. Even though the choice of weights is somewhat arbitrary, we can see that generally giving higher weights to higher n-gram orders yields better results.

We use the weights $w_1^8 = (0.0, 1.0, 1.0, 1.0, 1.0, 1.0, 2.0, 3.0)$ for the following experiments. It is interesting to compare these weights to the perplexities of the correct decipherment measured using different n-gram orders (Table 5). However, at this point we do not see any obvious connection between perplexities and weights w_n, and leave this as a further research direction.

6 Experimental Evaluation

6.1 Zodiac Cipher

Using our new algorithm we are able to decipher the Zodiac-408 with just a beam size of 26 and a language model order of size 8. By keeping track of the gold hypothesis while performing the beam search, we can see that the gold decipherment indeed always remains within the top 26 scoring hypotheses. Our new algorithm is able to decipher the Zodiac-408 cipher in less than 10s on a single CPU, as compared to 48h of CPU time using the previously published heuristic, which required a beam size of several million. Solving a cipher with such a small beam size can be seen as "reading off the solution".

6.2 Beale Cipher

We apply our algorithm to the second part of the Beale ciphers with a 8-gram language model.

Compared to the Zodiac-408, which has length 408 while having 54 different symbols (7.55 observations per symbol), part two of the Beale ciphers has length 762 while having 182 different symbols (4.18 observations per symbol). Compared to the Zodiac-408, this is both, in terms of redundancy, as well as in size of search space, a way more difficult cipher to break.

Here we run our algorithm with a beam size of 10M and achieve a decipherment accuracy of 157 out of 185 symbols correct yielding a symbol error rate of less than 5.4%. The gold decipherment is pruned out of the beam after 35 symbols have been fixed.

We also ran our algorithm on the other parts of the Beale ciphers: The first part has a length 520 and contains 299 different cipher symbols (1.74 observations per symbol), while part three has length 618 and has 264 symbols which is 2.34 observations per mapping. However, our algorithm does not yield any reasonable decipherments. Since length and number of symbols indicate that deciphering these ciphers is again more difficult than for part two, it is not clear whether the other parts are not a homophonic substitution cipher at all, or whether our algorithm is still not good enough to find the correct decipherment.

7 Conclusion

We presented two extensions to the beam search method presented in (Nuhn et al., 2012), that reduce the search effort to decipher the Zodiac-408 enormously. These improvements allow us to automatically decipher part two of the Beale ciphers. To the best of our knowledge, this has not been

done before. This algorithm might prove useful when applied to word substitution ciphers and to learning translations from monolingual data.

Abstract

Manual analysis and decryption of enciphered documents is a tedious and error prone work. Often—even after spending large amounts of time on a particular cipher—no decipherment can be found. Automating the decryption of various types of ciphers makes it possible to sift through the large number of encrypted messages found in libraries and archives, and to focus human effort only on a small but potentially interesting subset of them. In this work, we train a classifier that is able to predict which encipherment method has been used to generate a given ciphertext. We are able to distinguish 50 different cipher types (specified by the American Cryptogram Association) with an accuracy of 58.5%. This is a 11.2% absolute improvement over the best previously published classifier.

1 Introduction

Libraries and archives contain a large number of encrypted messages created throughout the centuries using various encryption methods. For the great majority of the ciphers an analysis has not yet been conducted, simply because it takes too much time to analyze each cipher individually, or because it is too hard to decipher them. Automatic methods for analyzing and classifying given ciphers makes it possible to sift interesting messages and by that focus the limited amount of human resources to a promising subset of ciphers.

For specific types of ciphers, there exist automated tools to decipher encrypted messages. However, the publicly available tools often depend on a more or less educated guess which type of encipherment has been used. Furthermore, they often still need human interaction and are only restricted to analyzing very few types of ciphers. In practice however, there are many different types of ciphers which we would like to analyze in a fully automatic fashion: Bauer (2010) gives a good overview over historical methods that have been used to encipher messages in the past. Similarly, the American Cryptogram Association (ACA) specifies a set of 56 different methods for enciphering a given plaintext:

Each encipherment method M_i can be seen as a function that transforms a given plaintext into a ciphertext using a given key, or short:

$$\text{cipher} = M_i(\text{plain}, \text{key})$$

When analyzing an unknown ciphertext, we are interested in the original plaintext that was used to generate the ciphertext, i.e. the opposite direction:

$$\text{plain} = M_i^{-1}(\text{cipher}, \text{key})$$

Obtaining the plaintext from an enciphered message is a difficult problem. We assume that the decipherment of a message can be separated into solving three different subproblems:

1. Find the encipherment method M_i that was used to create the cipher
$$\text{cipher} \quad \rightarrow \quad M_i$$
2. Find the key that was used together with the method M_i to encipher the plaintext to obtain $cipher = M_i(plain, key)$.
3. Decode the message using M_i and key
$$\text{cipher} \quad \rightarrow \quad M_i^{-1}(\text{cipher}, \text{key})$$

Thus, an intermediate step to deciphering an unknown ciphertext is to find out which encryption method was used. In this paper, we present a classifier that is able to predict just that: Given an unknown ciphertext, it can predict what kind of encryption method was most likely used to generate

it. The results of our classifier are a valuable input to human decipherers to make a first categorization of an unknown ciphertext.

2 Related Work

Central to this work is the list of encryption methods provided by the American Cipher Association[1]. This list contains detailed descriptions and examples of each of the cipher types, allowing us to implement them. Figure 3 lists these methods.

We compare our work to the only previously published cipher type classifier for classical ciphers[2]. This classifier is trained on $16,800$ ciphertexts and is implemented in javascript to run in the web browser: The user can provide the ciphertext as input to a web page that returns the classifier's predictions. The source code of the classifier is available online. Our work includes a reimplementation of the features used in that classifier.

As examples for work that deals with the automated decipherment of cipher texts, we point to (Ravi and Knight, 2011), and (Nuhn et al., 2013). These publications develop specialized algorithms for solving simple and homophonic substitution ciphers, which are just two out of the 56 cipher types defined by the ACA. We also want to mention (de Souza et al., 2013), which presents a cipher type classifier for the finalist algorithms of the Advanced Encryption Standard (AES) contest.

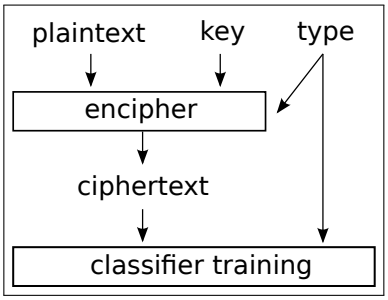

Figure 2: Overview over the data generation and training of the classifier presented in this work.

3 General Approach

Given a ciphertext, the task is to find the right encryption method. Our test set covers 50 out of 56 cipher types specified by ACA, as listed in Figure 3. We are going to take a machine learning approach which is based on the observation that we can generate an infinite amount of training data.

3.1 Data Flow

The training procedure is depicted in Figure 2: Based upon a large English corpus, we first choose possible plaintext messages. Then, for each encipherment method, we choose a random key and encipher each of the plaintext messages using the encipherment method and key. By doing this, we can obtain (a theoretically infinite) amount of labeled data of the form $(\text{type, ciphertext})$. We can then train a classifier on this data and evaluate it on some held out data.

Figure 1 shows that in general the key can consist of more than just a codeword: In this case, the method uses two codewords, a period length, two different permutation parameters, and a general decision whether to use a special "6×6" variant of the cipher or not. If not defined otherwise, we choose random settings for these parameters. If the parameters are integers, we choose random values from a uniform distribution (in a sensible range). In case of codewords, we choose the 450k most frequent words from an English dictionary. We train on cipher texts of random length.

3.2 Classifiers

The previous state-of-the-art classifier by BION uses a random forest classifier (Breiman, 2001). The version that is available online, uses 50 ran-

dom decision trees. The features used by this classifier are described in Section 4.

Further, we train a support vector machine using the libSVM toolkit (Chang and Lin, 2011). This is feasible for up to 100k training examples. Beyond this point, training times become too large. We perform multi class classification using ν-SVC and a polynomial kernel. Multi class classification is performed using one-against-one binary classification. We select the SVM's free parameters using a small development set of 1k training examples.

We also use Vowpal Wabbit (Langford et al., 2007) to train a linear classifier using stochastic gradient descent. Compared to training SVMs, Vowpal Wabbit is extremely fast and allows using a lot of training examples. We use a squared loss function, adaptive learning rates and don't employ any regularization. We train our classifier with up to 1M training examples. The best performing settings use one-against-all classification, 20 passes over the training data and the default learning rate. Quadratic features resulted in much slower training, while not providing any gains in accuracy.

4 Features

We reimplemented all of the features used in the BION classifier, and add three newly developed sets of features, resulting in a total of 58 features.

In order to further structure these features, we group these features as follows: We call the set of features that relate to the length of the cipher `LEN`. This set contains binary features firing when the cipher length is a multiple of 2, 3, 5, 25, any of 4-15, and any of 4-30. We call the set of features that are based on the fact that the ciphertext contains a specific symbol `HAS`. This set contains binary features firing when the cipher contains a digit, a letter (A-Z), the "#" symbol, the letter "j", the digit "0". We also introduce another set of features called `DGT` that contains two features, firing when the cipher is starting or ending with a digit. The set `VIG` contains 5 features: The feature score is based on the best possible bigram LM perplexity of a decipherment compatible with the decipherment process of the cipher types Autokey, Beaufort, Porta, Slidefair and Vigenere. Further, we also include the features `IC`, `MIC`, `MKA`, `DIC`, `EDI`, `LR`, `ROD` and `LDI`, `DBL`, `NOMOR`, `RDI`, `PTX`, `NIC`, `PHIC`, `BDI`, `CDD`, `SSTD`, `MPIC`, `SERP`, which were introduced in the BION classifier[3]. Thus, the first 22 data points in Figure 4 are based on previously known features by BION. We further present the following additional features.

4.1 Repetition Feature (`REP`)

This set of features is based on how often the ciphertext contains symbols that are repeated exactly n times in a row: For example the ciphertext shown in Figure 1 contains two positions with repetitions of length $n = 2$, because the ciphertext contains EE, as well as AA. Beyond length 2, there are no repeats. These numbers are then normalized by dividing them by the total number of repeats of length $2 \leq n \leq 5$.

4.2 Amsco Feature (`AMSC`)

The idea of the AMSCO cipher is to fill consecutive chunks of one and two plaintext characters into n columns of a grid (see Table 1). Then a permutation of the columns is performed, and the resulting permuted plaintext is read of line by line and forms the final ciphertext. This feature reads the ciphertext into a similar grid of up to 5 columns

[3] See `http://home.comcast.net/~acabion/acarefstats.html`

Plaintext	w oo	om t	e ba	ns l	f li
Permutation	3	5	1	4	2

Table 1: Example grid used for AMSCO ciphers.

and then tries all possible permutations to retain the original plaintext. The result of this operation is then scored with a bigram language model. Depending on whether the difference in perplexity between ciphertext and deciphered text exceeds a given threshold, this binary feature fires.

4.3 Variant Feature (VAR)

In the variant cipher, the plaintext is written into a block under a key word. All letters in the first column are enciphered by shifting them using the first key letter of the key word, the second column uses the second key letter, etc. For different periods (i.e. lengths of key words), the ciphertext is structured into n columns and unigram statistics for each column are calculated. The frequency profile of each column is compared to the unigram frequency profile using a perplexity measure. This binary feature fires when the resulting perplexities are lower than a specific threshold.

5 Results

Figure 4 shows the classification accuracy for the BION baseline, as well as our SVM and VW based classifiers for a test set of 305 ciphers that have been published in the ACA. The classifiers shown in this figure are trained on cipher texts of random length. We show the contribution of all the features we used in the classifier on the x-axis. Furthermore we also vary the amount of training data we use to train the classifiers from 10k to 1M training examples. It can be seen that when using the same features as BION, our prediction accuracy is compatible with the BION classifier. The main improvement of our classifier stems from the REP, AMSC and VAR features. Our best classifier is more than 11% more accurate than previous state-of-the-art BION classifier.

We identified the best classifier on a held-out set of 1000 ciphers, i.e. 20 ciphers for each cipher type. Here the three new features improve the VW-1M classifier from 50.9% accuracy to 56.0% accuracy, and the VW-100k classifier from 48.9% to 54.6%. Note that this held-out set is based on the exact same generator that we used to create the training data with. However, we also report the results of our method on the completely independently created ACA test set in Figure 4.

6 Conclusion

We presented a state-of-the art classifier for cipher type detection. The approach we present is easily extensible to cover more cipher types and allows incorporating new features.

Joint Learning of Chinese Words, Terms and Keywords

Ziqiang Cao[1] **Sujian Li**[1] **Heng Ji**[2]

Abstract

Previous work often used a pipelined framework where Chinese word segmentation is followed by term extraction and keyword extraction. Such framework suffers from error propagation and is unable to leverage information in later modules for prior components. In this paper, we propose a four-level Dirichlet Process based model (DP-4) to jointly learn the word distributions from the corpus, domain and document levels simultaneously. Based on the DP-4 model, a sentence-wise Gibbs sampler is adopted to obtain proper segmentation results. Meanwhile, terms and keywords are acquired in the sampling process. Experimental results have shown the effectiveness of our method.

1 Introduction

For Chinese language which does not contain explicitly marked word boundaries, word segmentation (WS) is usually the first important step for many Natural Language Processing (NLP) tasks including term extraction (TE) and keyword extraction (KE). Generally, Chinese terms and keywords can be regarded as words which are representative of one domain or one document respectively. Previous work of TE and KE normally used the pipelined approaches which first conducted WS and then extracted important word sequences as terms or keywords.

It is obvious that the pipelined approaches are prone to suffer from error propagation and fail to leverage information for word segmentation from later stages. Here, we provide one example in the *disease* domain, to demonstrate the common problems in current pipelined approaches and propose the basic idea of our joint learning of words, terms and keywords.

Example: 血小板减少症(thrombocytopenia) 同(with) 类肝素(heparinoid) 有(have) 关系(relation).

This is a correctly segmented Chinese sentence. The document containing the example sentence mainly talks about the property of "类肝素(heparinoid)" which can be regarded as one keyword of the document. At the same time, the word 血小板减少症(thrombocytopenia) appears frequently in the *disease* domain and can be treated as a domain-specific term.

However, for such a simple sentence, current segmentation tools perform poorly. The segmentation result with the state-of-the-art Conditional Random Fields (CRFs) approach (Zhao et al., 2006) is as follows:

血小板(blood platelet) 减少(reduction) 症(symptom)
同类(of same kind) 肝(liver) 素有(always) 关系(relation)

where 血小板减少症 is segmented into three common Chinese words and 类肝素 is mixed with its neighbors.

In a text processing pipeline of WS, TE and KE, it is obvious that imprecise WS results will make the overall system performance unsatisfying. At the same time, we can hardly make use of domain-level and document-level information collected in TE and KE to promote the performance of WS. Thus, one question comes to our minds: can words, terms and keywords be jointly learned with consideration of all the information from the corpus, domain, and document levels?

Recently, the hierarchical Dirichlet process (HDP) model has been used as a smoothed bigram model to conduct word segmentation (Goldwater et al., 2006; Goldwater et al., 2009). Meanwhile, one strong point of the HDP based models is that they can model the diversity and commonality in multiple correlated corpora (Ren et al., 2008; Xu et al., 2008; Zhang et al., 2010; Li et al., 2012; Chang et al., 2014). Inspired by such existing work, we propose a four-level DP based model,

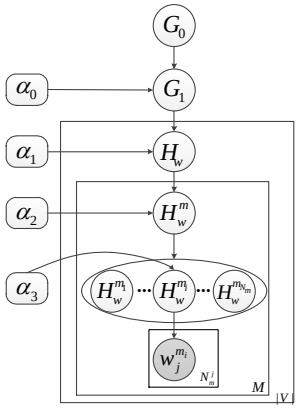

Figure 1: DP-4 Model

named DP-4, to adapt to three levels: corpus, domain and document. In our model, various DPs are designed to reflect the smoothed word distributions in the whole corpus, different domains and different documents. Same as the DP based segmentation models, our model can be easily used as a semi-supervised framework, through exerting on the corpus level the word distributions learned from the available segmentation results. Referring to the work of Mochihashi et al. (2009), we conduct word segmentation using a sentence-wise Gibbs sampler, which combines the Gibbs sampling techniques with the dynamic programming strategy. During the sampling process, the importance values of segmented words are measured in domains and documents respectively, and words, terms and keywords are jointly learned.

2 DP-4 Model

Goldwater et al. (2006) applied the HDP model on the word segmentation task. In essence, Goldwater's model can be viewed as a bigram language model with a unigram back-off. With the language model, word segmentation is implemented by a character-based Gibbs sampler which repeatedly samples the possible word boundary positions between two neighboring words, conditioned on the current values of all other words. However, Goldwater's model can be deemed as modeling the whole corpus only, and does not distinguish between domains and documents. To jointly learn the word information from the corpus, domain and document levels, we extend Goldwater's model by adding two levels (domain level and document level) of DPs, as illustrated in Figure 1.

2.1 Model Description

M DPs (H_w^m;$1 \leq m \leq M$) are designed specifically to word w to model the bigram distributions in each domain and these DPs share an overall base measure H_w, which is drawn from $DP(\alpha_0, G_1)$ and gives the bigram distribution for the whole corpus. Assuming the m^{th} domain includes N_m documents, we use $H_w^{m_j}$ ($1 \leq j \leq N_m$) to model the bigram distribution of the i^{th} document in the domain. Usually, given a domain, the bigram distributions of different documents are not conditionally independent and similar documents exhibit similar bigram distributions. Thus, the bigram distribution of one document is generated according to both the bigram distribution of the domain and the bigram distributions of other documents in the same domain. That is, $H_w^{m_j} \sim g(\alpha_3, H_w^m, H_w^{m-j})$ where H_w^{m-j} represents the bigram distributions of the documents in the m^{th} domain except the j^{th} document. Assuming the j^{th} document in the m^{th} domain contains N_m^j words, each word is drawn according to $H_w^{m_j}$. That is, $w_i^{m_j} \sim H_w^{m_j} (1 \leq i \leq N_m^j)$. Thus, our four-level DP model can be summarized formally as follows:

$$G_1 \sim DP(\alpha_0, G_0); H_w \sim DP(\alpha_1, G_1)$$
$$H_w^m \sim DP(\alpha_2, H_w); H_w^{m_j} \sim g\left(\alpha_3, H_w^m, H_w^{m-j}\right)$$
$$w_i^{m_j} | w_{i-1} = w \sim H_w^d$$

Here, we provide for our model the Chinese Restaurant Process (CRP) metaphor, which can create a partition of items into groups. In our model, the word type of the previous word w_{i-1} corresponds to a restaurant and the current word w_i corresponds to a customer. Each domain is analogous to a floor in a restaurant and a room denotes a document. Now, we can see that there are $|V|$ restaurants and each restaurant consists of M floors. The m^{th} floor contains N_m rooms and each room has an infinite number of tables with infinite seating capacity. Customers enter a specific room on a specific floor of one restaurant and seat themselves at a table with the label of a word type. Different from the standard HDP, each customer sits at an occupied table with probability proportional to both the numbers of customers already seated there and the numbers of customers with the same word type seated in the neighboring rooms, and at an unoccupied table with probability proportional to both the constant α_3 and the probability that the

customers with the same word type are seated on the same floor.

2.2 Model Inference

It is important to build an accurate G_0 which determines the prior word distribution $p_0(w)$. Similar to the work of Mochihashi et al. (2009), we consider the dependence between characters and calculate the prior distribution of a word w_i using the string frequency statistics (Krug, 1998):

$$p_0(w_i) = \frac{n_s(w_i)}{\sum n_s(.)} \tag{1}$$

where $n_s(w_i)$ counts the character string composed of w_i and the symbol "." represents any word in the vocabulary V.

Then, with the CRP metaphor, we can obtain the expected word unigram and bigram distributions on the corpus level according to G_1 and H_w:

$$p_1(w_i) = \frac{n(w_i) + \alpha_0 p_0(w_i)}{\sum n(.) + \alpha_0} \tag{2}$$

$$p_2(w_i|w_{i-1} = w) = \frac{n_w(w_i) + \alpha_1 p_1(w_i)}{\sum n_w(.) + \alpha_1} \tag{3}$$

where the subscript numbers indicate the corresponding DP levels. $n(w_i)$ denotes the number of w_i and $n_w(w_i)$ denotes the number of the bigram $< w, w_i >$ occurring in the corpus. Next, we can easily get the bigram distribution on the domain level by extending to the third DP.

$$p_3^m(w_i|w_{i-1} = w) = \frac{n_w^m(w_i) + \alpha_2 p_2(w_i|w_{i-1})}{\sum n_w^m(.) + \alpha_2} \tag{4}$$

where $n_w^m(w_i)$ is the number of the bigram $< w, w_i >$ occurring in the m^{th} domain.

To model the bigram distributions on the document level, it is beneficial to consider the influence of related documents in the same domain (Wan and Xiao, 2008). Here, we only consider the influence from the K most similar documents with a simple similarity metric $s(d_1, d_2)$ which calculates the Chinese character overlap ratio of two documents d_1 and d_2. Let d_m^j denote the j^{th} document in the m^{th} domain and $d_m^j[k](1 \le k \le K)$ the K most similar documents. d_m^j can be deemed to be "lengthened" by $d_m^j[k](1 \le k \le K)$. Therefore, we estimate the count of w_i in d_m^j as:

$$t_w^{d_m^j}(w_i) = n_w^{d_m^j}(w_i) + \sum_k s(d_m^j[k], d_m^j) n_w^{d_m^j[k]}(w_i) \tag{5}$$

where $n_w^{d_m^j[k]}(w_i)$ denotes the count of the bigram $< w, w_i >$ occurring in $d_m^j[k]$. Next, we model the bigram distribution in d_m^j as a DP with the base measure H_w^m :

$$p_4^{d_m^j}(w_i|w_{i-1} = w) = \frac{t_w^{d_m^j}(w_i) + \alpha_3 p_3^m(w_i|w_{i-1})}{\sum t_w^{d_m^j}(.) + \alpha_3} \tag{6}$$

With CRP, we can also easily estimate the unigram probabilities $p_3^m(w_i)$ and $p_4^{d_m^j}(w_i)$ respectively on the domain and document levels, through combining all the restaurants.

To measure whether a word is eligible to be a term, the score function $TH^m(\cdot)$ is defined as:

$$TH^m(w_i) = \frac{p_3^m(w_i)}{p_1(w_i)} \tag{7}$$

This equation is inspired by the work of Nazar (2011), which extracts terms with consideration of both the frequency in the domain corpus and the frequency in the general reference corpus. Similar to Eq. 7, we define the function $KH^{d_m^j}(\cdot)$ to judge whether w_i is an appropriate keyword.

$$KH^{d_m^j}(w_i) = \frac{p_4^{d_m^j}(w_i)}{p_1(w_i)} \tag{8}$$

During each sampling, we make use of Eqs. (7) and (8) to identify the most possible terms and keywords. Once a word is identified as a term or keyword, it will drop out of the sampling process in the following iterations. Its CRP explanation is that some customers (terms and keywords) find their proper tables and keep sitting there afterwards.

2.3 Sentence-wise Gibbs Sampler

The character-based Gibbs sampler for word segmentation (Goldwater et al., 2006) is extremely slow to converge, since there exists high correlation between neighboring words. Here, we introduce the sentence-wise Gibbs sampling technique as well as efficient dynamic programming strategy proposed by Mochihashi et al. (2009). The basic idea is that we randomly select a sentence in each sampling process and use the Viterbi algorithm (Viterbi, 1967) to find the optimal segmentation results according to the word distributions derived from other sentences. Different from Mochihashi's work, once terms or keywords are

identified, we do not consider them in the segmentation process. Due to space limitation, the algorithm is not detailed here and can be referred in (Mochihashi et al., 2009).

3 Experiment

3.1 Data and Setting

It is indeed difficult to find a standard evaluation corpus for our joint tasks, especially in different domains. As a result, we spent a lot of time to collect and annotate a new corpus [1] composed of ten domains (including *Physics*, *Computer*, *Agriculture*, *Sports*, *Disease*, *Environment*, *History*, *Art*, *Politics* and *Economy*) and each domain is composed of 200 documents. On average each document consists of about 4800 Chinese characters. For these 2000 documents, three annotators have manually checked the segmented words, terms and keywords as the gold standard results for evaluation. As we know, there exists a large amount of manually-checked segmented text for the general domain, which can be used as the training data for further segmentation. As with other nonparametric Bayesian models (Goldwater et al., 2006; Mochihashi et al., 2009), our DP-4 model can be easily amenable to semi-supervised learning by imposing the word distributions of the segmented text on the corpus level. The news texts provided by Peking University (named PKU corpus)[2] is used as the training data. This corpus contains about 1,870,000 Chinese characters and has been manually segmented into words.

In our experiments, the concentration coefficient (α_0) is finally set to 20 and the other three ($\alpha_{1\sim3}$) are set to 15. The parameter K which controls the number of similar documents is set to 3.

3.2 Performance Evaluation

The following baselines are implemented for comparison of segmentation results: (1) Forward maximum matching (FMM) algorithm with a vocabulary compiled from the PKU corpus; (2) Reverse maximum matching (RMM) algorithm with the compiled vocabulary; (3) Conditional Random Fields (CRFs)[3] based supervised algorithm trained from the PKU corpus; (4) HDP based semi-supervised algorithm (Goldwater et al., 2006) using the PKU corpus. The strength of Mochihashi et al. (2009)'s NPYLM based segmentation model is its speed due to the sentence-wise sampling technique, and its performance is similar to Goldwater et al. (2006)'s model. Thus, we do not consider the NPYLM based model for comparison here. Then, the segmentation results of FMM, RMM, CRF, and HDP methods are used respectively for further extracting terms and keywords. We use the mutual information to identify the candidate terms or keywords composed of more than two segmented words. As for DP-4, this recognition process has been done implicitly during sampling. To measure the candidate terms or keywords, we refer to the metric in Nazar (2011) to calculate their importance in some specific domain or document.

The metrics of F_1 and the out-of-vocabulary Recall (OOV-R) are used to evaluate the segmentation results, referring to the gold standard results. The second and third columns of Table 1 show the F_1 and OOV-R scores averaged on the 10 domains for all the compared methods. Our method significantly outperforms FMM, RMM and HDP according to t-test (p-value ≤ 0.05). From the segmentation results, we can see that the FMM and RMM methods are highly dependent on the compiled vocabulary and their identified OOV words are mainly the ones composed of a single Chinese character. The HDP method is heavily influenced by the segmented text, but it also exhibits the ability of learning new words. Our method only shows a slight advantage over the CRF approach. We check our segmentation results and find that the performance of the DP-4 model is depressed by the identified terms and keywords which may be composed of more than two words in the gold standard results, because the DP-4 model always treats the term or keyword as a single word. For example, in the gold standard, "岭南文化((Lingnan Culture)" is segmented into two words "岭南" and "文化", "数据接口(data interface)" is segmented into "数据" and "接口" and so on. In fact, our segmentation results correctly treat "岭南文化" and "数据接口" as words.

To evaluate the TE and KE performance, the top 50 (TE-50) and 100 (TE-100) accuracy are measured for the identified terms of one domain, while the top 5 (KE-5) and 10 (KE-10) accuracy for the keywords in one document, are shown in the right four columns of Table 1. We can see that DP-

[1] Nine domains are from http://www.datatang.com/data/44139 and we add an extra *Disease* domain.

[2] http://icl.pku.edu.cn

[3] We adopt CRF++(http://crfpp.googlecode.com/svn/trunk/doc/index.html)

4 performs significantly better than all the other methods in TE and KE results.

As for the ten domains, we find our approach behaves much better than the other approaches on the following three domains: *Disease*, *Physics* and *Computer*. It is because the language of these three domains is much different from that of the general domain (PKU corpus), while the rest domains are more similar to the general domain.

Method	F1	OOV-R	TE-50	TE-100	KE-5	KE-10
FMM	0.796	0.136	0.420	0.360	0.476	0.413

HDP	0.808	0.356	0.672	0.592	0.552	0.506
CRF	0.817	0.330	0.624	0.560	0.543	0.511
DP-4	**0.821**	**0.374**	**0.704**	**0.640**	**0.571**	**0.545**

Table 1: Comparison of WS, TE and KE Performance (averaged on the 10 domains).

4 Conclusion

This paper proposes a four-level DP based model to construct the word distributions from the corpus, domain and document levels simultaneously, through which Chinese words, terms and keywords can be learned jointly and effectively. In the future, we plan to explore how to combine more features such as part-of-speech tags into our model.

Cross-Lingual Part-of-Speech Tagging through Ambiguous Learning

Abstract

When Part-of-Speech annotated data is scarce, e.g. for under-resourced languages, one can turn to cross-lingual transfer and crawled dictionaries to collect partially supervised data. We cast this problem in the framework of *ambiguous learning* and show how to learn an accurate history-based model. Experiments on ten languages show significant improvements over prior state of the art performance.

1 Introduction

In the past two decades, supervised Machine Learning techniques have established new performance standards for many NLP tasks. Their success however crucially depends on the availability of annotated in-domain data, a not so common situation. This means that for many application domains and/or less-resourced languages, alternative ML techniques need to be designed to accommodate unannotated or partially annotated data.

Several attempts have recently been made to mitigate the lack of annotated corpora using parallel data pairing a (source) text in a resource-rich language with its counterpart in a less-resourced language. By transferring labels from the source to the target, it becomes possible to obtain noisy, yet useful, annotations that can be used to train a model for the target language in a *weakly supervised* manner. This research trend was initiated by Yarowsky et al. (2001), who consider the transfer of POS and other syntactic information, and further developed in (Hwa et al., 2005; Ganchev et al., 2009) for syntactic dependencies, in (Padó and Lapata, 2009; Kozhevnikov and Titov, 2013; van der Plas et al., 2014) for semantic role labeling and in (Kim et al., 2012) for named-entity recognition, to name a few.

Assuming that labels can actually be projected across languages, these techniques face the issue of extending standard supervised techniques with partial and/or uncertain labels in the presence of alignment noise. In comparison to the early approach of Yarowsky et al. (2001) in which POS are directly transferred, subject to heuristic filtering rules, recent works consider the integration of softer constraints using expectation regularization techniques (Wang and Manning, 2014), the combination of alignment-based POS transfer with additional information sources such as dictionaries (Li et al., 2012; Täckström et al., 2013) (Section 2), or even the simultaneous use of both techniques (Ganchev and Das, 2013).

In this paper, we reproduce the weakly supervised setting of Täckström et al. (2013). By recasting this setting in the framework of ambiguous learning (Bordes et al., 2010; Cour et al., 2011) (Section 3), we propose an alternative learning methodology and show that it improves the state of the art performance on a large array of languages (Section 4). Our analysis of the remaining errors suggests that in cross-lingual settings, improvements of error rates can have multiple causes and should be looked at with great care (Section 4.2).

All tools and resources used in this study are available at `http://perso.limsi.fr/wisniews/ambiguous`.

2 Projecting Labels across Aligned Corpora

Projecting POS information across languages relies on a rather strong assumption that morpho-syntactic categories in the source language can be directly related to the categories in the target language, which might not always be warranted (Evans and Levinson, 2009; Broschart, 2009). The universal reduced POS tagset proposed by Petrov et al. (2012) defines an operational, albeit rather empirical, ground to perform this mapping. It is made of the following 12 categories: NOUN (nouns), VERB (verbs), ADJ (ad-

jectives), ADV (adverbs), PRON (pronouns), DET (determiners and articles), ADP (prepositions and postpositions), NUM (numerals), CONJ (conjunctions), PRT (particles), '.' (punctuation marks) and X (a catch-all for other categories). These labels have been chosen for their stability across languages and for their usefulness in various multilingual applications. In the rest of this work, all annotations are mapped to this universal tagset.

Transfer-based methods have shown to be very effective, even if projected labels only deliver a noisy supervision, due to tagging (of the source language) and other alignment errors (Yarowsky et al., 2001). While this uncertainty can be addressed in several ways, recent works have proposed to combine projected labels with monolingual information in order to filter out invalid label sequences (Das and Petrov, 2011; Täckström et al., 2013). In this work we follow Täckström et al. (2013) and use two families of constraints:

Token constraints rely on word alignments to project labels of source words to target words through alignment links. Table 1 shows that, depenening on the language, only $50-80\%$ of the target tokens would benefit from label transfer.

Type constraints rely on a tag dictionary to define the set of possible tags for each word type. Type constraints reduce the possible labels for a given word and help filtering out cross-lingual transfer errors (up to 20%, as shown in Table 1). As in (Täckström et al., 2013), we consider two different dictionaries. The first one is extracted automatically from `Wiktionary`,[1] using the method of (Li et al., 2012). The second tag dictionary is built by using for each word the two most frequently projected POS labels from the training data.[2] In contrast to Täckström et al. (2013) we use the intersection[3] of the two type constraints instead of their union. Table 1 shows the precision and recall of the resulting constraints on the test data.

These two information sources are merged according to the rules of Täckström et al. (2013). These rules assume that type constraints are more reliable than token constraints and should take precedence: by default, a given word is associated to the set of possible tags licensed type constraints; additionally, when a POS tag can be projected through alignment *and* also satisfies the type constraints, then it is actually projected, thereby providing a full (yet noisy) supervision.

As shown in Table 1, token and type constraints complement each other effectively and greatly reduce label ambiguity. However, the transfer method sketched above associates each target word with a set of possible labels, of which only one is true. This situation is less favorable than standard supervised learning in which one unique gold label is available for each occurrence. We describe in the following section how to learn from this *ambiguous supervision* information.

3 Modeling Sequences under Ambiguous Supervision

We use a history-based model (Black et al., 1992) with a LaSO-like training method (Daumé and Marcu, 2005). History-based models reduce structured prediction to a sequence of multi-class classification problems. The prediction of a complex structure (here, a sequence of POS tags) is thus modeled as a sequential decision problem: at each

[1] `http://www.wiktionary.org/`

[2] This heuristic is similar to the way Täckström et al. (2013) filter the tag distribution with a threshold to build the projected type constraints.

[3] If the intersection is empty we use the constraints from `Wiktionary` first, if also empty, the projected constraints then, and by default the whole tag set.

position in the sequence, a multiclass classifier is used to make a decision, using features that describe both the input structure and the history of past decisions (i.e. the partially annotated sequence).

Let $\mathbf{x} = (\mathbf{x}_i)_{i=1}^n$ denote the observed sequence and $\mathcal{Y}$ be the set of possible labels (in our case the 12 universal POS tags). Inference consists in predicting labels one after the other using, for instance, a linear model:

$$y_i^* = \arg\max_{y \in \mathcal{Y}} \langle \mathbf{w} | \phi(\mathbf{x}, i, y, h_i) \rangle \quad (1)$$

where $\langle \cdot | \cdot \rangle$ is the standard dot product operation, y_i^* the predicted label for position i, $\mathbf{w}$ the weight vector, $h_i = y_1^*, ..., y_{i-1}^*$ the history of past decisions and ϕ a joint feature map. Inference can therefore be seen as a greedy search in the space of the $\#\{\mathcal{Y}\}^n$ possible labelings of the input sequence. Trading off the global optimality of inference for additional flexibility in the design of features and long range dependencies between labels has proved useful for many sequence labeling tasks in NLP (Tsuruoka et al., 2011).

The training procedure, sketched in Algorithm 1, consists in performing inference on each input sentence and correcting the weight vector each time a wrong decision is made. Importantly (Ross and Bagnell, 2010), the history used during training has to be made of the previous predicted labels so that the training samples reflect the fact that the history will be imperfectly known at test time.

This *reduction* of sequence labeling to multiclass classification allows us to learn a sequence model in an ambiguous setting by building on the theoretical results of Bordes et al. (2010) and Cour et al. (2011). The decision about the correctness of a prediction and the weight updates can be adapted to the amount of supervision information that is available.

Full Supervision In a fully supervised setting, the correct label is known for each word token: a decision is thus considered wrong when this gold label is not predicted. In this case, a standard perceptron update is performed:

$$\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t - \phi(\mathbf{x}, i, y_i^*, h_i) + \phi(\mathbf{x}, i, \hat{y}_i, h_i) \quad (2)$$

where y_i^* and $\hat{y}_i$ are the predicted and the gold label, respectively. This update is a stochastic gradient step that increases the score of the gold label while decreasing the score of the predicted label.

Ambiguous Supervision During training, each observation i is now associated with a set of possible labels, denoted by $\hat{\mathcal{Y}}_i$. In this case, a decision is considered wrong when the predicted label is not in $\hat{\mathcal{Y}}_i$ and the weight vector is updated as follows:

$$\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t - \phi(\mathbf{x}, i, y_i^*, h_i) + \sum_{\hat{y}_i \in \hat{\mathcal{Y}}_i} \phi(\mathbf{x}, i, \hat{y}_i, h_i) \quad (3)$$

Compared to (2), this rule uniformly increases the scores of all the labels in $\hat{\mathcal{Y}}_i$.

It can be shown (Bordes et al., 2010; Cour et al., 2011), under mild assumptions (namely that two labels never systematically co-occur in the supervision information), that the update rule (3) enables to learn a classifier in an ambiguous setting, as if the gold labels were known. Intuitively, as long as two labels are not systematically co-occurring in $\hat{\mathcal{Y}}$, updates will reinforce the correct labels more often than the spurious ones; at the end of training, the highest scoring label should therefore be the correct one.

Algorithm 1 Training algorithm. In the ambiguous setting, $\hat{\mathcal{Y}}_i$ contains all possible labels; in the supervised setting, it only contains the gold label.

$\mathbf{w}_0 \leftarrow \mathbf{0}$
for $t \in [\![1, T]\!]$ **do**
  Randomly pick example $\mathbf{x}, \hat{\mathbf{y}}$
  $h \leftarrow$ empty list
  for $i \in [\![1, n]\!]$ **do**
    $y_i^* = \arg\max_{y \in \mathcal{Y}} \langle \mathbf{w}_t | \phi(\mathbf{x}, i, y, h_i) \rangle$
    if $y_i^* \notin \hat{\mathcal{Y}}_i$ **then**
      $\mathbf{w}_{t+1} \leftarrow \text{update}(\mathbf{w}_t, \mathbf{x}, i, \hat{\mathcal{Y}}_i, y_i^*, h_i)$
    end if
    push(y_i^*, h)
  end for
end for
return $\frac{1}{T} \sum_{t=1}^T \mathbf{w}_t$

4 Empirical Study

Datasets Our approach is evaluated on 10 languages that present very different characteristics and cover several language families.[4] In all our experiments we use English as the source language. Parallel sentences[5] are aligned with the standard

[4] Resources considered in the related works are not freely available, which prevents us from presenting a more complete comparison.

[5] All resources and features used in our experiments are thoroughly documented in the supplementary material.

MOSES pipeline, using the intersection heuristic that only retains the most reliable alignment links.

The English side of the bitext is tagged using a standard linear CRF trained on the Penn Treebank. Tags are then transferred to the target language using the procedure described in Section 2. For each language, we train a tagger using the method described in Section 3 with $T = 100\,000$ iterations[6] using a feature set similar to the one of Li et al. (2012) and Täckström et al. (2013). The baseline system is our reimplementation of the partially observed CRF model of Täckström et al. (2013). Evaluation is carried out on the test sets of treebanks for which manual gold tags are known. For Czech and Greek, we use the CoNLL'07 Shared Task on Dependency Parsing; for Arabic, the Arabic Treebank; and otherwise the data of the Universal Dependency Treebank Project (McDonald et al., 2013). Tagging performance is evaluated with the standard error rate.

4.1 Results

Table 2 summarizes the performance achieved by our method trained in the ambiguous setting (HBAL) and by our re-implementation of the partially supervised CRF baseline. As an upper bound, we also report the score of our method when trained in a supervised (HBSL) settings considering the training part of the various treebanks, when it is available.[7] For the sake of comparison, we also list the *best scores* of previous studies. Note, however, that a direct comparison with these results is not completely fair as these systems were not trained and evaluated with the same exact resources (corpora,[8] type constraints, alignments, etc). Also note that the state-of-the-art scores have been achieved by different models, which have been selected based on their scores on the test set and not on a validation set.[9]

Experimental results show that HBAL significantly outperforms, on all considered languages but one, the partially observed CRF that was trained and tested in the same setting.

4.2 Discussion

The performance of our new method still falls short of the performance of a fully supervised POS tagger: for instance, in Spanish, full supervision reduces the error rate by a factor of 4. A fine-grained error analysis shows that many errors of HBAL directly result from the fact that, contrary to the fully supervised learner HBSL, our ambiguous setting suffers from a train/test mismatch, which has two main consequences. First, the train and test sets do not follow exactly the same normalization and tokenization conventions, which is an obvious source of mistakes. Second, and more importantly, many errors are caused by systematic differences between the test tags and the supervised tags (i.e. the English side of the bitext and `Wiktionary`). While some of these differences are linguistically well-justified and reflect fundamental differences in the language structure and usage, others seem to be merely due to arbitrary annotation conventions.

For instance, in Greek, proper names are labeled

[6] Preliminary experiments showed that increasing the number of iterations T in Algorithm 1 has no significant impact.

[7] In this setting, HBSL implements an averaged perceptron, and achieves results that are similar to those obtained with standard linear CRF.

[8] The test sets are only the same for Czech, Greek and Swedish.

[9] The partially observed CRF is the best model in (Täckström et al., 2013) only for German (de), Greek (el) and Swedish (sv), and uses only type constraints extracted from `Wiktionary`.

either as X (when they refer to a foreigner *and* are not transliterated) or as NOUN (in all other cases), while they are always labeled as NOUN in English. In French and in Greek, contractions of a preposition and a determiner such as '*στο*' ('*σε το*', meaning 'to the') or '*aux*' ('*à les*' also meaning 'to the') are labeled as ADP in the Universal Dependency Treebank but as DET in `Wiktionary` and are usually aligned with a determiner in the parallel corpora. In the Penn Treebank, quantifiers like 'few' or 'little' are generally used in conjunction with a determiner ('a few years', 'a little parable', ...) and labeled as ADJ; the corresponding Spanish constructions lack an article ('*mucho tempio*', '*pocos años*', ...) and the quantifiers are therefore labeled as DET. Capturing such subtle differences is hardly possible without prior knowledge and specifically tailored features.

This annotation mismatch problem is all the more important in settings like ours, that rely on several, independently designed, information sources, which follow contradictory annotation conventions and for which the mapping to the universal tagset is actually error-prone (Zhang et al., 2012). To illustrate this point, we ran three additional experiments to assess the impact of the train/test mismatch.

We first designed a control experiment in which the type constraints were manually completed with the gold labels of the most frequent errors of HBAL. These errors generally concern function words and can be assumed to result from systematic differences in the annotations rather than prediction errors. For instance, for French the type constraints for '*du*', '*des*', '*au*' and '*aux*' were corrected from DET to ADP. The resulting model, denoted 'HBAL + matched POS' in Table 2, significantly outperforms HBAL, stressing the divergence in the different annotation conventions.

Additionally, in order to approximate the ambiguous setting train/test mismatch, we learn two fully supervised Spanish taggers on the same training data as HBAL, using two different strategies to obtain labeled data. We first use HBSL (which was trained on the treebank) to automatically label the target side of the parallel corpus. In this setting, the POS tagger is trained with data from a different domain, but labeled with the same annotation scheme as a the test set. Learning with this fully supervised data yields an error rate of 4.2% for Spanish, almost twice as much as HBSL, bringing into light the impact of domain shift. We then use a generic tagger, FREELING,[10] to label the training data, this time with possible additional inconsistent annotations. The corresponding error rate for Spanish was 6.1%, to be compared with the 8.2% achieved by HBAL. The last two control experiments show that many of the remaining labeling errors seem to be due to domain and convention mismatches rather to the transfer/ambiguous setting, as supervised models also suffer from very similar conditions.

These observations show that the evaluation of transfer-based methods suffer from several biases. Their results must therefore be interpreted with great care.

5 Conclusion

In this paper, we have presented a novel learning methodology to learn from ambiguous supervision information, and used it to train several POS taggers. Using this method, we have been able to achieve performance that surpasses the best reported results, sometimes by a wide margin. Further work will attempt to better analyse these results, which could be caused by several subtle differences between HBAL and the baseline system. Nonetheless, these experiments confirm that cross-lingual projection of annotations have the potential to help in building very efficient POS taggers with very little monolingual supervision data. Our analysis of these results also suggests that, for this task, additional gains might be more easily obtained by fixing systematic biases introduced by conflicting mappings between tags or by train/test domain mismatch than by designing more sophisticated weakly supervised learners.

Acknowledgments

We wish to thank Thomas Lavergne and Alexandre Allauzen for early feedback and for providing us with the partially observed CRF implementation. We also thank the anonymous reviewers for their helpful comments.

Comparing Representations of Semantic Roles for String-To-Tree Decoding

Marzieh Bazrafshan and **Daniel Gildea**
Department of Computer Science
University of Rochester
Rochester, NY 14627

Abstract

We introduce new features for incorporating semantic predicate-argument structures in machine translation (MT). The methods focus on the completeness of the semantic structures of the translations, as well as the order of the translated semantic roles. We experiment with translation rules which contain the core arguments for the predicates in the source side of a MT system, and observe that using these rules significantly improves the translation quality. We also present a new semantic feature that resembles a language model. Our results show that the language model feature can also significantly improve MT results.

1 Introduction

In recent years, there have been increasing efforts to incorporate semantics in statistical machine translation (SMT), and the use of predicate-argument structures has provided promising improvements in translation quality. Wu and Fung (2009) showed that shallow semantic parsing can improve the translation quality in a machine translation system. They introduced a two step model, in which they used a semantic parser to rerank the translation hypotheses of a phrase-based system. Liu and Gildea (2010) used semantic features for a tree-to-string syntax based SMT system. Their features modeled deletion and reordering for source side semantic roles, and they improved the translation quality. Xiong et al. (2012) incorporated the semantic structures into phrase-based SMT by adding syntactic and semantic features to their translation model. They proposed two discriminative models which included features for predicate translation and argument reordering from source to target side. Bazrafshan and Gildea (2013) used semantic structures in a string-to-tree translation system by extracting translation rules enriched with semantic information, and showed that this can improve the translation quality. Li et al. (2013) used predicate-argument structure reordering models for hierarchical phrase-based translation, and they used linguistically motivated constraints for phrase translation.

In this paper, we experiment with methods for incorporating semantics in a string-to-tree MT system. These methods are designed to model the order of translation, as well as the completeness of the semantic structures. We extract translation rules that include the complete semantic structure in the source side, and compare that with using semantic rules for the target side predicates. We present a method for modeling the order of semantic role sequences that appear spread across multiple syntax-based translation rules, in order to overcome the problem that a rule representing the entire semantic structure of a predicate is often too large and too specific to apply to new sentences during decoding. For this method, we compare the verb-specific roles of PropBank and the more general thematic roles of VerbNet.

These essential arguments of a verbal predicate are called the *core* arguments. Standard syntax-based MT is incapable of ensuring that the target translation includes all of the core arguments of a predicate that appear in the source sentence. To encourage the translation of the likely core arguments, we follow the work of Bazrafshan and Gildea (2013), who use special translation rules with complete semantic structures of the predicates in the target side of their MT system. Each of these rules includes a predicate and all of its core arguments. Instead of incorporating only the target side semantic rules, we extract the special rules for both the source and the target sides, and compare the effectiveness of adding these rules to

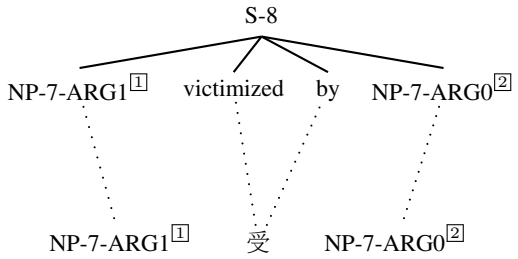

Figure 1: A complete semantic rule (Bazrafshan and Gildea (2013)).

the system separately and simultaneously.

Besides the completeness of the arguments, it is also important for the arguments to appear in the correct order. Our second method is designed to encourage correct order of translation for both the core and the non-core roles in the target sentence. We designed a new feature that resembles the language model feature in a standard MT system. We train a n-gram language model on sequences of semantic roles, by treating the semantic roles as the *words* in what we call the *semantic language*. Our experimental results show that the language model feature significantly improves translation quality.

Semantic Role Labeling (SRL): We use semantic role labelers to annotate the training data that we use to extract the translation rules. For target side SRL, the role labels are attached to the nonterminal nodes in the syntactic parse of each sentence. For source side SRL, the labels annotate the spans from the source sentence that they cover. We train our semantic role labeler using two different standards: Propbank (Palmer et al., 2005) and VerbNet (Kipper Schuler, 2005).

PropBank annotates the Penn Treebank with predicate-argument structures.It use generic labels (such as Arg0, Arg1, etc.) which are defined specifically for each verb. We trained a semantic role labeler on the annotated Penn Treebank data and used the classifier to tag our training data.

VerbNet is a verb lexicon that categorizes English verbs into hierarchical classes, and annotates them with thematic roles for the arguments that they accept. Since the thematic roles use more meaningful labels (e.g. Agent, Patient, etc.), a language model trained on VerbNet labels may be more likely to generalize across verbs than one trained on PropBank labels. It may also provide more information, since VerbNet has a larger set of labels than PropBank. To train the semantic role labeler on VerbNet, we used the mappings

$$\begin{array}{rl} A \rightarrow BC & c_0 \\ \quad [B,i,j] & c_1 \\ \quad [C,j,k] & c_2 \\ \hline \quad [A,i,k] & c_0 + c_1 + c_2 \end{array}$$

Figure 2: A deduction step in our baseline decoder

provided by the SemLink project (Palmer, 2009) to annotate the Penn Treebank with the VerbNet roles. These mappings map the roles in PropBank to the thematic roles of VerbNet. When there is no mapping for a role, we keep the role from Propbank.

2 Using Semantics in Machine Translation

In this section, we present our techniques for incorporating semantics in MT: source side semantic rules, and the semantic language model.

2.1 Source Side Semantic Rules

Bazrafshan and Gildea (2013) extracted translation rules that included a predicate and all of its arguments from the target side, and added those rules to the baseline rules of their string-to-tree MT system. Figure 1 shows an example of such rules, which we refer to as *complete semantic rules*. The new rules encourage the decoder to generate translations that include all of the semantic roles that appear in the source sentence.

In this paper, we use the same idea to extract rules from the semantic structures of the source side. The complete semantic rules consist of the smallest fragments of the combination of GHKM (Galley et al., 2004) rules that include one predicate and all of its core arguments that appear in the sentence. Rather than keeping the predicate and argument labels attached to the non-terminals, we remove those labels from our extracted semantic rules, to keep the non-terminals in the semantic rules consistent with the non-terminals of the baseline GHKM rules. This is also important when using both the source and the target semantic rules (i.e. Chinese and English rules), as it has been shown that there are cross lingual mismatches between Chinese and English semantic roles in bilingual sentences (Fung et al., 2007).

We extract a complete semantic rule for each verbal predicate of each sentence pair in the training data. To extract the target side complete semantic rules, using the target side SRL anno-

$A \rightarrow BC$ *to space*	c_0 (x1 x2 Destination)
$[B, i, j, (Agent,)]$	c_1
$[C, j, k, (PRED\_bring, Theme,)]$	c_2
$[A, i, k,$ (Agent, PRED_bring,-*-, Theme, Destination)$]$	$c_0 + c_1 + c_+$ + LMcost(Agent, PRED_bring,-*-, Theme, Destination)

Figure 3: A deduction step in the semantic language model method.

tated training data, we follow the general GHKM method, and modify it to ensure that each *frontier node* (Galley et al., 2004) in a rule includes either all or none of the semantic role labels (i.e. the predicate and all of its present core arguments) in its descendants in the target side tree. The resulting rule then includes the predicate and all of its arguments. We use the source side SRL annotated training data to extract the source side semantic rules. Since the annotations specify the spans of the semantic roles, we extract the semantic rules by ensuring that the span of the root (in the target side) of the extracted rule covers all of the spans of the roles in the predicate-argument structure.

The semantic rules are then used together with the original GHKM rules. We add a binary feature to distinguish the semantic rules from the rest. We experiment with adding the semantic rules from the source side, and compare that with adding semantic rules of both the source and the target side.

In all of the experiments in this paper, we use a string-to-tree decoder which uses a CYK style parser (Yamada and Knight, 2002). Figure 2 depicts a deduction step in the baseline decoder. The CFG rule in the first line is used to generate a new item A with span (i, k) using items B and C, which have spans (i, j) and (j, k) respectively. The cost of each item is shown on the right. For experimenting with complete semantic rules, in addition having more rules, the only other modification made to the baseline system is extending the feature vector to include the new feature. We do not modify the decoder in any significant way.

2.2 Semantic Language Model

The semantic language model is designed to encourage the correct order of translation for the semantic roles. While the complete translation rules of Section 2.1 contain the order of the translation for core semantic roles, they do not include the non-core semantic roles, that is, semantic roles which are not essential for the verbal predicates, but do contribute to the meaning of the predicate. In addition, the semantic LM can help in cases where no specific complete semantic rule can apply, which makes the system more flexible.

The semantic language model resembles a regular language model, but instead of words, it defines a probability distribution over sequences of semantic roles. For this method we also use a semantic role labeler on our training data, and use the labeled data to train a tri-gram semantic language model.

The rules are extracted using the baseline rule extraction method. As opposed to the previous method, the rules for this method are not derived by combining GHKM rules, but rather are regular GHKM rules which are annotated with semantic roles. We make a new field in each rule to keep the ordered list of the semantic roles in that rule. We also include the nonterminals of the right-hand-side of the rule in that ordered list, to be able to substitute the semantic roles from the input translation items in the correct order. The decoder uses this new field to save the semantic roles in the translation items, and propagates the semantic LM *states* in the same way that the regular language model states are propagated by the decoder.

We define a new feature for the semantic language model, and score the semantic states in each translation item, again analogously to a regular language model. Figure 3 depicts how the deduction for this method is different from our baseline. In this example, the semantic roles "Agent", "PRED_bring" and "Theme" come from the input items, and the role "Destination" (which tags the terminals "to space") comes from the translation rule.

We stemmed the verbs for training this feature, and also annotated our rules with stemmed verbal predicates. The stemming helps the training since the argument types of a verb are normally independent of its inflected variants.

	avg. BLEU Score

Table 1: Comparisons of the methods with the baseline. The BLEU scores are calculated on the top 3 results from 15 runs MERT for each experiments. The p-values are calculated by comparing each method against the baseline system.

3 Experiments

3.1 Experimental Setup

The data that we used for training the MT system was a Chinese-English corpus derived from newswire text from LDC.[1] The data consists of 250K sentences, which is 6.3M words in the English side. Our language model was trained on the English side of the entire data, which consisted of 1.65M sentences (39.3M words). Our development and test sets are from the newswire portion of NIST evaluations (2004, 2005, 2006). We used 392 sentences for the development set and 428 sentences for the test set. These sentences have lengths smaller than 30, and they each have 4 reference translations. We used our in-house string-to-tree decoder that uses Earley parsing. Other than the features that we presented for our new methods, we used a set of nine standard features. The rules for the baseline system were extracted using the GHKM method. Our baseline GHKM rules also include composed rules, where larger rules are constructed by combining two levels of the regular GHKM rules. We exclude any unary rules (Chung et al., 2011), and only keep rules that have scope up to 3 (Hopkins and Langmead, 2010). For the semantic language model, we used the SRILM package (Stolcke, 2002) and trained a tri-gram language model with the default Good-Turing smoothing.

Our target side semantic role labeler uses a maximum entropy classifier to label parsed sentences. We used Sections 02-22 of the Penn TreeBank to train the labeler, and sections 24 and 23 for development set and training set respectively. The labeler has a precision of 90% and a recall of 88%. We used the Chinese semantic role labeler of Wu and Palmer (2011) for source side SRL, which uses the LIBLINEAR (Fan et al., 2008) as a classifier. Minimum Error Rate Training (MERT) (Och, 2003) was used for tuning the feature weights. For all of our experiments, we ran 15 instances of MERT with random initial weight vectors, and used the weights of the top 3 results on the development set to test the systems on the test set. We chose to use the top 3 runs (rather than the best run) of each system to account for the instability of MERT (Clark et al., 2011). This method is designed to reflect the average performance of the MT system when trained with random restarts of MERT: we wish to discount runs in which the optimizer is stuck in a poor region of the weight space, but also to average across several good runs in order not to be mislead by the high variance of the single best run. For each of our MT systems, we merged the results of the top 3 runs on the test set into one file, and ran a statistical significance test, comparing it to the merged top 3 results from our baseline system. The 3 runs were merged by duplicating each run 3 times, and arranging them in the file so that the significance testing compares each run with all the runs of the baseline. We performed significance testing using paired bootstrap resampling (Koehn, 2004). The difference is considered statistically significant if $p < 0.05$ using 1000 iterations of paired bootstrap resampling.

3.2 Results

Our results are shown in Table 1. The second and the third columns contain the average BLEU score (Papineni et al., 2002) on the top three results on the development and test sets. The fourth column is the p-value for statistical significance testing against the baseline. The first row shows the results for our baseline. The second row contains the results for using the source (Chinese) side complete semantic rules of Section 2.1, and the third row is the results for combining both the source and the target side complete semantic rules. As noted before, in both of these experiments we also use the regular GHKM rules. The result show that the source side complete semantic rules improve the system ($p = 0.048$), and as we expected, combining the source and the tar-

Semantic Rules	this position that the us government should use goodwill toward the dprk .

(b) Comparison of the experiments with source and target side semantic rules and the baseline system.

Figure 4: Comparison of example translations from our semantic methods and the baseline system.

get side rules improves the system even more significantly ($p < 10^{-10}$). To measure the effect of combining the rules, in a separate experiment we replicated the complete semantic rules experiments of Bazrafshan and Gildea (2013), and ran statistical significance tests comparing the combination of the source and target rules with using only the source or the target semantic rules separately. The results showed that combining the semantic rules outperforms both of the experiments that used rules from only one side (with $p < 0.05$ in both cases).

The results for the language model feature are shown in the last two rows of the table. Using Propbank for language model training did not change the system in any significant way ($p = 0.108$), but using VerbNet significantly improved the results ($p = 0.025$). Figure 4(a) contains an example comparing the baseline system with the VerbNet language model. We can see how the VerbNet language model helps the decoder translate the argument in the correct order. The baseline system has also generated the correct arguments, but the output is in the wrong order. Figure 4(b) compares the experiment with semantic rules of both target and source side and the baseline system. Translation of the word "use" by our semantic rules is a good example showing how the decoder uses these semantic rules to generate a more complete predicate-argument structure.

4 Conclusions

We experimented with two techniques for incorporating semantics in machine translation. The models were designed to help the decoder translate semantic roles in the correct order, as well as generating complete predicate-argument structures. We observed that using a semantic language model can significantly improve the translations, and help the decoder to generate the semantic roles in the correct order. Adding translation rules with complete semantic structures also improved our MT system. We experimented with using source side *complete semantic rules*, as well as using rules for both the source and the target sides. Both of our experiments showed improvements over the baseline, and as expected, the second one had a higher improvement.

Abstract

We propose a simple unsupervised approach to detecting non-compositional components in multiword expressions based on Wiktionary. The approach makes use of the definitions, synonyms and translations in Wiktionary, and is applicable to any type of MWE in any language, assuming the MWE is contained in Wiktionary. Our experiments show that the proposed approach achieves higher F-score than state-of-the-art methods.

1 Introduction

A multiword expression (MWE) is a combination of words with lexical, syntactic or semantic idiosyncrasy (Sag et al., 2002; Baldwin and Kim, 2009). An MWE is considered (semantically) "non-compositional" when its meaning is not predictable from the meaning of its components. Conversely, compositional MWEs are those whose meaning is predictable from the meaning of the components. Based on this definition, a component is compositional within an MWE, if its meaning is reflected in the meaning of the MWE, and it is non-compositional otherwise.

Understanding which components are non-compositional within an MWE is important in NLP applications in which semantic information is required. For example, when searching for *spelling bee*, we may also be interested in documents about *spelling*, but not those which contain only *bee*. For *research project*, on the other hand, we are likely to be interested in documents which contain either *research* or *project* in isolation, and for *swan song*, we are only going to be interested in documents which contain the phrase *swan song*, and not just *swan* or *song*.

In this paper, we propose an unsupervised approach based on Wikitionary for predicting which components of a given MWE have a compositional usage. Experiments over two widely-used datasets show that our approach outperforms state-of-the-art methods.

2 Related Work

Previous studies which have considered MWE compositionality have focused on either the identification of non-compositional MWE token instances (Kim and Baldwin, 2007; Fazly et al., 2009; Forthergill and Baldwin, 2011; Muzny and Zettlemoyer, 2013), or the prediction of the compositionality of MWE types (Reddy et al., 2011; Salehi and Cook, 2013; Salehi et al., 2014). The identification of non-compositional MWE tokens is an important task when a word combination such as *kick the bucket* or *saw logs* is ambiguous between a compositional (generally non-MWE) and non-compositional MWE usage. Approaches have ranged from the unsupervised learning of type-level preferences (Fazly et al., 2009) to supervised methods specific to particular MWE constructions (Kim and Baldwin, 2007) or applicable across multiple constructions using features similar to those used in all-words word sense disambiguation (Forthergill and Baldwin, 2011; Muzny and Zettlemoyer, 2013). The prediction of the compositionality of MWE types has traditionally been couched as a binary classification task (compositional or non-compositional: Baldwin et al. (2003), Bannard (2006)), but more recent work has moved towards a regression setup, where the degree of the compositionality is predicted on a continuous scale (Reddy et al., 2011; Salehi and Cook, 2013; Salehi et al., 2014). In either case, the modelling has been done either over the whole MWE (Reddy et al., 2011; Salehi and Cook, 2013), or relative to each component within the MWE (Baldwin et al., 2003; Bannard, 2006). In this paper, we focus on the binary classification of MWE types relative to each component of the

MWE.

The work that is perhaps most closely related to this paper is that of Salehi and Cook (2013) and Salehi et al. (2014), who use translation data to predict the compositionality of a given MWE relative to each of its components, and then combine those scores to derive an overall compositionality score. In both cases, translations of the MWE and its components are sourced from PanLex (Baldwin et al., 2010; Kamholz et al., 2014), and if there is greater similarity between the translated components and MWE in a range of languages, the MWE is predicted to be more compositional. The basis of the similarity calculation is unsupervised, using either string similarity (Salehi and Cook, 2013) or distributional similarity (Salehi et al., 2014). However, the overall method is supervised, as training data is used to select the languages to aggregate scores across for a given MWE construction. To benchmark our method, we use two of the same datasets as these two papers, and repurpose the best-performing methods of Salehi and Cook (2013) and Salehi et al. (2014) for classification of the compositionality of each MWE component.

3 Methodology

Our basic method relies on analysis of lexical overlap between the component words and the definitions of the MWE in Wiktionary, in the manner of Lesk (1986). That is, if a given component can be found in the definition, then it is inferred that the MWE carries the meaning of that component. For example, the Wiktionary definition of *swimming pool* is "An artificially constructed pool of water used for swimming", suggesting that the MWE is compositional relative to both *swimming* and *pool*. If the MWE is not found in Wiktionary, we use Wikipedia as a backoff, and use the first paragraph of the (top-ranked) Wikipedia article as a proxy for the definition.

As detailed below, we further extend the basic method to incorporate three types of information found in Wiktionary: (1) definitions of each word in the definitions, (2) synonyms of the words in the definitions, and (3) translations of the MWEs and components.

3.1 Definition-based Similarity

The basic method uses Boolean lexical overlap between the target component of the MWE and a definition. A given MWE will often have multiple definitions, however, begging the question of how to combine across them, for which we propose the following three methods.

First Definition (FIRSTDEF): Use only the first-listed Wiktionary definition for the MWE, based on the assumption that this is the predominant sense.

All Definitions (ALLDEFS): In the case that there are multiple definitions for the MWE, calculate the lexical overlap for each independently and take a majority vote; in the case of a tie, label the component as non-compositional.

Idiom Tag (ITAG): In Wiktionary, there is facility for users to tag definitions as idiomatic.[1] If, for a given MWE, there are definitions tagged as idiomatic, use only those definitions; if there are no such definitions, use the full set of definitions.

3.2 Synonym-based Definition Expansion

In some cases, a component is not explicitly mentioned in a definition, but a synonym does occur, indicating that the definition is compositional in that component. In order to capture synonym-based matches, we optionally look for synonyms of the component word in the definition,[2] and expand our notion of lexical overlap to include these synonyms.

For example, for the MWE *china clay*, the definition is *kaolin*, which includes neither of the components. However, we find the component word *clay* in the definition for *kaolin*, as shown below.

> A fine clay, rich in kaolinite, used in ceramics, paper-making, etc.

This method is compatible with the three definition-based similarity methods described above, and indicated by the +SYN suffix (e.g. FIRSTDEF+SYN is FIRSTDEF with synonym-based expansion).

3.3 Translations

A third information source in Wiktionary that can be used to predict compositionality is sense-level translation data. Due to the user-generated nature of Wiktionary, the set of languages for which

[1] Although the recall of these tags is low (Muzny and Zettlemoyer, 2013).

[2] After removing function words, based on a stopword list.

	ENC	EVPC
WordNet	91.1%	87.5%
Wiktionary	96.7%	96.2%
Wiktionary+Wikipedia	100.0%	96.2%

Table 1: Lexical coverage of WordNet, Wiktionary and Wiktionary+Wikipedia over our two datasets.

translations are provided varies greatly across lexical entries. Our approach is to take whatever translations happen to exist in Wiktionary for a given MWE, and where there are translations in that language for the component of interest, use the LCS-based method of Salehi and Cook (2013) to measure the string similarity between the translation of the MWE and the translation of the components. Unlike Salehi and Cook (2013), however, we do not use development data to select the optimal set of languages in a supervised manner, and instead simply take the average of the string similarity scores across the available languages. In the case of more than one translation in a given language, we use the maximum string similarity for each pairing of MWE and component translation.

Unlike the definition and synonym-based approach, the translation-based approach will produce real rather than binary values. To combine the two approaches, we discretise the scores given by the translation approach. In the case of disagreement between the two approaches, we label the given MWE as non-compositional. This results in higher recall and lower precision for the task of detecting compositionality.

3.4 An Analysis of Wiktionary Coverage

A dictionary-based method is only as good as the dictionary it is applied to. In the case of MWE compositionality analysis, our primary concern is lexical coverage in Wiktionary, i.e., what proportion of a representative set of MWEs is contained in Wiktionary. We measure lexical coverage relative to the two datasets used in this research (described in detail in Section 4), namely 90 English noun compounds (ENCs) and 160 English verb particle constructions (EVPCs). In each case, we calculated the proportion of the dataset that is found in Wiktionary, Wiktionary+Wikipedia (where we back off to a Wikipedia document in the case that a MWE is not found in Wiktionary) and WordNet (Fellbaum, 1998). The results are found in Table 1, and indicate perfect coverage in Wiktionary+Wikipedia for the ENCs, and very high coverage for the EVPCs. In both cases, the coverage of WordNet is substantially lower, although still respectable, at around 90%.

4 Datasets

As mentioned above, we evaluate our method over the same two datasets as Salehi and Cook (2013) (which were later used, in addition to a third dataset of German noun compounds, in Salehi et al. (2014)): (1) 90 binary English noun compounds (ENCs, e.g. *spelling bee* or *swimming pool*); and (2) 160 English verb particle constructions (EVPCs, e.g. *stand up* and *give away*). Our results are not directly comparable with those of Salehi and Cook (2013) and Salehi et al. (2014), however, who evaluated in terms of a regression task, modelling the overall compositionality of the MWE. In our case, the task setup is a binary classification task relative to each of the two components of the MWE.

The ENC dataset was originally constructed by Reddy et al. (2011), and annotated on a continuous $[0, 5]$ scale for both overall compositionality and the component-wise compositionality of each of the modifier and head noun. The sampling was random in an attempt to make the dataset balanced, with 48% of compositional English noun compounds, of which 51% are compositional in the first component and 60% are compositional in the second component. We generate discrete labels by discretising the component-wise compositionality scores based on the partitions $[0, 2.5]$ and $(2.5, 5]$. On average, each NC in this dataset has 1.4 senses (definitions) in Wiktionary.

The EVPC dataset was constructed by Bannard (2006), and manually annotated for compositionality on a binary scale for each of the head verb and particle. For the 160 EVPCs, 76% are verb-compositional and 48% are particle-compositional. On average, each EVPC in this dataset has 3.0 senses (definitions) in Wiktionary.

5 Experiments

The baseline for each dataset takes the form of looking for a user-annotated idiom tag in the Wiktionary lexical entry for the MWE: if there is an idiomatic tag, both components are considered to be non-compositional; otherwise, both components are considered to be compositional. We expect this method to suffer from low precision for two

Method	First Component			Second Component

ALLDEFS+SYN $_{\text{COMB(LCS+DS+DSL2)}}$	81.2	88.1	**84.5**	87.3	80.6	73.3
ITAG+SYN $_{\text{COMB(LCS+DS+DSL2)}}$	81.0	88.1	84.1	**88.0**	81.1	73.9

Table 2: Compositionality prediction results over the ENC dataset, relative to the first component (the modifier noun) and the second component (the head noun)

reasons: first, the guidelines given to the annotators of our datasets might be different from what Wiktionary contributors assume to be an idiom. Second, the baseline method assumes that for any non-compositional MWE, all components must be equally non-compositional, despite the wealth of MWEs where one or more components are compositional (e.g. from the Wiktionary guidelines for idiom inclusion,[3] *computer chess*, *basketball player*, *telephone box*).

We also compare our method with: (1) "LCS", the string similarity-based method of Salehi and Cook (2013), in which 54 languages are used; (2) "DS", the monolingual distributional similarity method of Salehi et al. (2014); (3) "DS+DSL2", the multilingual distributional similarity method of Salehi et al. (2014), including supervised language selection for a given dataset, based on cross-validation; and (4) "LCS+DS+DSL2", whereby the first three methods are combined using a supervised support vector regression model. In each case, the continuous output of the model is equal-width discretised to generate a binary classification. We additionally present results for the combination of each of the six methods proposed in this paper with LCS, DS and DSL2, using a linear-kernel support vector machine (represented with the suffix "$_{\text{COMB(LCS+DS+DSL2)}}$" for a given method). The results are based on cross-validation, and for direct comparability, the partitions are exactly the same as Salehi et al. (2014).

Tables 2 and 3 provide the results when our proposed method for detecting non-compositionality is applied to the ENC and EVPC datasets, respectively. The inclusion of translation data was found to improve all of precision, recall and F-score across the board for all of the proposed methods. For reasons of space, results without translation data are therefore omitted from the paper.

Overall, the simple unsupervised methods proposed in this paper are comparable with the unsupervised and supervised state-of-the-art methods of Salehi and Cook (2013) and Salehi et al. (2014), with ITAG achieving the highest F-score for the ENC dataset and for the verb components of the EVPC dataset. The inclusion of synonyms boosts results in most cases.

When we combine each of our proposed methods with the string and distributional similarity methods of Salehi and Cook (2013) and Salehi et al. (2014), we see substantial improvements over the comparable combined method of "LCS+DS+DSL2" in most cases, demonstrating both the robustness of the proposed methods and their complementarity with the earlier methods. It is important to reinforce that the proposed methods make no language-specific assumptions and are therefore applicable to any type of MWE and any language, with the only requirement being that the MWE of interest be listed in the Wiktionary for

Table 3: Compositionality prediction results over the EVPC dataset, relative to the first component (the head verb) and the second component (the particle)

that language.

6 Error Analysis

We analysed all items in each dataset where the system score differed from that of the human annotators. For both datasets, the majority of incorrectly-labelled items were compositional but predicted to be non-compositional by our system, as can be seen in the relatively low precision scores in Tables 2 and 3. In many of these cases, the prediction based on definitions and synonyms was compositional but the prediction based on translations was non-compositional. In such cases, we arbitrarily break the tie by labelling the instance as non-compositional, and in doing so favour recall over precision.

Some of the incorrectly-labelled ENCs have a gold-standard annotation of around 2.5, or in other words are semi-compositional. For example, the compositionality score for *game* in *game plan* is 2.82/5, but our system labels it as non-compositional; a similar thing happens with *figure* and the EVPC *figure out*. Such cases demonstrate the limitation of approaches to MWE compositionality that treat the problem as a binary classification task.

On average, the EVPCs have three senses, which is roughly twice the number for ENCs. This makes the prediction of compositionality harder, as there is more information to combine across (an effect that is compounded with the addition of synonyms and translations). In future work, we hope to address this problem by first finding the sense which matches best with the sentences given to the annotators.

7 Conclusion

We have proposed an unsupervised approach for predicting the compositionality of an MWE relative to each of its components, based on lexical overlap using Wiktionary, optionally incorporating synonym and translation data. Our experiments showed that the various instantiations of our approach are superior to previous state-of-the-art supervised methods. All code to replicate the results in this paper has been made publicly available at `https://github.com/bsalehi/wiktionary_MWE_compositionality`.

Joint Emotion Analysis via Multi-task Gaussian Processes

Abstract

We propose a model for jointly predicting multiple emotions in natural language sentences. Our model is based on a low-rank coregionalisation approach, which combines a vector-valued Gaussian Process with a rich parameterisation scheme. We show that our approach is able to learn correlations and anti-correlations between emotions on a news headlines dataset. The proposed model outperforms both single-task baselines and other multi-task approaches.

1 Introduction

Multi-task learning (Caruana, 1997) has been widely used in Natural Language Processing. Most of these learning methods are aimed for Domain Adaptation (Daumé III, 2007; Finkel and Manning, 2009), where we hypothesize that we can learn from multiple domains by assuming similarities between them. A more recent use of multi-task learning is to model annotator bias and noise for datasets labelled by multiple annotators (Cohn and Specia, 2013).

The settings mentioned above have one aspect in common: they assume some degree of positive correlation between tasks. In Domain Adaptation, we assume that some "general", domain-independent knowledge exists in the data. For annotator noise modelling, we assume that a "ground truth" exists and that annotations are some noisy deviations from this truth. However, for some settings these assumptions do not necessarily hold and often tasks can be *anti-correlated*. For these cases, we need to employ multi-task methods that are able to learn these relations from data and correctly employ them when making predictions, avoiding negative knowledge transfer.

An example of a problem that shows this behaviour is Emotion Analysis, where the goal is to automatically detect emotions in a text (Strapparava and Mihalcea, 2008; Mihalcea and Strapparava, 2012). This problem is closely related to Opinion Mining (Pang and Lee, 2008), with similar applications, but it is usually done at a more fine-grained level and involves the prediction of a set of labels (one for each emotion) instead of a single label. While we expect some emotions to have some degree of correlation, this is usually not the case for all possible emotions. For instance, we expect *sadness* and *joy* to be anti-correlated.

We propose a multi-task setting for Emotion Analysis based on a vector-valued Gaussian Process (GP) approach known as *coregionalisation* (Álvarez et al., 2012). The idea is to combine a GP with a low-rank matrix which encodes task correlations. Our motivation to employ this model is three-fold:

- Datasets for this task are scarce and small so we hypothesize that a multi-task approach will results in better models by allowing a task to borrow statistical strength from other tasks;
- The annotation scheme is subjective and very fine-grained, and is therefore heavily prone to bias and noise, both which can be modelled easily using GPs;
- Finally, we also have the goal to learn a model that shows sound and interpretable correlations between emotions.

2 Multi-task Gaussian Process Regression

Gaussian Processes (GPs) (Rasmussen and Williams, 2006) are a Bayesian kernelised framework considered the state-of-the-art for regression. They have been recently used successfully for translation quality prediction (Cohn and Specia, 2013; Beck et al., 2013; Shah et al., 2013)

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1798–1803,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

and modelling text periodicities (Preotiuc-Pietro and Cohn, 2013). In the following we give a brief description on how GPs are applied in a regression setting.

Given an input $\mathbf{x}$, the GP regression assumes that its output y is a noise corrupted version of a latent function evaluation, $y = f(\mathbf{x}) + \eta$, where $\eta \sim \mathcal{N}(0, \sigma_n^2)$ is the added white noise and the function f is drawn from a GP prior:

$$f(\mathbf{x}) \sim \mathcal{GP}(\mu(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')), \tag{1}$$

where $\mu(\mathbf{x})$ is the *mean* function, which is usually the 0 constant, and $k(\mathbf{x}, \mathbf{x}')$ is the kernel or *covariance* function, which describes the covariance between values of f at locations $\mathbf{x}$ and $\mathbf{x}'$.

To predict the value for an unseen input $\mathbf{x}_*$, we compute the Bayesian posterior, which can be calculated analytically, resulting in a Gaussian distribution over the output y_*:[1]

$$\begin{aligned} y_* \sim \mathcal{N}(&\mathbf{k}_*(\mathbf{K} + \sigma_n \mathbf{I})^{-1}\mathbf{y}^T, \\ &k(\mathbf{x}_*, \mathbf{x}_*) - \mathbf{k}_*^T(\mathbf{K} + \sigma_n \mathbf{I})^{-1}\mathbf{k}_*), \end{aligned} \tag{2}$$

where $\mathbf{K}$ is the Gram matrix corresponding to the covariance kernel evaluated at every pair of training inputs and $\mathbf{k}_* = [\langle \mathbf{x}_1, \mathbf{x}_* \rangle, \langle \mathbf{x}_2, \mathbf{x}_* \rangle, \ldots, \langle \mathbf{x}_n, \mathbf{x}_* \rangle]$ is the vector of kernel evaluations between the test input and each training input.

2.1 The Intrinsic Coregionalisation Model

By extending the GP regression framework to vector-valued outputs we obtain the so-called coregionalisation models. Specifically, we employ a separable vector-valued kernel known as *Intrinsic Coregionalisation Model* (ICM) (Álvarez et al., 2012). Considering a set of D tasks, we define the corresponding vector-valued kernel as:

$$k((\mathbf{x}, d), (\mathbf{x}', d')) = k_{\text{data}}(\mathbf{x}, \mathbf{x}') \times \mathbf{B}_{d,d'}, \tag{3}$$

where k_{data} is a kernel on the input points (here a Radial Basis Function, RBF), d and d' are task or metadata information for each input and $\mathbf{B} \in \mathbb{R}^{D \times D}$ is the coregionalisation matrix, which encodes task covariances and is symmetric and positive semi-definite.

A key advantage of GP-based modelling is its ability to learn hyperparameters directly from data by maximising the marginal likelihood:

$$p(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta}) = \int_f p(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta}, f)p(f). \tag{4}$$

This process is usually performed to learn the noise variance and kernel hyperparameters, including the coregionalisation matrix. In order to do this, we need to consider how $\mathbf{B}$ is parameterised.

Cohn and Specia (2013) treat the diagonal values of $\mathbf{B}$ as hyperparameters, and as a consequence are able to leverage the inter-task transfer between each independent task and the global "pooled" task. They however fix non-diagonal values to 1, which in practice is equivalent to assuming equal correlation across tasks. This can be limiting, in that this formulation cannot model anti-correlations between tasks.

In this work we lift this restriction by adopting a different parameterisation of $\mathbf{B}$ that allows the learning of all task correlations. A straightforward way to do that would be to consider every correlation as an hyperparameter, but this can result in a matrix which is not positive semi-definite (and therefore, not a valid covariance matrix). To ensure this property, we follow the method proposed by Bonilla et al. (2008), which decomposes $\mathbf{B}$ using Probabilistic Principal Component Analysis:

$$\mathbf{B} = \mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^T + \text{diag}(\boldsymbol{\alpha}), \tag{5}$$

where $\mathbf{U}$ is an $D \times R$ matrix containing the R principal eigenvectors and Λ is a $R \times R$ diagonal matrix containing the corresponding eigenvalues. The choice of R defines the *rank* of $\mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^T$, which can be understood as the capacity of the manifold with which we model the D tasks. The vector $\boldsymbol{\alpha}$ allows for each task to behave more or less independently with respect to the global task. The final rank of $\mathbf{B}$ depends on both terms in Equation 5.

For numerical stability, we use the incomplete-Cholesky decomposition over the matrix $\mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^T$, resulting in the following parameterisation for $\mathbf{B}$:

$$\mathbf{B} = \tilde{\mathbf{L}}\tilde{\mathbf{L}}^T + \text{diag}(\boldsymbol{\alpha}), \tag{6}$$

where $\tilde{\mathbf{L}}$ is a $D \times R$ matrix. In this setting, we treat all elements of $\tilde{\mathbf{L}}$ as hyperparameters. Setting a larger rank allows more flexibility in modelling task correlations. However, a higher number of hyperparameters may lead to overfitting problems or otherwise cause issues in optimisation due

[1] We refer the reader to Rasmussen and Williams (2006, Chap. 2) for an in-depth explanation of GP regression.

to additional non-convexities in the log likelihood objective. In our experiments we evaluate this behaviour empirically by testing a range of ranks for each setting.

The low-rank model can subsume the ones proposed by Cohn and Specia (2013) by fixing and tying some of the hyperparameters:

Independent: fixing $\tilde{\mathbf{L}} = \mathbf{0}$ and $\boldsymbol{\alpha} = \mathbf{1}$;

Pooled: fixing $\tilde{\mathbf{L}} = \mathbf{1}$ and $\boldsymbol{\alpha} = \mathbf{0}$;

Combined: fixing $\tilde{\mathbf{L}} = \mathbf{1}$ and tying all components of $\boldsymbol{\alpha}$;

Combined+: fixing $\tilde{\mathbf{L}} = \mathbf{1}$.

These formulations allow us to easily replicate their modelling approach, which we evaluate as competitive baselines in our experiments.

3 Experimental Setup

To address the feasibility of our approach, we propose a set of experiments with three goals in mind:

- To find our whether the ICM is able to learn sensible emotion correlations;
- To check if these correlations are able to improve predictions for unseen texts;
- To investigate the behaviour of the ICM model as we increase the training set size.

Dataset We use the dataset provided by the "Affective Text" shared task in SemEval-2007 (Strapparava and Mihalcea, 2007), which is composed of 1000 news headlines annotated in terms of six emotions: *Anger, Disgust, Fear, Joy, Sadness* and *Surprise*. For each emotion, a score between 0 and 100 is given, 0 meaning total lack of emotion and 100 maximum emotional load. We use 100 sentences for training and the remaining 900 for testing.

Model For all experiments, we use a Radial Basis Function (RBF) data kernel over a bag-of-words feature representation. Words were downcased and lemmatized using the WordNet lemmatizer in the NLTK[2] toolkit (Bird et al., 2009). We then use the GPy toolkit[3] to combine this kernel with a coregionalisation model over the six emotions, comparing a number of low-rank approximations.

Baselines and Evaluation We compare prediction results with a set of single-task baselines: a Support Vector Machine (SVM) using an RBF kernel with hyperparameters optimised via cross-validation and a single-task GP, optimised via likelihood maximisation. The SVM models were trained using the Scikit-learn toolkit[4] (Pedregosa et al., 2011). We also compare our results against the ones obtained by employing the "Combined" and "Combined+" models proposed by Cohn and Specia (2013). Following previous work in this area, we use Pearson's correlation coefficient as evaluation metric.

4 Results and Discussion

4.1 Learned Task Correlations

Figure 1 shows the learned coregionalisation matrix setting the initial rank as 1, reordering the emotions to emphasize the learned structure. We can see that the matrix follows a block structure, clustering some of the emotions. This picture shows two interesting behaviours:

- *Sadness* and *fear* are highly correlated. *Anger* and *disgust* also correlate with them, although to a lesser extent, and could be considered as belonging to the same cluster. We can also see correlation between *surprise* and *joy*. These are intuitively sound clusters based on the polarity of these emotions.
- In addition to correlations, the model learns anti-correlations, especially between *joy/surprise* and the other emotions. We also note that *joy* has the highest diagonal value, meaning that it gives preference to independent modelling (instead of pooling over the remaining tasks).

Inspecting the eigenvalues of the learned matrix allows us to empirically determine its resulting rank. In this case we find that the model has learned a matrix of rank 3, which indicates that our initial assumption of a rank 1 coregionalisation matrix may be too small in terms of modelling capacity[5]. This suggests that a higher rank is justified, although care must be taken due to the local optima and overfitting issues cited in §2.1.

Table 1: Prediction results in terms of Pearson's correlation coefficient (higher is better). Boldface values show the best performing model for each emotion. The scores for the "All" column were calculated over the predictions for all emotions concatenated (instead of just averaging over the scores for each emotion).

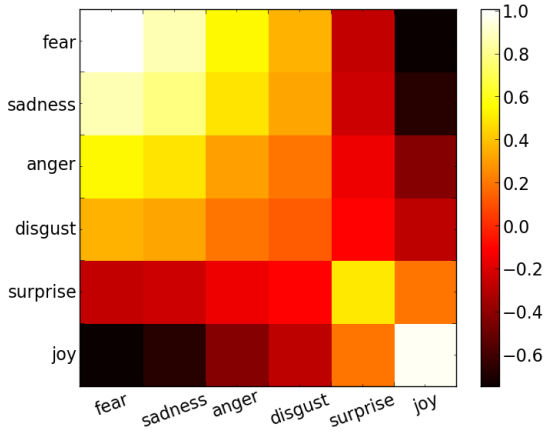

Figure 1: Heatmap showing a learned coregionalisation matrix over the emotions.

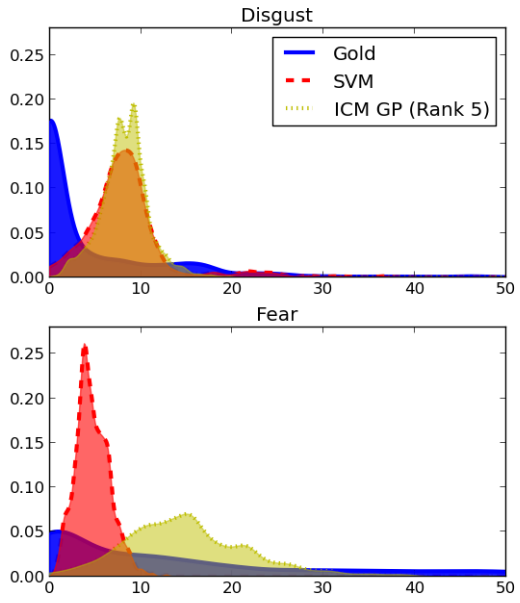

Figure 2: Test score distributions for *disgust* and *fear*. For clarity, only scores between 0 and 50 are shown. SVM performs better on *disgust*, while GP performs better on *fear*.

4.2 Prediction Results

Table 1 shows the Pearson's scores obtained in our experiments. The low-rank models outperformed the baselines for the full task (predicting all emotions) and for *fear*, *joy* and *surprise* subtasks. The rank 5 models were also able to outperform all GP baselines for the remaining emotions, but could not beat the SVM baseline. As expected, the "Combined" and "Combined+" performed worse than the low-rank models, probably due to their inability to model anti-correlations.

4.3 Error analysis

To check why SVM performs better than GPs for some emotions, we analysed their gold-standard score distributions. Figure 2 shows the smoothed distributions for *disgust* and *fear*, comparing the gold-standard scores to predictions from the SVM and GP models. The distributions for the training set follow similar shapes.

We can see that GP obtains better matching score distributions in the case when the gold-standard scores are more spread over the full support of response values, i.e., $[0, 100]$. Since our GP model employs a Gaussian likelihood, it is effectively minimising a squared-error loss. The SVM model, on the other hand, uses hinge loss, which is linear beyond the margin envelope constraints. This affects the treatment of outlier points, which attract quadratic cf. linear penalties for the GP and SVM respectively. Therefore, when training scores are more uniformly distributed (which is the case for *fear*), the GP model has to take the high scores into account, resulting in broader coverage of the full support. For *disgust*, the scores are much more peaked near zero, favouring the

more narrow coverage of the SVM.

More importantly, Figure 2 also shows that both SVM and GP predictions tend to exhibit a Gaussian shape, while the true scores show an exponential behaviour. This suggests that both models are making wrong prior assumptions about the underlying score distribution. For SVMs, this is a non-trivial issue to address, although it is much easier for GPs, where we can use a different likelihood distribution, e.g., a Beta distribution to reflect that the outputs are only valid over a bounded range. Note that non-Gaussian likelihoods mean that exact inference is no longer tractable, due to the lack of conjugacy between the prior and likelihood. However a number of approximate inference methods are appropriate which are already widely used in the GP literature for use with non-Gaussian likelihoods, including expectation propagation (Jylänki et al., 2011), the Laplace approximation (Williams and Barber, 1998) and Markov Chain Monte Carlo sampling (Adams et al., 2009).

4.4 Training Set Influence

We expect multi-task models to perform better for smaller datasets, when compared to single-task models. This stems from the fact that with small datasets often there is more uncertainty associated with each task, a problem which can be alleviated using statistics from the other tasks. To measure this behaviour, we performed an additional experiment varying the size of the training sets, while using 100 sentences for testing.

Figure 3 shows the scores obtained. As expected, for smaller datasets the single-task models are outperformed by ICM, but their performance become equivalent as the training set size increases. SVM performance tends to be slightly worse for most sizes. To study why we obtained an outlier for the single-task model with 200 sentences, we inspected the prediction values. We found that, in this case, predictions for *joy*, *surprise* and *disgust* were all around the same value.[6] For larger datasets, this effect disappears and the single-task models yield good predictions.

5 Conclusions and Future Work

This paper proposed an multi-task approach for Emotion Analysis that is able to learn correlations and anti-correlations between emotions. Our formulation is based on a combination of a Gaussian Process and a low-rank coregionalisation model, using a richer parameterisation that allows the learning of fine-grained task similarities. The proposed model outperformed strong baselines when applied to a news headline dataset.

As it was discussed in Section 4.3, we plan to further explore the possibility of using non-Gaussian likelihoods with the GP models. Another research avenue we intend to explore is to employ multiple layers of metadata, similar to the model proposed by Cohn and Specia (2013). An example is to incorporate the dataset provided by Snow et al. (2008), which provides multiple non-expert emotion annotations for each sentence, obtained via crowdsourcing. Finally, another possible extension comes from more advanced vector-valued GP models, such as the linear model of coregionalisation (Álvarez et al., 2012) or hierarchical kernels (Hensman et al., 2013). These models can be specially useful when we want to employ multiple kernels to explain the relation between the input data and the labels.

Abstract

Previous work on extracting ideology from text has focused on domains where expression of political views is expected, but it's unclear if current technology can work in domains where displays of ideology are considered inappropriate. We present a supervised ensemble n-gram model for ideology extraction with topic adjustments and apply it to one such domain: research papers written by academic economists. We show economists' political leanings can be correctly predicted, that our predictions generalize to new domains, and that they correlate with public policy-relevant research findings. We also present evidence that unsupervised models can under-perform in domains where ideological expression is discouraged.

1 Introduction

Recent advances in text mining demonstrate that political ideology can be predicted from text – often with great accuracy. Standard experimental settings in this literature are ones where ideology is explicit, such as speeches by American politicians or editorials by Israeli and Palestinian authors. An open question is whether ideology can be detected in arenas where it is strongly discouraged. A further consideration for applied researchers is whether these tools can offer insight into questions of import for policymakers. To address both of these issues, we examine one such domain that is both policy-relevant and where ideology is not overtly expressed: research papers written by academic economists.

Why economics? Economic ideas are important for shaping policy by influencing the public debate and setting the range of expert opinion on various policy options (Rodrik, 2014). Economics also views itself as a science (Chetty, 2013) carefully applying rigorous methodologies and using institutionalized safe-guards such as peer review. The field's most prominent research organization explicitly prohibits researchers from making policy recommendations in papers that it releases (National Bureau of Economic Research, 2010). Despite these measures, economics' close proximity to public policy decisions have led many to see it as being driven by ideology (A.S., 2010). Does this view of partisan economics have any empirical basis?

To answer the question of whether economics is politicized or neutral, we present a supervised ensemble n-gram model of ideology extraction with topic adjustments.[1] Our methodology is most closely related to Taddy (2013) and Gentzkow and Shapiro (2010), the latter of which used χ^2 tests to find phrases most associated with ideology as proxied by the language of U.S. Congresspersons. We improve on this methodology by accounting for ideological word choice within topics and incorporating an ensemble approach that increases predictive accuracy. We also motivate the need to adjust for topics even if doing so does not improve accuracy (although it does in this case). We further provide evidence that fully unsupervised methods (Mei et al., 2007; Lin et al., 2008; Ahmed and Xing, 2010; Paul and Girju, 2010; Eisenstein et al., 2011; Wang et al., 2012) may encounter difficulties learning latent ideological aspects when those aspects are not first order in the data.

Our algorithm is able to correctly predict the ideology of 69.2% of economists in our data purely from their academic output. We also show that our predictions generalize and are predictors of responses by a panel of top economists on issues of economic importance. In a companion paper (Jelveh et al., 2014), we further show that

[1]Grimmer and Stewart (2013) provide an overview of models used for ideology detection.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1804–1809,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

predicted ideologies are significantly correlated to economists' research findings. The latter result shows the relevance and applicability of these tools beyond the task of ideology extraction.

2 Data

Linking Economists to Their Political Activity: We obtain the member directory of the American Economics Association (AEA) and link it to two datasets: economists' political campaign contributions and petition signing activities. We obtain campaign contribution data from the Federal Election Commission's website and petition signing data from Hedengren et al. (2010). From this data, we construct a binary variable to indicate the ground-truth ideologies of economists. See our companion paper (Jelveh et al., 2014) for further details on the construction of this dataset. Revealed ideology through contributions and petitions is largely consistent. Of 441 economists appearing in both datasets, 83.4% showed agreement between contributions and petitions. For the final dataset of ground-truth authors we include all economists with campaign contributions and/or petition signatures, however, we drop those economists whose ideologies where different across the contribution and petition datasets. Overall, 60% of 2,204 economists with imputed ideologies in this final dataset are left-leaning while 40% lean rightwards.

Economic Papers Corpus: To create our corpus of academic writings by economists, we collect 17,503 working papers from NBER's website covering June 1973 to October 2011. We also obtained from JSTOR the fulltext of 62,888 research articles published in 93 journals in economics for the years 1991 to 2008. Combining the set of economists and papers leaves us with 2,171 authors with ground truth ideology and 17,870 papers they wrote. From the text of these papers we create n-grams of length two through eight. While n-grams greater than three words in length are uncommon, Margolin et al. (2013) demonstrate that ideological word choice can be detected by longer phrases. To capture other expressions of ideology not revealed in adjacent terms, we also include skipgrams of length two by combining non-adjacent terms that are three to five words apart. We remove phrases used by fewer than five authors.

Topic Adjustments: Table 1 presents the top 20 most conservative and liberal bigrams ranked by χ^2 scores from a Pearson's test of independence between phrase usage by left- and right-leaning economists. It appears that top ideological phrases are related to specific research subfields. For example, right-leaning terms 'free_bank', 'stock_return', and 'feder_reserv' are related to finance and left-leaning terms 'mental_health', 'child_care', and 'birth_weight' are related to health care. This observation leads us to ask: Are apparently ideological phrases merely a by-product of an economist's research interest rather than reflective of true ideology?

To see why this is a critical question, consider that ideology has both direct and indirect effects on word choice, the former of which is what we wish to capture. The indirect pathway is through topic: ideology may influence the research area an economist enters into, but not the word choice within that area. In that case, if more conservative economists choose macroeconomics, the observed correlation between macro-related phrases and right-leaning ideology would be spurious. The implication is that accounting for topics may not necessarily improve performance but provide evidence to support an underlying model of how ideology affects word choice. Therefore, to better capture the direct effect of ideology on phrase usage we adjust our predictions by topic by creating mappings from papers to topics. For a **topic mapping**, we predict economists' ideologies from their word choice *within* each topic and combine these results to form and overall prediction. We compare different supervised and unsupervised topic mappings and assess their predictive ability.

To create supervised topic mappings, we take advantage of the fact that economics papers are manually categorized by the Journal of Economic Literature (JEL). These codes are hierarchical indicators of an article's subject area. For example, the code C51 can be read, in increasing order of specificity, as Mathematical and Quantitative Methods (C), Econometric Modeling (C5), Model Construction and Estimation (C51). We construct two sets of topic mappings: **JEL1** derived from the 1st-level codes (e.g. C) and **JEL2** derived from the 2nd-level codes (e.g. C5). The former covers broad areas (e.g. macroeconomics, microeconomics, etc.) while the latter contains more refined ones (e.g. monetary policy, firm behavior, etc.).

For unsupervised mappings, we run Latent

Dirichilet Allocation (Blei et al., 2003) on our corpus. We use 30, 50, and 100 topics to create **LDA30**, **LDA50**, and **LDA100** topic mappings. We use the topic distributions estimated by LDA to assign articles to topics. A paper p is assigned to a topic t if the probability that t appears in p is greater than 5%. While 5% might seem to be a lower threshold, the topic distributions estimated by LDA tend to be sparse. For example, even with 50 topics to 'choose' from in **LDA50** and a threshold of 5%, 99.5% of the papers would be assigned to five or fewer topics. This compares favorably with JEL2 codings where 98.8% of papers have five or fewer topics.

3 Algorithm

There are two components to our topic-adjusted algorithm for ideology prediction. First, we focus on n-grams and skipgrams that are most correlated with ideology in the training data. For each topic within a topic mapping, we count the total number of times each phrase is used by all left- and all right-leaning economists. Then, we compute Pearson's χ^2 statistic and associated p-values and keep phrases with p ≤ 0.05. As an additional filter, we split the data into ten folds and perform the χ^2 test within each fold. For each topic, we keep phrases that are consistently ideological across all folds. This greatly reduces the number of ideological phrases. For **LDA50**, the mean number of ideological phrases per topic before the cross validation filter is 12,932 but falls to 963 afterwards.

With the list of ideological phrases in hand, the second step is to iterate over each topic and predict the ideologies of economists in our test set. To compute the predictions we perform partial least squares (PLS): With our training data, we construct the standardized frequency matrix $\mathbf{F}_{t,train}$ where the (e,p)-th entry is the number of times economist e used partisan phrase p across all of e's papers in t. This number is divided by the total number of phrases used by e in topic t. For papers with multiple authors, each author gets same count of phrases. About 5% of the papers in our dataset are written by authors with differing ideologies. We do not treat these differently. Columns of $\mathbf{F}_{t,train}$ are standardized to have unit variance. Let $\mathbf{y}$ be the vector of ground-truth ideologies, test set ideologies are predicted as follows:

1) Compute $\mathbf{w} = Corr(\mathbf{F}_{t,train}, \mathbf{y})$, the correlations between each phrase and ideology
2) Project to one dimension: $\mathbf{z} = \mathbf{F}_{t,train}\mathbf{w}$
3) Regress ideology, $\mathbf{y}$, on the constructed variable $\mathbf{z}$: $\mathbf{y} = b_1\,\mathbf{z}$
4) Predict ideology $\hat{y}_e$ of new economist by $\hat{y}_e = b_1 \tilde{\mathbf{f_e}}'\mathbf{w}$, ($\tilde{\mathbf{f_e}}$ is scaled frequency vector)

To avoid over-fitting we introduce an ensemble element: For each t, we sample from the list of significant n-grams in t and sample with replacement from the authors who have written in t.[2] PLS is performed on this sample data 125 times. Each PLS iteration can be viewed as a vote on whether an author is left- or right-leaning. We calculate the vote as follows. For each iteration, we predict the ideologies of economists in the *training data*. We find the threshold f that minimizes the distance between the true and false positive rates for the current iteration and the same rates for the perfect classifier: 1.0 and 0.0, respectively. Then, an author in the test set is voted left-leaning if $y_{t,test} \leq f$ and right-leaning otherwise.

For a given topic mapping, our algorithm returns a three-dimensional array with the (e,t,c)-th entry representing the number of votes economist e received in topic t for ideology c (left- or right-

[2]The number of phrases sampled each iteration is the square root of the number of ideological phrases in the topic.

leaning). To produce a final prediction, we sum across the second dimension and compute ideology as the percentage of right-leaning votes received across all topics within a topic-mapping. Therefore, ideology values closer to zero are associated with a left-leaning ideology and values closer to one are associated with a rightward lean.

To recap, we start with a topic mapping and then for each topic run an ensemble algorithm with PLS at its core.[3] The output for each topic is a set of votes. We sum across topics to compute a final prediction for ideology.

4 Validation and Results

We split our ground-truth set of 2,171 authors into training (80%) and test sets (20%) and compute predictions as above. As our data exhibits skew with 1.5 left-leaning for every right-leaning economist, we report the area under the curve (AUC) which is robust to class skew (Fawcett, 2006). It's worth noting that a classifier that randomly predicts a liberal economist 60% of the time would have an AUC of 0.5. To compare our model with fully unsupervised methods, we also include results from running the Topic-Aspect Model (TAM) (Paul and Girju, 2010) on our data. TAM decomposes documents into two components: one affecting topics and one affecting a latent aspect that influences all topics in a similar manner. We run TAM with 30 topics and 2 aspects (**TAM2/30**). We follow Paul and Girju and use the learned topic and aspect distributions as training data for a SVM.[4]

Columns 2 to 4 from Table 2 show that our models' predictions have a clear association with ground-truth ideology. The LDA topic mappings outperform the supervised mappings as well as a model that does not adjust for topics (**NoTopic**). Perhaps not surprisingly, TAM does not perform well in our domain. A drawback of unsupervised methods is that the learned aspects may not be related to ideology but some other hidden factor.

For further insight into how well our model generalizes, we use data from Gordon and Dahl (2013) to compare our predictions to potentially ideological responses of economists on a survey conducted by the University of Chicago.[5] Each survey question asks for an economists opinion on an issue of political relevance such as minimum wages or tax rates. For further details on the data see Gordon and Dahl. Of importance here is that Gordon and Dahl categorize 22 questions where agreement (disagreement) with the statement implies belief a conservative (liberal) viewpoint.

To see if our predicted ideologies are correlated with survey responses, we run an ordered-logistic regression (McCullagh, 1980). Survey responses are coded with the following order: Strongly Disagree, Disagree, Uncertain, Agree, Strongly Agree. We regress survey responses onto predicted ideologies. We also include question-level dummies and explanatory variables for a re-

spondent's gender, year of Ph.D., Ph.D. university, NBER membership, and experience in federal government. Table 3 shows the results of these regressions for three topic mappings. The correlation between our predictions and survey respondents are all strongly significant.

One way to interpret these results is to compare the change in predicted probability of providing an Agree or Strongly Agree answer (agreeing with the conservative view point) if we change predicted ideology from most liberal to most conservative. For **NoTopic**, this predicted probability is 35% when ideology is set to most liberal and jumps to 73.7% when set to most conservative. This difference increases for topic-adjusted models. For **LDA50**, the probability of a conservative answer when ideology is set to most liberal is 14.5% and 93.8% for most conservative.

Figure 1 compares the predicted probabilities of choosing different answers when ideology is set to most liberal and most conservative. Our topic-adjusted models suggest that the most conservative economists are much more likely to strongly agree with a conservative response than for the most liberal economists to strongly agree with a liberal response. It is worthwhile to note from the small increase in log-likelihood in Table 3 when controls are added, suggesting that our ideology scores are much better predictors of IGM responses than demographic and professional controls.

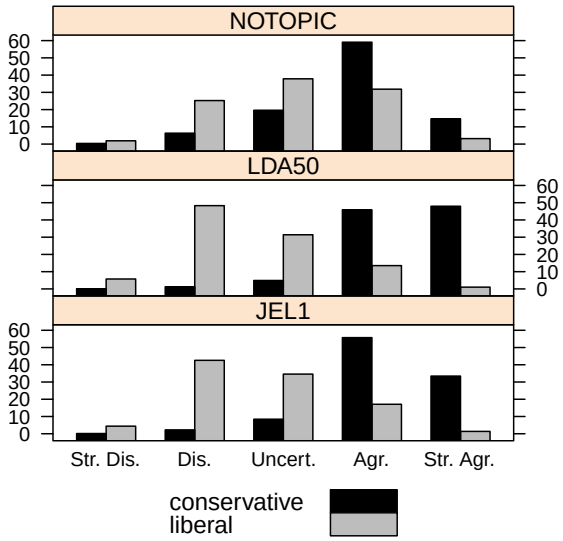

Figure 1: The predicted probability of agreeing with a conservative response when ideology is set to most liberal (gray) and most conservative (black).

5 Conclusions and Future Work

We've presented a supervised methodology for extracting political sentiment in a domain where it's discouraged and shown how it even predicts the partisanship calculated from completely unrelated IGM survey data. In a companion paper (Jelveh et al., 2014) we further demonstrate how this tool can be used to aid policymakers in de-biasing research findings. When compared to domains where ideological language is expected, our predictive ability is reduced. Future work should disentangle how much this difference is due to modeling decisions and limitations versus actual absence of ideology. Future works should also investigate how fully unsupervised methods can be extended to match our performance.

Abstract

We develop a statistical model of saccadic eye movements during reading of isolated sentences. The model is focused on representing individual differences between readers and supports the inference of the most likely reader for a novel set of eye movement patterns. We empirically study the model for biometric reader identification using eye-tracking data collected from 20 individuals and observe that the model distinguishes between 20 readers with an accuracy of up to 98%.

1 Introduction

During skilled reading, the eyes of a reader do not move smoothly over a text. Instead, reading proceeds by alternating between brief fixations on individual words and short ballistic movements called *saccades* that move the point of fixation to a new location. Evidence in psychological research indicates that patterns of fixations and saccades are driven partly by low-level visual cues (*e.g.*, word length), and partly by linguistic and cognitive processing of the text (Kliegl et al., 2006; Rayner, 1998).

Eye-movement patterns are frequently studied in cognitive psychology as they provide a rich and detailed record of the visual, oculomotor, and linguistic processes involved in reading. Computational models of eye-movement control developed in psychology, such as SWIFT (Engbert et al., 2005; Schad and Engbert, 2012) or E-Z Reader (Reichle et al., 1998; Reichle et al., 2012), simulate the generation of eye movements based on physiological and psychological constraints related to attention, visual perception, and the oculomotor system. Recently, the problem of modeling eye movements has also been approached from a machine-learning perspective. Matties and Søgaard (2013) and Hara et al. (2012) study conditional random field models to predict which words in a text are fixated by a reader. Nilsson and Nivre (2009) use a transition-based log-linear model to predict a sequence of fixations for a text.

A central observation made by these studies, as well as by earlier psychological work (Erdmann and Dodge, 1898; Huey, 1908), is that eye movement patterns vary significantly between individuals. As one example of the strength of individual differences in reading eye movements, we cite Dixon (1951) who compared the reading processes of university professors and graduate students of physics, education, and history on reading material in their own and the two other fields. He did not find strong effects of his experimental variables (i.e., field of research, expertise in research) but "if there is one thing that this study has shown, it is that individual differences in reading skill existed among the subjects of all departments. Fast and slow readers were found in every department, and the overlapping of distributions from passage to passage was enormous" (p. 173). Even though it is possible to predict across a large base of readers with some accuracy whether specific words will be fixated (Matties and Søgaard, 2013), a strong variation between readers in attributes such as the fraction of skipped words and total number of saccades has been observed (Hara et al., 2012).

Some recent work has studied eye movement patterns as a biometric feature. Most studies are based on an artificial visual stimulus, such as a moving (Kasprowski and Ober, 2004; Komogortsev et al., 2010; Rigas et al., 2012b; Zhang and Juhola, 2012) or fixed (Bednarik et al., 2005) dot on a computer screen, or a specific image stimulus (Rigas et al., 2012a). In the most common use

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1810–1815,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

case of biometric user identification, a decision on whether access should be granted has to be made after performing some test that requires the user's attention and therefore cannot take a long time. By contrast, our work is motivated by a less intrusive scenario in which the user is monitored continuously during access to, for instance, a device or document. When the accumulated evidence supports the conclusion that the user is not authorized, access can be terminated or additional credentials requested. In this use case, identification has to be based on saccadic eye movements that occur while a user is reading an arbitrary text—as opposed to movements that occur in response to a fixed, controlled visual stimulus. Holland and Komogortsev (2012) study reader recognition based on a set of aggregate features derived from eye movements, irrespective of the text being read; their work will serve as reference in our empirical study.

The paper is organized as follows. Section 2 details the problem setting. Section 3 introduces the statistical model and discusses parameter estimation and inference. Section 5 presents empirical results, Section 6 concludes.

2 Problem Setting and Notation

Let $\mathcal{R}$ denote a set of readers, and $\mathcal{X} = \{\mathbf{X}_1, ..., \mathbf{X}_n\}$ a set of texts. Each $r \in \mathcal{R}$ generates a set of eye movement patterns $\mathcal{S}^{(r)} = \{\mathbf{S}_1^{(r)}, \ldots, \mathbf{S}_n^{(r)}\}$ on the set of texts $\mathcal{X}$, by

$$\mathbf{S}_i^{(r)} \sim p(\mathbf{S}|\mathbf{X}_i, r)$$

where $p(\mathbf{S}|\mathbf{X}, r)$ is a reader-specific distribution over eye movement patterns given a text $\mathbf{X}$. A pattern is a sequence $\mathbf{S} = ((s_1, d_1), \ldots, (s_T, d_T))$ of fixations, consisting of a fixation position s_t (position in text that was fixated) and duration $d_t \in \mathbb{R}$ (length of fixation in milliseconds). In our experiments, individual sentences are presented in a single line on a screen, thus we only model a horizontal gaze position $s_t \in \mathbb{R}$.

At test time, we observe novel eye movement patterns $\bar{\mathcal{S}} = \{\bar{\mathbf{S}}_1, \ldots, \bar{\mathbf{S}}_m\}$ on a novel set of texts $\bar{\mathcal{X}} = \{\bar{\mathbf{X}}_1, ..., \bar{\mathbf{X}}_m\}$ generated by an unknown reader $r \in \mathcal{R}$. The goal is to infer

$$r_* = \arg\max_{r \in \mathcal{R}} p(r|\bar{\mathcal{S}}, \bar{\mathcal{X}}). \quad (1)$$

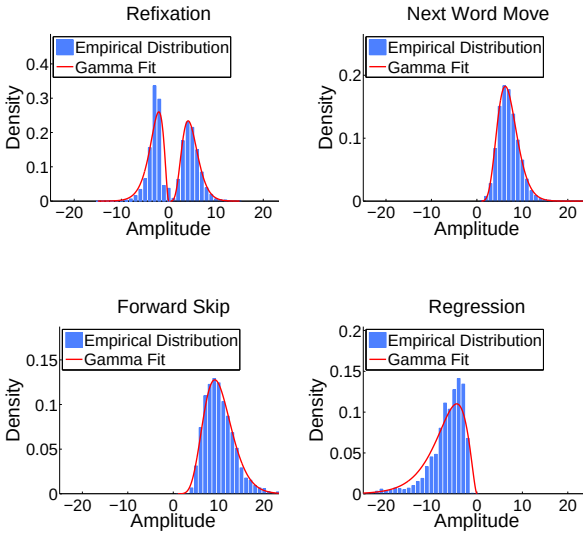

Figure 1: Empirical distributions over amplitudes and Gamma fits for different saccade types.

3 Statistical Model of Eye Movements

We solve Problem 1 by estimating reader-specific models $p(\mathbf{S}|\mathbf{X}; \boldsymbol{\theta}_r)$ for $r \in \mathcal{R}$, and solving for

$$p(r|\bar{\mathcal{S}}, \bar{\mathcal{X}}; \boldsymbol{\Theta}) \propto \left(\prod_{i=1}^{m} p(\bar{\mathbf{S}}_i|\bar{\mathbf{X}}_i; \boldsymbol{\theta}_r) \right) p(r) \quad (2)$$

where all $\boldsymbol{\theta}_r$ are aggregated into a global model $\boldsymbol{\Theta}$. Assuming a uniform prior $p(r)$ over readers, this reduces to predicting the reader r that maximizes the likelihood $p(\bar{\mathcal{S}}|\bar{\mathcal{X}}; \boldsymbol{\theta}_r) = \prod_{i=1}^{m} p(\bar{\mathbf{S}}_i|\bar{\mathbf{X}}_i; \boldsymbol{\theta}_r)$.

We formulate a model $p(\mathbf{S}|\mathbf{X}; \boldsymbol{\theta})$ of a sequence $\mathbf{S}$ of fixations given a text $\mathbf{X}$. The model defines a dynamic probabilistic process that successively generates the fixation positions s_t and durations d_t in $\mathbf{S}$, reflecting how a reader generates a sequence of saccades in response to a text stimulus $\mathbf{X}$. The joint distribution over all fixation positions and durations is assumed to factorize as

$$p(s_1, \ldots, s_T, d_1, \ldots, d_T|\mathbf{X}; \boldsymbol{\theta}) = p(s_1, d_1|\mathbf{X}; \boldsymbol{\theta}) \prod_{t=1}^{T-1} p(s_{t+1}, d_{t+1}|s_t, \mathbf{X}; \boldsymbol{\theta}).$$

The conditional $p(s_{t+1}, d_{t+1}|s_t, \mathbf{X}; \boldsymbol{\theta})$ models the generation of the next fixation position and duration given the current fixation position s_t. In the psychological literature, four different *saccadic types* are distinguished: a reader can refixate the current word (refixation), fixate the next word in the text (next word movement), move the

fixation to a word after the next word (forward skip), or regress to fixate a word occurring earlier than the currently fixated word in the text (regression) (Heister et al., 2012). We observe empirically, that modeling the amplitude as a mixture of four Gamma distributions matches the empirical distribution of amplitudes in our data well—see Figure 1. Modeling the amplitudes as a single distribution, instead of a mixture of four distributions, results in a substantially lower out-of-sampling likelihood of the model. Therefore, at each time t, the model first draws a saccadic type $u_{t+1} \in \{1, 2, 3, 4\}$ from a multinomial distribution and then generates a saccade amplitude a_{t+1} and fixation duration d_{t+1} from type-specific Gamma distributions. Formally, the generative process is given by

$$u_{t+1} \sim p(u|\boldsymbol{\pi}) = \text{Mult}(u|\boldsymbol{\pi}) \quad (3)$$
$$a_{t+1} \sim p(a|u_{t+1}, s_t, \mathbf{X}; \boldsymbol{\eta}) \quad (4)$$
$$d_{t+1} \sim p(d|u_{t+1}; \boldsymbol{\lambda}). \quad (5)$$

Afterwards the model updates the fixation position according to $s_{t+1} = s_t + a_{t+1}$. The joint parameter vector $\boldsymbol{\theta}$ concatenates parameters of the individual distributions in Equations 3 to 5. Figure 2 shows a slice in the dynamical model.

Given the current fixation position s_t, the text $\mathbf{X}$, and the chosen saccadic type u_{t+1}, the amplitude is constrained to fall within a specific interval—for instance, within the characters of the currently fixated word for refixations. Therefore, we model the distribution over the saccade amplitude given the saccadic type (Equation 4) as truncated Gamma distributions, given by[1]

$$\mathcal{G}(x|[l,r];\alpha,\beta) = \begin{cases} \frac{\mathcal{G}(x|\alpha,\beta)}{\int_l^r \mathcal{G}(\bar{x}|\alpha,\beta)\mathrm{d}\bar{x}} & \text{if } x \in [l,r] \\ 0 & \text{otherwise} \end{cases}$$

$$\text{where} \quad \mathcal{G}(x|\alpha,\beta) = \frac{1}{\beta^\alpha \Gamma(\alpha)} x^{\alpha-1} e^{\frac{-x}{\beta}}$$

is the Gamma distribution with shape parameter α and scale parameter β, and Γ is the Gamma function. For $x \sim \mathcal{G}(x|\alpha,\beta)$ it holds that $\mathcal{G}(x|[l,r];\alpha,\beta)$ is the conditional distribution of x given that $x \in [l,r]$. The distribution over a saccade amplitude given the saccade type is given by

$$p(a|u_{t+1}=1, s_t, \mathbf{X}; \boldsymbol{\eta}) = \begin{cases} \mu\mathcal{G}(a|[0,r];\alpha_1,\beta_1) & \text{if } a > 0 \\ (1-\mu)\mathcal{G}(-a|[0,l];\bar{\alpha}_1,\bar{\beta}_1) & \text{otherwise} \end{cases} \quad (6)$$

where the parameter μ reflects the probability for a forward saccade within a refixation, and

$$\begin{aligned} p(a|u_{t+1}=2, s_t, \mathbf{X}; \boldsymbol{\eta}) &= \mathcal{G}(a|[l^+, r^+];\alpha_2,\beta_2) \\ p(a|u_{t+1}=3, s_t, \mathbf{X}; \boldsymbol{\eta}) &= \mathcal{G}(a|(r^+, \infty);\alpha_3,\beta_3) \\ p(a|u_{t+1}=4, s_t, \mathbf{X}; \boldsymbol{\eta}) &= \mathcal{G}(-a|(-l, \infty);\alpha_4,\beta_4). \end{aligned} \quad (7)$$

Here, the truncation intervals reflect the constraints on the amplitude a_{t+1} given u_{t+1}, s_t and $\mathbf{X}$. Let w_l (w_r) denote the position of the left-most (right-most) character of the currently fixated word, and let w_l^+, w_r^+ denote these positions for the word following the currently fixated word. Then $l = w_l - s_t$, $r = w_r - s_t$, $l^+ = w_l^+ - s_t$, and $r^+ = w_r^+ - s_t$. The parameter vector $\boldsymbol{\eta}$ contains the parameters μ, $\bar{\alpha_1}$, $\bar{\beta_1}$ and α_i, β_i for $i \in \{2, 3, 4\}$.

The distribution over fixation durations given saccade type is modeled by a Gamma distribution

$$p(d|u_{t+1}; \boldsymbol{\lambda}) = \mathcal{G}(d|\gamma_{u_{t+1}}, \delta_{u_{t+1}})$$

with type-specific parameters γ_u, δ_u for $u \in \{1, 2, 3, 4\}$ that are concatenated into a parameter vector $\boldsymbol{\lambda}$.

It remains to specify the distribution over initial fixation positions and durations $p(s_1, d_1|\mathbf{X}; \boldsymbol{\theta})$, which is given by additional Gamma distributions

$$s_1 \sim \mathcal{G}(d|\alpha_0, \beta_0) \qquad d_1 \sim \mathcal{G}(d|\gamma_0, \delta_0)$$

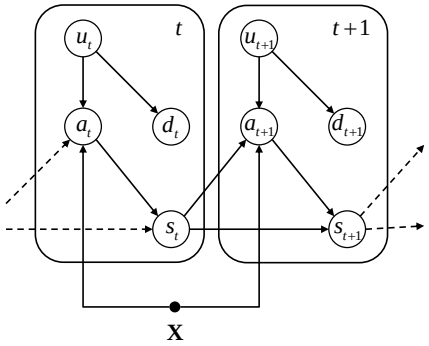

Figure 2: Graphical model notation of a slice in the dynamic model. Parameters are omitted to avoid notational clutter.

[1]The definition is straightforwardly generalized to open truncation intervals.

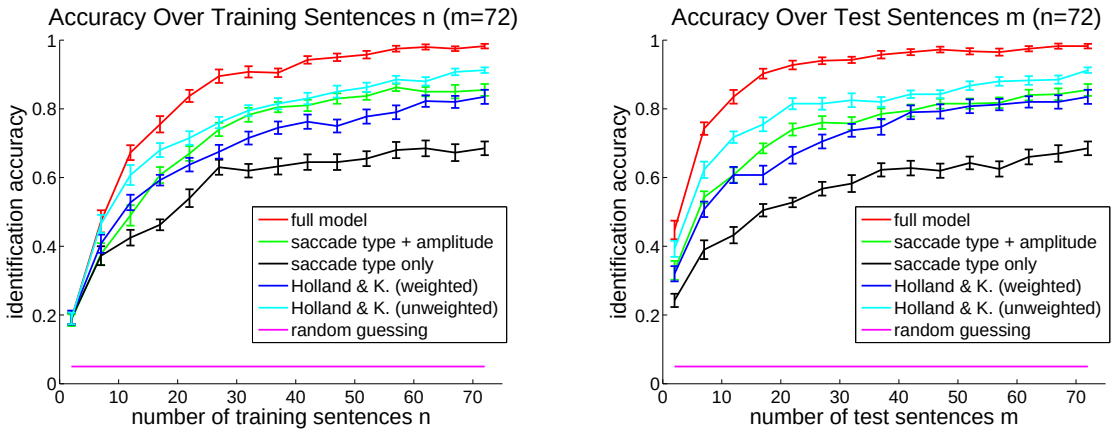

Figure 3: Reader identification accuracy as a function of the number of training sentences (left) and test sentences (right) read for different model variants. Error bars indicate the standard error.

where the parameters $\alpha_0, \beta_0, \gamma_0, \delta_0$ are aggregated into the joint parameter vector $\boldsymbol{\theta}$.

4 Parameter Estimation and Inference

Given a set $\mathcal{S}^{(r)}$ of eye movement observations for reader $r \in \mathcal{R}$ on texts $\mathcal{X}$, the MAP estimate of the parameters is

$$\begin{aligned}\boldsymbol{\theta}_r &= \arg\max_{\boldsymbol{\theta}} p(\boldsymbol{\theta}|\mathcal{S}^{(r)}, \mathcal{X}) \\ &= \arg\max_{\boldsymbol{\theta}} \left(\prod_{i=1}^{n} p(\mathbf{S}_i^{(r)}|\mathbf{X}_i; \boldsymbol{\theta}) \right) p(\boldsymbol{\theta}). \quad (8)\end{aligned}$$

A Dirichlet distribution (add-one smoothing) is a natural, conjugate prior for the multinomial distribution; we use uninformative priors for all other distributions. The structure of the model implies that the posterior can be maximized by fitting the parameters $\boldsymbol{\pi}$ to the observed saccadic types under the Dirichlet prior, and independently fitting the distributions $p(a_t|u_t, \mathbf{X}, s_t; \boldsymbol{\eta})$ and $p(d_t|u_t; \boldsymbol{\lambda})$ by maximum likelihood to the saccade amplitudes and durations observed for each saccade type. The resulting maximum likelihood problems are slightly non-standard in that we have to fit Gamma distributions that are truncated differently for each data point, depending on the textual content at the position where the saccade occurs (see Equations 6 and 7). We solve the resulting optimization problems using a Quasi-Newton method. To avoid overfitting, we use a backoff-smoothing technique for $p(a_t|u_t, \mathbf{X}, s_t; \boldsymbol{\eta})$ and $p(d_t|u_t; \boldsymbol{\lambda})$: we replace reader-specific parameter estimates by estimates obtained from the corresponding data of all readers if the number of data points from which the distributions are estimated falls below a cutoff value. The cutoff value is tuned by cross-validation on the training data.

At test time, we have to infer likelihoods $p(S_i|\mathbf{X}; \boldsymbol{\theta}_r)$ (Equation 2). This is done by evaluating the multinomial and (truncated) Gamma distributions in the model for the corresponding observations and model parameters.

5 Empirical Study

We empirically study the proposed model and several baselines using eye-movement records of 20 individuals (Heister et al., 2012). For each individual, eye movements are recorded while reading each of the 144 sentences in the *Potsdam Sentence Corpus* (Kliegl et al., 2006). The data set contains fixation positions and durations that have been obtained from raw eye movement data by appropriate preprocessing. Eye movements were recorded with an EyeLink II system with a 500-Hz sampling rate (SR Research, Osgoode, Ontario, Canada). All recordings and calibration were binocular. We randomly sample disjoint sets of n training sentences and m test sentences from the set of 144 sentences. Models are estimated on the eye movement records of individuals on the training sentences (Equation 8). The eye-movement records of one individual on all test sentences constitute a test example; the model infers the most likely individual to have generated these test observations (Equation 2). *Identification accuracy* is the fraction of times an individual is correctly inferred; random guessing yields an accuracy of 0.05. Results are averaged over 20 training and test sets.

We study the model introduced in Section 3

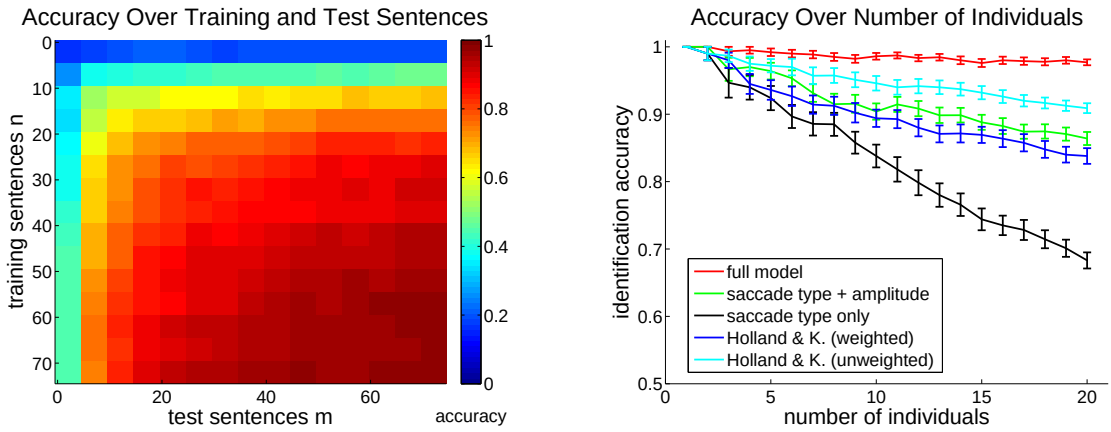

Figure 4: Identification accuracy as a function of the number of training and test sentences read for full model (left). Identification accuracy as a function of the number of individuals that have to be distinguished for different model variants (right). Error bars indicate the standard error.

(*full model*), a model variant in which the variable d_{t+1} and corresponding distribution is removed (*saccade type + amplitude*), and a simple model that only fits a multinomial distribution to saccade types (*saccade type only*). Additionally, we compare against the feature-based reader identification approach by Holland & Komogortsev (2012). Six of the 14 features used by Holland & Komogortsev depend on saccade velocities and vertical fixation positions. As this information was not available in the preprocessed data set that we used, we implemented the remaining features. There is extensive empirical evidence that saccade velocity scales with saccade amplitude. Specifically, the relationship between logarithmic peak saccade velocity and logarithmic saccade amplitude is linear over a wide range of amplitudes and velocities; this is known as the main sequence relationship (Bahill et al., 1975). Therefore, we do not expect that adding saccade velocities would dramatically affect performance of this baseline. Holland & Komogortsev employ a weighted combination of features; we report results for the method with and without feature weighting.

Figure 3 shows identification accuracy as a function of the number n of training sentences used to estimate model parameters (left) and as a function of the number m of test sentences on which inference of the most likely reader is based (right, cf. Equation 2). The full model achieves up to 98.25% accuracy, significantly outperforming the Holland & Komogortsev (2012) baseline (91.25%, without feature weighting) and simpler model variants. All methods perform much better than random guessing. Figure 4 (left) shows identification accuracy as a function of both training size n and test size m for the full model.

We finally study how identification accuracy changes with the number of individuals that have to be distinguished. To this end, we perform the same study as above, but with randomly sampled subsets of the overall set of 20 individuals. In these experiments, we average over 50 random train-test splits. Figure 4 (right) shows identification accuracy as a function of the number of individuals. We observe that identification accuracy drops with the number of individuals for all methods; our model consistently outperforms the baselines.

6 Conclusions

We have developed a model of individual differences in eye movements during reading, and studied its application in a biometric task. At test time, individuals are identified based on eye movements on novel text. Our approach thus provides potentially unobtrusive biometric identification without requiring users to react to a specific stimulus. Empirical results show clear advantages over an existing approach for reader identification.

Acknowledgments

We would like to thank Christoph Sawade for insightful discussions and help with the eye movement data. We gratefully acknowledge support from the German Research Foundation (DFG), grant LA 3270/1-1.

Muli-label Text Categorization with Hidden Components

Li Li Longkai Zhang Houfeng Wang

Abstract

Multi-label text categorization (MTC) is supervised learning, where a document may be assigned with multiple categories (labels) simultaneously. The labels in the MTC are correlated and the correlation results in some hidden components, which represent the "share" variance of correlated labels. In this paper, we propose a method with hidden components for MTC. The proposed method employs PCA to capture the hidden components, and incorporates them into a joint learning framework to improve the performance. Experiments with real-world data sets and evaluation metrics validate the effectiveness of the proposed method.

1 Introduction

Many real-world text categorization applications are multi-label text categorization (Srivastava and Zane-Ulman, 2005; Katakis et al., 2008; Rubin et al., 2012; Nam et al., 2013), where a documents is usually assigned with *multiple* labels simultaneously. For example, as figure 1 shows, a newspaper article concerning global warming can be classified into two categories, *Environment*, and *Science* simultaneously. Let $\mathcal{X} = R^d$ be the documents corpus, and $\mathcal{Y} = \{0, 1\}^m$ be the label space with m labels. We denote by $\{(\boldsymbol{x_1}, \boldsymbol{y_1}), (\boldsymbol{x_2}, \boldsymbol{y_2}), ..., (\boldsymbol{x_n}, \boldsymbol{y_n})\}$ the training set of n documents. Each document is denoted by a vector $\boldsymbol{x}_i = [x_{i,1}, x_{i,2}, ..., x_{i,d}]$ of d dimensions. The labeling of the i-th document is denoted by vector $\boldsymbol{y}_i = [y_{i,1}, y_{i,2}, ..., y_{i,m}]$, where y_{il} is 1 when the i-th document has the l-th label and 0 otherwise. The goal is to learn a function $\boldsymbol{f} : \mathcal{X} \rightarrow \mathcal{Y}$. Generally, we can assume $\mathbf{f}$ consists of m functions, one for a label.

$$\boldsymbol{f} = [f_1, f_2, ..., f_m]$$

Figure 1: A newspaper article concerning global warming can be classified into two categories, *Environment*, and *Science*.

The labels in the MLC are correlated. For example, a "politics" document is likely to be an "economic" document simultaneously, but likely not to be a "literature" document. According to the latent variable model (Tabachnick et al., 2001), the labels with correlation result in some hidden components, which represent the "share" variance of correlated labels. Intuitively, if we can capture and utilize these hidden components in MTC, the performance will be improved. To implement this idea, we propose a multi- label text categorization method with hidden components, which employ PCA to capture the hidden components, and then incorporates these hidden components into a joint learning framework. Experiments with various data sets and evaluation metrics validate the values of our method. The research close to our work is ML-LOC (Multi-Label learning using LOcal Correlation) in (Huang and Zhou, 2012). The differ-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1816–1821,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ences between ours and ML-LOC is that ML-LOC employs the cluster method to gain the local correlation, but we employ the PCA to obtain the hidden code. Meanwhile, ML-LOC uses the linear programming in learning the local code, but we employ the gradient descent method since we add non-linear function to the hidden code.

The rest of this paper is organized as follows. Section 2 presents the proposed method. We conduct experiments to demonstrate the effectiveness of the proposed method in section 3. Section 4 concludes this paper.

2 Methodology

2.1 Capturing Hidden Component via Principle Component Analysis

The first step of the proposed method is to capture hidden components of training instances. Here we employ Principal component analysis (PCA). This is because PCA is a well-known statistical tool that converts a set of observations of possibly correlated variables into a set of values of linearly uncorrelated variables called principle components. These principle components represent the inner structure of the correlated variables.

In this paper, we directly employ PCA to convert labels of training instances into their principle components, and take these principle components as hidden components of training instances. We denote by $\boldsymbol{h}_i$ the hidden components of the i-th instance captured by PCA.

2.2 Joint Learning Framework

We expand the original feature representation of the instance $\boldsymbol{x}_i$ by its hidden component code vector $\boldsymbol{c}_i$. For simplicity, we use logistic regression as the motivating example. Let $\boldsymbol{w}_l$ denote weights in the l-th function f_l, consisting of two parts: 1) $\boldsymbol{w}_l^x$ is the part involving the instance features. 2) $\boldsymbol{w}_l^c$ is the part involving the hidden component codes. Hence f_l is:

$$f_l(\boldsymbol{x}, \boldsymbol{c}) = \frac{1}{1 + \exp(-\boldsymbol{x}^T \boldsymbol{w}_l^x - \boldsymbol{c}^T \boldsymbol{w}_l^c)} \tag{1}$$

where $\boldsymbol{C}$ is the code vectors set of all training instances.

The natural choice of the code vector $\boldsymbol{c}$ is $\boldsymbol{h}$. However, when testing an instance, the labeling is unknown (exactly what we try to predict), consequently we can not capture $\boldsymbol{h}$ with PCA to replace the code vector $\boldsymbol{c}$ in the prediction function Eq.(1). Therefore, we assume a linear transformation $\boldsymbol{M}$ from the training instances to their independent components, and use $\boldsymbol{Mx}$ as the approximate independent component. For numerical stability, we add a non-linear function (e.g., the tanh function) to $\boldsymbol{Mx}$. This is formulated as follows.

$$\boldsymbol{c} = tanh(\boldsymbol{Mx}) \tag{2}$$

Aiming to the discrimination fitting and the independent components encoding, we optimize the following optimization problem.

$$\min_{\boldsymbol{W}, C} \sum_{i=1}^{n} \sum_{l=1}^{m} \ell(\boldsymbol{x}_i, \boldsymbol{c}_i, y_{il}, f_l) + \lambda_1 \Omega(\boldsymbol{f}) + \lambda_2 Z(\boldsymbol{C}) \tag{3}$$

The first term of Eq.(3) is the loss function. ℓ is the loss function defined on the training data, and $\boldsymbol{W}$ denotes all weights in the our model, i.e., $\boldsymbol{w}_1, ..., \boldsymbol{w}_l, ..., \boldsymbol{w}_m$. Since we utilize the logistic regression in our model, the loss function is defined as follows.

$$\begin{aligned} & \ell(\boldsymbol{x}, \boldsymbol{c}, y, f) \\ = \; & -y ln f(\boldsymbol{x}, \boldsymbol{c}) - (1 - y) ln(1 - f(\boldsymbol{x}, \boldsymbol{c})) \end{aligned} \tag{4}$$

The second term of Eq.(3) Ω is to punish the model complexity, which we use the ℓ_2 regularization term.

$$\Omega(\boldsymbol{f}) = \sum_{l=1}^{m} ||\boldsymbol{w}_l||^2. \tag{5}$$

The third term of Eq.(3) Z is to enforce the code vector close to the independent component vector. To obtain the goal, we use the least square error between the code vector and the independent component vector as the third regularized term.

$$Z(C) = \sum_{i=1}^{n} ||\boldsymbol{c}_i - \boldsymbol{h}_i||^2. \tag{6}$$

By substituting the Eq.(5) and Eq.(6) into Eq.(3) and changing $\boldsymbol{c}$ to $tanh(\boldsymbol{Mx})$ (Eq.(2)), we obtain the following optimization problem.

$$\begin{aligned} & \min_{\boldsymbol{W}, \boldsymbol{M}} \sum_{i=1}^{n} \sum_{l=1}^{m} \ell(\boldsymbol{x}_i, tanh(\boldsymbol{Mx}_i), y_{il}, \boldsymbol{f}) \\ & + \lambda_1 \sum_{l=1}^{m} ||\boldsymbol{w}_l||^2 + \lambda_2 \sum_{i=1}^{n} ||\boldsymbol{Mx}_i - \boldsymbol{h_i}||^2 \end{aligned} \tag{7}$$

2.3 Alternative Optimization method

We solve the optimization problem in Eq.(7) by the alternative optimization method, which optimize one group of the two parameters with the other fixed. When the $\boldsymbol{M}$ fixed, the third term of Eq.(7) is a constant and thus can be ignored, then Eq.(7) can be rewritten as follows.

$$\min_{\boldsymbol{W}} \sum_{i=1}^{n}\sum_{l=1}^{m} \ell(\boldsymbol{x}_i, tanh(\boldsymbol{M}\boldsymbol{x}_i), y_{il}, f_l) + \lambda_1 \sum_{l=1}^{m} ||\boldsymbol{w}_l||^2 \quad (8)$$

By decomposing Eq.(8) based on the label, the equation Eq.(8) can be simplified to:

$$\min_{\boldsymbol{w}_l} \sum_{i=1}^{n} \ell(\boldsymbol{x}_i, tanh(\boldsymbol{M}\boldsymbol{x}_i), y_{il}, f_l) + \lambda_1 ||\boldsymbol{w}_l||^2 \quad (9)$$

Eq.(9) is the standard logistic regression, which has many efficient optimization algorithms.

When $\boldsymbol{W}$ fixed, the second term is constant and can be omitted, then Ep.(7) can rewritten to Eq.(10). We can apply the gradient descent method to optimize this problem.

$$\min_{\boldsymbol{M}} \sum_{i=1}^{n}\sum_{l=1}^{m} \ell(\boldsymbol{x}_i, tanh(\boldsymbol{M}\boldsymbol{x}_i), y_{il}, f_l) + \lambda_2 \sum_{i=1}^{n} ||\boldsymbol{M}\boldsymbol{x}_i - \boldsymbol{h_i}||^2 \quad (10)$$

3 Experiments

3.1 Evaluation Metrics

Compared with the single-label classification, the multi-label setting introduces the additional degrees of freedom, so that various multi-label evaluation metrics are requisite. We use three different multi-label evaluation metrics, include the hamming loss evaluation metric.

The hamming loss is defined as the percentage of the wrong labels to the total number of labels.

$$Hammingloss = \frac{1}{m}|\mathbf{h}(\boldsymbol{x})\Delta\boldsymbol{y}| \quad (11)$$

where Δ denotes the symmetric difference of two sets, equivalent to XOR operator in Boolean logic. m denotes the label number.

The multi-label 0/1 loss, also known as subset accuracy, is the exact match measure as it requires any predicted set of labels $\mathbf{h}(\boldsymbol{x})$ to match the true set of labels S *exactly*. The 0/1 loss is defined as follows:

$$0/1loss = I(\mathbf{h}(\boldsymbol{x}) \neq \boldsymbol{y}) \quad (12)$$

Let a_j and r_j denote the precision and recall for the j-th label. The macro-averaged F is a harmonic mean between precision and recall, defined as follows:

$$F = \frac{1}{m}\sum_{i=j}^{m} \frac{2 * a_j * r_j}{a_j + r_j} \quad (13)$$

3.2 Datasets

We perform experiments on three MTC data sets: 1) the first data set is slashdot (Read et al., 2011). The slashdot data set is concerned about science and technology news categorization, which predicts multiply labels given article titles and partial blurbs mined from Slashdot.org. 2) the second data set is medical (Pestian et al., 2007). This data set involves the assignment of ICD-9-CM codes to radiology reports. 3) the third data set is tmc2007 (Srivastava and Zane-Ulman, 2005). It is concerned about safety report categorization, which is to label aviation safety reports with respect to what types of problems they describe. The characteristics of them are shown in Table 1, where n denotes the size of the data set, d denotes the dimension of the document instance, and m denotes the number of labels.

dataset	n	d	m	Lcard
slashdot	3782	1079	22	1.18
medical	978	1449	45	1.245
tmc2007	28596	500	22	2.16

Table 1: Multi-label data sets and associated statistics

The measure label cardinality $Lcard$, which is one of the standard measures of "multi-labelness", defined as follows, introduced in (Tsoumakas and Katakis, 2007).

$$Lcard(D) = \frac{\sum_{i=1}^{n}\sum_{j=1}^{m} y_j^i}{n}$$

where D denotes the data set, l_j^i denotes the j-th label of the i-th instance in the data set.

3.3 Compared to Baselines

To examine the values of the joint learning framework, we compare our method to two baselines. The baseline 1 eliminates the PCA, which just adds an extra set of non-linear features. To implement this baseline, we only need to set $\lambda_2 = 0$. The baseline 2 eliminates the joint learning framework. This baseline captures the hidden component codes with PCA, trains a linear regression model to fit the hidden component codes, and utilizes the outputs of the linear regression model as features.

For the proposed method, we set $\lambda_1 = 0.001$ and $\lambda_2 = 0.1$. For the baseline 2, we employ logistic regression with 0.001 $\ell 2$ regularization as the base classifier. Evaluations are done in ten-fold cross validation. Note that all of them produce real-valued predictions. A threshold t needs to be used to determine the final multi-label set $\boldsymbol{y}$ such that $l_j \in \boldsymbol{y}$ where $p_j \geq t$. We select threshold t, which makes the $Lcard$ measure of predictions for the training set is closest to the $Lcard$ measure of the training set (Read et al., 2011). The threshold t is determined as follows, where D_t is the training set and a multi-label model H_t predicts for the training set under threshold t.

$$t = \underset{t \in [0,1]}{\operatorname{argmin}} |Lcard(D_t) - Lcard(H_t(D_t))| \quad (14)$$

Table 2 reports our method wins over the baselines in terms of different evaluation metrics, which shows the values of PCA and our joint learning framework. The hidden component code only fits the hidden component in the baseline method. The hidden component code obtains balance of fitting hidden component and fitting the training data in the joint learning framework.

3.4 Compared to Other Methods

We compare the proposed method to BR, CC (Read et al., 2011), RAKEL (Tsoumakas and Vlahavas, 2007) and ML-KNN (Zhang and Zhou, 2007). entropy. ML-kNN is an adaption of kNN algorithm for multilabel classification. methods. Binary Revelance (BR) is a simple but effective method that trains binary classifiers for each label independently. BR has a low time complexity but makes an arbitrary assumption that the labels are independent from each other. CC organizes the classifiers along a chain and take predictions produced by the former classifiers as features of the latter classifiers. ML-kNN uses kNN algorithms independently for each label with considering prior probabilities. The Label Powerset (LP) method models independencies among labels by treating each label combination as a new class. LP consumes too much time, since there are 2^m label combinations with m labels. RAndom K labEL (RAKEL) is an ensemble method of LP. RAKEL learns several LP models with random subsets of size k from all labels, and then uses a vote process to determine the final predictions.

For our proposed method, we employ the setup in subsection 3.3. We utilize logistic regression with 0.001 $\ell 2$ regularization as the base classifier for BR, CC and RAKEL. For RAKEL, the number of ensemble is set to the number of label and the size of the label subset is set to 3. For MLKNN, the number of neighbors used in the k-nearest neighbor algorithm is set to 10 and the smooth parameter is set to 1. Evaluations are done in ten-fold cross validation. We employ the threshold-selection strategy introduced in subsection 3.3

Table 2 also reports the detailed results in terms of different evaluation metrics. The mean metric value and the standard deviation of each method are listed for each data set. We see our proposed method shows majorities of wining over the other state-of-the-art methods nearly at all data sets under hamming loss, 0/1 loss and macro f score. Especially, under the macro f score, the advantages of our proposed method over the other methods are very clear.

4 CONCLUSION

Many real-world text categorization applications are multi-label text categorization (MTC), where a documents is usually assigned with *multiple* labels simultaneously. The key challenge of MTC is the label correlations among labels. In this paper, we propose a MTC method via hidden components to capture the label correlations. The proposed method obtains hidden components via PCA and incorporates them into a joint learning framework. Experiments with various data sets and evaluation metrics validate the effectiveness of the proposed method.

Abstract

We describe a convolutional neural network that learns feature representations for short textual posts using hashtags as a supervised signal. The proposed approach is trained on up to 5.5 billion words predicting 100,000 possible hashtags. As well as strong performance on the hashtag prediction task itself, we show that its learned representation of text (ignoring the hashtag labels) is useful for other tasks as well. To that end, we present results on a document recommendation task, where it also outperforms a number of baselines.

1 Introduction

Hashtags (single tokens often composed of natural language n-grams or abbreviations, prefixed with the character '#') are ubiquitous on social networking services, particularly in short textual documents (a.k.a. posts). Authors use hashtags to diverse ends, many of which can be seen as labels for classical NLP tasks: disambiguation (`chips #futurism` vs. `chips #junkfood`); identification of named entities (`#sf49ers`); sentiment (`#dislike`); and topic annotation (`#yoga`). *Hashtag prediction* is the task of mapping text to its accompanying hashtags. In this work we propose a novel model for hashtag prediction, and show that this task is also a useful surrogate for learning good representations of text.

Latent representations, or *embeddings*, are vectorial representations of words or documents, traditionally learned in an unsupervised manner over large corpora. For example LSA (Deerwester et al., 1990) and its variants, and more recent neural-network inspired methods like those of Bengio et al. (2006), Collobert et al. (2011) and word2vec (Mikolov et al., 2013) learn word embeddings. In the word embedding paradigm, each word is represented as a vector in $\mathbb{R}^n$, where n is a hyperparameter that controls capacity. The embeddings of words comprising a text are combined using a model-dependent, possibly learned function, producing a point in the same embedding space. A similarity measure (for example, inner product) gauges the pairwise relevance of points in the embedding space.

Unsupervised word embedding methods train with a reconstruction objective in which the embeddings are used to predict the original text. For example, word2vec tries to predict all the words in the document, given the embeddings of surrounding words. We argue that hashtag prediction provides a more direct form of supervision: the tags are a labeling by the author of the salient aspects of the text. Hence, predicting them may provide stronger semantic guidance than unsupervised learning alone. The abundance of hashtags in real posts provides a huge labeled dataset for learning potentially sophisticated models.

In this work we develop a convolutional network for large scale ranking tasks, and apply it to hashtag prediction. Our model represents both words and the entire textual post as embeddings as intermediate steps. We show that our method outperforms existing unsupervised (word2vec) and supervised (WSABIE (Weston et al., 2011)) embedding methods, and other baselines, at the hashtag prediction task.

We then probe our model's generality, by transfering its learned representations to the task of *personalized document recommendation*: for each of M users, given N previous positive interactions with documents (likes, clicks, etc.), predict the $N+1$'th document the user will positively interact with. To perform well on this task, the representation should capture the user's interest in textual content. We find representations trained on hashtag prediction outperform representations from unsupervised learning, and that our convolu-

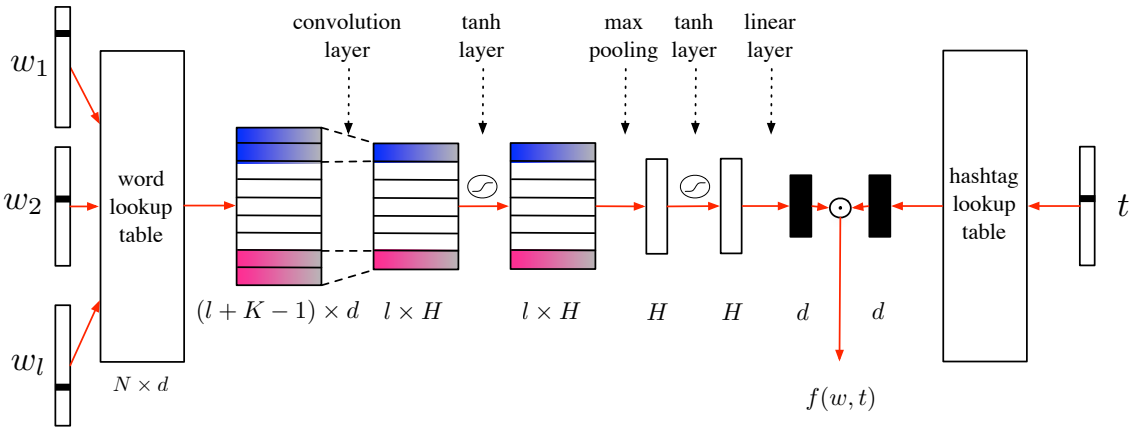

Figure 1: #TAGSPACE convolutional network $f(w,t)$ for scoring a (document, hashtag) pair.

tional architecture performs better than WSABIE trained on the same hashtag task.

2 Prior Work

Some previous work (Davidov et al., 2010; Godin et al., 2013; She and Chen, 2014) has addressed hashtag prediction. Most such work applies to much smaller sets of hashtags than the 100,000 we consider, with the notable exception of Ding et al. (2012), which uses an unsupervised method.

As mentioned in Section 1, many approaches learn unsupervised word embeddings. In our experiments we use word2vec (Mikolov et al., 2013) as a representative scalable model for unsupervised embeddings. WSABIE (Weston et al., 2011) is a supervised embedding approach that has shown promise in NLP tasks (Weston et al., 2013; Hermann et al., 2014). WSABIE is shallow, linear, and ignores word order information, and so may have less modeling power than our approach.

Convolutional neural networks (CNNs), in which shared weights are applied across the input, are popular in the vision domain and have recently been applied to semantic role labeling (Collobert et al., 2011) and parsing (Collobert, 2011). Neural networks in general have also been applied to part-of-speech tagging, chunking, named entity recognition (Collobert et al., 2011; Turian et al., 2010), and sentiment detection (Socher et al., 2013). All these tasks involve predicting a limited (2-30) number of labels. In this work, we make use of CNNs, but apply them to the task of ranking a very large set of tags. We thus propose a model and training scheme that can scale to this class of problem.

3 Convolutional Embedding Model

Our model #TAGSPACE (see Figure 1), like other word embedding models, starts by assigning a d-dimensional vector to each of the l words of an input document $w_1, \ldots, w_l$, resulting in a matrix of size $l \times d$. This is achieved using a matrix of $N \times d$ parameters, termed the lookup-table layer (Collobert et al., 2011), where N is the vocabulary size. In this work N is 10^6, and each row of the matrix represents one of the million most frequent words in the training corpus.

A convolution layer is then applied to the $l \times d$ input matrix, which considers all successive windows of text of size K, sliding over the document from position 1 to l. This requires a further $Kd \times H$ weights and H biases to be learned. To account for words at the two boundaries of the document we also apply a special padding vector at both ends. In our experiments K was set to 5 and H was set to 1000. After the convolutional step, a $\tanh$ nonlinearity followed by a $\max$ operation over the $l \times H$ features extracts a fixed-size (H-dimensional) global feature vector, which is independent of document size. Finally, another $\tanh$ non-linearity followed by a fully connected linear layer of size $H \times d$ is applied to represent the entire document in the original embedding space of d-dimensions.

Hashtags are also represented using d-dimensional embeddings using a lookup-table. We represent the top 100,000 most frequent tags. For a given document w we then rank any given hashtag t using the scoring function:

$$f(w,t) = e_{conv}(w) \cdot e_{lt}(t)$$

where $e_{conv}(w)$ is the embedding of the document by the CNN just described and $e_{lt}(t)$ is the embedding of a candidate tag t. We can thus rank all candidate hashtags via their scores $f(w,t)$, largest first.

To train the above scoring function, and hence the parameters of the model we minimize a ranking loss similar to the one used in WSABIE as a training objective: for each training example, we sample a positive tag, compute $f(w,t^+)$, then sample random tags $\bar{t}$ up to 1000 times until $f(w,\bar{t}) > m + f(w,t^+)$, where m is the margin. A gradient step is then made to optimize the pairwise hinge loss:

$$\mathcal{L} = \max\{0, m - f(w,t^+) + f(w,\bar{t})\}.$$

We use $m = 0.1$ in our experiments. This loss function is referred to as the WARP loss in (Weston et al., 2011) and is used to approximately optimizing the top of the ranked list, useful for metrics like precision and recall@k. In particular, the search for a negative candidate tag means that more energy is spent on improving the ranking performance of positive labels already near the top of the ranked list, compared to only randomly sampling of negatives, which would optimize the average rank instead.

Minimizing our loss is achieved with parallel stochastic gradient descent using the hogwild algorithm (Niu et al., 2011). The lookup-table layers are initialized with the embeddings learned by WSABIE to expedite convergence. This kind of 'pre-training' is a standard trick in the neural network literature, see e.g. (Socher et al., 2011).

The ranking loss makes our model scalable to 100,000 (or more) hashtags. At each training example only a subset of tags have to be computed, so it is far more efficient than a standard classification loss that considers them all.

4 Experiments

4.1 Data

Our experiments use two large corpora of posts containing hashtags from a popular social network.[1] The first corpus, which we call *people*, consists of 201 million posts from individual user accounts, comprising 5.5 billion words.

The second corpus, which we call *pages*, consists of 35.3 million page posts, comprising 1.6 billion words. These posts' authorial voice is a public entity, such as a business, celebrity, brand, or product. The posts in the pages dataset are presumably intended for a wider, more general audience than the posts in the people dataset. Both are summarized in Table 1.

Dataset	Posts (millions)	Words (billions)	Top 4 tags
Pages	35.3	1.6	`#fitness`, `#beauty`, `#luxury`, `#cars`
People	201	5.5	`#FacebookIs10`, `#love`, `#tbt`, `#happy`

Table 1: Datasets used in hashtag prediction.

Both corpora comprise posts between February 1st and February 17th, 2014. Since we are not attempting a multi-language model, we use a simple trigram-based language prediction model to consider only posts whose most likely language is English.

The two datasets use hashtags very differently. The pages dataset has a fatter head, with popular tags covering more examples. The people dataset uses obscure tags more heavily. For example, the top 100 tags account for 33.9% of page tags, but only 13.1% of people tags.

4.2 Hashtag prediction

The hashtag prediction task attempts to rank a post's ground-truth hashtags higher than hashtags it does not contain. We trained models on both the people and page datasets, and collected precision at 1, recall at 10, and mean rank for 50,000 randomly selected posts withheld from training. A further 50,000 withheld posts are used for selecting hyperparameters. We compare #TAGSPACE with the following models:

Frequency This simple baseline ignores input text, always ranking hashtags by their frequency in the training data.

#words This baseline assigns each tag a static score based on its frequency plus a large bonus if it corresponds to a word in the input text. For example, on input "crazy commute this am", #words ranks `#crazy`, `#commute`, `#this` and `#am` highest, in frequency order.

Word2vec We trained the unsupervised model of Mikolov et al. (2013) on both datasets, treating hashtags the same as all other words. To ap-

Table 2: #TAGSPACE (256 dim) predictions for some example posts.

ply these word embeddings to ranking, we first sum the embeddings of each word in the text (as word2vec does), and then rank hashtags by similarity of their embedding to that of the text.[2]

WSABIE (Weston et al., 2011) is a supervised bilinear embedding model. Each word and tag has an embedding. The words in a text are averaged to produce an embedding of the text, and hashtags are ranked by similarity to the text embedding. That is, the model is of the form:

$$f(w,t) = w^\top U^\top V t$$

where the post w is represented as a bag of words (a sparse vector in $\mathbb{R}^N$), the tag is a one-hot-vector in $\mathbb{R}^N$, and U and V are $k \times N$ embedding matrices. The WARP loss, as described in section 3, is used for training.

Performance of all these models at hashtag prediction is summarized in Tables 3 and 4. We find similar results for both datasets. The frequency and #words baselines perform poorly across the board, establishing the need to learn from text. Among the learning models, the unsupervised word2vec performs the worst. We believe this is due to it being unsupervised – adding supervision better optimizes the metric we evaluate. #TAGSPACE outperforms WSABIE at all dimensionalities. Due to the relatively large test sets, the results are statistically significant; for example, comparing #TAGSPACE (64 dim) beats Wsabie (64 dim) for the page dataset 56% of the time, and draws 23% of the time in terms of the rank metric, and is statistically significant with a Wilcoxon signed-rank test.

Some example predictions for #TAGSPACE are given for some constructed examples in Table 2. We also show nearest word embeddings to the posts. Training data was collected at the time of the pax winter storm, explaining predictions for the first post, and Kevin Spacey appears in the show "House of Cards,". In all cases the hashtags reveal labels that capture the semantics of the posts, not just syntactic similarity of individual words.

Comparison to Production System We also compare to a proprietary system in production in Facebook for hashtag prediction. It trains a logistic regression model for every hashtag, using a bag of unigrams, bigrams, and trigrams as the

[2]Note that the unsupervised Word2vec embeddings could be used as input to a supervised classifier, which we did not do. For a supervised embedding baseline we instead use WSABIE. WSABIE trains word embeddings U and hashtag embeddings V in a supervised fashion, whereas Word2vec trains them both unsupervised. Adding supervision to Word2vec would effectively do something in-between: U would still be unsupervised, but V would then be supervised.

#TAGSPACE	256	**37.42%**	**43.01%**	**1155**

Table 4: Hashtag test results for pages dataset.

input features. Unlike the other models we consider here, this baseline has been trained using a set of approximately 10 million posts. Engineering constraints prevent measuring mean rank performance. We present it here as a serious effort at solving the same problem from outside the embedding paradigm. On the people dataset this system achieves 3.47% P@1 and 5.33% R@10. On the pages dataset it obtains 5.97% P@1 and 6.30% R@10. It is thus outperformed by our method. However, we note the differences in experimental setting mean this comparison is perhaps not completely fair (different training sets). We expect performance of linear models such as this to be similar to WSABIE as that has been in the case in other datasets (Gupta et al., 2014), but at the cost of more memory usage. Note that models like logistic regression and SVM do not scale well if you have millions of hashtags, which we could handle in our models.

4.3 Personalized document recommendation

To investigate the generality of these learned representations, we apply them to the task of recommending documents to users based on the user's interaction history. The data for this task comprise anonymized day-long interaction histories for a tiny subset of people on a popular social networking service. For each of the 34 thousand people considered, we collected the text of between 5 and 167 posts that she has expressed previous positive interactions with (likes, clicks, etc.). Given the person's trailing $n-1$ posts, we use our models to predict the n'th post by ranking it against 10,000 other unrelated posts, and measuring precison and recall. The score of the n^{th} post is obtained by taking the max similarity over the $n-1$ posts. We use cosine similarity between post embeddings instead of the inner product that was used for hashtag training so that the scores are not unduly influenced by document length. All learned hashtag models were trained on the people dataset. We also consider a TF-IDF weighted bag-of-words baseline (BoW). The results are given in Table 5.

Method	dim	P@1	R@10	R@50
Word2Vec	256	0.75%	1.96%	3.82%
BoW	-	1.36%	4.29%	8.03%
WSABIE	64	0.98%	3.14%	6.65%
WSABIE	128	1.02%	3.30%	6.71%
WSABIE	256	1.01%	2.98%	5.99%
WSABIE	512	1.01%	2.76%	5.19%
#TAGSPACE	64	1.27%	4.56%	9.64%
#TAGSPACE	128	1.48%	4.74%	9.96%
#TAGSPACE	256	**1.66%**	**5.29%**	**10.69%**
WSABIE+ BoW	64	1.61%	4.83%	9.00%
#TAGSPACE+ BoW	64	1.80%	5.90%	11.22%
#TAGSPACE+ BoW	256	**1.92%**	**6.15%**	**11.53%**

Table 5: Document recommendation task results.

Hashtag-based embeddings outperform BoW and unsupervised embeddings across the board, and #TAGSPACE outperforms WSABIE. The best results come from summing the bag-of-words scores with those of #TAGSPACE.

5 Conclusion

#TAGSPACE is a convolutional neural network that learns to rank hashtags with a minimum of task-specific assumptions and engineering. It performs well, beating several baselines and an industrial system engineered for hashtag prediction. The semantics of hashtags cause #TAGSPACE to learn a representation that captures many salient aspects of text. This representation is general enough to port to the task of personalized document recommendation, where it outperforms other well-known representations.

Abstract

In this paper, we provide a new method for decoding tree transduction based sentence compression models augmented with language model scores, by jointly decoding two components. In our proposed solution, rich local discriminative features can be easily integrated without increasing computational complexity. Utilizing an unobvious fact that the resulted two components can be independently decoded, we conduct efficient joint decoding based on dual decomposition. Experimental results show that our method outperforms traditional beam search decoding and achieves the state-of-the-art performance.

1 Introduction

Sentence compression is the task of generating a grammatical and shorter summary for a long sentence while preserving its most important information. One specific instantiation is deletion-based compression, namely generating a compression by dropping words. Various approaches have been proposed to challenge the task of deletion-based compression. Earlier pioneering works (Knight and Marcu, 2000) considered several insightful approaches, including noisy-channel based generative models and discriminative decision tree models. Structured discriminative compression models (McDonald, 2006) are capable of integrating rich features and have been proved effective for this task. Another powerful paradigm for sentence compression should be mentioned here is constraints-based compression,including integer linear programming solutions (Clarke and Lapata, 2008) and first-order Markov logic networks (Huang et al., 2012; Yoshikawa et al., 2012).

A notable class of methods that explicitly deal with syntactic structures are tree transduction models (Cohn and Lapata, 2007; Cohn and Lapata, 2009). In such models a synchronous grammar is extracted from a corpus of parallel syntax trees with leaves aligned. Compressions are generated from the grammar with learned weights. Previous works have noticed that local coherence is usually needed by introducing ngram language model scores, which will make accurate decoding intractable. Traditional approaches conduct beam search to find approximate solutions (Cohn and Lapata, 2009).

In this paper we propose a joint decoding strategy to challenge this decoding task. We address the problem as jointly decoding a simple tree transduction model that only considers rule weights and an ngram compression model. Although either part can be independently solved by dynamic programming, the naive way to integrate two groups of partial scores into a huge dynamic programming chart table is computationally impractical. We provide an effective dual decomposition solution that utilizes the efficient decoding of both parts. By integrating rich structured features that cannot be efficiently involved in normal formulation, results get significantly improved.

2 Motivation

Under the tree transduction models, the sentence compression task is formulated as learning a mapping from an input source syntax tree to a target tree with reduced number of leaves. This mapping is known as a synchronous grammar. The synchronous grammar discussed through out this paper will be synchronous tree substitution grammar (STSG), as in previous studies.

In such formulations, sentence compression is finding the best derivation from a syntax tree that produces a simpler target tree, under the current definition of grammar and learned parameters. Each derivation is attached with a score. For the sake of efficient decoding, the score often decom-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1828–1833,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

poses with rules involved in the derivation. A typical score definition for a derivation $\mathbf{y}$ of source tree $\mathbf{x}$ is in such form (Cohn and Lapata, 2008; Cohn and Lapata, 2009):

$$S(\mathbf{x},\mathbf{y}) = \sum_{r \in \mathbf{y}} \mathbf{w}^T \phi_r(\mathbf{x}) + \log P(ngram(\mathbf{y})) \quad (1)$$

The first term is a weighted sum of features $\phi_r(\mathbf{x})$ defined on each rule r. It is plausible to introduce local scores from ngram models. The second term in the above score definition is added with such purpose.

Cohn and Lapata (2009) explained that exact decoding of Equation 1 is intractable. They proposed a beam search decoding strategy coupled with cube-pruning heuristic (Chiang, 2007), which can further improve decoding efficiency at the cost of largely losing exactness in log probability calculations. For efficiency reasons, rich local ngram features have not been introduced as well.

3 Components of Joint Decoding

The score in Equation 1 consists of two parts: sum of weighted rule features and local ngram scores retrieved from a language model. There is an implicit fact that either part can be used alone with slight modifications to generate a coarse candidate compression. Therefore, we can build a joint decoding system that consists of these two independently decodable components.

In this section we will refer to these two independent models as the pure tree transduction model and the pure ngram compression model, described in Section 3.1 and Section 3.2 respectively. There is a direct generalization of the ngram model by introducing rich local features, which results in the structured discriminative models (Section 3.3).

3.1 Pure Tree Transduction model

By merely considering scores from tree transduction rules, i.e. the first part of Equation 1, we can have our scores factorized with rules. Then finding the best derivation from a STSG grammar can be easily solved by a dynamic programming process described by Cohn and Lapata (2007).

This simplified pure tree transduction model can still produce decent compressions if the rule weights are properly learned during training.

3.2 Pure Ngram based Compression

The pure ngram based model will try to find the most locally smooth compression, reflected by having the maximum log probability score of ngrams.

To avoid the trivial solution of deleting all words, we find the target compression with specified length by dynamic programming.

Furthermore, we can integrate features other than log probabilities. This is equivalent to using a structured discriminative model with rich features on ngrams of candidate compressions.

3.3 Structured Discriminative Model

The structured discriminative model proposed by McDonald (2006) defines rich features on bigrams of possible compressions. The score is defined as weighted linear combination of those features:

$$f(\mathbf{x},\mathbf{z}) = \sum_{j=2}^{|\mathbf{z}|} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, L(\mathbf{z}_{j-1}), L(\mathbf{z}_j)) \quad (2)$$

where the function $L(\mathbf{z}_k)$ maps a token $\mathbf{z}_k$ in compression $\mathbf{z}$ back to the index of the original sentence $\mathbf{x}$. Decoding can still be efficiently done by dynamic programming.

With rich local structural information, the structured discriminative model can play a complementary role to the tree transduction model that focus more on global syntactic structures.

4 Joint Decoding

From now on the remaining issue is jointly decoding the components. Either part factorizes over local structures: rules for the tree transduction model and ngrams for the language model or structured discriminative model. We may build a large dynamic programming table to utilize this kind of locality. Unfortunately this is computationally impractical. It is mathematically equivalent to perform exact dynamic programming decoding of Equation 1, which would consume asymptotically $O(SRL^{2(n-1)V})$ [1] time for building the chart (Cohn and Lapata, 2009). Cohn and Lapata (2009) proposed a beam search approximation along with cube-pruning heuristics to reduce the time complexity down to $O(SRBV)$ [2].

[1] S, R, L and V denote respectively for the number of source tree nodes, the number of rules, size of target lexicon and number of variables involved in each rule.

[2] B denotes the beam width.

In this work we utilize the efficiency of independent decoding from the two components respectively and then combine their solutions according to certain standards. This naturally results in a dual decomposition (Rush et al., 2010) solution.

Dual decomposition has been applied in several natural language processing tasks, including dependency parsing (Koo et al., 2010), machine translation (Chang and Collins, 2011; Rush and Collins, 2011) and information extraction (Reichart and Barzilay, 2012). However, the strength of this inference strategy has seldom been noticed in researches on language generation tasks.

We briefly describe the formulation here.

4.1 Description

We denote the pure tree transduction part and the pure ngram part as $g(\mathbf{y})$ and $f(\mathbf{z})$ respectively. Then joint decoding is equivalent to solving:

$$\max_{\mathbf{y}\in\mathcal{Y},\mathbf{z}\in\mathcal{Z}} \quad g(\mathbf{y}) + f(\mathbf{z}) \tag{3}$$

$$\text{s.t.} \quad \mathbf{z}_{kt} = \mathbf{y}_{kt},\ \forall k \in \{1,...,n\},\ \forall t \in \{0,1\},$$

where $\mathbf{y}$ denotes a derivation which yields a final compression $\{\mathbf{y}_1,...,\mathbf{y}_m\}$. This derivation comes from a pure tree transduction model. $\mathbf{z}$ denotes the compression composed of $\{\mathbf{z}_1,...,\mathbf{z}_m\}$ from an ngram compression model. Without loss of generality, we consider $\mathbf{y}_k$ and $\mathbf{z}_k$ as indicators that take value 1 if the k's token of original sentence has been preserved in the compression and 0 if it has been deleted. In the constraints of problem 3, $\mathbf{y}_{kt}$ or $\mathbf{z}_{kt}$ denote indicator variables that take value 1 if $\mathbf{y}_k$ or $\mathbf{z}_k = t$ and 0 otherwise.

Let $L(u,\mathbf{y},\mathbf{z})$ be the Lagrangian of (3). Then the dual objective naturally factorizes into two parts that can be evaluated independently:

$$\begin{aligned} L(u) &= \max_{\mathbf{y}\in\mathcal{Y},\mathbf{z}\in\mathcal{Z}} L(u,\mathbf{y},\mathbf{z}) \\ &= \max_{\mathbf{y}\in\mathcal{Y},\mathbf{z}\in\mathcal{Z}} g(\mathbf{y}) + f(\mathbf{z}) + \sum_{k,t} u_{kt}(\mathbf{z}_{kt} - \mathbf{y}_{kt}) \\ &= \max_{\mathbf{y}\in\mathcal{Y}}(g(\mathbf{y}) - \sum_{k,t} u_{kt}\mathbf{y}_{kt}) + \\ &\quad \max_{\mathbf{z}\in\mathcal{Z}}(f(\mathbf{z}) + \sum_{k,t} u_{kt}\mathbf{z}_{kt}) \end{aligned}$$

With this factorization, Algorithm 1 tries to solve the dual problem $\min_u L(u)$ by alternatively decoding each component.

This framework is feasible and plausible in that the two subproblems (line 3 and line 4 in Algorithm 1) can be easily solved with slight modifications on the values of the original dynamic programming chart. Joint decoding of a pure tree transduction model and a structured discriminative model is almost the same.

Algorithm 1 Dual Decomposition Joint Decoding

1: **Initialization**: $u_k^{(0)} = 0,\ \forall k \in \{1,...,n\}$
2: **for** $i = 1$ to MAX_ITER **do**
3: $\quad \mathbf{y}^{(i)} \leftarrow \text{argmax}_{\mathbf{y}\in\mathcal{Y}}(g(\mathbf{y}) - \sum_{k,t} u_{kt}^{(i-1)}\mathbf{y}_{kt})$
4: $\quad \mathbf{z}^{(i)} \leftarrow \text{argmax}_{\mathbf{z}\in\mathcal{Z}}(f(\mathbf{z}) + \sum_{k,t} u_{kt}^{(i-1)}\mathbf{z}_{kt})$
5: $\quad$ **if** $\mathbf{y}_{kt}^{(i)} = \mathbf{z}_{kt}^{(i)}\ \forall k\ \forall t$ **then**
6: $\quad\quad$ **return** $(\mathbf{y}^{(i)}, \mathbf{z}^{(i)})$
7: $\quad$ **else**
8: $\quad\quad u_{kt}^{(i)} \leftarrow u_{kt}^{(i-1)} - \delta_i(\mathbf{z}_{kt}^{(i)} - \mathbf{y}_{kt}^{(i)})$
9: $\quad$ **end if**
10: **end for**

The asymptotic time complexity of Algorithm 1 is $O(k(SRV + L^{2(n-1)}))$, where k denotes the number of iterations. This is a significant reduction of $O(SRL^{2(n-1)V})$ by directly solving the original problem and is also comparable to $O(SRBV)$ of conducting beam search decoding.

We apply a similar heuristic with Rush and Collins (2012) to set the step size $\delta_i = \frac{1}{t+1}$, where $t < i$ is the number of past iterations that increase the dual value. This setting decreases the step size only when the dual value moves towards the wrong direction. We limit the maximum iteration number to 50 and return the best primal solution $\mathbf{y}^{(i)}$ among all previous iterations for cases that do not converge in reasonable time.

5 Experiments

5.1 Baselines

The pure tree transduction model and the discriminative model naturally become part of our baselines for comparison [3]. Besides comparing our methods against the tree-transduction model with ngram scores by beam search decoding, we also compare them against the available previous work from Galanis and Androutsopoulos (2010). This state-of-the-art work adopts a two-stage method to rerank results generated by a discriminative maximum entropy model.

5.2 Data Preparation

We evaluated our methods on two standard corpora [4], refer to as Written and Spoken respectively.

[3] The pure ngram language model should not be considered here as it requires additional length constraints and in general does not produce competitive results at all merely by itself.

[4] Available at http://jamesclarke.net/research/resources

We split the datasets according to Table 1.

Table 1: Dataset partition (number of sentences)

Corpus	Training	Development	Testing
Written	1,014	324	294
Spoken	931	83	254

All tree transduction models require parallel parse trees with aligned leaves. We parsed all sentences with the Stanford Parser [5] and aligned sentence pairs with minimum edit distance heuristic [6]. Syntactic features of the discriminative model were also taken from these parse trees.

For systems involving ngram scores, we trained a trigram language model on the Reuters Corpus (Volume 1) [7] with modified Kneser-Ney smoothing, using the widely used tool SRILM [8].

5.3 Model Training

The training process of a tree transduction model followed similarly to Cohn and Lapata (2007) using structured SVMs (Tsochantaridis et al., 2005). The structured discriminative models were trained according to McDonald (2006).

5.4 Evaluation Metrics

We assessed the compression results by the F1-score of grammatical relations (provided by a dependency parser) of generated compressions against the gold-standard compression (Clarke and Lapata, 2006). All systems were controlled to produce similar compression ratios (CR) for fair comparison. We also reported manual evaluation on a sampled subset of 30 sentences from each dataset. Three unpaid volunteers with self-reported fluency in English were asked to rate every candidate. Ratings are in the form of 1-5 scores for each compression.

6 Results

We report test set performance of the structured discriminative model, the pure tree transduction (T3), Galanis and Androutsopoulos (2010)'s method (G&A2010), tree transduction with language model scores by beam search and the proposed joint decoding solutions.

[5] http://nlp.stanford.edu/software/lex-parser.shtml

[6] Ties were broken by always aligning a token in compression to its last appearance in the original sentence. This may better preserve the alignments of full constituents.

[7] http://trec.nist.gov/data/reuters/reuters.html

[8] http://www-speech.sri.com/projects/srilm/

Table 2 shows the compression ratios and F-measure of grammatical relations in average for each dataset. Table 3 presents averaged human rating results for each dataset. We carried out pairwise t-test to examine the statistical significance of the differences [9]. In both datasets joint decoding with dual decomposition solution outperforms other systems, especially when structured models involved. We can also find certain improvements of joint modeling with dual decomposition on the original beam search decoding of Equation 1, under very close compression ratios.

Joint decoding of pure tree transduction and discriminative model gives better performance than the joint model of tree transduction and language model. From Table 3 we can see that integrating discriminative model will mostly improve the preservation of important information rather than grammaticality. This is reasonable under the fact that the language model is trained on large scale data and will often preserve local grammatical coherence, while the discriminative model is trained on small but more compression specific corpora.

Table 2: Results of automatic evaluation. (†: sig. diff. from T3+LM(DD); *: sig. diff. from T3+Discr.(DD) for $p < 0.01$)

Written	CR(%)	GR-F1(%)
Discriminative	70.3	$52.4^{\dagger *}$

under generation of pure tree transduction is that it mainly deals with global syntactic integrity merely in terms of the application of synchronous rules. Introducing language model scores will smooth the candidate compressions and avoid many aggressive decisions of tree transduction. Discriminative models are good at local decisions with poor consideration of grammaticality. We can see that the joint models have collected their predictive power together. Unfortunately we can still observe some redundancy from our outputs in the examples. The size of training corpus is not large enough to provide enough lexicalized information.

On the other hand, the time consumption of the joint model with dual decomposition decoding in our experiments matched the aforementioned asymptotic analysis. The training process based on new decoding method consumes similar time as beam search with cube-pruning heuristic.

7 Conclusion and Future Work

In this paper we propose a joint decoding scheme for tree transduction based sentence compression. Experimental results suggest that the proposed framework works well. The overall performance gets further improved under our framework by introducing the structured discriminative model.

As several recent efforts have focused on extracting large-scale parallel corpus for sentence compression (Filippova and Altun, 2013), we would like to study how larger corpora can affect tree transduction and our joint decoding solution. Meanwhile, We would like to explore on how other text-rewriting problems can be formulated as a joint model and be applicable to similar strategies described in this work.

Abstract

The current state-of-the-art single-document summarization method generates a summary by solving a Tree Knapsack Problem (TKP), which is the problem of finding the optimal rooted subtree of the dependency-based discourse tree (DEP-DT) of a document. We can obtain a gold DEP-DT by transforming a gold Rhetorical Structure Theory-based discourse tree (RST-DT). However, there is still a large difference between the ROUGE scores of a system with a gold DEP-DT and a system with a DEP-DT obtained from an automatically parsed RST-DT. To improve the ROUGE score, we propose a novel discourse parser that directly generates the DEP-DT. The evaluation results showed that the TKP with our parser outperformed that with the state-of-the-art RST-DT parser, and achieved almost equivalent ROUGE scores to the TKP with the gold DEP-DT.

1 Introduction

Discourse structures of documents are believed to be highly beneficial for generating informative and coherent summaries. Several discourse-based summarization methods have been developed, such as (Marcu, 1998; Daumé III and Marcu, 2002; Hirao et al., 2013; Kikuchi et al., 2014). Moreover, the current best ROUGE score for the summarization benchmark data of the RST-discourse Treebank (Carlson et al., 2002) has been provided by (Hirao et al., 2013), whose method also utilizes discourse trees. Thus, the discourse-based summarization approach is one promising way to obtain high-quality summaries.

One possible weakness of discourse-based summarization techniques is that they rely greatly on the accuracy of the discourse parser they use. For example, the above discourse-based summarization methods utilize discourse trees based on the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) for their discourse information. Unfortunately, the current state-of-the-art RST parser, as described in (Hernault et al., 2010), is insufficient as an off-the-shelf discourse parser. In fact, there is empirical evidence that the quality (i.e., ROUGE score) of summaries from auto-parsed discourse trees is significantly degraded compared with those generated from gold discourse trees (Marcu, 1998; Hirao et al., 2013).

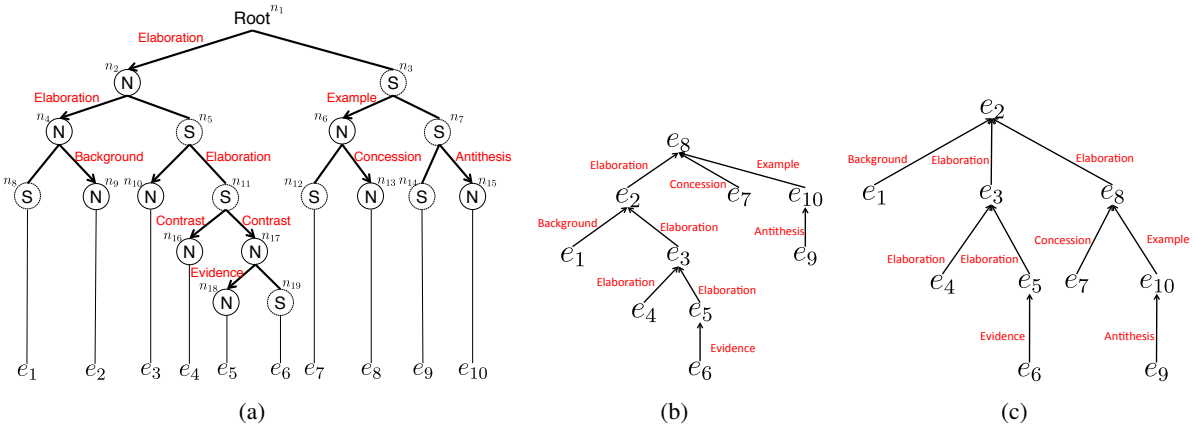
From this background, the goal of this paper is to develop an appropriate discourse parser for discourse-based summarization. We first focus on one of the best discourse-based single document summarization methods as proposed in (Hirao et al., 2013). Their method formulates a single document summarization problem as a Tree Knapsack Problem (TKP) over a dependency-based discourse tree (DEP-DT). In their method, DEP-DTs are automatically transformed from (auto-parsed) RST-discourse trees (RST-DTs) by heuristic rules. Instead, we develop a DEP-DT parser, that directly provides DEP-DTs for their state-of-the-art discourse-based summarization method. We show that summaries generated by our parser improve the ROUGE scores to almost the same level as those generated by gold DEP-DTs. We also investigate the way in which the parsing accuracy helps to improve the ROUGE scores.

2 Single-Document Summarization as a Tree Knapsack Problem

Hirao et al. (2013) formulated single-document summarization as a TKP that is run on the DEP-DT. They obtained a summary by trimming the DEP-DT, i.e. the summary is a rooted subtree of the DEP-DT.

Suppose that we have N EDUs in a document,

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1834–1839,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics



(a) (b) (c)

Figure 1: Examples of RST-DT and DEP-DT. $e_1, \cdots, e_{10}$ are EDUs. (a) Example of an RST-DT from (Marcu, 1998). $n_1, \cdots, n_{19}$ are the non-terminal nodes. (b) Example of the DEP-DT obtained from the incorrect RST-DT that is made by swapping the Nucleus-Satellite relationship of the node n_2 and the node n_3. (c) The correct DEP-DT obtained from the RST-DT in (a).

and the i-th EDU e_i has l_i words. L is the maximum number of words allowed in a summary. In the TKP, if we select e_i, we need to select its parent EDU in the DEP-DT. We denote parent(i) as the index of the parent of e_i in the DEP-DT. $\mathbf{x}$ is an N-dimensional binary vector that represents a summary, i.e. $x_i = 1$ denotes that e_i is included in the summary. The TKP is defined as the following ILP problem:

$$\begin{aligned} \underset{\mathbf{x}}{\text{maximize}} \quad & \textstyle\sum_{i=1}^{N} F(e_i) x_i \\ s.t. \quad & \textstyle\sum_{i=1}^{N} l_i x_i \leq L \\ & \forall i : x_{\text{parent}(i)} \geq x_i \\ & \forall i : x_i \in \{0, 1\}, \end{aligned}$$

where $F(e_i)$ is the score of e_i. We define $F(e_i)$ as follows:

$$F(e_i) = \frac{\sum_{w \in W(e_i)} \text{tf}(w, D)}{\text{Depth}(e_i)},$$

where $W(e_i)$ is the set of words contained in e_i. tf(w, D) is the term frequency of word w in a document D. Depth(e_i) is the depth of e_i in the DEP-DT.

3 Tree Knapsack Problem with Dependency-based Discourse Parser

3.1 Motivation

In (Hirao et al., 2013), they automatically obtain the DEP-DT by transforming from the parsed RST-DT. We simply followed their method for obtaining the DEP-DTs [1]. The transformation algorithm can be found in detail in (Hirao et al., 2013). Figure 1(a) shows an example of the RST-DT. According to RST, a document is represented as a tree whose terminal nodes correspond to elementary discourse units (EDUs) and whose non-terminal nodes indicate the role of the contiguous EDUs, namely, 'nucleus (N)' or 'satellite (S)'. Since a nucleus is more important than a satellite in terms of the writer's purpose, a satellite is always a child of a nucleus in the RST-DT. Some discourse relations between a nucleus and a satellite or two nuclei are defined.

Since the TKP of (Hirao et al., 2013) employs a DEP-DT obtained from an automatically parsed RST-DT, their method strongly relies on the accuracy of the RST parser. For example, in Figure 1(a), if the RST-DT parser incorrectly sets the node n_2 as Satellite and the node n_3 as Nucleus, we obtain an incorrect DEP-DT in Figure 1(b) because the transformation algorithm uses the Nucleus-Satellite relationships in the RST-DT. The dependency relationships in Figure 1(b) are quite different from that of the correct DEP-DT in Figure 1(c). In this example, the parser failed to determine the most salient EDU e_2, that is the root EDU of the gold DEP-DT. Thus, the summary extracted from this DEP-DT will have a low ROUGE score.

The results motivated us to design a new discourse parser fully trained on the DEP-DTs and

[1] Li et al. also defined a similar transformation algorithm (Li et al., 2014). In this paper, we follow the transformation algorithm defined in (Hirao et al., 2013).

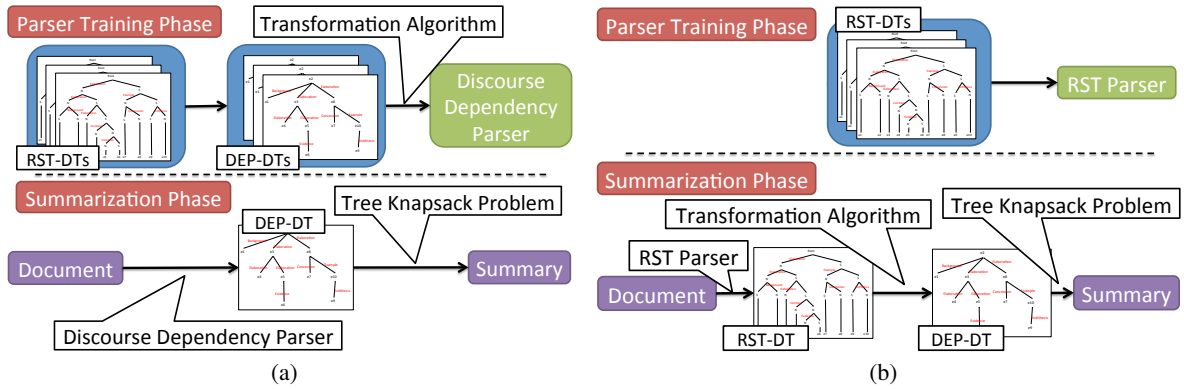


Figure 2: (a) Overview of our proposed method. In the parser training phase, the parser is trained on the DEP-DTs, and in the summarization phase, the document is directly parsed into the DEP-DT. (b) Overview of (Hirao et al., 2013). In the parser training phase, the parser is trained on RST-DTs, and in the summarization phase, the document is parsed into the RST-DT, and then transformed into the DEP-DT.

that could directly generate the DEP-DT. Figure 2(a) shows an overview of the TKP combined with our DEP-DT parser. In the parser training phase, we transform RST-DTs into DEP-DTs, and directly train our parser with the DEP-DTs. In the summarization phase, our method parses a raw document directly into a DEP-DT, and generates a summary with the TKP.

3.2 Description of Discourse Dependency Parser

Our parser is based on the first-order Maximum Spanning Tree (MST) algorithm (McDonald et al., 2005b). Our parser extracts the features from the EDU e_i and the EDU e_j. We use almost the features as those shown in (Hernault et al., 2010). **Lexical N-gram features** use the beginning (or end) lexical N-grams ($N \in \{1, 2, 3\}$) in e_i and e_j. We also include POS tags for the beginning (or end) lexical N-grams ($N \in \{1, 2, 3\}$) in e_i and e_j. **Organizational features** include the distance between e_i and e_j. They also include the number of tokens, and features for identifying whether or not e_i and e_j belong to the same sentence (or paragraph). Soricut et al. (2003) introduced **dominance set features**. They include syntactic labels and the lexical heads of head and attachment nodes along with their dominance relationship. We cannot use the **strong compositionality features** and **rhetorical structure features** described in (Hernault et al., 2010) because we have to know the subtree structures in advance when using these features.

To train the parser, we choose the Margin Infused Relaxed Algorithm (MIRA) (McDonald et al., 2005a; Crammer et al., 2006). We denote $s(\mathbf{w}, \mathbf{y}) = \mathbf{w}^T \mathbf{f}_\mathbf{y}$ as a score function given a weight vector $\mathbf{w}$ and a DEP-DT $\mathbf{y}$. $L(\mathbf{y}, \mathbf{y}^\star)$ is a loss function, and we define it as the number of EDUs that have an incorrect parent EDU in a predicted DEP-DT $\mathbf{y}^\star = \arg\max_{\mathbf{y}} s(\mathbf{w}, \mathbf{y})$. Then, we solve the following optimization problem:

$$\begin{aligned} &\min_{\mathbf{w}} \ ||\mathbf{w} - \mathbf{w}^{(t)}|| \\ &\text{s.t.} \ \ s(\mathbf{w}, \mathbf{y}) - s(\mathbf{w}, \mathbf{y}^\star) \geq L(\mathbf{y}, \mathbf{y}^\star), \end{aligned} \tag{1}$$

where $\mathbf{w}^{(t)}$ is a weight vector in the t-th iteration.

3.3 Redesign of Loss Function for Tree Knapsack Problem

When we make a summary by solving a TKP, we do not necessarily need a DEP-DT where all of the parent-child relationships are correct. This is because we rarely select the EDUs around the leaves in the DEP-DT. On the other hand, the parent-child relationships around the root EDU in the DEP-DT are important because we often select the EDUs around the root EDU. Incorporating these intuitions enables us to develop a DEP-DT parser optimized for the TKP. To incorporate this information, we define the following loss function:

$$L_{\text{Depth}}(\mathbf{y}, \mathbf{y}^\star) = \sum_{(i,r,j) \in \mathbf{y}} \frac{[1 - I(\mathbf{y}^\star, i, j)]}{\text{Depth}(e_i)}, \tag{2}$$

where $I(\mathbf{y}^\star, i, j)$ is an indicator function that equals 1 if EDU e_j is the parent of EDU e_i in the

DEP-DT $\mathbf{y}^\star$ and 0 otherwise. In Section 4, we report results with the original loss function $L(\cdot,\cdot)$ and with the modified loss function $L_{\text{Depth}}(\cdot,\cdot)$.

4 Experimental Evaluation

4.1 Corpus

We used the RST-DT corpus (Carlson et al., 2002) for our experimental evaluations. The corpus consists of 385 Wall Street Journal articles with RST annotation, and 30 of these documents also have one human-made reference summary. We used these 30 documents as the test documents for the summarization evaluation, and used the remaining 355 RST annotated documents as the training data for the parser. Note that we did not use the 30 test documents for the summarization evaluation when we trained the parser.

4.2 Summarization Evaluation

We compared the following three systems that differ in the way they obtain the DEP-DT.

TKP-GOLD Used a DEP-DT converted from a gold RST-DT.

TKP-DIS-DEP Used a DEP-DT automatically parsed by our discourse dependency-based parser (DIS-DEP). Figure 2(a) shows an overview of this system.

TKP-DIS-DEP-LOSS Used a DEP-DT automatically parsed by our discourse dependency-based parser (DIS-DEP). Figure 2(a) shows an overview of this system. It is trained with the loss function defined in equation (2).

TKP-HILDA Used a DEP-DT obtained by transforming a RST-DT parsed by HILDA, a state-of-the-art RST-DT parser (Hernault et al., 2010). Figure 2(b) shows an overview of this system.

Hirao et al. (2013) proved that TKP-HILDA outperformed other methods including Marcu's method (Marcu, 1998), a simple knapsack model, a maximum coverage model and LEAD method that simply takes the first L tokens (L = summary length). Thus, we only employed TKP-HILDA as our baseline.

We follow the evaluation conditions described in (Hirao et al., 2013). The number of tokens in each summary is determined by the number in the human-annotated reference summary. The average length of the reference summaries corresponds to about 10% of the words in the source document. This is also the commonly used evaluation condition for single-document summarization evaluation on the RST-DT corpus. We employed the recall of ROUGE-1, 2 as the evaluation measures.

	ROUGE-1	ROUGE-2
TKP-GOLD	0.321	0.112
TKP-DIS-DEP	0.319	0.109
TKP-DIS-DEP-LOSS	0.323	0.121
TKP-HILDA	0.284	0.093

Table 1: ROUGE Recall scores

Table 1 shows ROUGE scores on the RST-DT corpus. We can see TKP-DIS-DEP and TKP-DIS-DEP-LOSS outperformed TKP-HILDA, and achieved almost the same ROUGE scores as TKP-GOLD. Wilcoxon's signed rank test in terms of ROUGE rejected the null hypothesis, "there is a difference between TKP-HILDA and TKP-DIS-DEP (or TKP-DIS-DEP-LOSS)" (Wilcoxon, 1945). This would be because test documents are relatively small.

We analyzed the differences between the proposed systems (TKP-DIS-DEP and TKP-DIS-DEP-LOSS) and TKP-HILDA. First, we evaluated the overlaps between the EDUs in summaries generated by the system and the EDUs in summaries generated by TKP-GOLD. To see the overlaps, we calculated the average F-value using Recall and Precision defined as follows: Recall $= |S_s \cap S_g|/|S_g|$, Precision $= |S_s \cap S_g|/|S_s|$, where S_s is a set of EDUs in a summary generated by a system, and S_g a set of EDUs in a summary generated by TKP-GOLD. The first line in Table 2 shows the results. TKP-DIS-DEP and TKP-DIS-DEP-LOSS outperformed TKP-HILDA as regards the average F-values. The result revealed that TKP-DIS-DEP and TKP-DIS-DEP-LOSS have more EDUs in common with TKP-GOLD than TKP-HILDA. This result is evidence that TKP-DIS-DEP and TKP-DIS-DEP-LOSS outperformed TKP-HILDA in terms of ROUGE score.

Second, we evaluated the root accuracy (RA), the rate at which a parser can find the root of DEP-DTs. Since the root of a gold DEP-DT is the most salient EDU in a document, it should be included in the summary. The second line in Table 2 shows that our methods succeeded in extracting the root

	TKP-DIS-DEP	TKP-DIS-DEP-LOSS	TKP-HILDA
Avg F-value	$0.532^{\star}$	$0.532^{\star}$	0.415
RA	$0.933^{\star}$	$0.933^{\star}$	0.733
Avg DAS	$0.847^{\star}$	$0.843^{\star}$	0.596

$\star$: significantly better than TKP-HILDA ($p < .05$)

Table 2: Average F-value, Root Accuracy (RA), and average Dependency Accuracy in Summary (DAS). Wilcoxon's signed rank test in terms of average F-value, RA and DAS accepted the null hypothesis.

TKP-GOLD:
Elcotel Inc. expects fiscal second-quarter earnings to trail 1988 results. **Elcotel, a telecommunications company, had net income of $272,000, or five cents a share, in its year-earlier second quarter.** The lower results, Mr. Pierce said. Elcotel will also benefit from moving into other areas. Elcotel has also developed an automatic call processor. Automatic call processors will provide that system for virtually any telephone, Mr. Pierce said, not just phones.

TKP-DIS-DEP, TKP-DIS-DEP-LOSS:
Elcotel Inc. expects fiscal second-quarter earnings to trail 1988 results. Elcotel, a telecommunications company, had net income of $272,000, or five cents a share, in its year-earlier second quarter. George Pierce, chairman and chief executive officer, said in an interview. Although Mr. Pierce expects that line of business to strengthen in the next year. Elcotel will also benefit from moving into other areas. Elcotel has also developed an automatic call processor.

TKP-HILDA:
Elcotel Inc. expects fiscal second-quarter earnings to trail 1988 results. **That several new products will lead to a "much stronger" performance in its second half.** George Pierce, chairman and chief executive officer, said in an interview. Mr. Pierce said Elcotel should realize a minimum of $10 of recurring net earnings for each machine each month. Elcotel has also developed an automatic call processor. Automatic call processors will provide that system for virtually any telephone.

Figure 3: Summaries of wsj_2317. The sentences shown in bold-face are the root EDUs in each DEP-DT of the summary.

of DEP-DT with high accuracy.

Third, to evaluate the coherency of the generated summaries, we compared the average Dependency Accuracy in Summary (DAS), which is defined as follows:

$$\mathrm{DAS}(S) = \frac{1}{|S|} \sum_{e \in S} \delta(e),$$

$$\delta(e) = \begin{cases} 1 & (\text{if parent}(e) \in S) \\ 0 & (\text{otherwise}), \end{cases}$$

where S is a set of EDUs contained in the summary and parent(e) returns the parent EDU of e in the gold DEP-DT. DAS(S) measures the rate of the correct parent-child relationships in S. When DAS equals 1, the summary is a rooted subtree of the gold DEP-DT. The third line in Table 2 shows the results. The results demonstrate that the summaries generated by TKP-DIS-DEP or TKP-DIS-DEP-LOSS tend to preserve the upper level dependency relationships between the EDUs within the gold DEP-DT.

Figure 3 shows summaries of wsj_2317 generated by the three systems. The EDUs corresponding to the root of the DEP-DT are used in each system shown in boldface. We can see that the root EDU in the gold DEP-DT is found in the summaries generated by TKP-DIS-DEP and TKP-DIS-DEP-LOSS, but not in the summary generated by TKP-HILDA.

5 Conclusion

In this paper, we proposed a novel dependency-based discourse parser for single-document summarization. The parser enables us to obtain the DEP-DT without transforming the RST-DT. The evaluation results showed that the TKP with our parser outperformed that with the state-of-the-art RST-DT parser, and achieved almost equivalent ROUGE scores to the TKP with the gold DEP-DT.

Abstract

We show that semantic relationships can be used to improve word alignment, in addition to the lexical and syntactic features that are typically used. In this paper, we present a method based on a neural network to automatically derive word similarity from monolingual data. We present an extension to word alignment models that exploits word similarity. Our experiments, in both large-scale and resource-limited settings, show improvements in word alignment tasks as well as translation tasks.

1 Introduction

Word alignment is an essential step for learning translation rules in statistical machine translation. The task is to find word-level translation correspondences in parallel text. Formally, given a source sentence $\mathbf{e}$ consisting of words $e_1, e_2, \ldots, e_l$ and a target sentence $\mathbf{f}$ consisting of words $f_1, f_2, \ldots, f_m$, we want to infer an alignment $\mathbf{a}$, a sequence of indices $a_1, a_2, \ldots, a_m$ which indicates, for each target word f_i, the corresponding source word e_{a_i} or a null word. Machine translation systems, including state-of-the-art systems, then use the word-aligned corpus to extract translation rules.

The most widely used methods, the IBM models (Brown et al., 1993) and HMM (Vogel et al., 1996), define a probability distribution $p(\mathbf{f}, \mathbf{a} \mid \mathbf{e})$ that models how each target word f_i is generated from a source word e_{a_i} with respect to an alignment $\mathbf{a}$. The models, however, tend to misalign low-frequency words as they have insufficient training samples. The problem can get worse in low-resource languages. Two branches of research have tried to alleviate the problem. The first branch relies solely on the parallel data; however, additional assumptions about the data are required. This includes, but is not limited to, applying prior distributions (Mermer and Saraçlar, 2011; Vaswani et al., 2012) or smoothing techniques (Zhang and Chiang, 2014). The other branch uses information learned from monolingual data, which is generally easier to acquire than parallel data. Previous work in this branch mostly involves applying syntactic constraints (Yamada and Knight, 2001; Cherry and Lin, 2006; Wang and Zong, 2013) and syntactic features (Toutanova et al., 2002) into the models. The use of syntactic relationships can, however, be limited between historically unrelated language pairs.

Our motivation lies in the fact that a meaningful sentence is not merely a grammatically structured sentence; its semantics can provide insightful information for the task. For example, suppose that the models are uncertain about aligning e to f. If the models are informed that e is semantically related to e', f is semantically related to f', and f' is a translation of e', it should intuitively increase the probability that f is a translation of e. Our work focuses on using such a semantic relationship, in particular, word similarity, to improve word alignments.

In this paper, we propose a method to learn similar words from monolingual data (Section 2) and an extension to word alignment models in which word similarity can be incorporated (Section 3). We demonstrate its application in word alignment and translation (Section 4) and then briefly discuss the novelty of our work in comparison to other methods (Section 5).

2 Learning word similarity

Given a word w, we want to learn a word similarity model $p(w' \mid w)$ of what words w' might be used in place of w. Word similarity can be used to improve word alignment, as in this pa-

[†]Most of the work reported here was performed while the second author was at the University of Southern California.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1840–1845,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

per, but can potentially be useful for other natural language processing tasks as well. Such a model might be obtained from a monolingual thesaurus, in which humans manually provide subjective evaluation for word similarity probabilities, but an automatic method would be preferable. In this section, we present a direct formulation of the word similarity model, which can automatically be trained from monolingual data, and then consider a more practical variant, which we adopt in our experiments.

2.1 Model

Given an arbitrary word type w, we define a word similarity model $p(w' \mid w)$ for all word types w' in the vocabulary V as

$$p(w' \mid w) = \sum_c p(c \mid w)\, p(w' \mid c)$$

where c is a word context represented by a sequence $w_1, w_2, \ldots, w_{2n}$ consisting of n word tokens on the left and n word tokens on the right of w, excluding w. The submodel $p(c \mid w)$ can be a categorical distribution. However, modeling the word context model, $p(w' \mid c)$, as a categorical distribution would cause severe overfitting, because the number of all possible contexts is $|V|^{2n}$, which is exponential in the length of the context. We therefore parameterize it using a feedforward neural network as shown in Figure 1, since the structure has been shown to be effective for language modeling (Bengio et al., 2006; Vaswani et al., 2013). The input to the network is a one-hot representation of each word in c, where the special symbols <s>, </s>, <unk> are reserved for sentence beginning, sentence ending, and words not in the vocabulary. There is an output node for each $w' \in V$, whose activation is $p(w' \mid c)$. Following Bengio et al. (2006), the network uses a shared linear projection matrix to the input embedding layer, which allows information sharing among the context words and also substantially reduces the number of parameters. The input embedding layer has a dimensionality of 150 for each input word. The network uses two hidden layers with 1,000 and 150 rectified linear units, respectively, and a softmax output layer. We arbitrarily use $n = 5$ throughout this paper.

2.2 Training

We extract training data by either collecting or sampling the target words $w \in V$ and their word contexts from monolingual data. The submodel $p(c \mid w)$ can be independently trained easily by maximum likelihood estimation, while the word context model $p(w' \mid c)$ may be difficult to train at scale. We follow previous work (Mnih and Teh, 2012; Vaswani et al., 2013) in adopting noise-contrastive estimation (Gutmann and Hyvärinen, 2010), a fast and simple training algorithm that scales independently of the vocabulary size.

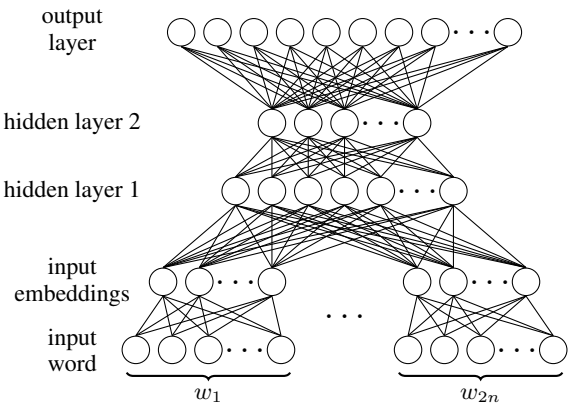

Figure 1: The structure of the word context model

2.3 Model variants

The above formulation of the word similarity model can be interpreted as a mixture model in which w' is similar to w if any of the context probabilities agrees. However, to guard against false positives, we can alternatively reformulate it as a product of experts (Hinton, 1999),

$$p(w' \mid w) = \frac{1}{Z(w)} \exp \sum_c p(c \mid w) \log p(w' \mid c)$$

where $Z(w)$ is a normalization constant. Under this model, w' is similar to w if *all* of the context probabilities agree. Both methods produce reasonably good word similarity; however, in practice, the latter performs better.

Since most of the $p(w' \mid w)$ will be close to zero, for computational efficiency, we can select the k most similar words and renormalize the probabilities. Table 1 shows some examples learned from the 402M-word Xinhua portion of the English Gigaword corpus (LDC2007T07), using a vocabulary V of the 30,000 most frequent words. We set $k = 5$ for illustration purposes.

3 Word alignment model

In this section, we present our word alignment models by extending the standard IBM models.

$p(w' \mid \text{country})$		$p(w' \mid \text{region})$		$p(w' \mid \text{area})$	
country	0.8363	region	0.8338	area	0.8551
region	0.0558	area	0.0760	region	0.0524
nation	0.0522	country	0.0524	zone	0.0338
world	0.0282	province	0.0195	city	0.0326
city	0.0273	city	0.0181	areas	0.0258

Table 1: Examples of word similarity

The method can easily be applied to other related models, for example, the log-linear reparameterization of Model 2 by Dyer et al. (2013). Basically, all the IBM models involve modeling lexical translation probabilities $p(f \mid e)$ which are parameterized as categorical distributions. IBM Model 1, for instance, is defined as

$$p(\mathbf{f}, \mathbf{a} \mid \mathbf{e}) \propto \prod_{i=1}^{m} p(f_i \mid e_{a_i}) = \prod_{i=1}^{m} t(f_i \mid e_{a_i})$$

where each $t(f \mid e)$ denotes the model parameters directly corresponding to $p(f \mid e)$. Models 2–5 and the HMM-based model introduce additional components in order to capture word ordering and word fertility. However, they have $p(f \mid e)$ in common.

3.1 Model

To incorporate word similarity in word alignment models, we redefine the lexical translation probabilities as

$$p(f \mid e) = \sum_{e', f'} p(e' \mid e)\, t(f' \mid e')\, p(f \mid f')$$

for all f, e, including words not in the vocabulary. While the factor $p(e' \mid e)$ can be directly computed by the word similarity model, the factor $p(f \mid f')$ can be problematic because it vanishes for f out of vocabulary. One possible solution would be to use Bayes' rule

$$p(f \mid f') = \frac{p(f' \mid f)\, p(f)}{p(f')}$$

where $p(f' \mid f)$ is computed by the word similarity model. However, we find that this is prone to numerical instability and other complications. In our experiments, we tried the simpler assumption that $p(f \mid f') \approx p(f' \mid f)$, with the rationale that both probabilities are measures of word similarity, which is intuitively a symmetric relation. We also compared the performance of both methods. Table 2 shows that this simple solution works as well as the more exact method of using Bayes' rule. We describe the experiment details in Section 4.

Model	F1	BLEU	
		Test 1	Test 2
Chinese-English			
Bayes' rule	75.7	30.0	27.0
Symmetry assumption	75.3	29.9	27.0
Arabic-English			
Bayes' rule	70.4	37.9	36.7
Symmetry assumption	69.5	38.2	36.8

Table 2: Assuming that word similarity is symmetric, i.e. $p(f \mid f') \approx p(f' \mid f)$, works as well as computing $p(f \mid f')$ using Bayes' rule.

3.2 Re-estimating word similarity

Depending on the quality of word similarity and the distribution of words in the parallel data, applying word similarity directly to the model could lead to an undesirable effect where similar but not interchangeable words rank in the top of the translation probabilities. On the other hand, if we set

$$p(e' \mid e) = \mathbb{1}[e' = e]$$
$$p(f' \mid f) = \mathbb{1}[f' = f]$$

where $\mathbb{1}$ denotes the indicator function, the model reduces to the standard IBM models. To get the best of both worlds, we smooth the two models together so that we rely more on word similarity for rare words and less for frequent words

$$\tilde{p}(w' \mid w) = \frac{\text{count}(w)\mathbb{1}[w' = w] + \alpha\, p(w' \mid w)}{\text{count}(w) + \alpha}$$

This can be thought of as similar to Witten-Bell smoothing, or adding α pseudocounts distributed according to our $p(w' \mid w)$. The hyperparameter α controls how much influence our word similarity model has. We investigated the effect of α by varying this hyperparameter in our word alignment experiments whose details are described in Section 4. Figure 2 shows that performance of the model, as measured by F1 score, is rather insensitive to the choice of α. We used a value of 40 in our experiments.

3.3 Training

Our word alignment models can be trained in the same way as the IBM models using the Expectation Maximization (EM) algorithm to maximize the likelihood of the parallel data. Our extension only introduces an additional time complexity on the order of $\mathcal{O}(k^2)$ on top of the base models, where k is the number of word types used to estimate the full-vocabulary word similarity models.

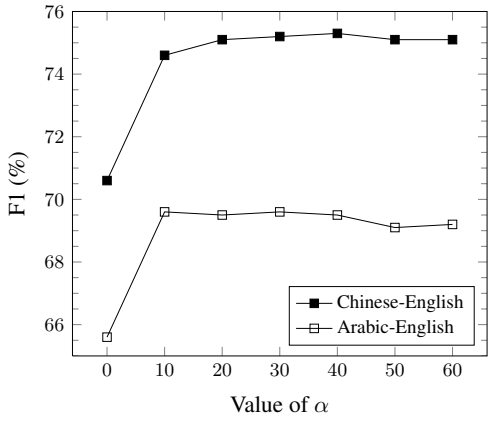

Figure 2: Alignment F1 is fairly insensitive to α over a large range of values

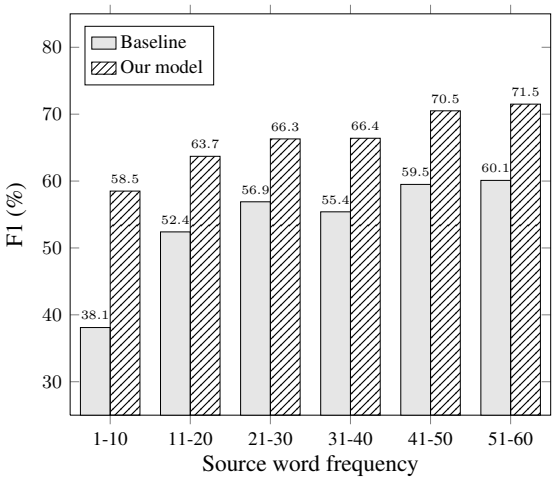

Figure 3: F1 scores for words binned by frequency. Our model gives the largest improvements for the lowest-frequency words.

The larger the value of k is, the closer to the full-vocabulary models our estimations are. In practice, a small value of k seems to be effective since $p(w' \mid w)$ is negligibly small for most w'.

4 Experiments

4.1 Alignment experiments

We conducted word alignment experiments on 2 language pairs: Chinese-English and Arabic-English. For Chinese-English, we used 9.5M+12.3M words of parallel text from the NIST 2009 constrained task[1] and evaluated on 39.6k+50.9k words of hand-aligned data (LDC2010E63, LDC2010E37). For Arabic-English, we used 4.2M+5.4M words of parallel text from the NIST 2009 constrained task[2] and evaluated on 10.7k+15.1k words of hand-aligned data (LDC2006E86). To demonstrate performance under resource-limited settings, we additionally experimented on only the first eighth of the full data, specifically, 1.2M+1.6M words for Chinese-English and 1.0M+1.4M words for Arabic-English. We trained word similarity models on the Xinhua portions of English Gigaword (LDC2007T07), Chinese Gigaword (LDC2007T38), and Arabic Gigaword (LDC2011T1), which are 402M, 323M, and 125M words, respectively. The vocabulary V was the 30,000 most frequent words from each corpus and the $k = 10$ most similar words were used.

We modified GIZA++ (Och and Ney, 2003) to incorporate word similarity. For all experiments, we used the default configuration of GIZA++: 5 iterations each of IBM Model 1, 2, HMM, 3 and 4. We aligned the parallel texts in both forward and backward directions and symmetrized them using grow-diag-final-and (Koehn et al., 2005). We evaluated alignment quality using precision, recall, and F1.

The results in Table 3 suggest that our modeling approach produces better word alignments. We found that our models not only learned smoother translation models for low frequency words but also ranked the conditional probabilities more accurately with respect to the correct translations. To illustrate this, we categorized the alignment links from the Chinese-English low-resource experiment into bins with respect to the English source word frequency and individually evaluated them. As shown in Figure 3, the gain for low frequency words is particularly large.

4.2 Translation experiments

We also ran end-to-end translation experiments. For both languages, we used subsets of the NIST 2004 and 2006 test sets as development data. We used two different data sets as test data: different subsets of the NIST 2004 and 2006 test sets (called Test 1) and the NIST 2008 test sets (called Test 2). We trained a 5-gram language model on the Xinhua portion of English Gigaword (LDC2007T07). We used the Moses toolkit (Koehn et al., 2007) to

Our model (resource-limited)	59.4	80.7	68.4	35.0	33.8	28.7	28.6

Table 3: Experimental results. Our model improves alignments and translations on both language pairs.

build a hierarchical phrase-based translation system (Chiang, 2007) trained using MIRA (Chiang, 2012). Then, we evaluated the translation quality using BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014), and performed significance testing using bootstrap resampling (Koehn, 2004) with 1,000 samples.

Under the resource-limited settings, our methods consistently show 1.1–1.3 BLEU (0.8–1.2 METEOR) improvements on Chinese-English and 0.8–0.9 BLEU (0.8–0.9 METEOR) improvements on Arabic-English, as shown in Table 3. These improvements are statistically significant ($p < 0.01$). On the full data, our method improves Chinese-English translation by 0.3–0.5 BLEU (0.3 METEOR), which is unfortunately not statistically significant, and Arabic-English translation by 0.5–0.6 BLEU (0.5 METEOR), which is statistically significant ($p < 0.01$).

5 Related work

Most previous work on word alignment problems uses morphosyntactic-semantic features, for example, word stems, content words, orthography (De Gispert et al., 2006; Hermjakob, 2009). A variety of log-linear models have been proposed to incorporate these features (Dyer et al., 2011; Berg-Kirkpatrick et al., 2010). These approaches usually require numerical optimization for discriminative training as well as language-specific engineering and may limit their applications to morphologically rich languages.

A more semantic approach resorts to training word alignments on semantic word classes (Ma et al., 2011). However, the resulting alignments are only used to supplement the word alignments learned on lexical words. To our knowledge, our work, which directly incorporates semantic relationships in word alignment models, is novel.

6 Conclusion

We have presented methods to extract word similarity from monolingual data and apply it to word alignment models. Our method can learn similar words and word similarity probabilities, which can be used inside any probability model and in many natural language processing tasks. We have demonstrated its effectiveness in statistical machine translation. The enhanced models can significantly improve alignment quality as well as translation quality.

Abstract

In this paper, we propose a new framework that unifies the output of three information extraction (IE) tasks - entity mentions, relations and events as an information network representation, and extracts all of them using one single joint model based on structured prediction. This novel formulation allows different parts of the information network fully interact with each other. For example, many relations can now be considered as the resultant states of events. Our approach achieves substantial improvements over traditional pipelined approaches, and significantly advances state-of-the-art end-to-end event argument extraction.

1 Introduction

Information extraction (IE) aims to discover entity mentions, relations and events from unstructured texts, and these three subtasks are closely interdependent: entity mentions are core components of relations and events, and the extraction of relations and events can help to accurately recognize entity mentions. In addition, the theory of eventualities (Dölling, 2011) suggested that relations can be viewed as states that events start from and result in. Therefore, it is intuitive but challenging to extract all of them simultaneously in a single model. Some recent research attempted to jointly model multiple IE subtasks (e.g., (Roth and Yih, 2007; Riedel and McCallum, 2011; Yang and Cardie, 2013; Riedel et al., 2009; Singh et al., 2013; Li et al., 2013; Li and Ji, 2014)). For example, Roth and Yih (2007) conducted joint inference over entity mentions and relations; Our previous work jointly extracted event triggers and arguments (Li et al., 2013), and entity mentions and relations (Li and Ji, 2014). However, a single model that can extract all of them has never been studied so far.

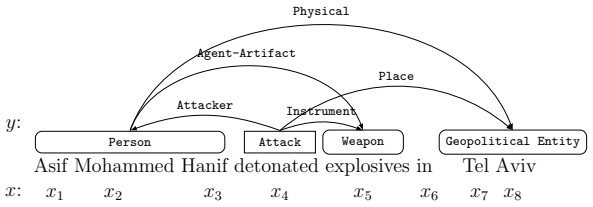

Figure 1: Information Network Representation. Information nodes are denoted by rectangles. Arrows represent information arcs.

For the first time, we uniformly represent the IE output from each sentence as an *information network*, where entity mentions and event triggers are nodes, relations and event-argument links are arcs. We apply a structured perceptron framework with a segment-based beam-search algorithm to construct the *information networks* (Collins, 2002; Li et al., 2013; Li and Ji, 2014). In addition to the perceptron update, we also apply k-best MIRA (McDonald et al., 2005), which refines the perceptron update in three aspects: it is flexible in using various loss functions, it is a large-margin approach, and it can use mulitple candidate structures to tune feature weights.

In an *information network*, we can capture the interactions among multiple nodes by learning joint features during training. In addition to the cross-component dependencies studied in (Li et al., 2013; Li and Ji, 2014), we are able to capture interactions between relations and events. For example, in Figure 1, if we know that the *Person* mention "*Asif Mohammed Hanif*" is an *Attacker* of the *Attack* event triggered by "*detonated*", and the *Weapon* mention "*explosives*" is an *Instrument*, we can infer that there exists an *Agent-Artifact* relation between them. Similarly we can infer the *Physical* relation between "*Asif Mohammed Hanif*" and "*Tel Aviv*".

However, in practice many useful interactions are missing during testing because of the data spar-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1846–1851,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

sity problem of event triggers. We observe that 21.5% of event triggers appear fewer than twice in the ACE'05[1] training data. By using only lexical and syntactic features we are not able to discover the corresponding nodes and their connections. To tackle this problem, we use FrameNet (Baker and Sato, 2003) to generalize event triggers so that semantically similar triggers are clustered in the same frame.

The following sections will elaborate the detailed implementation of our new framework.

2 Approach

We uniformly represent the IE output from each sentence as an *information network* $y = (V, E)$. Each node $v_i \in V$ is represented as a triple $\langle u_i, v_i, t_i \rangle$ of start index u_i, end index v_i, and node type t_i. A node can be an entity mention or an event trigger. A particular type of node is $\perp$ (neither entity mention nor event trigger), whose maximal length is always 1. Similarly, each information arc $e_j \in E$ is represented as $\langle u_j, v_j, r_j \rangle$, where u_j and v_j are the end offsets of the nodes, and r_j is the arc type. For instance, in Figure 1, the event trigger "*detonated*" is represented as $\langle 4, 4, \texttt{Attack} \rangle$, the entity mention "*Asif Mohammed Hanif*" is represented as $\langle 1, 3, \texttt{Person} \rangle$, and their argument arc is $\langle 4, 3, \texttt{Attacker} \rangle$. Our goal is to extract the whole information network y for a given sentence x.

2.1 Decoding Algorithm

Our joint decoding algorithm is based on extending the segment-based algorithm described in our previous work (Li and Ji, 2014). Let $x = (x_1, ..., x_m)$ be the input sentence. The decoder performs two types of actions at each token x_i from left to right:

- NODEACTION(i, j): appends a new node $\langle j, i, t \rangle$ ending at the i-th token, where $i - d_t < j \leq i$, and d_t is the maximal length of type-t nodes in training data.
- ARCACTION(i, j): for each $j < i$, incrementally creates a new arc between the nodes ending at the j-th and i-th tokens respectively: $\langle i, j, r \rangle$.

After each action, the top-k hypotheses are selected according to their features $\mathbf{f}(x, y')$ and weights $\mathbf{w}$:

$$\underset{y' \in buffer}{\text{best}_\text{k}} \ \mathbf{f}(x, y') \cdot \mathbf{w}$$

Since a relation can only occur between a pair of entity mentions, an argument arc can only occur between an entity mention and an event trigger, and each edge must obey certain entity type constraints, during the search we prune invalid ARCACTIONs by checking the types of the nodes ending at the j-th and the i-th tokens. Finally, the top hypothesis in the beam is returned as the final prediction. The upper-bound time complexity of the decoding algorithm is $O(d \cdot b \cdot m^2)$, where d is the maximum size of nodes, b is the beam size, and m is the sentence length. The actual execution time is much shorter, especially when entity type constraints are applied.

2.2 Parameter Estimation

For each training instance (x, y), the structured perceptron algorithm seeks the assignment with the highest model score:

$$z = \underset{y' \in \mathcal{Y}(x)}{\text{argmax}} \, \mathbf{f}(x, y') \cdot \mathbf{w}$$

and then updates the feature weights by using:

$$\mathbf{w}^{new} = \mathbf{w} + \mathbf{f}(x, y) - \mathbf{f}(x, z)$$

We relax the exact inference problem by the aforementioned beam-search procedure. The standard perceptron will cause invalid updates because of inexact search. Therefore we apply early-update (Collins and Roark, 2004), an instance of violation-fixing methods (Huang et al., 2012). In the rest of this paper, we override y and z to denote prefixes of structures.

In addition to the simple perceptron update, we also apply k-best MIRA (McDonald et al., 2005), an online large-margin learning algorithm. During each update, it keeps the norm of the change to feature weights $\mathbf{w}$ as small as possible, and forces the margin between y and the k-best candidate z greater or equal to their loss $L(y, z)$. It is formulated as a quadratic programming problem:

$$\begin{aligned} &\min \|\mathbf{w}^{new} - \mathbf{w}\| \\ &\text{s.t. } \mathbf{w}^{new}\mathbf{f}(x, y) - \mathbf{w}^{new}\mathbf{f}(x, z) \geq L(y, z) \\ &\forall z \in best_k(x, \mathbf{w}) \end{aligned}$$

We employ the following three loss functions for comparison:

[1] http://www.itl.nist.gov/iad/mig//tests/ace

Freq.	Relation Type	Event Type	Arg-1	Arg-2	Example
159	Physical	Transport	Artifact	Destination	He$_{(arg-1)}$ was escorted$_{(trigger)}$ into Iraq$_{(arg-2)}$.
46	Physical	Attack	Target	Place	Many people$_{(arg-1)}$ were in the cafe$_{(arg-2)}$ during the blast$_{(trigger)}$.
42	Agent-Artifact	Attack	Attacker	Instrument	Terrorists$_{(arg-1)}$ might use$_{(trigger)}$ the devices$_{(arg-2)}$ as weapons.
41	Physical	Transport	Artifact	Origin	The truck$_{(arg-1)}$ was carrying$_{(trigger)}$ Syrians fleeing the war in Iraq$_{(arg-2)}$.
33	Physical	Meet	Entity	Place	They$_{(arg-1)}$ have reunited$_{(trigger)}$ with their friends in Norfolk$_{(arg-2)}$.
32	Physical	Die	Victim	Place	Two Marines$_{(arg-1)}$ were killed$_{(trigger)}$ in the fighting in Kut$_{(arg-2)}$.
28	Physical	Attack	Attacker	Place	Protesters$_{(arg-1)}$ have been clashing$_{(trigger)}$ with police in Tehran$_{(arg-2)}$.
26	ORG-Affiliation	End-Position	Person	Entity	NBC$_{(arg-2)}$ is terminating$_{(trigger)}$ freelance reporter Peter Arnett$_{(arg-1)}$.

Table 1: Frequent overlapping relation and event types in the training set.

- The first one is F_1 loss:

$$L_1(y, z) = 1 - \frac{2 \cdot |y \cap z|}{|y| + |z|}$$

When counting the numbers, we treat each node and arc as a single unit. For example, in Figure 1, $|y| = 6$.

- The second one is 0-1 loss:

$$L_2(y, z) = \begin{cases} 1 & y \neq z \\ 0 & y = z \end{cases}$$

It does not discriminate the extent to which z deviates from y.

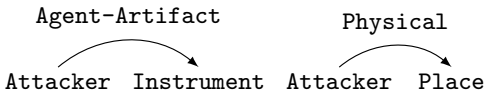
- The third loss function counts the difference between y and z:

$$L_3(y, z) = |y| + |z| - 2 \cdot |y \cap z|$$

Similar to F_1 loss function, it penalizes both missing and false-positive units. The difference is that it is sensitive to the size of y and z.

2.3 Joint Relation-Event Features

By extracting three core IE components in a joint search space, we can utilize joint features over multiple components in addition to factorized features in pipelined approaches. In addition to the features as described in (Li et al., 2013; Li and Ji, 2014), we can make use of joint features between relations and events, given the fact that relations are often ending or starting states of events (Dölling, 2011). Table 1 shows the most frequent overlapping relation and event types in our training data. In each partial structure y' during the search, if both arguments of a relation participate in an event, we compose the corresponding argument roles and relation type as a joint feature for y'. For example, for the structure in Figure 1, we obtain the following joint relation-event features:



Split	Sentences	Mentions	Relations	Triggers	Arguments
Train	7.2k	25.7k	4.8k	2.8k	4.5k
Dev	1.7k	6.3k	1.2k	0.7k	1.1k
Test	1.5k	5.3k	1.1k	0.6k	1.0k

Table 2: Data set

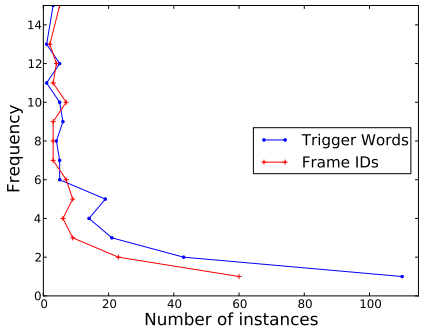


Figure 2: Distribution of triggers and their frames.

2.4 Semantic Frame Features

One major challenge of constructing information networks is the data sparsity problem in extracting event triggers. For instance, in the sentence: "*Others were* **mutilated** *beyond recognition.*" The *Injure* trigger "*mutilated*" does not occur in our training data. But there are some similar words such as "*stab*" and "*smash*". We utilize FrameNet (Baker and Sato, 2003) to solve this problem. FrameNet is a lexical resource for semantic frames. Each frame characterizes a basic type of semantic concept, and contains a number of words (lexical units) that evoke the frame. Many frames are highly related with ACE events. For example, the frame "*Cause_harm*" is closely related with *Injure* event and contains 68 lexical units such as "*stab*", "*smash*" and "*mutilate*".

Figure 2 compares the distributions of trigger words and their frame IDs in the training data. We can clearly see that the trigger word distribution suffers from the long-tail problem, while Frames reduce the number of triggers which occur only

Methods	Entity Mention (%)			Relation (%)			Event Trigger (%)			Event Argument (%)		
	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1

once in the training data from 100 to 60 and alleviate the sparsity problem. For each token, we exploit the frames that contain the combination of its lemma and POS tag as features. For the above example, "*Cause_harm*" will be a feature for "*mutilated*". We only consider tokens that appear in at most 2 frames, and omit the frames that occur fewer than 20 times in our training data.

3 Experiments

3.1 Data and Evaluation

We use ACE'05 corpus to evaluate our method with the same data split as in (Li and Ji, 2014). Table 2 summarizes the statistics of the data set. We report the performance of extracting entity mentions, relations, event triggers and arguments separately using the standard F_1 measures as defined in (Ji and Grishman, 2008; Chan and Roth, 2011):

- An entity mention is correct if its entity type (7 in total) and head offsets are correct.
- A relation is correct if its type (6 in total) and the head offsets of its two arguments are correct.
- An event trigger is correct if its event subtype (33 in total) and offsets are correct.
- An argument link is correct if its event subtype, offsets and role match those of any of the reference argument mentions.

In this paper we focus on entity arguments while disregard values and time expressions because they can be most effectively extracted by handcrafted patterns (Chang and Manning, 2012).

3.2 Results

Based on the results of our development set, we trained all models with 21 iterations and chose the beam size to be 8. For the k-best MIRA updates, we set k as 3. Table 3 compares the overall performance of our approaches and baseline methods.

Our joint model with perceptron update outperforms the state-of-the-art pipelined approach in (Li et al., 2013; Li and Ji, 2014), and further improves the joint event extraction system in (Li et al., 2013) ($p < 0.05$ for entity mention extraction, and $p < 0.01$ for other subtasks, according to Wilcoxon Signed RankTest). For the k-best MIRA update, the L_3 loss function achieved better performance than F_1 loss and 0-1 loss on all sub-tasks except event argument extraction. It also significantly outperforms perceptron update on relation extraction and event argument extraction ($p < 0.01$). It is particularly encouraging to see the end output of an IE system (event arguments) has made significant progress (12.2% absolute gain over traditional pipelined approach).

3.3 Discussions

3.3.1 Feature Study

Rank	Feature		Weight
1	Frame=Killing	Die	0.80
2	Frame=Travel	Transport	0.61
3	Physical(Artifact, Destination)		0.60
4	w_1="home"	Transport	0.59
5	Frame=Arriving	Transport	0.54
6	ORG-AFF(Person, Entity)		0.48
7	Lemma=charge	Charge-Indict	0.45
8	Lemma=birth	Be-Born	0.44
9	Physical(Artifact,Origin)		0.44
10	Frame=Cause_harm	Injure	0.43

Table 4: Top Features about Event Triggers.

Table 4 lists the weights of the most significant features about event triggers. The 3rd, 6th, and 9th rows are joint relation-event features. For instance, *Physical(Artifact, Destination)* means the arguments of a *Physical* relation participate in a *Transport* event as *Artifact* and *Destination*. We can see that both the joint relation-event features

and FrameNet based features are of vital importance to event trigger labeling. We tested the impact of each type of features by excluding them in the experiments of "MIRA w/ L_3 loss". We found that FrameNet based features provided 0.8% and 2.2% F_1 gains for event trigger and argument labeling respectively. Joint relation-event features also provided 0.6% F_1 gain for relation extraction.

3.3.2 Remaining Challenges

Event trigger labeling remains a major bottleneck. In addition to the sparsity problem, the remaining errors suggest to incorporate external world knowledge. For example, some words act as triggers for some certain types of events only when they appear together with some particular arguments:

- "*Williams picked up the child again and this time,* **threw**$_{\texttt{Attack}}$ **her** *out the window.*"
  The word "*threw*" is used as an *Attack* event trigger because the *Victim* argument is a "*child*".
- "*Ellison to spend $10.3 billion to* **get**$_{\texttt{Merge_Org}}$ *his* **company**." The common word "*get*" is tagged as a trigger of *Merge_Org*, because its object is "*company*".
- "*We believe that the likelihood of them* **using**$_{\texttt{Attack}}$ *those* **weapons** *goes up.*"
  The word "*using*" is used as an *Attack* event trigger because the *Instrument* argument is "*weapons*".

Another challenge is to distinguish physical and non-physical events. For example, in the sentence:

- "*we are paying great attention to their ability to* **defend**$_{\texttt{Attack}}$ *on the ground.*",

our system fails to extract "*defend*" as an *Attack* trigger. In the training data, "*defend*" appears multiple times, but none of them is tagged as *Attack*. For instance, in the sentence:

- "*North Korea could do everything to* **defend** *itself.* "

"*defend*" is not an *Attack* trigger since it does not relate to physical actions in a war. This challenge calls for deeper understanding of the contexts.

Finally, some pronouns are used to refer to actual events. Event coreference is necessary to recognize them correctly. For example, in the following two sentences from the same document:

- "*It's important that people all over the world know that we don't believe in the* **war**$_{\texttt{Attack}}$.",
- "*Nobody questions whether* **this**$_{\texttt{Attack}}$ *is right or not.*"

"*this*" refers to "*war*" in its preceding contexts. Without event coreference resolution, it is difficult to tag it as an *Attack* event trigger.

4 Conclusions

We presented the first joint model that effectively extracts entity mentions, relations and events based on a unified representation: information networks. Experiment results on ACE'05 corpus demonstrate that our approach outperforms pipelined method, and improves event-argument performance significantly over the state-of-the-art. In addition to the joint relation-event features, we demonstrated positive impact of using FrameNet to handle the sparsity problem in event trigger labeling.

Although our primary focus in this paper is information extraction in the ACE paradigm, we believe that our framework is general to improve other tightly coupled extraction tasks by capturing the inter-dependencies in the joint search space.

Abstract

The efficiency of Information Extraction systems is known to be heavily influenced by domain-specific knowledge but the cost of developing such systems is considerably high. In this article, we consider the problem of event extraction and show that learning word representations from unlabeled domain-specific data and using them for representing event roles enable to outperform previous state-of-the-art event extraction models on the MUC-4 data set.

1 Introduction

In the Information Extraction (IE) field, event extraction constitutes a challenging task. An event is described by a set of participants (*i.e.* attributes or roles) whose values are text excerpts. The event extraction task is related to several subtasks: event mention detection, candidate role-filler extraction, relation extraction and event template filling. The problem we address here is the detection of role-filler candidates and their association with specific roles in event templates. For this task, IE systems adopt various ways of extracting patterns or generating rules based on the surrounding context, local context and global context (Patwardhan and Riloff, 2009). Current approaches for learning such patterns include bootstrapping techniques (Huang and Riloff, 2012a; Yangarber et al., 2000), weakly supervised learning algorithms (Huang and Riloff, 2011; Sudo et al., 2003; Surdeanu et al., 2006), fully supervised learning approaches (Chieu et al., 2003; Freitag, 1998; Bunescu and Mooney, 2004; Patwardhan and Riloff, 2009) and other variations. All these methods rely on substantial amounts of manually annotated corpora and use a large body of linguistic knowledge. The performance of these approaches is related to the amount of knowledge engineering deployed and a good choice of features and classifiers. Furthermore, the efficiency of the system relies on the a priori knowledge of the applicative domain (the nature of the events) and it is generally difficult to apply a system on a different domain with less annotated data without reconsidering the design of the features used. An important step forwards is TIER$_{light}$ (Huang and Riloff, 2012a) that targeted the minimization of human supervision with a bootstrapping technique for event roles detection. Also, PIPER (Patwardhan and Riloff, 2007; Patwardhan, 2010) distinguishes between relevant and irrelevant regions and learns domain-relevant extraction patterns using a semantic affinity measure. Another possible approach for dealing with this problem is to combine the use a restricted set of manually annotated data with a much larger set of data extracted in an unsupervised way from a corpus. This approach was experimented for relations in the context of Open Information Extraction (Soderland et al., 2010) but not for extracting events and their participants to our knowledge.

In this paper, we propose to approach the task of labeling text spans with event roles by automatically learning relevant features that requires limited prior knowledge, using a neural model to induce semantic word representations (commonly referred as *word embeddings*) in an unsupervised fashion, as in (Bengio et al., 2006; Collobert and Weston, 2008). We exploit these word embeddings as features for a supervised event role (multiclass) classifier. This type of approach has been proved efficient for numerous tasks in natural language processing, including named entity recognition (Turian et al., 2010), semantic role labeling (Collobert et al., 2011), machine translation (Schwenk and Koehn, 2008; Lambert et al., 2012), word sense disambiguation (Bordes et al., 2012) or sentiment analysis (Glorot et al., 2011; Socher et al., 2011) but has never been used, to our knowl-

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

edge, for an event extraction task. Our goal is two-fold: (1) to prove that using as only features word vector representations makes the approach competitive in the event extraction task; (2) to show that these word representations are scalable and robust when varying the size of the training data. Focusing on the data provided in MUC-4 (Lehnert et al., 1992), we prove the relevance of our approach by outperforming state-of-the-art methods, in the same evaluation environment as in previous works.

2 Approach

In this work, we approach the event extraction task by learning word representations from a domain-specific data set and by using these representations to identify the event roles. This idea relies on the assumption that the different words used for a given event role in the text share some semantic properties, related to their context of use and that these similarities can be captured by specific representations that can be automatically induced from the text, in an unsupervised way. We then propose to rely only on these word representations to detect the event roles whereas, in most works (Riloff, 1996; Patwardhan and Riloff, 2007; Huang and Riloff, 2012a; Huang and Riloff, 2012b), the role fillers are represented by a set of different features (raw words, their parts-of-speech, syntactic or semantic roles in the sentence).

Furthermore, we propose two additional contributions to the construction of the word representations. The first one is to exploit limited knowledge about the event types (seed words) to improve the learning procedure by better selecting the dictionary. The second one is to use a *max* operation[1] on the word vector representations in order to build noun phrase representations (since slot fillers are generally noun phrases), which represents a better way of aggregating the semantic information born by the word representations.

2.1 Inducing Domain-Relevant Word Representations

In order to induce the domain-specific word representations, we project the words into a 50-dimensional word space. We chose a single layer neural network (NN) architecture that avoids strongly engineered features, assumes little prior knowledge about the task, but is powerful enough to capture relevant domain information. Following (Collobert et al., 2011), we use an NN which learns to predict whether a given text sequence (short word window) exists naturally in the considered domain. We represent an input sequence of n words as $\langle w_i \rangle = \langle w_{i-(n/2)} \ldots, w_i, \ldots w_{i+(n/2)} \rangle$. The main idea is that each sequence of words in the training set should receive a higher score than a sequence in which one word is replaced with a random one. We call the sequence with a random word *corrupted* ($\langle \bar{w_i} \rangle$) and denote as *correct* ($\langle w_i \rangle$) all the sequences of words from the data set. The goal of the training step is then to minimize the following loss function for a word w_i in the dictionary D: $C_{w_i} = \sum_{w_i \in D} max(0, 1 - g(\langle w_i \rangle) + g(\langle \bar{w_i} \rangle))$, where $g(\cdot)$ is the scoring function given by the neural network. Further details and evaluations of these embeddings can be found in (Bengio et al., 2003; Bengio et al., 2006; Collobert and Weston, 2008; Turian et al., 2010). For efficiency, words are fed to our architecture as indices taken from a finite dictionary. Obviously, a simple index does not carry much useful information about the word. So, the first layer of our network maps each of these word indices into a feature vector, by a lookup table operation. Our first contribution intervenes in the process of the choosing the proper dictionary. (Bengio, 2009) has shown that the order of the words in the dictionary of the neural network is not indifferent to the quality of the achieved representations: he proposed to order the dictionary by frequency and select the words for the corrupted sequence according to this order. In our case, the most frequent words are not always the most relevant for the task of event role detection. Since we want to have a training more focused to the domain specific task, we chose to order the dictionary by word relevance to the domain. We accomplish this by considering a limited number of seed words for each event type that needs to be discovered in text (e.g. *attack, bombing, kidnapping, arson*). We then rate with higher values the words that are more similar to the event types words, according to a given semantic similarity, and we rank them accordingly. We use the "Leacock Chodorow" similarity from Wordnet 3.0 (Leacock and Chodorow, 1998). Initial experimental results proved that using this domain-

[1] This max operation consists in taking, for each component of the vector, the max value of this component for each word vector representation.

oriented order leads to better performance for the task than the order by frequency.

2.2 Using Word Representations to Identify Event Roles

After having generated for each word their vector representation, we use them as features for the annotated data to classify event roles. However, event role fillers are not generally single words but noun phrases that can be, in some cases, identified as named entities. For identifying the event roles, we therefore apply a two-step strategy. First, we extract the noun chunks using SENNA[2] parser (Collobert et al., 2011; Collobert, 2011) and we build a representation for these chunks defined as the maximum, per column, of the vector representations of the words it contains. Second, we use a statistical classifier to recognize the slot fillers, using this representation as features. We chose the extra-trees ensemble classifier (Geurts et al., 2006), which is a meta estimator that fits a number of randomized decision trees (*extra-trees*) on various sub-samples of the data set and use averaging to improve the predictive accuracy and control over-fitting.

3 Experiments and Results

3.1 Task Description

We conducted the experiments on the official MUC-4 training corpus that consists of 1,700 documents and instantiated templates for each document. The task consists in extracting information about terrorist events in Latin America from news articles. We classically considered the following 4 types of events: *attack*, *bombing*, *kidnapping* and *arson*. These are represented by templates containing various slots for each piece of information that should be extracted from the document (perpetrators, human targets, physical targets, etc). Following previous works (Huang and Riloff, 2011; Huang and Riloff, 2012a), we only consider the "String Slots" in this work (other slots need different treatments) and we group certain slots to finally consider the five slot types *PerpInd* (individual perpetrator), *PerpOrg* (organizational perpetrator), *Target* (physical target), *Victim* (human target name or description) and *Weapon* (instrument id or type). We used 1,300 documents (DEV) for training, 200 documents (TST1+TST2) for tuning, and 200 documents (TST3+TST4) as the blind test set. To compare with similar works, we do not evaluate the template construction and only focus on the identification of the slot fillers: for each answer key in a reference template, we check if we find it correctly with our extraction method, using head noun matching (e.g., the victim *her mother Martha Lopez Orozco de Lopez* is considered to match *Matha Lopez*), and merging duplicate extractions (so that different extracted slot fillers sharing the same head noun are counted only once). We also took into account the answer keys with multiple values in the reference, dealing with conjunctions (when several victims are named, we need to find all of them) and disjunctions (when several names for the same organization are possible, we need to find any of them). Our results are reported as Precision/Recall/F1-score for each event role separately and averaged on all roles.

3.2 Experiments

In all the experiments involving our model, we established the following stable choices of parameters: 50-dimensional vectors obtained by training on sequences of 5 words, which is consistent with previous studies (Turian et al., 2010; Collobert and Weston, 2008). All the hyper-parameters of our model (e.g. learning rate, size of the hidden layer, size of the word vectors) have been chosen by finetuning our event extraction system on the TST1+TST2 data set. For *DRVR-50* and *W2V-50*, the embeddings were built from the whole training corpus (1,300 documents) and the dictionary was made of all the words of this corpus under their inflected form.

We used the extra-trees ensemble classifier implemented in (Pedregosa et al., 2011), with hyper-parameters optimized on the validation data: forest of 500 trees and the maximum number of features to consider when looking for the best split is $\sqrt{number\_features}$. We present a 3-fold evaluation: first, we compare our system with state-of-the-art systems on the same task, then we compare our domain-relevant vector representations (*DRVR-50*) to more generic word embeddings (*C&W50*, *HLBL-50*)[3] and finally to another

Table 1: Accuracy of "String Slots" on the TST3 + TST4 test set P/R/F1 (Precision/Recall/F1-Score)

word representation construction on the domain-specific data (*W2V-50*)[4].

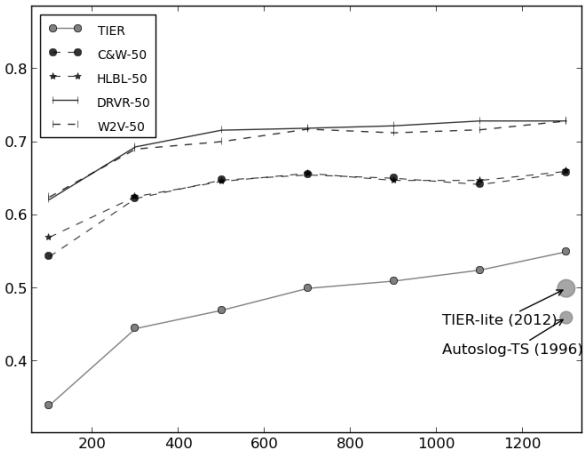

Figure 1: F1-score results for event role labeling on MUC-4 data, for different size of training data, of "String Slots" on the TST3+TST4 with different parameters, compared to the learning curve of TIER (Huang and Riloff, 2012a). The grey points represent the performances of other IE systems.

Figure 1 presents the average F1-score results, computed over the slots PerpInd, PerpOrg, Target, Victim and Weapon. We observe that models relying on word embeddings globally outperform the state-of-the-art results, which demonstrates that the word embeddings capture enough semantic information to perform the task of event role labeling on "String Slots" without using any additional hand-engineered features. Moreover, our representations (*DRVR-50*) clearly surpass the models based on generic embeddings (C&W-50 and HLBL-50) and obtain better results than W2V-50, based the competitive model of (Mikolov et al., 2013a), even if the difference is small. We can also note that the performance of our model is good even with a small amount of training data, which makes it a good candidate to easily develop an event extraction system on a new domain.

Table 1 provides a more detailed analysis of the comparative results. We can see in this table that our results surpass those of previous systems (0.73 vs. 0.59) with, particularly, a consistently higher precision on all roles, whereas recall is smaller for certain roles (Target and Weapon). To further explore the impact of these representations, we compared our word embeddings with other word embeddings (*C&W-50*, *HLBL-50*) and report the results in Figure 1 and Table 1. The results show that our model also outperforms the models using others word embeddings (F1-score of 0.73 against 0.65, 0.66). This proves that a model learned on a domain-specific data set does indeed provide better results, even if its size is much smaller (whereas it is usually considered that neural models require often important training data). Finally, we also achieve slightly better results than *W2V-50* with other word representations built on the same corpus, which shows that the choices made for the word representation construction, such as the use of domain information for word ordering, tend to have a positive impact.

newswire corpus

[4] *W2V-50* are the embeddings induced from the MUC4 data set using the negative sampling training algorithm (Mikolov et al., 2013a; Mikolov et al., 2013b; Mikolov et al., 2013c), available at `https://code.google.com/p/word2vec/`

4 Conclusions and Perspectives

We presented in this paper a new approach for event extraction by reducing the features to only use unsupervised word representations and a small set of seed words. The word embeddings induced from a domain-specific corpus bring improvement over state-of-art models on the standard MUC-4 corpus and demonstrate a good scalability on different sizes of training data sets. Therefore, our proposal offers a promising path towards easier and faster domain adaptation. We also prove that using a domain-specific corpus leads to better word vector representations for this task than using other publicly-available word embeddings (even if they are induced from a larger corpus).

As future work, we will reconsider the architecture of the neural network and we will refocus on creating a deep learning model while taking advantage of a larger set of types of information such as syntactic information, following (Levy and Goldberg, 2014), or semantic information, following (Yu and Dredze, 2014).

Abstract

This paper proposes a history-based structured learning approach that jointly extracts entities and relations in a sentence. We introduce a novel simple and flexible table representation of entities and relations. We investigate several feature settings, search orders, and learning methods with inexact search on the table. The experimental results demonstrate that a joint learning approach significantly outperforms a pipeline approach by incorporating global features and by selecting appropriate learning methods and search orders.

1 Introduction

Extraction of entities and relations from texts has been traditionally treated as a pipeline of two separate subtasks: entity recognition and relation extraction. This separation makes the task easy to deal with, but it ignores underlying dependencies between and within subtasks. First, since entity recognition is not affected by relation extraction, errors in entity recognition are propagated to relation extraction. Second, relation extraction is often treated as a multi-class classification problem on pairs of entities, so dependencies between pairs are ignored. Examples of these dependencies are illustrated in Figure 1. For dependencies between subtasks, a *Live_in* relation requires *PER* and *LOC* entities, and vice versa. For in-subtask dependencies, the *Live_in* relation between "Mrs. Tsutayama" and "Japan" can be inferred from the two other relations.

Figure 1 also shows that the task has a flexible graph structure. This structure usually does not cover all the words in a sentence differently from other natural language processing (NLP) tasks such as part-of-speech (POS) tagging and dependency parsing, so local constraints are considered to be more important in the task.

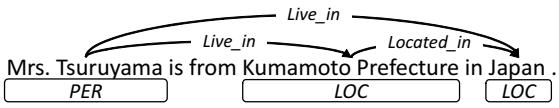

Figure 1: An entity and relation example (Roth and Yih, 2004). Person (*PER*) and location (*LOC*) entities are connected by *Live_in* and *Located_in* relations.

Joint learning approaches (Yang and Cardie, 2013; Singh et al., 2013) incorporate these dependencies and local constraints in their models; however most approaches are time-consuming and employ complex structures consisting of multiple models. Li and Ji (2014) recently proposed a history-based structured learning approach that is simpler and more computationally efficient than other approaches. While this approach is promising, it still has a complexity in search and restricts the search order partly due to its semi-Markov representation, and thus the potential of the history-based learning is not fully investigated.

In this paper, we introduce an entity and relation table to address the difficulty in representing the task. We propose a joint extraction of entities and relations using a history-based structured learning on the table. This table representation simplifies the task into a table-filling problem, and makes the task flexible enough to incorporate several enhancements that have not been addressed in the previous history-based approach, such as search orders in decoding, global features from relations to entities, and several learning methods with inexact search.

2 Method

In this section, we first introduce an entity and relation table that is utilized to represent the whole

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1858–1869,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

entity and relation structures in a sentence. We then overview our model on the table. We finally explain the decoding, learning, search order, and features in our model.

2.1 Entity and relation table

The task we address in this work is the extraction of entities and their relations from a sentence. Entities are typed and may span multiple words. Relations are typed and directed.

We use words to represent entities and relations. We assume entities do not overlap. We employ a BILOU (Begin, Inside, Last, Outside, Unit) encoding scheme that has been shown to outperform the traditional BIO scheme (Ratinov and Roth, 2009), and we will show that this scheme induces several label dependencies between words and between words and relations in §2.3.2. A label is assigned to a word according to the relative position to its corresponding entity and the type of the entity. Relations are represented with their types and directions. $\perp$ denotes a non-relation pair, and $\rightarrow$ and $\leftarrow$ denote left-to-right and right-to-left relations, respectively. Relations are defined on not entities but words, since entities are not always given when relations are extracted. Relations on entities are mapped to relations on the last words of the entities.

Based on this representation, we propose an entity and relation table that jointly represents entities and relations in a sentence. Figure 2 illustrates an entity and relation table corresponding to an example in Figure 1. We use only the lower triangular part because the table is symmetric, so the number of cells is $n(n+1)/2$ when there are n words in a sentence. With this entity and relation table representation, the joint extraction problem can be mapped to a table-filling problem in that labels are assigned to cells in the table.

2.2 Model

We tackle the table-filling problem by a history-based structured learning approach that assigns labels to cells one by one. This is mostly the same as the traditional history-based model (Collins, 2002) except for the table representation.

Let $\mathbf{x}$ be an input table, $\mathbf{Y}(\mathbf{x})$ be all possible assignments to the table, and $s(\mathbf{x}, \mathbf{y})$ be a scoring function that assesses the assignment of $\mathbf{y} \in \mathbf{Y}(\mathbf{x})$ to $\mathbf{x}$. With these definitions, we define our model to predict the most probable assignment as follows:

$$\mathbf{y}^* = \arg\max_{\mathbf{y} \in \mathbf{Y}(\mathbf{x})} s(\mathbf{x}, \mathbf{y}) \quad (1)$$

This scoring function is a decomposable function, and each decomposed function assesses the assignment of a label to a cell in the table.

$$s(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{|\mathbf{x}|} s(\mathbf{x}, \mathbf{y}, 1, i) \quad (2)$$

Here, i represents an index of a cell in the table, which will be explained in §2.3.1. The decomposed function $s(\mathbf{x}, \mathbf{y}, 1, i)$ corresponds to the i-th cell. The decomposed function is represented as a linear model, i.e., an inner product of features and their corresponding weights.

$$s(\mathbf{x}, \mathbf{y}, 1, i) = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{y}, 1, i) \quad (3)$$

The scoring function are further divided into two functions as follows:

$$s(\mathbf{x}, \mathbf{y}, 1, i) = s_{local}(\mathbf{x}, \mathbf{y}, i) + s_{global}(\mathbf{x}, \mathbf{y}, 1, i) \quad (4)$$

Here, $s_{local}(\mathbf{x}, \mathbf{y}, i)$ is a local scoring function that assesses the assignment to the i-th cell without considering other assignments, and $s_{global}(\mathbf{x}, \mathbf{y}, 1, i)$ is a global scoring function that assesses the assignment in the context of 1st to $(i-1)$-th assignments. This global scoring function represents the dependencies between entities, between relations, and between entities and relations. Similarly, features $\mathbf{f}$ are divided into local features $\mathbf{f}_{local}$ and global features $\mathbf{f}_{global}$, and they are defined on its target cell and surrounding contexts. The features will be explained in §2.5. The weights $\mathbf{w}$ can also be divided, but they are tuned jointly in learning as shown in §2.4.

2.3 Decoding

The scoring function $s(\mathbf{x}, \mathbf{y}, 1, i)$ in Equation (2) uses all the preceding assignments and does not rely on the Markov assumption, so we cannot employ dynamic programming.

We instead employ a beam search to find the best assignment with the highest score (Collins and Roark, 2004). The beam search assigns labels to cells one by one with keeping the top K best assignments when moving from a cell to the next cell, and it returns the best assignment when labels are assigned to all the cells. The pseudo code for decoding with the beam search is shown in Figure 3.

	Mrs.	Tsutayama	is	from	Kumamoto	Prefecture	in	Japan	.
Mrs.	B-PER								
Tsutayama	⊥	L-PER							
is	⊥	⊥	O						
from	⊥	⊥	⊥	O

in	⊥	⊥	⊥	⊥	⊥	⊥	O		
Japan	⊥	Live_in→	⊥	⊥	⊥	Located_in→	⊥	U-LOC	
.	⊥	⊥	⊥	⊥	⊥	⊥	⊥	⊥	⊥

Figure 2: The entity and relation table for the example in Figure 1.

INPUT: $\mathbf{x}$: input table with no assignment,
K: beam size
OUTPUT: best assignment $\mathbf{y}^*$ for $\mathbf{x}$
1: $b \leftarrow [\mathbf{x}]$
2: **for** $i = 1$ to $|\mathbf{x}|$ **do**
3: $T \leftarrow \emptyset$
4: **for** $k = 1$ to $|b|$ **do**
5: **for** $a \in \mathbf{A}(i, b[k])$ **do**
6: $T \leftarrow T \cup$ append(a, $b[k]$)
7: **end for**
8: **end for**
9: $b \leftarrow$ top K tables from T using the scoring function in Equation (2)
10: **end for**
11: return b[0]

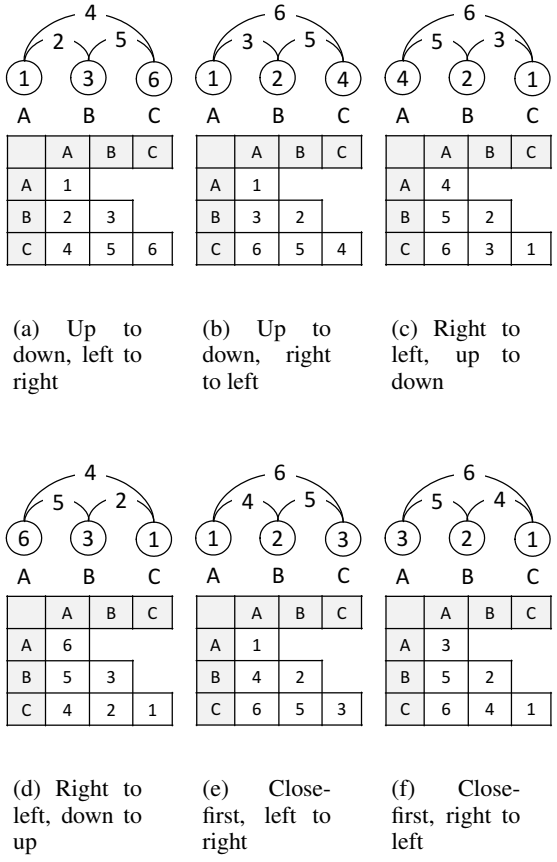
Figure 3: Decoding with the beam search. $\mathbf{A}(i, t)$ returns possible assignments for i-th cell of a table t, and append(a, t) returns a table t updated with an assignment a.

We explain how to map the table to a sequence (line 2 in Figure 3), and how to calculate possible assignments (line 6 in Figure 3) in the following subsections.

2.3.1 Table-to-sequence mapping

Cells in an input table are originally indexed in two dimensions. To apply our model in §2.2 to the cells, we need to map the two-dimensional table to a one-dimensional sequence. This is equivalent to defining a search order in the table, so we will use the terms "mapping" and "search order" interchangeably.

Since it is infeasible to try all possible mappings, we define six promising static mappings (search orders) as shown in Figure 4. Note that the "left" and "right" directions in the captions correspond to not word orders, but tables. We define two mappings (Figures 4(a) and 4(b)) with the highest priority on the "up to down" order, which checks a sentence forwardly (from the beginning of a sentence). Similarly, we also define two mappings (Figures 4(c) and 4(d)) with the highest priority on the "right to left" order, which check a sentence backwardly (from the end of a sentence). From another point of view, entities are detected before relations in Figures 4(b) and 4(c) whereas the order in a sentence is prioritized in Figures 4(a)



(a) Up to down, left to right

(b) Up to down, right to left

(c) Right to left, up to down

(d) Right to left, down to up

(e) Close-first, left to right

(f) Close-first, right to left

Figure 4: Static search orders.

Condition	Possible labels on w_i
Relation(s) on w_{i-1}	B-*, O, U-*
Relation(s) on w_i	L-*, U-*

L-*, U-*	*
Label on w_{i+1}	Relations from/to w_i
I-*, L-*	$\perp$
B-*, U-*, O	*

Table 2: Label dependencies from entities to relations.

and 4(d). We further define two close-first mappings (Figures 4(e) and 4(f)) since entities are easier to find than relations and close relations are easier to find than distant relations.

We also investigate dynamic mappings (search orders) with an easy-first policy (Goldberg and Elhadad, 2010). Dynamic mappings are different from the static mappings above, since we reorder the cells before each decoding[1]. We evaluate the cells using the local scoring function, and assign indices to the cells so that the cells with higher scores have higher priorities. In addition to this naïve easy-first policy, we define two other dynamic mappings that restricts the reordering by combining the easy-first policy with one of the following two policies: entity-first (all entities are detected before relations) and close-first (closer cells are detected before distant cells) policies.

2.3.2 Label dependencies

To avoid illegal assignments to a table, we have to restrict the possible assignments to the cells according to the preceding assignments. This restriction can also reduce the computational costs.

We consider all the dependencies between cells to allow the assignments of labels to the cells in an arbitrary order. Our representation of entities and relations in §2.1 induces the dependencies between entities and between entities and relations. Tables 1-3 summarize these dependencies on the i-th word w_i in a sentence. We can further utilize dependencies between entity types and relation types if some entity types are involved in a limited number of relation types or vice versa. We note that the dependencies between entity types and relation types include not only words participating in relations but also their surrounding words. For example, the label on w_{i-1} can restrict the types of relations involving w_i. We employ these type dependencies in the evaluation, but we omit these dependencies here since these dependencies are dependent on the tasks.

[1]It is also possible to reorder the cells during decoding, but it greatly increases the computational costs.

Label on w_{i-2}	Possible labels on w_i
B-TYPE	B-*, I-TYPE, L-TYPE, O, U-*
I-TYPE	B-*, I-TYPE, L-TYPE, O, U-*
L-TYPE	B-*, I-*, L-*, O, U-*

O/S	B-*, I-*, L-*, O, U-*

Table 3: Label dependencies between entities. TYPE represents an entity type, and O/S means the word is outside of a sentence.

2.4 Learning

The goal of learning is to minimize errors between predicted assignments $\mathbf{y}^*$ and gold assignments $\mathbf{y}^{gold}$ by tuning the weights $\mathbf{w}$ in the scoring function in Equation 3. We employ a margin-based structured learning approach to tune the weights $\mathbf{w}$. The pseudo code is shown in Figure 5. This approach enhances the traditional structured percep-

INPUT: training sets $D = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{N}$,
T: iterations
OUTPUT: weights $\mathbf{w}$

1: $\mathbf{w} \leftarrow \mathbf{0}$
2: **for** $t = 1$ to T **do**
3: **for** $\mathbf{x}, \mathbf{y} \in D$ **do**
4: $\mathbf{y}^* \leftarrow$ best assignment for $\mathbf{x}$ using decoding in Figure 3 with s' in Equation (5)
5: **if** $\mathbf{y}^* \neq \mathbf{y}^{gold}$ **then**
6: $m \leftarrow \arg\max_i \{s'(\mathbf{x}, \mathbf{y}^{gold}, 1, i) - s'(\mathbf{x}, \mathbf{y}^*, 1, i)\}$
7: $\mathbf{w} \leftarrow \text{update}(\mathbf{w}, f(\mathbf{x}, \mathbf{y}^{gold}, 1, m), f(\mathbf{x}, \mathbf{y}^*, 1, m))$
8: **end if**
9: **end for**
10: **end for**
11: return $\mathbf{w}$

Figure 5: Margin-based structured learning approach with a max-violation update. $\text{update}(\mathbf{w}, f(\mathbf{x}, \mathbf{y}^{gold}, 1, m), f(\mathbf{x}, \mathbf{y}^*, 1, m))$ depends on employed learning methods.

tron (Collins, 2002) in the following ways. Firstly, we incorporate a margin Δ into the scoring function as follows so that wrong assignments with small differences from gold assignments are penalized (lines 4 and 6 in Figure 5) (Freund and Schapire, 1999).

$$\mathbf{s}'(\mathbf{x}, \mathbf{y}) = \mathbf{s}(\mathbf{x}, \mathbf{y}) + \Delta(\mathbf{y}, \mathbf{y}^{gold}) \quad (5)$$

Similarly to the scoring function $\mathbf{s}$, the margin Δ is defined as a decomposable function using 0-1 loss as follows:

$$\begin{aligned} \Delta(\mathbf{y}, \mathbf{y}^{gold}) &= \sum_{i=1}^{|\mathbf{x}|} \Delta(y_i, y_i^{gold}), \\ \Delta(y_i, y_i^{gold}) &= \begin{cases} 0 & \text{if } y_i = y_i^{gold} \\ 1 & \text{otherwise} \end{cases} \end{aligned} \quad (6)$$

Secondly, we update the weights $\mathbf{w}$ based on a max-violation update rule following Huang et al. (2012) (lines 6-7 in Figure 5). Finally, we employ not only perceptron (Collins, 2002) but also AROW (Mejer and Crammer, 2010; Crammer et al., 2013), AdaGrad (Duchi et al., 2011), and DCD-SSVM (Chang and Yih, 2013) for learning methods (line 7 in Figure 5.) We employ parameter averaging except for DCD-SSVM. AROW and AdaGrad store additional information for covariance and feature counts respectively, and DCD-SSVM keeps a working set and performs additional updates in each iteration. Due to space limitations, we refer to the papers for the details of the learning methods.

2.5 Features

Here, we explain the local features $\mathbf{f}_{local}$ and the global features $\mathbf{f}_{global}$ introduced in §2.2.

2.5.1 Local features

Our focus is not to exploit useful local features for entities and relations, so we incorporate several features from existing work to realize a reasonable baseline. Table 4 summarizes the local features. Local features for entities (or words) are similar to the features used by Florian et al. (2003), but some features are generalized and extended, and gazetteer features are excluded. For relations (or pairs of words), we employ and extend features in Miwa et al. (2009).

2.5.2 Global features

We design global features to represent dependencies among entities and relations. Table 5 summarizes the global features[2]. These global features are activated when all the information is available during decoding.

We incorporate label dependency features like traditional sequential labeling for entities. Although our model can include other non-local features between entities (Ratinov and Roth, 2009), we do not include them expecting that global features on entities and relations can cover them. We design three types of global features for relations. These features are activated when all the participating relations are not $\perp$ (non-relations). Features except for the "Crossing" category are similar to global relation features in Li and Ji (2014). We further incorporate global features for both entities and relations. These features are activated when the relation label is not $\perp$. These features can act as a bridge between entities and relations.

3 Evaluation

In this section, we first introduce the corpus and evaluation metrics that we employed for evaluation. We then show the performance on the training data set with explaining the parameters used

[2]We tried other "Entity+Relation" features to represent a relation and both its participating entities, but they slightly degraded the performance in our preliminary experiments.

Target	Category	Features
Word (Entity)	Lexical	Character n-grams (n=2,3,4)
		Attributes by parsers (base form, POS)
		Word types (all-capitalized, initial-capitalized, all-digits, all-puncts, all-digits-or-puncts)
	Contextual	Word n-grams (n=1,2,3) within a context window size of 2
Word pair (Relation)	Entity	Entity lexical features of each word
	Contextual	Word n-grams (n=1,2,3) within a context window size of 2
	Shortest path	Walk features (word-dependency-word or dependency-word-dependency) on the shortest paths in parsers' outputs
		n-grams (n=2,3) of words and dependencies on the paths
		n-grams (n=1,2) of token modifier-modifiee pairs on the paths
		The length of the paths

Table 4: Local features.

Target	Category	Details
Entity	Bigram	Bigrams of labels
		Combinations of two labels and their corresponding POS tags
		Combinations of two labels and their corresponding words
	Trigram	Trigrams of labels
		Combinations of three labels and each of their corresponding POS tags
		Combinations of three labels and each of their corresponding words
	Entity	Combinations of a label and its corresponding entity
Relation	Entity-sharing	Combinations of two relation labels that share a word (i.e., relations in same columns or same rows in a table)
		Combinations of two relation labels and the shared word
		Relation shortest path features between non-shared words, augmented by a combination of relation labels and the shared word
	Cyclic	Combinations of three relation labels that make a cycle
	Crossing	Combinations of two relation labels that cross each other
Entity + Relation	Entity-relation	Relation label and the label of its participating entity
		Relation label and the label and word of its participating entity

Table 5: Global features.

for the test set evaluation, and show the performance on the test data set.

3.1 Evaluation settings

We used an entity and relation recognition corpus by Roth and Yih (2004)[3]. The corpus defines four named entity types *Location*, *Organization*, *Person*, and *Other* and five relation types *Kill*, *Live_In*, *Located_In*, *OrgBased_In* and *Work_For*.

All the entities were words in the original corpus because all the spaces in entities were replaced with slashes. Previous systems (Roth and Yih, 2007; Kate and Mooney, 2010) used these word boundaries as they were, treated the boundaries as given, and focused the entity classification problem alone. Differently from such systems, we recovered these spaces by replacing these slashes with spaces to evaluate the entity boundary detection performance on this corpus. Due to this replacement and the inclusion of the boundary detection problem, our task is more challenging than the original task, and our results are not comparable with those by the previous systems.

The corpus contains 1,441 sentences that contain at least one relation. Instead of 5-fold cross validation on the entire corpus by the previous systems, we split the data set into training (1,153 sentences) and blind test (288 sentences) data sets and

[3]conll04.corp at `http://cogcomp.cs.illinois.edu/page/resource_view/43`

developed the system on the training data set. We tuned the hyper-parameters using a 5-fold cross validation on the training data set, and evaluated the performance on the test set.

We prepared a pipeline approach as a baseline. We first trained an entity recognition model using the local and global features, and then trained a relation extraction model using the local features and global features without global "Relation" features in Table 5. We did not employ the global "Relation" features in this baseline since it is common to treat relation extraction as a multi-class classification problem.

We extracted features using the results from two syntactic parsers Enju (Miyao and Tsujii, 2008) and LRDEP (Sagae and Tsujii, 2007). We employed feature hashing (Weinberger et al., 2009) and limited the feature space to 2^{24}. The numbers of features greatly varied for categories and targets. They also caused biased predictions that prefer entities to relations in our preliminary experiments. We thus chose to re-scale the features as follows. We normalized local features for each feature category and then for each target. We also normalized global features for each feature category, but we did not normalize them for each target since normalization was impossible during decoding. We instead scaled the global features, and the scaling factor was tuned by using the same 5-fold cross validation above.

We used the F1 score on relations with entities as our primary evaluation measure and used it for tuning parameters. In this measure, a relation with two entities is considered correct when the offsets and types of the entities and the type of the relation are all correct. We also evaluated the F1 scores for entities and relations individually on the test data set by checking their corresponding cells. An entity is correct when the offset and type are correct, and a relation is correct when the type is correct and the last words of two entities are correct.

3.2 Performance on Training Data Set

It is infeasible to investigate all the combinations of the parameters, so we greedily searched for a *default parameter setting* by using the evaluated results on the training data set. The default parameter setting was the best setting except for the beam size. We show learning curves on the training data set in Figure 6 when we varied each parameter from the default parameter setting. We employed 5-fold cross validation. The default parameter setting used DCD-SSVM as the learning method, entity-first, easy-first as the search order, local and global features, and 8 as the beam size. This section discusses how these parameters affect the performance on the training data set and explains how the parameter setting was selected for the test set.

Figure 6(a) compares the learning methods introduced in §2.4. DCD-SSVM and AdaGrad performed slightly better than perceptron, which has often been employed in history-based structured learning. AROW did not show comparable performance to the others. We ran 100 iterations to find the number of iterations that saturates learning curves. The large number of iterations took time and the performance of DCD-SSVM almost converged after 30 iterations, so we employed 50 iterations for other evaluation on the training data set. AdaGrad got its highest performance more quickly than other learning methods and AROW converged slower than other methods, so we employed 10 for AdaGrad, 90 for AROW, and 50 iterations for other settings on the test data set.

The performance was improved by widening the beam as in Figure 6(b), but the improvement was gradually diminished as the beam size increased. Since the wider beam requires more training and test time, we chose 8 for the beam size.

Figure 6(c) shows the effects of joint learning as well as features explained in §2.5. We show the performance of the pipeline approach (Pipeline) introduced in §3.1, and the performance with local features alone (Local), local and global features without global "Relation" features in Table 5 (Local+global ($-$relation)) and all local and global features (Local+global). We note that Pipeline shows the learning curve of relation extraction in the pipeline approach. Features in "Local+global ($-$relation)" are the same as the features in the pipeline approach, and the result shows that the joint learning approach performed slightly better than the pipeline approach. The incorporation of global "Entity" and "Entity+Relation" features improved the performance as is common with the existing pipeline approaches, and relation-related features further improved the performance.

Static search orders in §2.3.1 also affected the performance as shown in Figure 6(d), although search orders are not investigated in the joint entity and relation extraction. Surprisingly, the gap

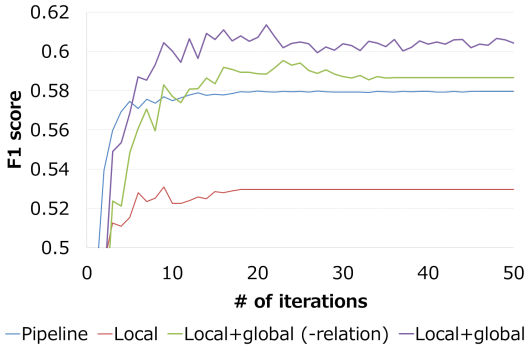
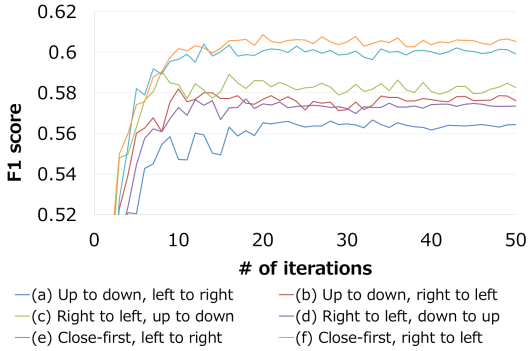
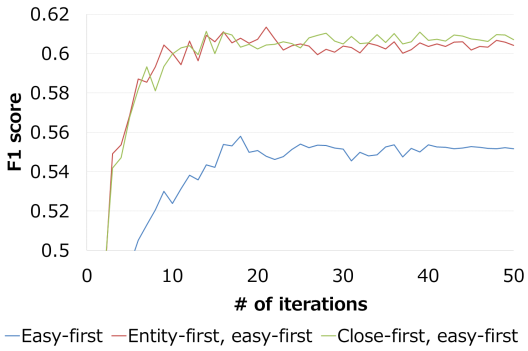
(b) Beam sizes



(c) Features and pipeline / joint approaches



(d) Static search orders



(e) Dynamic search orders

Figure 6: Learning curves of entity and relation extraction on the training data set using 5-fold cross validation.

between the performances with the best order and worst order was about 0.04 in an F1 score, which is statistically significant, and the performance can be worse than the pipeline approach in Figure 6(c). This means improvement by joint learning can be easily cancelled out if we do not carefully consider search order. It is also surprising that the second worst order (Figure 4(b)) is the most intuitive "left-to-right" order, which is closest to the order in Li and Ji (2014) among the six search orders.

Figure 6(e) shows the performance with dynamic search orders. Unfortunately, the easy-first policy did not work well on this entity and relation task, but, with the two enhancements, dynamic orders performed as well as the best static order in Figure 6(d). This shows that entities should be de-

tected earlier than relations on this data set.

3.3 Performance on Test Data Set

Table 6 summarizes the performance on the test data set. We employed the default parameter setting explained in §3.2, and compared parameters by changing the parameters shown in the first column. We performed a statistical test using the approximate randomization method (Noreen, 1989) on our primary measure ("Entity+Relation"). The results are almost consistent with the results on the training data set with a few exceptions.

Differently from the results on the training data set, AdaGrad and AROW performed significantly worse than perceptron and DCD-SSVM and they performed slightly worse than the pipeline approach. This result shows that DCD-SSVM performs well with inexact search and the selection of learning methods can significantly affect the entity and relation extraction performance.

The joint learning approach showed a significant improvement over the pipeline approach with relation-related global features, although the joint learning approach alone did not show a significant improvement over the pipeline approach. Unfortunately, no joint learning approach outperformed the pipeline approach in entity recognition. This may be partly because hyper-parameters were tuned to the primary measure. The results on the pipeline approach also indicate that the better performance on entity recognition does not necessarily improve the relation extraction performance.

Search orders also affected the performance, and the worst order (right to left, down to up) and best order (close-first, left to right) were significantly different. The performance of the worst order was worse than that of the pipeline approach, although the difference was not significant. These results show that it is necessary to carefully select the search order for the joint entity and relation extraction task.

3.4 Comparison with Other Systems

To compare our model with the other systems (Roth and Yih, 2007; Kate and Mooney, 2010), we evaluated the performance of our model when the entity boundaries were given. Differently from our setting in §3.1, we used the gold entity boundaries encoded in the BILOU scheme and assigned entity labels to the boundaries. We performed 5-fold cross validation on the data set following Roth and Yih (2007) although the split was different from theirs since their splits were not available. We employed the default parameter setting in §3.2 for this comparison.

Table 7 shows the evaluation results. Although we cannot directly compare the results, our model performs better than the other models. Compared to Table 6, Table 7 also shows that the inclusion of entity boundary detection degrades the performance about 0.09 in F-score.

4 Related Work

Search order in structured learning has been studied in several NLP tasks. Left-to-right and right-to-left orderings have been often investigated in sequential labeling tasks (Kudo and Matsumoto, 2001). Easy-first policy was firstly introduced by Goldberg and Elhadad (2010) for dependency parsing, and it was successfully employed in several tasks, such as joint POS tagging and dependency parsing (Ma et al., 2012) and co-reference resolution (Stoyanov and Eisner, 2012). Search order, however, has not been focused in relation extraction tasks.

Named entity recognition (Florian et al., 2003; Nadeau and Sekine, 2007) and relation extraction (Zelenko et al., 2003; Miwa et al., 2009) have often been treated as separate tasks, but there are some previous studies that treat entities and relations jointly in learning. Most studies built joint learning models upon individual models for subtasks, such as Integer Linear Programming (ILP) (Roth and Yih, 2007; Yang and Cardie, 2013) and Card-Pyramid Parsing (Kate and Mooney, 2010). Our approach does not require such individual models, and it also can detect entity boundaries that these approaches except for Yang and Cardie (2013) did not treat. Other studies (Yu and Lam, 2010; Singh et al., 2013) built global probabilistic graphical models. They need to compute distributions over variables, but our approach does not. Li and Ji (2014) proposed an approach to jointly find entities and relations. They incorporated a semi-Markov chain in representing entities and they defined two actions during search, but our approach does not employ such representation and actions, and thus it is more simple and flexible to investigate search orders.

5 Conclusions

In this paper, we proposed a history-based structured learning approach that jointly detects enti-

ties and relations. We introduced a novel entity and relation table that jointly represents entities and relations, and showed how the entity and relation extraction task can be mapped to a simple table-filling problem. We also investigated search orders and learning methods that have been fixed in previous research. Experimental results showed that the joint learning approach outperforms the pipeline approach and the appropriate selection of learning methods and search orders is crucial to produce a high performance on this task.

As future work, we plan to apply this approach to other relation extraction tasks and explore more suitable search orders for relation extraction tasks. We also plan to investigate the potential of this table representation in other tasks such as semantic parsing and co-reference resolution.

ZORE: A Syntax-based System for Chinese Open Relation Extraction

Likun Qiu and Yue Zhang
Singapore University of Technology and Design, Singapore
qiulikun@gmail.com, yue_zhang@sutd.edu.sg

Abstract

Open Relation Extraction (ORE) overcomes the limitations of traditional IE techniques, which train individual extractors for every single relation type. Systems such as ReVerb, PATTY, OLLIE, and Exemplar have attracted much attention on English ORE. However, few studies have been reported on ORE for languages beyond English. This paper presents a syntax-based Chinese (Zh) ORE system, ZORE, for extracting relations and semantic patterns from Chinese text. ZORE identifies relation candidates from automatically parsed dependency trees, and then extracts relations with their semantic patterns iteratively through a novel double propagation algorithm. Empirical results on two data sets show the effectiveness of the proposed system.

1 Introduction

Traditional Information Extraction (IE) systems train extractors for pre-specified relations (Kim and Moldovan, 1993). This approach cannot scale to the web, where target relations are not defined in advance. Open Relation Extraction (ORE) attempts to solve this problem by shallow-parsing-based, syntax-based or semantic-role-based pattern matching without pre-defined relation types, and has achieved great success on open-domain corpora ranging from news to Wikipedia (Banko et al., 2007; Wu and Weld, 2010; Nakashole et al., 2012; Etzioni et al., 2011; Moro and Navigli, 2013). Many NLP and IR applications, including selectional preference learning, commonsense knowledge and entailment rule mining, have benefited from ORE (Ritter et al., 2010). However, most existing ORE systems focus on English, and little research has been reported on other languages. In addition, existing ORE techniques are mainly concerned with the extraction of textual relations, without trying to give semantic analysis, which is the advantage of traditional IE.

Our goal in this paper is to present a syntax-based Chinese (Zh) ORE system, ZORE, which extracts relations by using syntactic dependency patterns, while associating them with explicit semantic information. An example is shown is Figure 1, where the relation *(奥巴马 (Obama) 总统 (President) , Pred[毕业 (graduate)],* 哈佛 *(Harvard)* 法学院 *(Law School))* is extracted from the given sentence "奥巴马 *(Obama)* 总统 *(President)* 毕业 *(graduate)* 于 *(from)* 哈佛 *(Harvard)* 法学院 *(Law School)*", and generalized into the syntactic-semantic pattern {*nsubj-NR(Af) Pred[毕业 (graduate)] prep-于 (from) pobj-NN(Di)*}. Here, *Af* and *Di* stand for human and institution, respectively, according to a Chinese taxonomy *Extended Cilin* (Che et al., 2010).

Rather than extracting binary relations and then generalizing them into semantic patterns, which most previous work does (Mausam et al., 2012; Nakashole et al., 2012; Moro and Navigli, 2012; Moro and Navigli, 2013), we develop a novel method that extracts relations and patterns simultaneously. A double propagation algorithm is used to make relation and pattern information reinforce each other, so that negative effects from automatic syntactic and semantic analysis errors can be mitigated. In this way, semantic pattern information is leveraged to improve relation extraction.

We manually annotate two sets of data, from news text and Wikipedia, respectively. Experiments on both data sets show that the double propagation algorithm gives better precision and recall compared to the baseline. To our knowledge, we are one of the first to report empirical results on Chinese ORE. The ZORE system, together with the two sets of test data we annotated, and the sets of 5 million relations and 344K semantic patterns extracted from news and Wikipedia, is freely re-

leased[1].

2 Basic Definitions for Open Information Extraction

ZORE is applied to web text to extract general relations and their semantic types. Our definition of relations follow previous work on ORE (Moro and Navigli, 2013), but with language-specific adjustments. In this section, we use the sentence in Figure 1 as an instance to describe the basic definitions for ZORE.

Definition 1 (predicate phrase) A ***predicate phrase*** is a sequence of words that contains at least one verb or copula, and governs one or more noun phrases syntactically. For instance, a predicate phrase for the sentence in Figure 1 is "毕业 *(graduate)*". Following Fader et al. (2011), Mausam et al. (2012) and Nakashole et al. (2012), in case of light verb constructions, the verb and its direct object jointly serve as predicate phrase. We do not include prepositions into the predicate phrases.

Definition 2 (argument) An ***argument*** is a base noun phrase governed by a predicate phrase *directly* or *indirectly* with a preposition. For instance, "奥巴马 (Obama) 总统 (President)" and "哈佛 (Harvard) 法学院 (Law School)" are two arguments of the predicate phrase "毕业 *(graduate)*".

Definition 3 (relation) A ***binary relation*** is a triple that consists of the predicate phrase *Pred* and its two arguments *x* and *y*. Accordingly, an *n-ary relation* contains *n* arguments. For instance, the sentence in Figure 1 contains the binary relation *(奥巴马 (Obama) 总统 (President), Pred[毕业 (graduate)], 哈佛 (Harvard) 法学院 (Law School))*. In English, the two arguments of a binary relation are usually positioned on the left and right of *Pred*, respectively. Hence, shallow patterns are highly useful for English relation extraction (Banko et al., 2007). In Chinese, however, the two arguments can be both on the left, both on the right or one on the left and one on the right of the predicate, and the resulting binary relation can be either *(x, y, Pred)*, *(Pred, x, y)* and *(x, Pred, y)*, depending on the sentence. This makes the detection of relation phrases more complicated.

Definition 4 (syntactic pattern) A ***syntactic pattern*** is the syntactic abstraction of a relation. A relation can be generalized into the combination of words, POS-tags and syntactic dependency labels (Nakashole et al., 2012). For instance, the syntactic pattern of the sentence in Figure 1 is {*nsubj-NR(A) Pred[毕业] prep-于 pobj-NN(A)*}. It consists of four sub-patterns. The first, *nsubj-NR(A)*, denotes that the current phrase acts as the subject of the predicate phrase with the POS-tag *NR* (proper nouns). Here, "*(A)*" means that the phrase is an argument of the extracted relation. The second sub-pattern denotes that the predicate phrase of the example is "毕业 *(graduate)*". Note that the words between the predicate and arguments (e.g., *prep-于*) are included into the pattern directly (Nakashole et al., 2012; Mausam et al., 2012).

Definition 5 (semantic signature) The ***semantic signature*** of a relation consists of the semantic categories of the arguments. The semantic signature of Figure 1 is *(Af, Di)*, where *Af* and *Di* denotes *human* and *institute*, respectively.

Definition 6 (semantic pattern) A ***semantic pattern*** is the semantic abstraction of a relation. It is the combination of a syntactic pattern and a semantic signature. For instance, the syntactic pattern {*nsubj-NR(A) Pred[毕业] prep-于 pobj-NN(A)*}, combined with the semantic signature *(Af, Di)*, results in the semantic pattern {*nsubj-NR(Af) Pred[毕业] prep-于 pobj-NN(Di)*}.

[1]https://sourceforge.net/projects/zore/

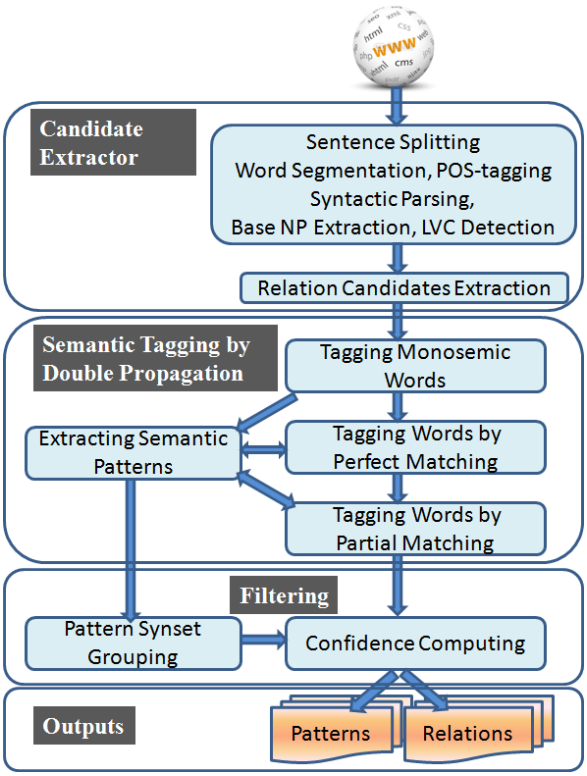

Figure 2: Architecture of ZORE.

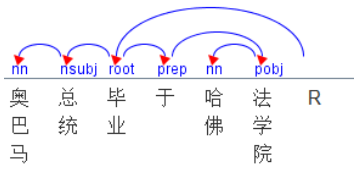

Figure 3: Parsing result of the example sentence in Figure 1, in Stanford dependencies.

3 ZORE

The architecture of ZORE is shown in Figure 2. It consists of three components. The first is a relation candidate extractor, which consumes input text and performs sentence segmentation, word segmentation, POS tagging, syntactic parsing, base NP extraction, light verb structure (LVC) detection and relation candidate extraction. The output is a set of relation candidates. The second component tags relations and extracts semantic patterns by a double propagation algorithm. In the third component, extracted patterns are grouped into synsets, and relations are filtered by confidence scores.

3.1 Extracting Relation Candidates

3.1.1 Parsing and Base NP Extraction

ZORE analyzes the syntactic structures of input texts by applying a pipeline of NLP tools. Each sentence is segmented into a list of words by using the Stanford segmenter (Chang et al., 2008), and parsed by using ZPar (Zhang and Clark, 2011), with POS tags and constituent structures by the CTB standard (Xue et al., 2005). The resulting constituent trees are transformed into projective trees with Stanford dependencies by using the Stanford parser (Chang et al., 2009). Figure 4 shows the parse tree of the sentence in Figure 1.

Next, base noun phrases (NPs) are extracted from the dependency tree. Here a base NP is a maximum phrase whose words can only have POS from the first row of Table 1. The head word of a base NP can be either a noun, a pronoun, a number or a measure word (the second row of Table 1). The dependency labels within a base NP can only be from the third row of Table 1. Obviously, a base NP does not contain other base NPs, and is also not contained by any other base NP.

3.1.2 Detecting Light Verb Constructions

In linguistics, a *light verb* is a verb that has little semantic content of its own, and typically forms a predicate with a noun (Butt, 2003). Example predicates by light verb constructions (LVC) include "*is a capital of*" and "*claim responsibility for*", where "is" and "claim" are light verbs. Improper handling of LVC can cause a significant problem by uninformative extractions (Etzioni et al., 2011). For example, if "is" and "claim" are extracted as predicates, the resulting relations (such as (*Hamas, claimed, responsibility*) from the sentence "Hamas claimed responsibility for the Gaza attack") might not bare useful information. ReVerb (Etzioni et al., 2011) handles this problem by hard syntactic constraints, taking the noun phrase (e.g., responsibility) between a verb phrase (e.g., "claim") and a preposition (e.g., "for") as a part of the predicate phrase rather than an argument, leading to the relation *(Hamas, claimed responsibility for, the Gaza attack)*.

In Chinese, LVCs are highly frequent and should be handled properly in order to ensure that the extracted relations are informative. However, the syntactic constraints in ReVerb can not be transferred to Chinese directly, because the word orders of English and Chinese are quite different.

	Labels
Base NP modifier	*NN (common noun), M (measure word), CD (cardinal number), OD (ordinal number), PN (pronoun), NR (proper noun), NT (temporal noun), JJ (other noun-modifier), or PU (punctuation)*
Base NP head	*NN (common noun), M (measure word), CD (cardinal number), OD (ordinal number), PN (pronoun), NR (proper noun), NT (temporal noun)*
Labels in base NPs	*nn (noun compound modifier), conj (conjunct), nummod (number modifier), cc (coordinating conjunction), clf (classifier modifier), det (determiner), ordmod (ordinal number modifier), punct (punctuation), dep (other dependencies), or amod (adjectival modifier)*
Labels from base NPs to predicate phrase	*nsubj (nominal subject), conj (conjunct), dobj (direct object), advmod (adverbial modifier), prep (prepositional modifier), pobj (prepositional object), lobj (localizer object), range (dative object that is a quantifier phrase), tmod (temporal modifier), plmod (localizer modifier of a preposition), attr (attributive), loc (localizer), top (topic), xsubj (controlling subject), ba ("ba" construction), nsubjpass (nominal passive subject)*

Table 1: Constraints on POS-tags and dependency labels. Labels in the top three rows are used for base NP extraction, while labels in the last row for traversing from a base NP to the predicate phrase.

In Chinese, prepositions acting as the modifier of a verb can be on both the left and right of the verb. For instance, the sentence "奥巴马 *(Obama)* 总统 *(President)* 于 *(from)* 哈佛 *(Harvard)* 法学院 *(Law School)* 毕业 *(graduate)*" is a paraphrase of the sentence in Figure 1, with the preposition 于 *(from)* on the left of the predicate phrase.

Chinese LVCs can be classified into two types, which we refer to as dummy-LVCs and common LVCs, respectively. For the first type, the predicate is a dummy verb such as "进行 *(do)*" and "予以 *(give)*", which has a noun phrase as its object. Since dummy verbs in Chinese are a closed set, we detect this type of LVCs (such as *"进行 (do) 会谈 (talk)"*) by finding the dummy verb from a lexicon. For the second type of LVCs, the predicate is a common verb, which has a nominalized structure or a common noun as its object. For instance, "展开 *(launch)* 调查 *(investigation)*" belongs to this type of construction.

Common LVCs are more difficult to detect than dummy-LVCs. We detect common LVCs by the context. Besides the NPs in the LVC itself, a common LVC typically governs two NPs, with the latter being connected to the predicate phrase by an LVC-related preposition such as "对 (for), 对于 (for), 针对 (for), 向 (to), 同 (with), 与 (with), 和 (with) ". Based on the observation, a basic idea of identifying common LVCs is to find verb-object structures that frequently co-occur with a LVC-related preposition in a large-scale corpus parsed automatically. For a given verb-object v, let f^v and f^p denote the frequency of v and the frequency of v co-occurring with an LVC-related preposition, respectively. We define the statistical strength of v to be an LVC as the ratio f^p/f^v. If the statistical strength of v exceeds a threshold t^{lvc}, we identify v as a LVC. Table 2 illustrates some high-frequency LVCs extracted by the method automatically.

3.1.3 Extracting Relation Candidates

ZORE tries to extract relation candidates from sentences that contain two or more base NPs. Given two base NPs, we traverse the dependency tree to obtain the shortest path that connects them. The path can contain only dependency labels in the fourth row of Table 1, and should contain at least one of the labels from "nsubj" and "dobj" to ensure that a predicate phrase is included in the path. If such a path is acquired, other base NPs governed by the same predicate phrase are included into the target relation, resulting in a n-ary relation candidates with each base NP being an argument. According to the predicate phrase, relation candidates can be classified into the following classes.

Common and dummy LVC relations. In this type of relations, the predicate phrase of the path is an LVC (e.g., a light verb and a nominal object). The two base NPs can be the subject or prepositional object of the light verb. For instance, in the sentence "霍迪尼 *(Houdini)* 对 *(to)* 我的 *(my)* 事业 *(career)* 有 *(have)* 很大 *(big)* 影响 *(influence)*", "有 *(have)*"and "影响 *(influence)*" are combined into a common LVC and taken as the predicate phrase, resulting the relation *(霍迪尼 (Houdini), Pred[有 (have) 影响 (influence)], 我的 (my) 事业 (career))*. In the corresponding English sentence, the predicate phrase "*be a big influence in*" is also an LVC structure.

Verb relations. In this type of relations, a verb acts as the predicate phrase. For instance, the relation *(奥巴马 (Obama) 总统 (President), Pred[毕业 (graduate)], 哈佛 (Harvard) 法学院 (Law School))* extracted from the sentence in Figure 1 is a typical verb relation.

Relative-clause relations. In an relative-clause

Verb	Noun
进行 (do) (*)	发行 (distribution), 分析 (analysis), 收集 (collection), 修改 (modification), 访问 (visit), 处罚 (punishment)
有 (have) (*)	影响(effect), 贡献 (contribution), 兴趣 (interest), 帮助 (help), 认识 (understanding), 期望 (expectation)
产生 (generate) (**)	影响 (effect), 兴趣 (interest), 怀疑(doubt), 冲击 (shock), 好感 (good feeling), 恐惧 (fear)
造成 (cause) (**)	影响 (effect), 破坏(destruction), 伤害 (harm), 威胁 (threat), 压力 (pressure), 干扰 (distraction)
表示 (express) (**)	满意 (satisfaction), 欢迎 (welcome), 尊重 (respect), 担忧 (worry), 哀悼 (mourning), 感谢 (gratitude)
展开 (launch) (**)	调查 (investigation), 攻击 (attack),攻势 (offensive), 批评 (criticism), 批判 (negotiation), 诉讼 (lawsuit)

Table 2: Instances of dummy-LVCs (*) and common LVCs (**). A verb in the left column is combined with a noun in the right column to form an LVC, which serves as the predicate phrase.

relation, the head word is a noun, modified by an relative clause, but acting as an argument of the predicate of the relative clause semantically. The sentence "毕业 *(graduate)* 于 *(from)* 哈佛 *(Harvard)* 法学院 *(Law School)* 的 *(de, an auxiliary word)* 奥巴马 *(Obama)* 总统 *(president)*" is a paraphrase of the sentence in Figure 1, with the same predicate phrase and arguments. However, the relation extracted from this phrase is an relative-clause relation *(Pred[*毕业 *(graduate)],* 哈佛 *(Harvard)* 法学院 *(Law School),* 奥巴马 *(Obama)* 总统 *(president))*, which belongs to the same pattern synset as the relation of Figure 1.

3.2 Semantic Tagging by Double Propagation

The basic idea of our approach is to identify relations and patterns iteratively through semantically tagging the head words of arguments in relation candidates. Given a set of relation candidates and a semantic taxonomy, the propagation consists of three steps. In Step 1, monosemic arguments in candidate relations are tagged with a semantic category, such as *Af* and *Di*, to obtain semantic patterns. In Step 2 and Step 3, untagged ambiguous and unknown words are tagged by perfect matching and partial matching, respectively. In the end of each step, semantic patterns are generalized from extracted and tagged relations, and then used to help relation tagging in the next step. Because of the two-way information exchange, we call this method *double propagation*. The method can also be treated as similar to bootstrapping (Yangarber et al., 2000; Qiu et al., 2009).

3.2.1 Step 1: Tagging Monosemic Arguments

Each argument in a relation candidate is a base NP. Since base NPs are endocentric, we can take the semantic category of the head word of a base NP as the semantic category of the base NP. In a taxonomy, each word is associated with one or more semantic categories. In this step, however, only monosemic words are tagged, while both ambiguous words and unknown words are left untagged.

Most named entities are not included in the taxonomy. However, after POS-tagging, most of them are detected as NR (proper noun). As a result, they are taken as ambiguous words that can be person names, organization names or location names. The named entities that are not included in the taxonomy are tagged in Steps 2 and 3.

After this step, all the arguments in some relation candidates have been tagged with semantic categories. We refer to these relation candidates as *tagged relation candidates*, and the remaining relation candidates as *untagged relation candidates*. Tagged relation candidate are generalized into semantic patterns, consisting of syntactic patterns and semantic signatures, as illustrated in Figure 1 and Section 2. We call the set of resulting semantic patterns Set^{SemPat}.

3.2.2 Step 2: Tagging by Perfect Pattern Matching

In this step, the arguments in the untagged relation candidates are tagged by semantic pattern matching. Given an untagged relation candidate *r*, we acquire a set of *possible* semantic categories for each argument with an *ambiguous* head word. For the arguments with *unknown* head words, we acquire a set of *possible* semantic categories according to their characters. Qiu et al. (2011) demonstrate that 98% Chinese words have at least one synonym, which shares at least one character. For Chinese nouns, the set of synonyms usually shares the last one or two characters. According to this, our strategy for acquiring possible semantic categories for an unknown word is as follows.

Given an unknown word w^u, if we find a known word w^k that shares the last two character with w^u, the semantic categories of w^k will be used as the possible semantic categories of w^u. Otherwise, if we find a known word w^k that share the last one character with w^u, the semantic categories of w^k will be used as the possible categories of w^u.

We then acquire possible semantic signatures of untagged relation candidates, of which all the arguments are tagged with possible semantic categories. As in Step 1, we generalize relation *r* into a syntactic pattern pat^{syn}, and then combine pat^{syn} with each *possible* semantic signature of *r* to generate *possible* semantic patterns. In case one or more possible semantic patterns of *r* exist in Set^{SemPat}, if the highest frequency of these patterns is above a threshold t^{sem}, the corresponding pattern will be taken as the semantic pattern of *r*, from which we infer the semantic signature for *r* and then the semantic category for the head word of each argument of *r*. After this step, the frequency of each semantic pattern in Set^{SemPat} is updated according to the newly tagged relation candidates.

3.2.3 Step 3: Tagging by Partial Pattern Matching

In this step, we tag the ambiguous and unknown words by partial matching rather than perfect matching of the whole semantic pattern. This can be treated as a back-off of the last step.

We first split *n*-ary semantic patterns in Set^{SemPat} into binary semantic patterns, and calculate their frequencies. Second, we split each untagged relation candidate *r* into several binary sub-relations and then search for the corresponding semantic patterns as in Step 2 — for each binary sub-relation, we obtain a binary semantic signature with the highest frequency. By combining the binary semantic signatures, we obtain one *n*-ary semantic signature for *r*, based on which all the unknown and ambiguous words can be tagged with a semantic categories. If all the arguments of a relation candidate *r* are tagged, *r* is treated as tagged. Finally, according to the newly tagged relations, statistics in Set^{SemPat} are updated.

3.3 Grouping Patterns into Synsets

In this step, we group semantic patterns from Set^{SemPat} into *pattern synsets*, based on a single-pass clustering process (Papka and Allan, 1998). Given two semantic patterns $SemPat_i$ and $SemPat_j$, we refer to their corresponding syntactic pattern, semantic signature and predicate phrases as $SynPat_i$ and $SynPat_j$, $SemSig_i$ and $SemSig_j$, $Pred_i$ and $Pred_j$, respectively. Not taking the predicate phrase into account, $SynPat_i$ and $SynPat_j$ are identical, and we call them *loosely identical* ($\approx$).

The algorithm in Figure 4 is used to group

if $Pred_i$ = "是 (is)" **or** $Pred_j$ = "是 (is)": **return** *false*.
else if ARGCOUNT($SemPat_i$) = 2 **and** ARGCOUNT($SemPat_j$) = 2 **and** SEMCAT(arg_1) = SEMCAT(arg_2):
  if $SynPat_i \approx SynPat_j$ **and** ISSONONYM ($Pred_i$, $Pred_j$): **return** *true*.
  else if $Pred_i = Pred_j$: **return** *true*.
  else: **return** *false*.
else if $Pred_i = Pred_j$ **and** $SemSig_i = SemSig_j$: **return** *true*.
else if ISSYNONYM($Pred_i$, $Pred_j$) **and** $SemSig_i = SemSig_j$ **and** $SynPat_i \approx SynPat_j$: **return** *true*.
else: **return** *false*.

Figure 4: Algorithm for pattern synset grouping.

Type	Feature	Weight
Base	*r* covers all words in *c*	0.96
Base	There are commas within *r*	-0.47
Base	LENGTH(*r*)<10 words	0.35
Base	10 words≤LENGTH(*r*)<20 words	0.11
Base	20 words≤LENGTH(*r*)	-1.06
Base	COUNT(*arguments*)=2	0.14
Base	COUNT(*arguments*)=3	0.33
Base	COUNT(*arguments*)=4	-0.60
Base	COUNT(*arguments*)> 4	-0.46
SemPat	Being tagged in Step 3	0.87
SemPat	Being tagged before Step 3	0.75
SemPat	50≤SIZE(*SemPat*) and untagged	-0.05
SemPat	50≤SIZE(*SemPat*) and tagged	0.65
SemPat	10≤SIZE(*SemPat*)<50 and untagged	-0.16
SemPat	10≤SIZE(*SemPat*)<50 and tagged	0.39
SemPat	5≤SIZE(*SemPat*)<10 and untagged	-0.22
SemPat	5≤SIZE(*SemPat*)<10 and tagged	0.36
SemPat	SIZE(*SemPat*) <5 and untagged	-0.92
SemPat	SIZE(*SemPat*) <5 and tagged	-0.64

Table 3: Features of the logistic regression classifier with weights trained on Wiki-500 dataset.

patterns, where ARGCOUNT($SynPat_j$) denotes the number of arguments in $SemPat_i$, SEMCAT(arg_1) indicates the semantic category of the first argument, and ISSYNONYM ($Pred_i$, $Pred_j$) returns whether two predicates are synonyms. In similarity-based single-pass clustering, the topic excursion problem is common (Papka and Allan, 1998). But since our similarity measure is symmetric, we do not suffer from this problem.

3.4 Computing the Confidence for Relations

Without filtering, the extraction algorithm in the previous sections may yield false relations. Following previous ORE systems, we make a balance between recall and precision by using a confidence threshold (Fader et al., 2011). A logistic regression classifier is used to give a confidence score to each relation, with features shown in Table 3. In the table, *c*, *r*, *arguments* and *SemPat* denote

Dataset	Source	#Sen	#Rel
Wiki-500	Chinese Wikipedia	500	561
Sina-500	Sina News	500	707

Table 4: Annotated relation datasets.

clause, relation, arguments in a relation, and semantic pattern, respectively. LENGTH(r), COUNT(*arguments*) and SIZE(*SemPat*) indicate the number of words in r, the number of arguments in r, and the number of relations that belong to the same semantic pattern *SemPat* as r. Because semantic patterns from the double propagation algorithm are used as features in the classifier, they participate in relation extraction also. Their effect on relation extraction can directly demonstrate the effectiveness of double propagation.

4 Experiments

4.1 Experimental Setup

We run ZORE on two difference corpora: the Chinese edition of Wikipedia (Wiki), which contains 4.3 million sentences (as of March 29, 2014), and a corpus from the Sina News archive (Sina News), which includes 6.1 million sentences from January 2013 to May 2013. The sentences that do not end with punctuations are filtered. The Chinese taxonomy *Extended Cilin*[2] (*Cilin*) (Che et al., 2010) is used to give semantic categories for each word. *Cilin* contains 77,492 Chinese words, organized into a five-level hierarchy. There are 12 categories in the top level, 94 in the second and 1492 in the third. In this paper, the second level is used for semantic categories. We create two test sets, containing 500 sentences from Wiki and 500 sentences from Sina News, respectively (see Table 4), annotated by two independent annotators using the annotation strategy of Fader et al. (2011). The thresholds t^{lvc} and t^{sem} for pattern matching are set as 0.4 and 5, tuned on 100 sentences from Wiki-500 dataset, respectively.

4.2 Evaluation of Relation Extraction

First, we compare ZORE with a baseline system to illustrate the effectiveness of the double propagation algorithm. The baseline system does not have the double propagation tagging component in Figure 2, using the logistic regression classifier in Section 3.4.1 with the 9 base features to filter extracted relation candidates. It is similar to the architecture of ReVerb (Fader et al., 2011). We

[2]http://ir.hit.edu.cn/demo/ltp/Sharing_Plan.htm

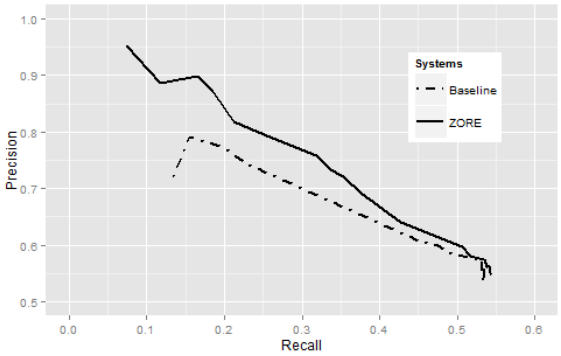

Figure 5: Performance on Wiki.

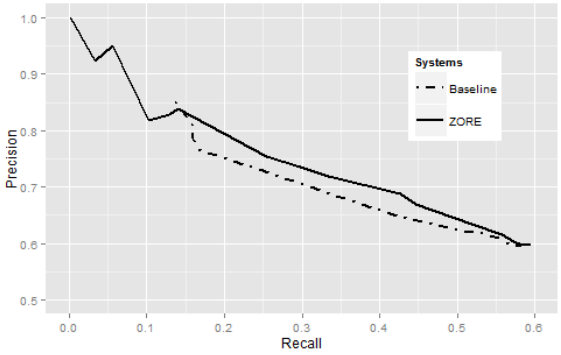

Figure 6: Performance on Sina News.

measure the precision and recall of the extracted relations. An extracted relation is considered correct only when the predicate phrase and all the arguments match the the gold set. On each data set, we perform 5-fold cross-validation test and take the average as the final precision and recall.

Figures 5 and 6 show the comparison of the two systems on Wiki and Sina News, respectively. On Wiki, ZORE has higher precision than the baseline at all levels of recall. When the recall is 0.3, the precision of ZORE is 0.77, 0.11 higher than the baseline. The result on Sina News is similar. The second column of Table 3 shows the weights of all features trained on the Wiki data set, which indicates that the semantic pattern features can give a positive effect on relation filtering.

Second, we compare the intermediate results at Steps 1, 2, and 3 in Section 3.2, respectively. The precision, recall and F1 of the three steps with different numbers of Wiki sentences (from 10K to 5M sentences) are shown in Table 5. This figure shows that Step 2 achieves higher precision than Step 1 at all levels of recall, indicating that the word sense tagging method in step 2 is useful for

Sentences	Step 1			Step 2			Step 3		
	P	R	F1	P	R	F1	P	R	F1
10K	0.947	0.032	0.062	**0.960**	0.043	0.082	0.933	0.075	0.139
50K	0.894	0.075	0.138	0.922	0.105	0.189	0.907	0.139	0.241
100K	0.897	0.093	0.169	0.924	0.130	0.228	0.909	0.160	0.272
200K	0.901	0.114	0.202	0.926	0.157	0.268	0.892	0.191	0.315
500K	0.891	0.146	0.251	0.909	0.196	0.322	0.860	0.230	0.363
1M	0.860	0.164	0.275	0.885	0.219	0.351	0.842	0.248	0.383
2M	0.797	0.182	0.296	0.819	0.250	0.383	0.788	0.278	0.411
3M	0.784	0.187	0.302	0.802	0.253	0.385	0.778	0.282	0.414
4M	0.739	0.178	0.287	0.801	0.258	0.390	0.778	0.287	0.419
5M	0.779	0.189	0.304	0.798	0.260	0.392	**0.768**	**0.289**	**0.420**

Table 5: Accuracies on different numbers Wiki sentences.

a significant boost of recall, together with a little improvement in precision. In particular, Step 2 can extract about 20% relations with relatively high precision (about 90%). The result of Step 3 is better to that of Step 2 in terms of F1-measure, with the highest F1-measure achieved by this step.

4.3 Evaluation of Patterns

ZORE acquires 122K and 222K patterns from Wiki and Sina News, clustered into 59K and 118K pattern synsets, respectively. The frequency distribution of the Wiki patterns is shown in Figure 7, which conforms to Zipf's law.

To assess the accuracy of pattern extraction, we rank the extracted patterns by the size, and evaluated the precision of the top 100 and a random set of 100 pattern synsets. Two annotators were shown a pattern synset with its semantic signature and a few example relations, and then asked to judge whether it indicates a valid semantic relation or not. The results are shown in Table 6. The averaged precision is 92% for the top 100 set, and 85% for the random 100 set.

The patterns in a pattern synset can be taken as paraphrases (Barzilay and Lee, 2003). We observe that two synonymous patterns might differ in three aspects. First, two patterns can differ by the predicates, which are synonyms. For instance, the verbs "担任, 当, 任, 出任, 为, 做" are synonyms, meaning "to hold the appointment of". Second, two patterns in the same synset can belong to different syntactic patterns, and therefore are paraphrases in the syntactic level. For instance, the semantic patterns of the two sentences "毕业 *(graduate)* 于 *(from)* 哈佛 *(Harvard)* 法学院 *(Law School)* 的 *(de, an auxiliary word)* 奥巴马 *(Obama)* 总统 *(president)*" and "奥巴马 *(Obama)* 总统 *(president)* 从*(from)* 哈佛 *(Harvard)* 法学院 *(Law School)* 毕业 *(graduate)*" are both synonymous to that of the sentence in Figure 1; all the three patterns are found in the same synset obtained by ZORE. Third, two patterns can differ only by the POS-tag. For instance, "奥巴马 *(Obama)* 从*(from)* 哈佛 *(Harvard)* 法学院 *(Law School)* 毕业 *(graduate)*" and "那个 *(That)* 律师 *(attorney)* 从*(from)* 哈佛 *(Harvard)* 法学院 *(Law School)* 毕业 *(graduate)*" are synonyms with different POS-tags for the first argument (i.e. N-R and NN). According to the grouping algorithm in Section 3.3, all the three types of paraphrases are grouped in a pattern synset, which makes some synsets very large. The largest synset contains 110 patterns, while the top 100 synsets contain more than 20 patterns.

4.4 Error analysis

We analyze the incorrect extractions (precision loss) and missed correct relations (recall loss) returned by Step 2, running on 500K sentences. Table 7 summarizes the types of correct relations that are missed by ZORE. 40% missed relations are due to the minimum frequency constraint on semantic patterns, which is used for a balance between precision and recall. Another main source of failure is the incorrect identification of the predicate phrase due to parsing errors, which account for 37% of the total errors. Other sources of failures include redundant arguments and segmentation errors. Most redundant arguments are related to prepositions such as "按照 (according to)" and "根据 (on the basis of)". For instance, in the sentence "按照 (according to) 这个 (the) 观点 (point of view) ， (,) 根本 (fundamental) 问题 (problem) 是 (is)", an incorrect binary relation *(这个 (the) 观点 (point of view), 根本 (fundamental) 问题 (problem), Pred[是 (is)])* is extracted, because the prepositional object "这个 (the) 观点 (point of view)" is tagged as an argument of the predicate phrase "是 (is)".

Table 8 summarizes the major types of incor-

Corpus	Patterns	Synsets	Top100	Random100
Wiki	122,723	59,298	0.93	0.87
Sina	222,773	118,923	0.91	0.83

Table 6: Precision of pattern synsets.

40%	Relations filtered by semantic pattern constraint
37%	Could not identify correct predicates because of preprocessing errors
12%	Too many arguments because of parsing errors
11%	Segmentation and POS tagging errors

Table 7: Relations missed by ZORE.

rect relations, 56% of which were caused by parsing errors, and 34% of which were due to word segmentation and POS tagging errors. Although many errors have been filtered by ZORE, the biggest source of errors is still syntactic analysis, which is very important for high quality of ORE.

5 Related Work

English has been the major language on which ORE research has been conducted. Previous work on English ORE has evolved from shallow-syntactic (Banko et al., 2007; Fader et al., 2011; Merhav et al., 2012) to full-syntactic (Nakashole et al., 2012; Mausam et al., 2012; Moro and Navigli, 2013; Xu et al., 2013) and semantic (Johansson and Nugues, 2008) systems.

It has been shown that a full-syntactic system based on dependency grammar can give significantly better results than shallow syntactic systems based on surface POS-patterns, yet enjoy higher efficiency compared with semantic systems (Mesquita et al., 2013). Our investigation on Chinese ORE takes root in full dependency syntax and is hence able to identify patterns that involve long-range dependencies. Considering the characteristics of the Chinese language, such as the lack of morphology and function words, and the high segmentation and word sense ambiguities, we incorporate semantic ontology information into the design of the system to improve the output quality without sacrificing efficiency.

The state-of-the-art systems most closely related to our approach are PATTY (Nakashole et al., 2012) and the system of Moro and Navigli (2013). Both, however, extract relations first, and then defines patterns based on extracted relations. This paper differs in that patterns and relations are extracted in a simultaneous process and so they can improve each other. Previous studies show that pattern generalization benefit from relation extrac-

56%	Parsing errors

17%	POS tagging errors
6%	Redundant arguments
6%	Other, including base NP extraction errors

Table 8: Incorrect extractions by ZORE.

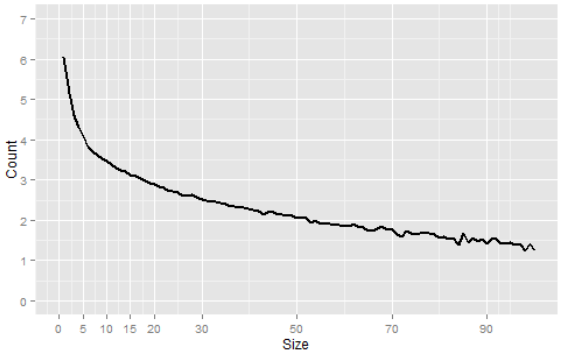

Figure 7: The frequency distribution of patterns extracted from Wiki. Size and Count denote the number of relations that belong to a semantic pattern and the logarithmic number of semantic patterns that have the same size, respectively.

tion (Nakashole et al., 2012; Moro and Navigli, 2013), and relation extraction can benefit from pattern generalization (Mausam et al., 2012). By using double propagation, not only can we make relation and pattern extraction benefit from each other, but we can also tag relations and patterns with semantic categories in a joint process.

There has been a line of research on Chinese relation extraction, where both feature-based (Zhou et al., 2005; Li et al., 2008) and kernel-based (Zhang et al., 2006; Che et al., 2005) methods have been applied. In addition, semantic ontologies such as *Extended Cilin* have been shown useful for Chinese relation extraction (Liu et al., 2013). However, these studies have focused on traditional IE, with pre-defined relations. In contrast, we investigate ORE for Chinese, finding that semantic ontologies useful for this task also. Tseng et al. (2014) is the only previous research focusing on Chinese ORE. Their system can be considered as a pipeline of word segmentation, POS-tagging and parsing, while our work gives semantic interpretation and explicitly deals with statistical errors in parsing by a novel double propagation algorithm between patterns and relations.

6 Conclusion and Future Work

We presented a Chinese ORE system that integrates relation extraction with semantic pattern generalization by double propagation. Experimental results on two datasets demonstrated the effectiveness of the proposed algorithm. We make the ZORE system, together with the large scale relations and pattern synsets extracted by ZORE, freely available at (`https://sourceforge.net/projects/zore/`). Another version of ZORE (ZORE-PMT), which is based on the dependency tagset from PMT1.0 (Qiu et al., 2014), is also provided.

Our error analysis demonstrates that the quality of syntactic parsing is crucial to the accuracy of syntax-based Chinese ORE. Improvements to syntactic analysis is likely to lead to improved ORE. In addition, the idea of double propagation can be generalized into information propagation between relation extraction and syntactic analysis. We plan to investigate the use of ORE in improving syntactic analysis in future work.

Coarse-grained Candidate Generation and Fine-grained Re-ranking for Chinese Abbreviation Prediction

Abstract

Correctly predicting abbreviations given the full forms is important in many natural language processing systems. In this paper we propose a two-stage method to find the corresponding abbreviation given its full form. We first use the contextual information given a large corpus to get abbreviation candidates for each full form and get a coarse-grained ranking through graph random walk. This coarse-grained rank list fixes the search space inside the top-ranked candidates. Then we use a similarity sensitive re-ranking strategy which can utilize the features of the candidates to give a fine-grained re-ranking and select the final result. Our method achieves good results and outperforms the state-of-the-art systems. One advantage of our method is that it only needs weak supervision and can get competitive results with fewer training data. The candidate generation and coarse-grained ranking is totally unsupervised. The re-ranking phase can use a very small amount of training data to get a reasonably good result.

1 Introduction

Abbreviation Prediction is defined as finding the meaningful short subsequence of characters given the original fully expanded form. As an example, "HMM" is the abbreviation for the corresponding full form "Hidden Markov Model". While the existence of abbreviations is a common linguistic phenomenon, it causes many problems like spelling variation (Nenadić et al., 2002). The different writing manners make it difficult to identify the terms conveying the same concept, which will hurt the performance of many applications, such as information retrieval (IR) systems and machine translation (MT) systems.

Previous works mainly treat the Chinese abbreviation generation task as a sequence labeling problem, which gives each character a label to indicate whether the given character in the full form should be kept in the abbreviation or not. These methods show acceptable results. However they rely heavily on the character-based features, which means it needs lots of training data to learn the weights of these context features. The performance is good on some test sets that are similar to the training data, however, when it moves to an unseen context, this method may fail. This is always true in real application contexts like the social media where there are tremendous new abbreviations burst out every day.

A more intuitive way is to find the full-abbreviation pairs directly from a large text corpus. A good source of texts is the news texts. In a news text, the full forms are often mentioned first. Then in the rest of the news its corresponding abbreviation is mentioned as an alternative. The co-occurrence of the full form and the abbreviation makes it easier for us to mine the abbreviation pairs from the large amount of news texts. Therefore, given a long full form, we can generate its abbreviation candidates from the given corpus, instead of doing the character tagging job.

For the abbreviation prediction task, the candidate abbreviation must be a sub-sequence of the given full form. An intuitive way is to select all the sub-sequences in the corpus as the candidates. This will generate large numbers of irrelevant candidates. Instead, we use a contextual graph random walk method, which can utilize the contextual information through the graph, to select a coarse grained list of candidates given the full form. We only select the top-ranked candidates to reduce the search space. On the other hand, the candidate generation process can only use limited contextual information to give a coarse-grained ranked list of candidates. During generation, can-

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

didate level features cannot be included. Therefore we propose a similarity sensitive re-ranking method to give a fine-grained ranked list. We then select the final result based on the rank of each candidate.

The contribution of our work is two folds. Firstly we propose an improved method for abbreviation generation. Compared to previous work, our method can perform well with less training data. This is an advantage in the context of social media. Secondly, we build a new abbreviation corpus and make it publicly available for future research on this topic.

The paper is structured as follows. Section 1 gives the introduction. In section 2 we describe the abbreviation task. In section 3 we describe the candidate generation part and in section 4 we describe the re-ranking part. Experiments are described in section 5. We also give a detailed analysis of the results in section 5. In section 6 related works are introduced, and the paper is concluded in the last section.

2 Chinese Abbreviation Prediction System

Chinese Abbreviation Prediction is the task of selecting representative characters from the long full form[1]. Previous works mainly use the sequence labeling strategies, which views the full form as a character sequence and give each character an extra label 'Keep' or 'Skip' to indicate whether the current character should be kept in the abbreviation. An example is shown in Table 1. The sequence labeling method assumes that the character context information is crucial to decide the keep or skip of a character. However, we can give many counterexamples. An example is "北京大学"(Peking University) and "清华大学"(Tsinghua University), whose abbreviations correspond to "北大" and '清华' respectively. Although sharing a similar character context, the third character '大' is kept in the first case and is skipped in the second case.

We believe that a better way is to extract these abbreviation-full pairs from a natural text corpus where the full form and its abbreviation co-exist. Therefore we propose a two stage method. The first stage generates a list of candidates given a large corpus. To reduce the search space, we adopt graph random walk to give a coarse-grained ranking and select the top-ranked ones as the candidates. Then we use a similarity sensitive re-ranking method to decide the final result. Detailed description of the two parts is shown in the following sections.

[1]Details of the difference between English and Chinese abbreviation prediction can be found in Zhang et al. (2012).

Full form	香	港	大	学
Status	Skip	Keep	Keep	Skip
Result		港	大	

Table 1: The abbreviation "港大" of the full form "香港大学" (Hong Kong University)

3 Candidate Generation through Graph Random Walk

3.1 Candidate Generation and Graph Representation

Chinese abbreviations are sub-sequences of the full form. We use a brute force method to select all strings in a given news article that is the sub-sequence of the full form. The brute force method is not time consuming compared to using more complex data structures like trie tree, because in a given news article there are a limited number of sub-strings which meet the sub-sequence criteria for abbreviations. When generating abbreviation candidates for a given full form, we require the full form should appear in the given news article at least once. This is a coarse filter to indicate that the given news article is related to the full form and therefore the candidates generated are potentially meaningful.

The main motivation of the candidate generation stage in our approach is that the full form and its abbreviation tend to share similar context in a given corpus. To be more detailed, given a word context window w, the words that appear in the context window of the full form tend to be similar to those words in the context window of the abbreviations.

We use a bipartite graph $G(V_{word}, V_{context}, E)$ to represent this phenomena. We build bipartite graphs for each full form individually. For a given full form v_{full}, we first extract all its candidate abbreviations V_C. We have two kinds of nodes in the bipartite graph: the word nodes and the context nodes. We construct the word nodes as $V_{word} = V_C \cup \{v_{full}\}$, which is the node set of the full form and all the candidates. We construct the context nodes $V_{context}$ as the words that appear

in a fixed window of V_{word}. To reduce the size of the graph, we make two extra assumptions: 1) We only consider the nouns and verbs in the context and 2) context words should appear in the vocabulary for more than a predefined threshold (i.e. 5 times). Because G is bipartite graph, the edges E only connect word node and context nodes. We use the number of co-occurrence of the candidate and the context word as the weight of each edge and then form the weight matrix W. Details of the bipartite graph construction algorithm are shown in Table 2. An example bipartite graph is shown in figure 1.

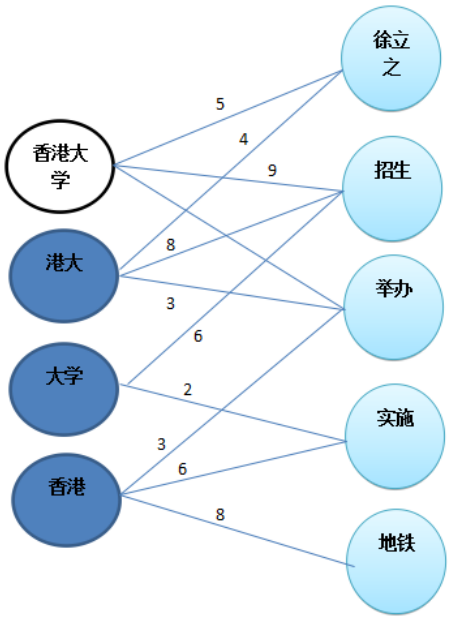

Figure 1: An example of the bipartite graph representation. The full form is "香港大学"(Hong Kong University), which is the first node on the left. The three candidates are "港大", "香港", "大学", which are the nodes on the left. The context words in this example are "徐立之"(Tsui Lap-chee, the headmaster of Hong Kong University), "招生"(Enrollment), "举办"(Hold), "实施"(Enact), "地铁"(Subway), which are the nodes on the right. The edge weight is the co-occurrence of the left word and the right word.

3.2 Coarse-grained Ranking Using Random Walks

We perform Markov Random Walk on the constructed bipartite graph to give a coarse-grained ranked list of all candidates. In random walk, a *walker* starts from the full form source node S (in later steps, v_i) and randomly *walks* to another node v_j with a transition probability p_{ij}. In random walk we assume the *walker* do the *walking* n times and finally stops at a final node. When the walking is done, we can get the probability of each node that the *walker* stops in the end. Because the *destination* of each step is selected based on transition probabilities, the word node that shares more similar contexts are more likely to be the final stop. The random walk method we use is similar to those defined in Norris (1998); Zhu et al. (2003); Sproat et al. (2006); Hassan and Menezes (2013); Li et al. (2013).

The transition probability p_{ij} is calculated using the weights in the weight matrix W and then normalized with respect to the source node v_i with the formula $p_{ij} = \frac{w_{ij}}{\sum_l w_{il}}$. When the graph random walk is done, we get a list of coarse-ranked candidates, each with a confidence score derived from the context information. By performing the graph random walk, we reduce the search space from exponential to the top-ranked ones. Now we only need to select the final result from the candidates, which we will describe in the next section.

4 Candidate Re-ranking

Although the coarse-grained ranked list can serve as a basic reference, it can only use limited information like co-occurrence. We still need a re-ranking process to decide the final result. The reason is that we cannot get any candidate-specific features when the candidate is not fully generated. Features such as the length of a candidate are proved to be useful to rank the candidates by previous work. In this section we describe our second stage for abbreviation generation, which we use a similarity sensitive re-ranking method to find the final result.

4.1 Similarity Sensitive Re-ranking

The basic idea behind our similarity sensitive re-ranking model is that we penalize the mistakes based on the similarity of the candidate and the reference. If the model wrongly selects a less similar candidate as the result, then we will attach a large penalty to this mistake. If the model wrongly chooses a candidate but the candidate is similar to the reference, we slightly penalize this mistake. The similarity between a candidate and the reference is measured through character similarity, which we will describe later.

Input: the full form v_{full}, news corpus U
Output: bipartite graph $G(V_{word}, V_{context}, E)$

Candidate vector $V_c = \emptyset$, $V_{context} = \emptyset$
for each document d in U
  if d contains v_{full}
  add all words w in the window of v_{full} into $V_{context}$
  for each n-gram s in d
  if s is a sub-sequence of v_{full}
  add s into V_c
  add all word w in the window of s into $V_{context}$
  end if
  end for
  end if
end for
$V_{word} = V_c \cup \{v_{full}\}$
for each word v_i in V_{word}
  for each word v_j in $V_{context}$
  calculate edge weight in E based on co-occurrence
  end for
end for
Return $G(V_{word}, V_{context}, E)$

Table 2: Algorithm for constructing bipartite graphs

We first give some notation of the re-ranking phase.

1. $f(x, y)$ is a scoring function for a given combination of x and y, where x is the original full form and y is an abbreviation candidate. For a given full form x_i with K candidates, we assume its corresponding K candidates are y_i^1,y_i^2,...,y_i^K.

2. evaluation function $s(x, y)$ is used to measure the similarity of the candidate to the reference, where x is the original full form and y is one abbreviation candidate. We require that $s(x, y)$ should be in $[0, 1]$ and $s(x, y) = 1$ if and only if y is the reference.

One choice for $s(x, y)$ may be the indicator function. However, indicator function returns zero for all false candidates. In the abbreviation prediction task, some false candidates are much closer to the reference than the rest. Considering this, we use a Longest Common Subsequence(LCS) based criterion to calculate $s(x, y)$. Suppose the length of a candidate is a, the length of the reference is b and the length of their LCS is c, then we can define precision P and recall R as:

$$\begin{aligned} P =& \frac{c}{a}, \\ R =& \frac{c}{b}, \\ F =& \frac{2 * P * R}{P + R} \end{aligned} \tag{1}$$

It is easy to see that F is a suitable $s(x, y)$. Therefore we can use the F-score as the value for $s(x, y)$.

3. $\phi(x, y)$ is a feature function which returns a m dimension feature vector. m is the number of features in the re-ranking.

4. $\vec{w}$ is a weight vector with dimension m. $\vec{w}^T\phi(x, y)$ is the score after re-ranking. The candidate with the highest score will be our final result.

Given these notations, we can now describe our re-ranking algorithm. Suppose we have the training set $X = \{x_1, x_2, ..., x_n\}$. We should find the weight vector $\vec{w}$ that can minimize the loss function:

$$\begin{aligned} Loss(\vec{w}) = \sum_{i=1}^{n} \sum_{j=1}^{k} ((s(x_i, y_i^1) - s(x_i, y_i^j)) \\ * I(\vec{w}^T\phi(x_i, y_i^j) \geq \vec{w}^T\phi(x_i, y_i^1))) \end{aligned} \tag{2}$$

$I(x)$ is the indicator function. It equals to 1 if and only if $x \geq 0$. $I(j) = 1$ means that the candidate which is less 'similar' to the reference is ranked higher than the reference. Intuitively, $Loss(\vec{w})$ is the weighted sum of all the wrongly ranked candidates.

It is difficult to optimize $Loss(\vec{w})$ because $Loss(\vec{w})$ is discontinuous. We make a relaxation here[2]:

$$\begin{aligned} L(\vec{w}) = & \sum_{i=1}^{n}\sum_{j=1}^{k}((s(x_i, y_i^1) - s(x_i, y_i^j)) \\ & * \frac{1}{1 + e^{-\vec{w}^T(\phi(x_i, y_i^j) - \phi(x_i, y_i^1))}}) \\ & \leq \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{k}((s(x_i, y_i^1) - s(x_i, y_i^j)) \\ & * I(\vec{w}^T\phi(x_i, y_i^j) \geq \vec{w}^T\phi(x_i, y_i^1))) \\ & = \frac{1}{2}Loss(\vec{w}) \end{aligned} \tag{3}$$

From the equations above we can see that $2L(\vec{w})$ is the upper bound of our loss function $Loss(\vec{w})$. Therefore we can optimize $L(\vec{w})$ to approximate $Loss(\vec{w})$.

We can use optimization methods like gradient descent to get the $\vec{w}$ that minimize the loss function. Because L is not convex, it may go into a local minimum. In our experiment we held out 10% data as the develop set and try random initialization to decide the initial $\vec{w}$.

4.2 Features for Re-ranking

One advantage of the re-ranking phase is that it can now use features related to candidates. Therefore, we can use a variety of features. We list them as follows.

1. **The coarse-grained ranking score from the graph random walk phase**. From the description of the previous section we know that this score is the probability a 'walker' 'walk' from the full form node to the current candidate. This is a coarse-grained score because it can only use the information of words inside the window. However, it is still informative because in the re-ranking phase we cannot collect this information directly.
2. **The character uni-grams and bi-grams in the candidate**. This kind of feature cannot be used in the traditional character tagging methods.
3. **The language model score of the candidate**. In our experiment, we train a bi-gram language model using Laplace smoothing on the Chinese Gigaword Data[3].
4. **The length of the candidate**. Intuitively, abbreviations tend to be short. Therefore length can be an important feature for the re-ranking.
5. **The degree of ambiguity of the candidate**. We first define the degree of ambiguity d_i of a character c_i as the number of identical words that contain the character. We then define the degree of ambiguity of the candidate as the sum of all d_i in the candidates. We need a dictionary to extract this feature. We collect all words in the PKU data of the second International Chinese Word Segmentation Bakeoff[4].
6. **Whether the candidate is in a word dictionary**. We use the PKU dictionary in feature 5.
7. **Whether all bi-grams are in a word dictionary**. We use the PKU dictionary in feature 5.
8. **Adjacent Variety(AV) of the candidate**. We define the left AV of the candidate as the probability that in a corpus the character in front of the candidate is a character in the full form. For example if we consider the full form "北京大学"(Peking University) and the candidate "京大", then the left AV of "京大" is the probability that the character preceding "京大" is '北' or '京' or '大' or '学' in a corpus. We can similarly define the right AV, with respect to characters follow the candidate.

The AV feature is very useful because in some cases a substring of the full form may have a confusingly high frequency. In the example of "北京大学"(Peking University), an article in the corpus may mention "北京大学"(Peking University) and

[2]To prove this we need the following two inequalities: 1) when $x \geq 0$, $I(x) \leq \frac{2}{1+e^{-x}}$ and 2) $s(x_i, y_i^1) - s(x_i, y_i^j) \geq 0$.

[3]http://www.ldc.upenn.edu/Catalog/catalogEntry.jsp?catalogId=LDC2003T09

[4]http://www.sighan.org/bakeoff2005/

“东京大学”(Tokyo University) at the same time. Then the substring “京大学” may be included in the candidate generation phase for “北京大学” with a high frequency. Because the left AV of “京大学” is high, the re-ranker can easily detect this false candidate.

In practice, all the features need to be scaled in order to speed up training. There are many ways to scale features. We use the most intuitive scaling method. For a feature value x, we scale it as $(x-mean)/(max-min)$. Note that for language model score and the score of random walk phase, we scale based on their log value.

5 Experiments

5.1 Dataset and Evaluation metrics

For the dataset, we collect 3210 abbreviation pairs from the Chinese Gigaword corpus. The abbreviation pairs include noun phrases, organization names and some other types. The Chinese Gigaword corpus contains news texts from the year 1992 to 2007. We only collect those pairs whose full form and corresponding abbreviation appear in the same article for at least one time. For full forms with more than one reasonable reference, we keep the most frequently used one as its reference. We use 80% abbreviation pairs as the training data and the rest as the testing data.

We use the top-K accuracy as the evaluation metrics. The top-K accuracy is widely used as the measurement in previous work (Tsuruoka et al., 2005; Sun et al., 2008, 2009; Zhang et al., 2012). It measures what percentage of the reference abbreviations are found if we take the top k candidate abbreviations from all the results. In our experiment, we compare the top-5 accuracy with baselines. We choose the top-10 candidates from the graph random walk are considered in re-ranking phase and the measurement used is top-1 accuracy because the final aim of the algorithm is to detect the exact abbreviation, rather than a list of candidates.

5.2 Candidate List

Table 3 shows examples of the candidates. In our algorithm we further reduce the search space to only incorporate 10 candidates from the candidate generation phase.

K	Top-K Accuracy
1	6.84%
2	19.35%
3	49.01%
4	63.70%
5	73.60%

Table 4: Top-5 accuracy of the candidate generation phase

5.3 Comparison with baselines

We first show the top-5 accuracy of the candidate generation phase Table 4. We can see that, just like the case of using other feature alone, using the score of random walk alone is far from enough. However, the first 5 candidates contain most of the correct answers. We use the top-5 candidates plus another 5 candidates in the re-ranking phase.

We choose the character tagging method as the baseline method. The character tagging strategy is widely used in the abbreviation generation task (Tsuruoka et al., 2005; Sun et al., 2008, 2009; Zhang et al., 2012). We choose the ‘SK’ labeling strategy which is used in Sun et al. (2009); Zhang et al. (2012). The ‘SK’ labeling strategy gives each character a label in the character sequence, with ‘S’ represents ’Skip’ and ‘K’ represents ‘Keep’. Same with Zhang et al. (2012), we use the Conditional Random Fields (CRFs) model in the sequence labeling process.

The baseline method mainly uses the character context information to generate the candidate abbreviation. To be fair we use the same feature set in Sun et al. (2009); Zhang et al. (2012). One drawback of the sequence labeling method is that it relies heavily on the character context in the full form. With the number of new abbreviations grows rapidly (especially in social media like Facebook or twitter), it is impossible to let the model ‘remember’ all the character contexts. Our method is different from theirs, we use a more intuitive way which finds the list of candidates directly from a natural corpus.

Table 5 shows the comparison of the top-5 accuracy. We can see that our method outperforms the baseline methods. The baseline model performs well when using character features (Column 3). However, it performs poorly without the character features (Column 2). In contrast, without the character features, our method (Column 4) works much better than the sequence labeling method.

Full form	Reference	Generated Candidates	#Enum	#Now
国际政治系 (Department of International Politics)	国政系	国政系,政治系,国际政治,国政治,国政,政治,国际	30	7
无核武器国家 (Non-nuclear Countries)	无核国	核国,无核,核武,核国家,无核国,武器国,无核国家,核武器国,无核武器,核武器国家,核武器,国家,武器	62	13
贩卖毒品 (Drug trafficking)	贩毒	卖毒品,贩毒品,贩卖,毒品,贩毒	14	5
长江经济联合发展股份有限公司 (Yangtze Joint River Economic Development Inc.)	长发公司	合股,长发,长发公司,长江公司,长江经济,联合发展,经济发展,经济联合,长江联合发展,长江发展公司,长江经济联合,经济联合发展,长江经济联合发展,股份有限公司,有限公司,长江,公司,股份,联合,经济	16382	20

Table 3: Generated Candidates. #Enum is the number of candidates generated by enumerating all possible candidates. #Now is the number of candidates generated by our method.

When we add character features, our method (Column 5) still outperforms the sequence labeling method.

K	CRF-char	Our-char	CRF	Our
1	38.00%	**48.60%**	53.27%	**55.61%**
2	38.16%	70.87%	65.89%	73.10%
3	39.41%	81.78%	72.43%	81.96%
4	55.30%	87.54%	78.97%	87.57%
5	62.31%	89.25%	81.78%	89.27%

Table 5: Comparison of the baseline method and our method. CRF-char ('-' means minus) is the baseline method without character features. CRF is the baseline method. Our-char is our method without character features. We define character features as the features that consider the characters from the original full form as their parts.

5.4 Performance with less training data

One advantage of our method is that it only requires weak supervision. The baseline method needs plenty of manually collected full-abbreviation pairs to learn a good model. In our method, the candidate generation and coarse-grained ranking is totally unsupervised. The re-ranking phase needs training instances to decide the parameters. However we can use a very small amount of training data to get a reasonably good model. Figure 2 shows the result of using different size of training data. We can see that the performance of the baseline methods drops rapidly when there are less training data. In contrast, when using less training data, our method does not suffer that much.

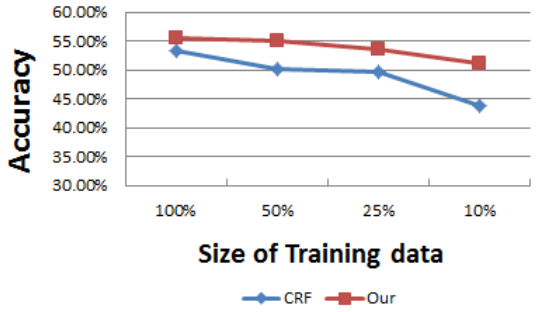

Figure 2: Top-1 accuracy when changing the size of training data. For example, "50%" means "using 50% of all the training data".

5.5 Comparison with previous work

We compare our method with the method in the previous work DPLVM+GI in Sun et al. (2009), which outperforms Tsuruoka et al. (2005); Sun et al. (2008). We also compare our method with the web-based method CRF+WEB in Zhang et al. (2012). Because the comparison is performed on different corpora, we run the two methods on our data. Table 6 shows the top-1 accuracy. We can see that our method outperforms the previous

methods.

System	Top-K Accuracy
DPLVM+GI	53.29%
CRF+WEB	54.02%
Our method	**55.61%**

Table 6: Comparison with previous work. The search results of CRF+WEB is based on March 9, 2014 version of the Baidu search engine.

5.6 Error Analysis

We perform cross-validation to find the errors and list the two major errors below:

1. Some full forms may correspond to more than one acceptable abbreviation. In this case, our method may choose the one that is indeed used as the full form's abbreviation in news texts, but not the same as the standard reference abbreviations. The reason for this phenomenon may lie in the fact that the verification data we use is news text, which tends to be formal. Therefore when a reference is often used colloquially, our method may miss it. We can relieve this by changing the corpus we use.

2. Our method may provide biased information when handling location sensitive phrases. Not only our system, the system of Sun et al. (2009); Zhang et al. (2012) also shows this phenomenon. An example is the case of "香港民主同盟" (Democracy League of Hong Kong). Because most of the news is about news in mainland China, it is hard for the model to tell the difference between the reference "港同盟" and a false candidate "民盟"(Democracy League of China).

   Another ambiguity is "清华大学"(Tsinghua University), which has two abbreviations "清大" and "清华". This happens because the full form itself is ambiguous. Word sense disambiguation can be performed first to handle this kind of problem.

6 Related Work

Abbreviation generation has been studied during recent years. At first, some approaches maintain a database of abbreviations and their corresponding "full form" pairs. The major problem of pure database-building approach is obvious. It is impossible to cover all abbreviations, and the building process is quite laborious. To find these pairs automatically, a powerful approach is to find the reference for a full form given the context, which is referred to as "abbreviation generation".

There is research on using heuristic rules for generating abbreviations Barrett and Grems (1960); Bourne and Ford (1961); Taghva and Gilbreth (1999); Park and Byrd (2001); Wren et al. (2002); Hearst (2003). Most of them achieved high performance. However, hand-crafted rules are time consuming to create, and it is not easy to transfer the knowledge of rules from one language to another.

Recent studies of abbreviation generation have focused on the use of machine learning techniques. Sun et al. (2008) proposed an SVM approach. Tsuruoka et al. (2005); Sun et al. (2009) formalized the process of abbreviation generation as a sequence labeling problem. The drawback of the sequence labeling strategies is that they rely heavily on the character features. This kind of method cannot fit the need for abbreviation generation in social media texts where the amount of abbreviations grows fast.

Besides these pure statistical approaches, there are also many approaches using Web as a corpus in machine learning approaches for generating abbreviations. Adar (2004) proposed methods to detect such pairs from biomedical documents. Jain et al. (2007) used web search results as well as search logs to find and rank abbreviates full pairs, which show good result. The disadvantage is that search log data is only available in a search engine backend. The ordinary approaches do not have access to search engine internals. Zhang et al. (2012) used web search engine information to rerank the candidate abbreviations generated by statistical approaches. Compared to their approaches, our method only uses a fixed corpus, instead of using collective information, which varies from time to time.

Some of the previous work that relate to abbreviations focuses on the task of "abbreviation disambiguation", which aims to find the correct abbreviation-full pairs. In these works, machine learning approaches are commonly used (Park and Byrd, 2001; HaCohen-Kerner et al., 2008; Yu et al., 2006; Ao and Takagi, 2005). We focus on another aspect. We want to find the abbreviation

given the full form. Besides, Sun et al. (2013) also works on abbreviation prediction but focuses on the negative full form problem, which is a little different from our work.

One related research field is text normalization, with many outstanding works (Sproat et al., 2001; Aw et al., 2006; Hassan and Menezes, 2013; Ling et al., 2013; Yang and Eisenstein, 2013). While the two tasks share similarities, abbreviation prediction has its identical characteristics, like the sub-sequence assumption. This results in different methods to tackle the two different problems.

7 Conclusion

In this paper, we propose a unified framework for Chinese abbreviation generation. Our approach contains two stages: candidate generation and re-ranking. Given a long term, we first generate a list of abbreviation candidates using the co-occurrence information. We give a coarse-grained rank using graph random walk to reduce the search space. After we get the candidate lists, we can use the features related to the candidates. We use a similarity sensitive re-rank method to get the final abbreviation. Experiments show that our method outperforms the previous systems.

Abstract

Distant supervision has become the leading method for training large-scale relation extractors, with nearly universal adoption in recent TAC knowledge-base population competitions. However, there are still many questions about the best way to learn such extractors. In this paper we investigate four orthogonal improvements: integrating named entity linking (NEL) and coreference resolution into argument identification for training and extraction, enforcing type constraints of linked arguments, and partitioning the model by relation type signature.

We evaluate sentential extraction performance on two datasets: the popular set of NY Times articles partially annotated by Hoffmann et al. (2011) and a new dataset, called GoReCo, that is comprehensively annotated for 48 common relations. We find that using NEL for argument identification boosts performance over the traditional approach (named entity recognition with string match), and there is further improvement from using argument types. Our best system boosts precision by 44% and recall by 70%.

1 Introduction

Relation extractors are commonly trained by distant supervision (also known as knowledge-based weak supervision (Hoffmann et al., 2011)), an autonomous technique that creates a labeled training set by heuristically matching the contents of a knowledge base (KB) to *mentions* (substrings) in a textual corpus. For example, if a KB contained the ground tuple BornIn(Albert Einstein, Ulm) then

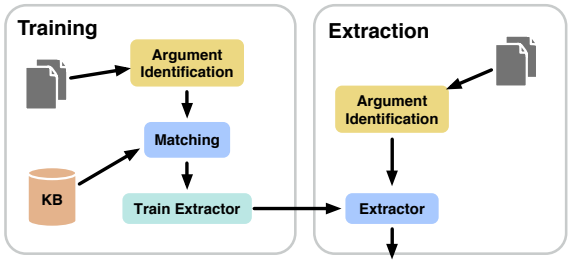

Figure 1: Distantly supervised extraction pipeline.

a distant supervision system might label the sentence "While $[\text{Einstein}]_1$ was born in $[\text{Ulm}]_2$, he moved to Munich at an early age." as a positive training instance of the BornIn relation. Although distant supervision is a simple idea and often creates data with false positives, it has become ubiquitous; for example, all top-performing systems in recent TAC-KBP slot filling competitions used the method.

Surprisingly, however, many aspects of distant supervision are poorly studied. In response we perform an extensive search of ways to improve distant supervision and the extraction process, including using named entity linking (NEL) and coreference to identify arguments for distant supervision and extraction, as well as using type constraints and partitioning the trained model by relation type signatures.

The first step in the distant supervision process is *argument identification* (Figure 1) — finding textual mentions referring to entities that might be in some relation. Next comes *matching*, where KB facts, e.g. tuples such as $R(e_1, e_2)$, are associated with sentences mentioning entities e_1 and e_2 in the assumption that many of these sentences describe the relation R. Most previous systems perform these steps by first using named entity recognition (NER) to identify possible arguments and then using a simple string match, but this crude

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1891–1901,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

approach misses many possible instances. Since the separately-studied task of named entity linking (NEL) is precisely what is needed to perform distant supervision, it is interesting to see if today's optimized linkers lead to improved performance when used to train extractors.

Coreference, the task of clustering mentions that describe the same entity, may also be useful for increasing the number of candidate arguments. Consider the following variant of our previous example: "While $[\text{he}]_1$ was born in $[\text{Ulm}]_2$, $[\text{Einstein}]_3$ moved to Munich at an early age." Since mentions 1 and 3 corefer, one could consider using either the pair $\langle 1, 2\rangle$ or $\langle 3, 2\rangle$ (or both) for training. Intuitively, it seems that $\langle 1, 2\rangle$ is more representative of BornIn and might generalize better, so we consider the use of coreference at both training and extraction time.

Semantic relations often have selectional preferences (also known as type signatures); for example, BornIn holds between people and locations. Therefore, it seems promising to include entity types, whether coarse or fine grained in the distantly supervised relation extraction process. We consider two ways of adding this information. By using NEL to get linked entities, we can impose type constraints on the relation extraction system to only allow relations over appropriately typed mentions. We also investigate using coarse types from NER to learn separate models for different relation type signatures in order to make the models more effective.

In summary, this paper represents the following contributions:

- We explore several dimensions for improving distantly supervised relation extraction, including better argument identification during training and extraction using both NEL and coreference, partitioning the model by relation type signatures, and enforcing type constraints of linked arguments as a post-processing step. While some of these ideas may seem straightforward, to our knowledge they have not been systematically studied. And, as we show, they lead to dramatic improvements.

- Since previous datasets are incapable of measuring an extractor's true recall, we introduce GoReCo, a new exhaustively-labeled dataset with gold annotations for sentential instances of 48 relations across 128 newswire documents from the ACE 2004 corpus (Doddington et al., 2004).

- We demonstrate that NEL argument identification boosts both precision and recall, and using type constraints with linked arguments further boosts precision, yielding a 43% increase in precision and 27% boost to recall. Using coreference during training argument identification gives an additional 7% improvement to precision and further boosts recall by 9%. Partitioning the model by relation type signature offers further benefits, so our best system yields a total boost of 44% to precision and 70% to recall.

2 Distantly Supervised Extraction

At a sentence-level, the goal for relation extraction is to determine for each sentence, what facts are expressed. We describe these as *relation annotations* of the form $s{\rightarrow}R(m_1, m_2)$, where s is a sentence, $R \in \mathcal{R}$ is a relation name, $\mathcal{R}$ is our finite set of target relations, and m_1 and m_2 are *grounded entity mentions* of the form (s, t_1, t_2, e), where t_1 and t_2 delimit a text span in the sentence, and e is a grounded entity.

2.1 Training

During training, the contents of the KB are heuristically matched to the training corpus according to the *distant supervision hypothesis*: if a relation holds between two entities, any sentence containing those two entities is likely to express that relation.

The training KB Δ contains *fact tuples* of form $R(e_1, e_2)$, where $R \in \mathcal{R}$ is a relation name, $\mathcal{R}$ is our finite set of target relations, and e_1 and e_2 are ground entities. The training text corpus Σ contains documents, which contain sentences. *Argument identification* is performed over the text corpus to get grounded mentions m. Then during sentential instance generation, *sentential instances* of the form (s, m_1, m_2) are generated representing a sentence with two grounded mentions. At this point, these sentential instances can be matched to the seed KB, yielding *candidate relation annotations* of the form $s{\rightarrow}R(m_1, m_2)$ by finding all relations that hold over the entities in a sentential instance. These candidate relation annotations are all positive instances to use for training. Negative instance generation is also performed, generating

negative examples of the form $s \rightarrow NA(m_1, m_2)$ indicating that no relation holds between m_1 and m_2. There are several heuristics for generating negative instances, and the number of negative examples and how they are treated can greatly affect performance (Min et al., 2013).

Because the distant supervision hypothesis often does not hold, this training data is noisy. That a fact is in the KB does not imply that the sentence in question is expressing the relation. There has been much work in combating noise in distant supervision training data, but one of the most successful ideas is to train a multi-instance classifier which assumes at-least-one relation holds for positive bags. We use Hoffmann et al. (2011)'s MULTIR system, which uses a probabilistic graphical model to jointly reason at the corpus-level and sentence-level, handles overlapping relations in the KB so that multiple relations can hold over an entity pair, and scales to large datasets.

2.2 Extraction

The trained relation extractor can assign a most likely relation and a confidence score to a sentential instance (s, m_1, m_2). To get these sentential instances, argument identification and sentential instance generation are applied to new documents. Then the relation extractor potentially yields a relation annotation of the form $s \rightarrow R(m_1, m_2)$, or potentially no relation. At extraction time a mention m might have a NIL link if a corresponding ground entity was not found during argument identification (meaning the entity is not in the KB). The relation annotations have associated confidence scores, so a threshold can be chosen to only use high-confidence relation annotations.

3 Argument Identification

An important piece of relation extraction is determining what can be an argument, and how to form a semantic representation of it. We define an argument identification function $\textit{ArgIdent}_{\Delta}(D)$, which takes a document D, finds potential arguments, and links them to entities in Δ if possible, yielding $\mathbf{m}$, a set of grounded mentions in D. Previous relation extraction systems have based this on NER. We evaluate NER-based argument identification against argument identification based on NEL, as well as NEL with coreference.

3.1 Named Entity Recognition

Named entity recognition (NER) tags spans of tokens with basic types such as PERSON, ORGANIZATION, LOCATION, and MISC. This is a high accuracy tagging task often performed using a sequence classifier (Finkel et al., 2005). Relation extraction systems can base their argument identification on NER, by using NER to identify text spans indicating entities and then find corresponding entities in the KB through exact string match (Riedel et al., 2010). Some downsides of using NER with exact string match for relation extraction is that it does not allow for overlapping mentions, it can only capture arguments with full names, and it can only capture arguments with types of the NER system, e.g., "politician" might not be captured.

3.2 Named Entity Linking

Named entity linking (NEL) is the task of grounding textual mentions to entities in a KB, such as Wikipedia. Thus "named entity" here, has a somewhat broader definition than in NER — these are any entities in the KB, not just those expressed with proper names. Hachey et al. (2013) define three stages that NEL systems take to perform this task: extraction (mention detection), search (generating candidate KB entities for a mention), and disambiguation (selecting the best entity for a mention). There has been much work on the task of NEL in recent years (Milne and Witten, 2008; Kulkarni et al., 2009; Ratinov et al., 2011; Cheng and Roth, 2013).

Our definition of a function $\textit{ArgIdent}(D)$ is completely served by an NEL system. It can find any entity in the KB, and those entities are grounded. Additionally, NEL can have overlapping mentions as well as support for abbreviated mentions like "Obama", or acronyms like "US". NEL does not seek to capture anaphoric mentions, however.

3.3 Coreference Resolution

Coreference resolution is the task of clustering mentions of entities together, typically within a single document. Using coreference, we can find even more mentions than NEL, since it can find pronouns and anaphoric mentions. We seek to use coreference to add additional arguments to those found by NEL, and we refer to this combined argument identification method as *NEL+Coref*. Tak-

ing in arguments from NEL argument identification and coreference clusters, we ground the clusters by picking the most common grounded entity from NEL mentions that occur in a coreference cluster. A difficulty is that mentions from NEL and coreference can have small differences in text spans, such as whether determiners are included. We try to assign each NEL argument to a coreference cluster, first looking for an exact span match, then by looking for the shortest coreference mention that contains it. If the coreference cluster already has matched an NEL argument through exact span match that is different from the one found by looking for the shortest containing coreference mention, the new NEL argument is not added. This gives for each coreference cluster a possible grounding to an entity in the KB. What is provided as final arguments for NEL+Coref argument identification are, in order, grounded NEL arguments, grounded coreference arguments that do not overlap with previous arguments, NIL arguments from NEL that do not overlap with previous arguments, and NIL arguments from coreference that do not overlap with previous arguments.

4 Type-Awareness

Relations have expected types for each argument. Entity types, whether coarse-grained, such as from NER, or fine-grained, such as from Freebase entities, are an important source of information that can be useful for making decisions in relation extraction. We bring type-awareness into the system through partitioning the model, as well as by enforcing type constraints on output relation annotations.

Model Partitioning Instead of building a single relation extractor that can generate sentential instances and then relation annotations with arguments of any type, we can instead build separate relation extractors for each possible coarse type signature, e.g., (PERSON, PERSON), (PERSON, LOCATION), etc., and combine the extractions from the extractor for each type signature. This modification allows each trained model to only handle instances of specific types, and thus relations of that type signature, allowing each to do a better job of choosing relations within the type signature.

Type Constraints We can additionally reject relation annotations where the types of the arguments do not agree with the expected types of the relation. That is, we only accept a relation annotation $s \rightarrow R(m_1, m_2)$ when *EntityTypes*$(e_1) \cap \tau_1 \neq \emptyset$ and *EntityTypes*$(e_2) \cap \tau_2 \neq \emptyset$, where m_1 is linked to e_1, m_2 is linked to e_2, *EntityTypes* provides the set of valid types for an entity, τ_1 is the set of allowed types for the first argument of target relation r, and τ_2 for the second argument.

5 Evaluation Setups

Relation extraction is often evaluated from a macro-reading perspective (Mitchell et al., 2009), in which the extracted facts, $R(e_1, e_2)$, are judged true or false independent of any supporting sentence. For these experiments, however, we take a micro-reading approach in order to strictly evaluate whether a relation extractor is able to extract every fact expressed by a sentence $s \rightarrow R(m_1, m_2)$. Micro-reading is more difficult, but it provides fully semantic information at the sentence and document level allowing detailed justifications, and, for our purposes, allows us to better understand the effects of our modifications. In order to fairly evaluate different systems, even those using different methods of argument identification, we want to use gold evaluation data allowing for varying mention types. We additionally use Hoffmann et al. (2011)'s sentential evaluation as-is in order to better compare with prior work. For our training corpus, we use the TAC-KBP 2009 (McNamee and Dang, 2009) English newswire corpus containing one million documents with 27 million sentences.

5.1 Hoffmann et al. Sentential Evaluation

Hoffmann et al. (2011) generated their gold data by taking the union of sentential instances where some system being evaluated extracted a relation as well as the sentential instances matching arguments in the KB. They took a random sample of these sentential instances and manually labeled them with either a single relation or *NA*. Although this process provides good coverage, since is is sampled from extractions over a large corpus, it does not allow one to measure true recall. Indeed, Hoffmann's method *significantly overestimates recall*, since the random sample is only over sentential instances where a program detected an extraction or a KB match was found. Furthermore, this test set only contains sentential instances in which arguments are marked using NER, which makes it impossible to determine if the use of NEL or

coreference confers any benefit.

Finally, it does not allow for the possibility that there may be multiple relations that should be extracted for a pair of arguments. For example, a CeoOf relation, and an EmployedBy relation might both be present for (Larry Page, Google). To address these issues, we manually annotate a full set of documents with relation annotations. Because we are evaluating changing various aspects of the distant supervision process, we cannot use Riedel et al. (2010)'s distant supervision data as-is as others did on the Hoffmann et al. (2011) sentential evaluation. Instead, we use the TAC-KBP data described above.

5.2 GoReCo Evaluation

In order to allow for variations on mentions (NER, NEL, and coreference each has its own definition of what a mention boundary should be), we want gold relation annotations over coreference clusters broadly defined to allow mentions obtained from NER and NEL, as well as gold coreference mentions. So as long as a relation extraction system extracts a relation annotation $s \rightarrow R(m_1, m_2)$ where m_1 and m_2 are allowed options (based on text spans), it will get credit for extracting the relation annotation. We introduce the GoReCo (gold relations and coreference) evaluation to satisfy these constraints.

We start with an existing gold coreference dataset, ACE 2004 (Doddington et al., 2004) newswire, consisting of 128 documents. To get relation annotations over coreference clusters, we define two human annotation tasks and use the BRAT (Stenetorp et al., 2012) tool for visualization and relation and coreference annotations.

Relation Annotation The annotator is presented with a document with gold mentions indicated and asked to determine for each sentence, what facts involving target relations are expressed by the sentence. They draw an arrow for each fact and label it with the relation. They also have the ability to add mentions not present (ReAnn mentions).

Supplemental Coreference Mentions from NER and NEL are displayed along with ACE and ReAnn mentions from the previous task. The annotator draws coreference links from NER or NEL mentions to an ACE or ReAnn mention if they are coreferent.

We randomly shuffle the 128 ACE 2004 newswire documents and use 64 as a development set and 64 as a test set. To complete annotations of these documents, we only used one original human annotator (hired using the oDesk crowdsourcing platform) and found mistakes by having others check the work, as well as checking false positives of relation extractors on the development set to find patterns of annotation mistakes. On average, there are 7 relation annotations per document.

For the GoReCo evaluation, we define our train/test split (with the separate TAC-KBP corpus used for training) such that each has a different set of documents and entities, in order to evaluate how well the system performs on unseen entities. To do this, we remove entities found in the gold evaluation set from the training KB. (We do not remove entities for the Hoffmann et al. (2011) evaluation, since they do not.) We choose the threshold confidence score for each system using the development set to optimize for F1 and report results on the test set.

5.2.1 Target Relations

Since we use a different evaluation, we also seek to choose a more comprehensive and interesting set of relations than prior work. Riedel et al. (2010), whose train and test data is also used by Hoffmann et al. (2011) and Surdeanu et al. (2012), use Freebase properties under domains /people, /business, and /location. Since /location relations such as /location/location/contains dominate the results (and are relatively uninteresting in that they rarely change), we do not use any /location relations, and instead use the domains /people, /business, and /organization (Google, 2012).

Since many Freebase properties are between an entity and a table instead of another entity, we also use joined relations, such as /people/person/employment_history $\bowtie$ /business/employment_tenure/company , in this case representing employment. We bring in an additional 20 relations of this form, also under /person, /business, and /organization. Additionally we use NELL (Carlson et al., 2010a) relations mapped to Freebase by Zhang et al. (2012).

We only include a relation in our set of target relations if both of its entity arguments are contained in the set of entities found via NER with exact string match or NEL over the training corpus. We also remove inverse relations, since they represent needless duplication. This gives us a set

$\mathcal{R}$ of 105 target relations based on joins and unions of Freebase properties. Of the 105 target relations, 48 were used at least once in the GoReCo data.

6 Experiments and Results

We conduct experiments to determine how changing distantly supervised relation extraction along various dimensions affects performance. We examine the choice of argument identification during training and extraction, as well as the effects of model type partitioning, and type constraints. We consider the space of all combinations of these dimensions, but focus on specific combinations where we find improvements.

6.1 Relation Extraction Setup

We use and modify Hoffmann et al. (2011)'s system MultiR to control our experiments and as a baseline. For NER argument identification as well as for the use of NER in the features, we use use Stanford NER (Finkel et al., 2005). For NEL argument identification we use Wikipedia Miner with the default threshold 0.5, and allowing repeated mentions (Milne and Witten, 2008). Since Wikipedia Miner does not support NIL links, we use non-overlapping NER mentions as NIL links. For coreference, we use Stanford's sieve-based deterministic coreference system (Lee et al., 2013). For sentential instance generation, we take all pairs of non-overlapping arguments in a sentence (in either order). If the arguments have KB links, we do not allow sentential instances where both arguments represent the same entity. We use the same lexical and syntactic features as MultiR, based on the features of Mintz et al. (2009). As required for features, we use Stanford CoreNLP's tokenizer, part of speech tagger (Toutanova et al., 2003), and dependency parser (de Marneffe and Manning, 2008), and use the Charniak Johnson constiuent parser (Charniak and Johnson, 2005). For negative training generation, we take a similar approach to Riedel et al. (2010) and define a percentage parameter n of the number of negative instances divided by the number of total instances. Experimenting with $n \in \{0, 20\%, 80\%\}$, we find that $n = 20\%$ works best for our evaluations, optimizing for F1, although using 80% negative training gives high precision at lower recall. We use frequency-based feature selection to eliminate features that appear less than 10 times, which is helpful both for reducing overfitting as well as constraining memory usage. Since the perceptron learning of MultiR is sensitive to instance ordering, we perform 10 random shuffles and average the models.

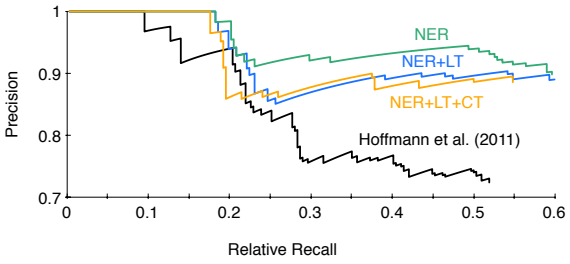

Figure 2: Methods evaluated in the context of Hoffmann et al. (2011)'s sentential extraction evaluation. NER: our NER baseline used for training and extraction, LT: use NEL for training only, CT: use coreference for training only. (NER+LT+CT means we use NER for extraction, and NEL+Coref for training.)

For model type partitioning, when training with NER, we ensure that the NER types match the coarse relation type signatures. For NEL, we attempt to use NER for coarse types of arguments, but if an NER type is not present, we map the Freebase type to its FIGER type (Ling and Weld, 2012) to its coarse type. For type constraints, we use Freebase's expected input and output types for relations. For NIL links, we use the NER type of PERSON, ORGANIZATION, or LOCATION, if available, mapping it to appropriate Freebase types.

6.2 NER Baseline

As a result of a larger training set, as well as model averaging, our baseline, which is otherwise equivalent to the methods of Hoffmann et al. (2011) and uses their MultiR system, has slightly higher precision as shown in Figure 2, curve NER. It is also higher than that of Xu et al. (2013), who achieved higher performance than Hoffmann et al. (2011); our baseline gets 89.9% precision and 59.6% relative recall, while Xu et al. (2013)'s system gets 84.6% precision and 56.1% relative recall. See Figure 3 and Table 1 for results on GoReCo.

6.3 NEL and Type Constraints

On GoReCo, using NEL argument identification increases recall and gives higher precision over the entire curve. We further find that filtering results using type constraints gives a large boost in pre-

cision at a small cost to recall. Note the increase in performance from NER to NEL to NEL+TC in Figure 3a, as well as in Table 1. Using NEL gives more recall, since it is able to capture arguments that NER cannot, such as professions like "paleontologist". The decrease in recall from type constraints comes from false positives in the type constraints process including from non-ideal links, e.g., "paleontologist" might get linked to the entity Paleontology, so will not have the type required for the Profession relation.

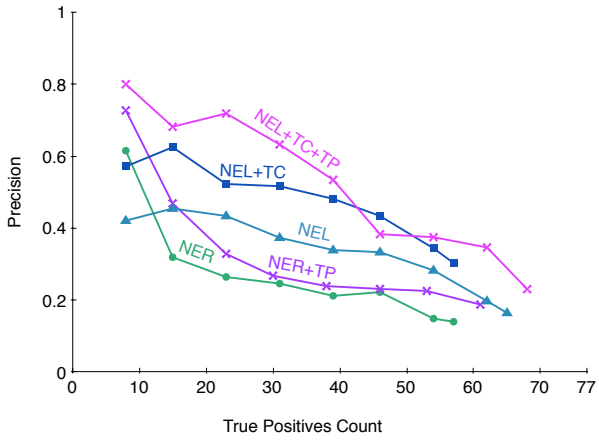
On the Hoffmann et al. (2011) sentential evaluation, we were not able to use NEL argument identification at extraction time, because the instances in the test set are from NER argument identification. We tried using NEL only at training time and found that it got similar performance to using NER (Figure 2, curve NER+LT). Doing the same on GoReCo yielded slightly lower recall, because of the mismatch of features learned from NEL arguments (Figure 3b, curve NER+LT).

6.4 NEL+Coref Argument Identification

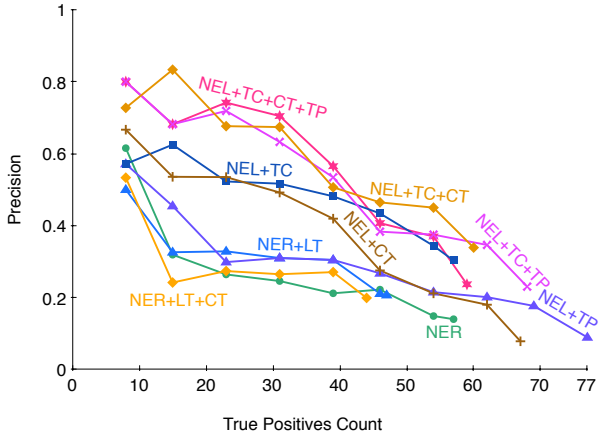
Using NEL+Coref for both training and extraction (see Table 1) introduces noise from arguments not encountered during training time, but using NEL+Coref just for training results in a decrease in recall but similar precision (Figures 2 and 3b).

We found using NEL+Coref at test time unhelpful for this dataset, because there were no examples we could find where coreference could recover arguments that NEL could not. There were three true positives from NEL+Coref involving pronouns in the GoReCo development set, but there were also proper name versions of the arguments nearby in the same sentences, making coreference unnecessary. Additionally, coreference brings in many mentions such as times like "Friday" or "1954" that do not have corresponding KB matches during training time. These sentential instances have similar features to others involving coreference mentions, and there are not negative instances to weigh against these, since these types do not appear in the training data. Better features more suited to coreference mentions could be helpful here.

At both training and extraction time, coreference can cluster together mentions that can be considered to be separate, such as in "Brian Kain, a 33-year-old accountant", "Brian Kain" and "accountant" are coreferent in the gold ACE 2004



(a)



(b)

Figure 3: Precision versus true positives count curves for different versions of the system evaluated on the GoReCo test set, containing 470 gold instances. NER/NEL: argument identification used in training and extraction, LT: use NEL for training only, CT: use coreference for training only, TC: type constraints, TP: model type partitioning.

dataset. This means that type constraints will disregard a Profession annotation between these when it should not, because "Brian Kain" (which would have been a NIL link) gets the link of "accountant". This effect contributes to the decrease in recall.

6.5 Model Type Partitioning

Using type partitioning helps both NER and NEL based models as shown with the +TP curves in Figure 3). Partitioning by type signature results in each model being able to better choose relations for sentential instances of that type signature. In the Partitioned columns of Table 1, removing type partitioning from the best system (NEL training

	Single			Partitioned		
	R	P	F1	R	P	F1
NER training						
NER extraction	7.9	21.8	11.6	11.3	21.0	14.7
NEL extraction	8.5	21.4	12.2	9.8	19.7	13.1
NEL training						
NER extraction	9.6	21.1	13.2	8.9	25.1	13.2
NEL extraction	10.0	30.5	15.1	**15.3**	16.7	16.0
NEL w/TC extraction	11.7	31.1	17.0	13.4	31.3	**18.8**
NEL+Coref training						
NER extraction	9.4	19.2	12.6	6.8	28.3	11.0
NEL extraction	12.1	27.5	16.8	11.1	21.6	14.6
NEL w/TC extraction	**12.8**	**33.3**	**18.5**	12.1	**34.1**	17.9
NEL+Coref extraction	10.6	20.4	14.0	10.0	12.9	11.3
NEL+Coref w/TC extraction	9.4	22.7	13.3	7.9	19.1	11.1

Table 1: Evaluation of different versions of the relation extraction system on the GORECO test set. For nearly all systems, partitioning the model by argument types boosts F1, as does using NEL at either training or extraction time, and using coreference at training time with type constraints (w/TC) raises F1 except with coreference at extraction time and when combined with type partitioning.

and extraction, with type constraints, Partitioned) results in a decrease in F1 from 18.8% to 17.0%. Table 2 shows by-relation performance results for the best system (curve NEL+TC+TP in Figure 3a).

6.6 Other Dimensions Explored

We also experimented with adding generalized features that replaced lexemes with WordNet classes (Fellbaum, 1998), which had uneven results. We observed a small but consistent improvement on the NER baseline (11.6% F1 to 12.7% F1 on GORECO), but after introducing NEL argument identification and partitioning, we no longer observed the improvement. For some relations, there was a small gain in recall that was offset by a loss in precision, but for others, the gain in recall outweighed the loss of precision.

We experimented with a negative instance feedback loop that ran a trained extractor over the training corpus and tested whether each extraction made was in fact a negative example. Even though the training corpus contains one million documents, this method only yielded a few thousand new negative instances due to the difficulty of being certain an extraction should be negative. A naïve approach would simply ensure that both entities participate in a relation in the KB; this is troublesome, because of KB incompleteness and because of type errors. For example Freebase contains BornIn(Barack Obama, Honolulu), but our extractor extracted BornIn(Barack Obama, Hawaii). To avoid labeling this true extraction as a negative instance we have to be robust about location semantics. We selected new negative instances $NA(e_1, e_2)$ from our initial extractor that had e_1 in the knowledge base, with e_1 participating as the first argument in the extracted relation but without e_2 as the second argument. The results were promising for some relations but overall inconclusive as identifying true negatives is quite difficult.

Relation	#Extractions	#TP	#FP
Nationality	**50**	11	38
Profession	43	**23**	20
EmployedBy	27	17	10
Spouse	22	2	20
LivedIn	6	4	2
OrgInCitytown	4	3	1
AthletePlaysForTeam	2	2	0
OrgType	1	1	0

Table 2: By-relation evaluation of the best system (NEL with type constraints and type partitioning) on the GORECO test set. The true positives (TP) are the number of gold relations over coreference clusters that matched, so multiple extractions can match a single true positive.

7 Related Work

There has been much recent work on distantly supervised relation extraction. Mintz et al. (2009) use Freebase to train relation extractors over Wikipedia without labeled data using multi-class logistic regression and lexical and syntactic features. Hoffmann et al. (2011) use a probabilistic graphical model for multi-instance, multi-label

learning and extract over newswire text using Freebase relations. Surdeanu et al. (2012) take a similar approach and use soft constraints and logistic regression. Riedel et al. (2013) integrate open information extraction with schema-based, proposing a universal schema approach, including using features based on latent types. There has also been recent work on reducing noise in distantly supervised relation extraction (Nguyen and Moschitti, 2011; Takamatsu et al., 2012; Roth et al., 2013; Ritter et al., 2013). Xu et al. (2013) and Min et al. (2013) improve the quality of distant supervision training data by reducing false negative examples.

Distant supervision is related to semi-supervised bootstrap learning work such as Carlson et al. (2010b) and many others. Note that distant supervision can be viewed as a subroutine of bootstrap learning; bootstrap learning can continue the process of distant supervision by taking the new tuples found and then training on those again, and repeating the process.

There has also been work on performing NEL and coreference jointly (Cucerzan, 2007; Hajishirzi et al., 2013), however these systems do not perform relation extraction. Singh et al. (2013) performs joint relation extraction, NER, and coreference in a fully-supervised manner. They get slight improvement by adding coreference, but do not use NEL. Ling and Weld (2013) extend MULTIR to find meronym relations in a biology textbook. They get slight improvement over NER by using coreference to pick the best mention of an entity in the sentence for the meronym relation at training and extraction time.

8 Conclusions and Future Work

Given the growing importance of distant supervision, a comprehensive understanding of its variants is crucial. While some of the optimizations we propose may seem intuitive, they have not previously been systematically explored. Our experiments show that NEL, type constraints, and type partitioning are extremely important in order to best take advantage of the seed KB during training as well as known information at extraction time. Our best system results in a 44% increase in precision, and a 70% increase in recall over our NER baseline using GORECO. While we were not able to evaluate all our methods on Hoffmann et al. (2011)'s sentential evaluation, our baseline performs significantly better than previous methods, especially in precision, and training-only modifications perform similarly in both evaluations.

Future work will explore the use of NEL in distantly supervised relation extraction further, tuning a confidence parameter for the NEL system, and determining whether different confidence parameters should be used for training and extraction. Another possible direction is interleaving NEL with relation extraction by using newly extracted facts to try to improve NEL performance.

We freely distribute GORECO a new gold standard evaluation for relation extraction consisting of exhaustive annotations of the 128 documents from ACE 2004 newswire for 48 relations. The source code of our system, its output, as well as our gold data are available at
`http://cs.uw.edu/homes/mkoch/re`.

Automatic Inference of the Tense of Chinese Events Using Implicit Linguistic Information

Abstract

We address the problem of automatically inferring the tense of events in Chinese text. We use a new corpus annotated with Chinese semantic tense information and other implicit Chinese linguistic information using a "distant annotation" method. We propose three improvements over a relatively strong baseline method – a statistical learning method with extensive feature engineering. First, we add two sources of implicit linguistic information as features – eventuality type and modality of an event, which are also inferred automatically. Second, we perform joint learning on semantic tense, eventuality type, and modality of an event. Third, we train artificial neural network models for this problem and compare its performance with feature-based approaches. Experimental results show considerable improvements on Chinese tense inference. Our best performance reaches 68.6% in accuracy, outperforming a strong baseline method.

1 Introduction

As a language with no grammatical tense, Chinese does not encode the temporal location of an event directly in a verb, while in English, the grammatical tense of a verb is a strong indicator of the temporal location of an event. In this paper we address the problem of inferring the semantic tense, or the temporal location of an event (e.g., present, past, future) in Chinese text. The semantic tense is defined relative to the utterance time or document creation time, and it does not always agree with the grammatical tense in languages like English where there is grammatical tense. Inferring semantic tense potentially benefits natural language processing tasks such as Machine Translation and Information Extraction (Xue, 2008; Reichart and Rappoport, 2010; Ye et al., 2006; Ye, 2007; Liu et al., 2011), but previous work has shown that automatic inference of the semantic tense of events in Chinese is a very challenging task (Xue, 2008; Ye et al., 2006; Liu et al., 2011).

There are at least two reasons why this is a difficult problem. First, since Chinese does not have grammatical tense which could serve as an important clue when annotating the semantic tense of an event, generating consistent annotation for Chinese semantic tense has proved to be a challenge. Xue and Zhang (2014) use a "distant annotation" method to address this problem. They take advantage of an English-Chinese parallel corpus with manual word alignments (Li et al., 2012) , and perform annotation on the English side, which provides more explicit information such as grammatical tense that helps annotators decide the appropriate semantic tense. The annotations are then projected to the Chinese side via the word alignments. They show consistent annotation agreements on semantic tense. Second, the lack of grammatical tense also makes automatic inference of Chinese semantic tense challenging since the grammatical tense would be an important source of information for predicting the semantic tense. Previous work has shown that it is very difficult to achieve high accuracy using standard machine learning techniques such as Maximum Entropy and Conditional Random Field classifiers combined with extensive feature engineering.

We address these challenges in two ways. First of all, we take advantage of the newly annotated corpus described in (Xue and Zhang, 2014) in which semantic tense is annotated together with eventuality type and modality using the distant annotation method. This makes it possible to use these two additional sources of information to help predict tense. Eventuality type and modality are intricately tied to tense. For example, Smith and

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1902–1911,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

Erbaugh (2005) show that states by default hold in the present but (episodic) events occur by default in the past. This means knowing the eventuality type of an event would help determine the tense. Eventuality type and modality are also annotated on the English side and then projected onto the Chinese side via manual word alignments, taking advantage of the rich morphosyntactic clues in English. High inter-annotator agreement scores are also reported on eventuality type and modality.

We experimented with two ways of using eventuality type and modality information. In the first approach, we first train statistical machine learning models to predict eventuality type and modality and then use these two sources of information as features to predict semantic tense. In the second approach we trained joint learning models between semantic tense and eventuality type, and between semantic tense and modality. We show both approaches improve the tense inference accuracy over a baseline where these two sources of information are not used. Second, in our statistical machine learning experiments on tense inference using feature engineering, we find that the design of feature templates has great influence on the results. So in order to explore more possible feature combinations and mitigate the feature engineering work, we apply artificial neural network models to this problem. This shows improvements on tense inference accuracy as well in some of the experiment settings.

The rest of the paper is organized as follows. Section 2 discusses related work in automatic tense inference. Section 3 briefly introduces the distant annotation method. In section 4, we describe our experiments and analyze the experimental results. We conclude this paper in section 7.

2 Related Work

Inferring the semantic tense of events in Chinese text is not a new topic. There have been several attempts at it, yet high accuracy in this task has proved to be elusive. Using a corpus with tense annotated directly in Chinese text, Xue (2008) performed extensive feature engineering in a machine learning framework to address this problem. They used both local lexical features and structured features extracted from manually annotated syntactic parsing trees. In our baseline method, we adopt most of their features as the baseline, only on a new corpus in which semantic tenses are not annotated directly on Chinese events but projected from annotations from the English side of a parallel Chinese-English corpus. In our experiments, we also use structural features extracted from automatic parse trees, so our experimental settings are more realistic.

Ye et al. (2006) took a similar approach in which they predict tense with feature engineering in a statistical learning framework. They also used a Chinese-English parallel corpus and projected tense for English events onto Chinese events via human alignments. The main difference between their data and ours is that they used the grammatical tense of the English events, while we use human-annotated semantic tense which we believe are more "transferrable" across languages as it is free of the language-specific idiosyncrasies of grammatical tense. In addition, they also used human annotated linguistic information as "latent" features in their work, which are similar to our implicit linguistic features. However, the "latent" features that they used in their system are human-annotated, while the eventuality type and modality features in our system are predicted automatically. Another difference is that they ignored events that are not verbs. For example, they excluded verbal expressions in Chinese that are translated into nominal phrases in English. In contrast, we kept all events in our data, and they can be realized as verbs, nouns, as well as words in other parts of speech. We performed separate experiments on events realized as verbal expressions and events not in verbal expressions to investigate their impact on semantic tense inference.

Liu et al. (2011) introduced more global features in a machine learning framework, and on top of that proposed an iterative learning algorithm which better handles noisy data, but they also ignored events that are not realized as verbal expressions, or events that are verbal expressions but have more than one verb in them. They mainly focused on events that are one-verb expressions.

In a similar work on inferring tense in English text, Reichart and Rappoport (2010) aimed at inferring fine-grained semantic tenses for events in English. They introduced a fine-grained sense taxonomy for tense in a more general Tense Sense Disambiguation (TSD) task to annotate and disambiguate semantic tenses. The underlying senses include "things that are always true", "general and repeated actions and habits", "plans, expectations

and hopes", etc., which encode a combination of tense, eventuality type and modality. In the corpus that we use, the same information is organized in a more structured manner along three dimensions – semantic tense, eventuality type, and modality.

3 Distant Annotation

Figure 1 shows the distant annotation procedure from (Xue and Zhang, 2014). Starting with a word-aligned parallel English-Chinese corpus, all sentences are part-of-speech (POS) tagged first and then all verb instances in the English text as well as expressions aligned with verb instances on the Chinese side are targeted for annotation. As we will show in Section 4, these expressions include verbs as well as nouns, prepositions and word sequences "headed" by a verb. We consider those expressions as events. Annotators work only on the English side and tag every event with a pre-defined semantic tense label. These labels are then projected from the English side to the Chinese side via word alignments. The resulting corpus contains events annotated with semantic tense labels in both languages. Categories for semantic tense are "Past", "Present", "Future", "Relative Past", "Relative Present", "Relative Future", and "None".

Events annotated with relative tenses are also linked to another event that serves as the temporal reference for the event in question. In some cases the relative tense can be resolved to an absolute tense. For example, if an event is annotated with a "relative past" tense to a reference event that is annotated with a present tense, then the semantic tense of that event can resolve to an absolute "past" tense. In other cases, they can not be resolved. For example, if an event is labeled with a "relative future" tense and the reference event has a past tense, then its tense cannot be resolved to an absolute tense, which is defined with regard to the utterance time or document creation time. In our work, where possible, we resolve these links and keep only absolute tense labels. For events with relative tenses that can not be resolved (i.e. events which are "Relative Future" to "Past" events, or events which are "Relative Past" to "Future" events), we use "None" as the default label.

Eventuality type and modality are labeled in the same way as auxiliary annotation that can help with the inference of tense. Labels for eventuality type include "Episodic", "Habitual", "State", "Progressive", "Completed", and "None". Labels for modality are "Actual", "Intended", "Hypothetical", "Modalized", and "None". Readers are refered to (Xue and Zhang, 2014) for detailed explanations of each label.

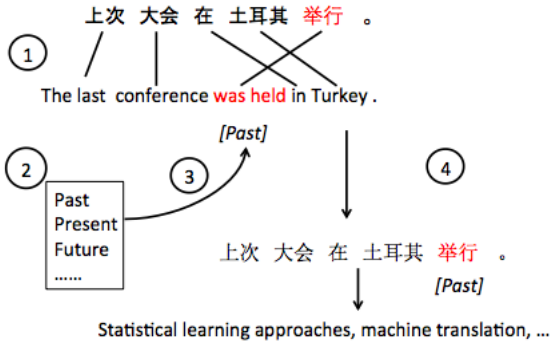

Figure 1: Distant annotation procedure.

As we mentioned in Section 2, in this corpus not only verbs but also their counterparts on the opposite language are considered as events, yielding events that may not be verbs. For example, in the following sentence pair (1), the Chinese verb (VV) "利用" is aligned with an English noun (NN) "use". In the sentence pair (2), the English verb (VBG) "opening" is aligned with an Chinese noun (NN) "开放".

(1) Statistics show that , in the past five years , Guangxi's foreign trade and its **use** of foreign investments has expanded rapidly.

统计资料显示，过去五年广西对外贸易和**利用(li4yong4)**外资规模迅速扩大。

(2) Beihai has already become a bright star arising from China's policy of **opening** up to the outside world.

北海已成为中国对外**开放(kai1fang4)**中升起的一颗明星。

In this corpus, events could be either one verb, or a verb compound, or a verb sequence "headed" by a verb, or even nouns and words of other parts of speech.

4 Experiments

4.1 Experimental Setting

Xue and Zhang (2014) annotated semantic tense, eventuality type and modality on top of the Parallel Aligned Treebank (Li et al., 2012), a corpus

of word-aligned Chinese-English sentences treebanked based on the Penn TreeBank (Marcus et al., 1993) and the Chinese TreeBank (Xue et al., 2005) standards. Human annotation of tense is performed on the newswire and webblog sections of this corpus. They report that the average pairwise agreement among three annotators consistently stays above 80% and the average Kappa score consistently exceeds 70%, indicating reliable annotation.

Apart from using the entire corpus, we also conducted experiments on three different subsets of the corpus. An examination of the data indicates that newswire data is grammatically more formal and complete than webblog data, so we also conducted separate experiments on newswire data only. Considering that the diversity of the parts of speech of the events may affect the inference accuracy and that most of our features extracted from the parse trees assume that our events being verbs, we also conducted experiments exclusively on "v_events". "v_events" consist of two parts. One part is events that are realized as a single word and the word is a verb; the other one is events which have multiple words but there is only one verb among them. In the latter case, we stripped off words tagged with other parts of speech and only keep the verbs as events. This makes it more effective to use features from previous work that are designed for single verbs. One such feature is the aspect marker. Distinctions between newswire and webblog data and between v_events and other events are further explored in Section 5.1 and Section 5.2. Table 1 presents the statistics for each subset of the experimental data.

dataset	# of v_events	# of all events
nw	6,686	8,268
all	17,153	20,885

Table 1: Statistics of four subsets of the annotated corpus (Chinese side). "nw" denotes the newswire data. "v_events" denotes events that consist of or can be reduced to only a single verb.

For each subset, randomly selected 80% were used as the training set, while 10% were used as the development set and 10% were used as the test set.

4.2 Baseline

Based on previous approaches on Chinese tense inference, we used a Maximum Entropy model with extensive feature engineering as our baseline method. We use the implementation of the Maximum Entropy algorithm in Mallet [1] for our experiments. The corpus is parsed using the Berkeley Parser for the purpose of extracting structure features. Since the Parallel Alignment TreeBank is a subset of the Chinese TreeBank (CTB) 8.0, we automatically parsed the CTB 8.0 by doing a 10-fold cross validation. The bracketing F-score is 80.5%. Feature extractions are performed on the automatic parse trees. Adopted features include previous word and its POS tag, next word and its POS tag, aspect marker following the event, 得following the event, the governing verb of the event, the character string of the main verb in the previous clause that is coordinated with the clause the event is in, whether the event is in quote, and left modifiers of the event including head of adverbial phrases, temporal noun phrases, prepositional phrases, localizer phrases, as well as subordinating clauses. Readers are referred to (Xue, 2008) for details of these features. Since in this corpus an event can span over more than one verb, we also use the character string and the POS string of the entire event instead of one word and one POS tag as features.

- The character string of an event – it could be one or more words. In our corpus, only 69.7% events consist of single word (e.g. "居住", "live"), the other 30.3% of the events are expressed with two or more words (e.g. "引发+了", "have caused").
- The POS string of an event – it could be verbs, nouns, or POS sequences of other word sequences. Table 2 shows the top ten POS tag or POS tag sequences with example word or word sequences.

Other features that we used in the baseline system are as follows.

- DEC – if the word immediately following an event has the POS tag "DEC", use its character string as a feature. In most cases, "DEC" is the POS tag for "的" when it used as a complementizer marking the boundary in a relative clause. This feature implies that an event

[1] http://mallet.cs.umass.edu/

POS	freq	examples
VV	48.2%	居住(live)
NN	5.8%	开放(opening)
VC	5.2%	是(is)
VV+AS	5.2%	引发+了(have caused)
VV+DEC	3.2%	隔绝+的(isolated)
AD+VV	3.0%	正在+建议(is suggesting)
VA	3.0%	大(is big)
AD	2.0%	似乎(seemed)
VE	1.9%	有(there is)
P	1.8%	根据(according to)

Table 2: Frequencies and examples of the ten most frequent POS tag or POS tag sequences for events in our corpus.

is inside a relative clause modifying a noun phrase and it is more often stative than eventive.

- Determiners – we find the subject of an event from its parse tree and extract the determiner of the subject, if there is one, as a feature. This feature indicates different types of agents, and different types of agents often signal different types of events. For example, individual agents tend to perform one-time episodic actions which are by default located in the past or described by a state in the present, while multiple agents tend to involved in habitual actions that spans over a long period of time.

Baseline results are reported in Table 5 and Table 6, in MaxEnt_b rows.

4.3 Eventuality Type and Modality as Features

Xue and Zhang (2014) reports that gold eventuality type and modality labels significantly help the inference of tense in Chinese, improving the accuracy by more than 20%. However, it is unrealistic to expect to have human annotated eventuality type and modality labels in a random new data set if we want to use these two sources of implicit linguistic information in any Chinese text. So we trained statistical learning models to automatically extract these two labels. We trained Maximum Entropy models and ran a 10-fold cross validation on the entire corpus in order to get automatic labels for every event. Feature used for labeling modality are as follows. Table 3 shows the average accuracies for automatic modality labeling.

- The character string of an event.
- The POS string of an event.
- The character string of an event's governing verb and its POS tag.
- Whether the event is in a conditional clause. If an event is in a subtree with the functional tag "CND", return "True"; otherwise, return "False". This feature indicates that the event's modality label is "Hypothetical".
- Whether the event is in a purpose or reason clause. If an event is in a subtree with the functional tag "PRP", return "True"; otherwise, return "False" as a feature. This feature indicates the event's modality label is "Intended".
- Whether the event string is the start of a sentence. If an event is the start of a sentence, return "True"; otherwise, return "False". Sentences that start with an event is often imperative, and the event generally has "modalized" modality label.

dataset	v_events	all events
nw	81.1%	81.2%
all	75.4%	76.4%

Table 3: Average modality labeling accuracy, using a 10-fold cross validation.

Statistics show that the five labels for modality have a skewed distribution in this corpus. Among all events, 67.3% of them fall in the "Actual" category, while the events of all the other categories are around or less than 10%. Similar distributions are found in all four subsets of the data. Still, compared with always choosing the most frequent label (around 67% accuracy), we still get a big improvement from our statistical model, even though only a very simple set of features are used.

Features used for labeling eventuality type are as follows. Table 4 shows the average accuracies for automatic eventuality type labeling.

- The character string of an event.
- The POS string of an event.

- Adverbs on the left that modifies the event.
- Aspect marker following the event
- Whether the event is Inside a relative clause. If an event is in a CP subtree with the word "的" and POS tag "DEC" as its last node, return "True"; otherwise, return "False". Events in relative clauses modifying a noun phrase and tend to be more often stative than eventive.

dataset	v_events	all events
nw	68.7%	67.7%
all	65.3%	65.1%

Table 4: Average automatic eventuality type labeling accuracy using a 10-fold cross validation.

The six labels of eventuality type are also distributed unevenly. The first group of columns in Figure 3 shows the distribution of all events. Over 65% of events are either "Episodic" or "State", while the other types of events are less than 15%. There are two categories that are even less than 5%. However, even though we only use some simple features, our model still beats the most frequent label baseline (around 35% accuracy) by a big margin, as shown in Table 4.

Tense inference accuracies using automatic eventuality type and/or modality features are reported in Table 5 and Table 6, in MaxEnt_e, MaxEnt_m, and MaxEnt_em rows.

4.4 Joint Learning

Apart from using eventuality type and modality labels as features, we also conducted joint learning experiments on them. Joint learning are applied on 1) tense and eventuality type, and 2) tense and modality. Features used are the union of the two sets of features in inferring each single label. MaxEnt_jle and MaxEnt_jlm rows in Table 5 and Table 6 present the experimental results on joint learning.

4.5 Artificial Neural Network

For each of the experiments using the maximum entropy algorithm, we conducted a neural network experiment using the same setting in order to explore more possible feature combinations and mitigate the feature engineering work. We convert the features in each of our tense inference methods into feature vectors. If a feature is not a word, we use a one-hot representation for that feature (a vector with all 0s except for a 1 at the place of the feature's index in our feature lexicon). If a feature is a word, we convert it into a word embedding. To get a dictionary of word embeddings, we use the word2vec tool [2] (Mikolov et al., 2013) and train it on the Chinese Gigaword corpus (LDC2003T09). For each word embedding, a 300-dimensional vector is used. Artificial neural networks are built using the theano package [3] (Bergstra et al., 2010). We use 5000 hidden units for all networks and set the learning rate α = 0.01. Experimental results are presented in the ANN rows of Tables 5 and 6.

5 Results Analysis

A comparison of the baseline accuracy for the four different subsets of the data shows that (1) tense inference is slightly better on v_events than on all events, but the difference is not substantial; and (2) tense inference on newswire data performs better than on all data by around 8% on v_events and around 5% on all events, verifying our assumption that automatic tense inference is easier on newswire data than webblog data. Although our experiments are performed on different data sets from that of previous work, our baseline method still shows strong results compared with previous work (Xue, 2008; Ye et al., 2006; Liu et al., 2011).

Adding automatic eventuality type and modality labels as features for semantic tense inference leads to improvements over the baseline on all four data subsets. In fact they provide considerable improvements (around 2% increase) on newswire v_events dataset. MaxEnt_e rows report results when only automatic eventuality type is added as a feature, and MaxEnt_m rows report results when only automatic modality is added as a feature. They both outperform (or, in several datasets, match) the baseline results on all datasets. MaxEnt_em rows report results when both automatic linguistic labels are added as features, and they show further improvements over when only one source of information is used. Analysis of the results shows again that tense inference accuracy is higher than webblog data under this experiment condition. The results also show that after adding eventuality type and modality as features,

ANN_jle	61.4%	63.0%
ANN_jlm	62.9%	63.5%

Table 6: Accuracy of tense inference on all events. Best performances for each group of methods are in bold.

the improvements on v_events (0.7% and 1.8%) are much bigger than that on all events (0.2% and 0.4%), regardless of the data genre (newswire or weblog).

In order to test the potential for these two new features, we also conducted experiments using gold eventuality type and/or modality labels as features for the Maximum Entropy models (Table 5 and Table 6, MaxEnt_ge, MaxEnt_gm, and MaxEnt_gem rows.). They outperform our best MaxEnt results by around 10% on newswire data and around 15% on all data, indicating strong potentials for more accurately classified automatic eventuality type and modality labels.

Results also show that joint learning with modality proves to be working better than the baseline (Table 5 and Table 6, MaxEnt_jle, MaxEnt_jlm). In fact, on the datasets with all events, joint learning with modality produces the highest accuracy among all approaches. However, joint learning with eventuality is even worse than the baseline. One possible explanation is that the lower eventuality type classification accuracy affects the tense inference accuracy. We also believe there is still room for improvement with features tuned for the joint learning model. Simply adding the features may not be the best strategy.

On the entire dataset, regardless of v_events or other events, results of the neural network models show improvements over the maximum entropy models under most experimental conditions. A clear trend is that artificial neural networks help more on all data than on newswire data only, indicating greater potentials of the neural network models to select and combine features with carefully trained parameters, given noisier but larger training sets.

Experimental results also show significant differences in accuracy between newswire data and webblog data, and smaller but still recognizable difference between v_events and all events. Therefore, we specifically look into distinctions between these data sets.

5.1 Newswire Data vs. Webblog Data

Considering the big gap in accuracy between newswire and webblog data in our baseline results, we delve deeper into the data and found several major distinctions between these two domains that might have contributed to the rather significant difference in performance on tense inference. First, we look into the word frequency distribution of the two datasets. Here by "word" we mean the character string of an event. We find that both datasets have a small portion of words with high frequencies, but the webblog dataset contains much more low-frequent words than the newswire dataset. In Figure 2, the x-axis shows possible frequencies of words and the y-axis shows the number of words at a particular frequency. It can be seen that the num-

ber of words that appear only once in the webblog dataset is about three times as large as that in the newswire dataset. The entire newswire dataset has a vocabulary of only 2671 entries, while the webblog dataset has a vocabulary size of 6117. This greatly reduces the coverage of features extracted from the training dataset on the events in the test dataset.

Second, webblog data contains more events that are "inherently" ambiguous on temporal location. Among four possible labels for tense in this corpus, "None" is for events whose temporal locations are not clear even to human annotators. Statistics show that in webblog data about 13.4% of the events are tagged as "None", while in newswire data only around 6.7% are "None". Another piece of evidence showing webblog data is harder to process is the different inter-annotator agreement scores for tense annotation on newswire and webblog data reported by (Xue and Zhang, 2014). Newswire data has a 89.0% agreement score and a 84.9% kappa score, while webblog data only has a 81.0% agreement score and a 72.7% kappa. Third, automatic parse trees for newswire data is also more accurate than that for webblog data. The bracketing F-score of automatically parsed newswire data is 83.0% while it is only 80.4% for weblog data. Moreover, sentences in newswire data are more grammatically complete. Analysis shows that webblog data has more dropped constituents in sentences. There are around 40.5% sentences in newswire data that have nominal empty categories, while in webblog data the number is 48.1%. Dropped constituents affect the structures of parse trees and some of the features, which can affect tense inference accuracy.

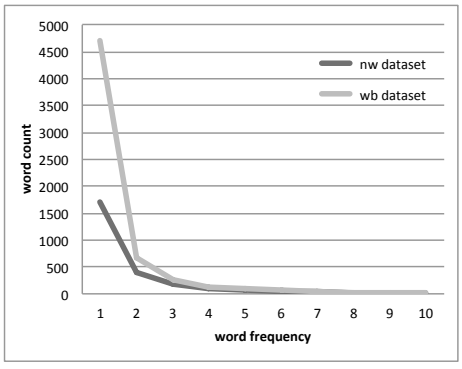

Figure 2: Word frequency distribution in newswire and webblog datasets.

5.2 V_events vs. All Events

In our definition, v_events are (1) events that are single verbs (example 1, 3, 7, 9 in Table 2), and (2) events that are multi-word sequences but only one word among them is a verb and any non-verb words are stripped off (verbs in example 4, 5, 6 in Table 2). Conversely, events that do not fall into this definition include (1) events that have no verbs in their surface form (example 2, 8, 10 in Table 2), and (2) events that have more than one verb in their surface form (e.g. "使+成为(shi3+cheng2wei2)", VV+VV, "make it become"). So from the point of view of a statistical learning algorithm, every v_event has one and only one verb. This makes sure that all features that we used are applicable to v_events. For other events, however, some features may be not applicable. For example, for an event which has a nominal expression, aspect marker, DER, and DEC features are all "None" because these features are only applicable to verbs. Another major distinction between v_events and "other events" is that the distributions of eventuality type labels on them are very different, presented in the second and third groups of columns in Figure 3. There is a rather high percentage of "State" among "other events" and very low percentage of "Completed" and "None". The highly uneven distribution of eventuality type labels make it less effective as a feature for tense inference.

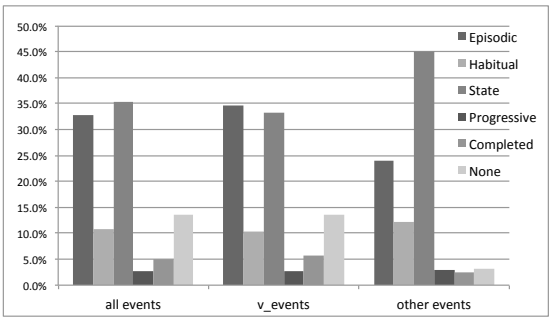

Figure 3: Statistics of eventuality types on different events.

We also find that, on newswire datasets, maximum entropy models and neural network models do not show much difference in performance. To understand this result better, we plot learning curves of the artificial neural network model, trained and tested on newswire v_events dataset. In Figure 4, the black line represents the error rate on training set, and the grey line represents the er-

ror rate on test set. As the size of training data grows, the error rate on the training set gets larger because with more training examples the training set becomes noisier and it gets harder to model all samples with the same number of features; and the error rate on the test set gets smaller because a bigger training set reduces the data sparsity and trains the parameters better. Both lines end at a rather high error rate (around 30%, i.e. only around 70% in accuracy) which means the current network is general enough to cover most cases in the test set, but it is under-fitting the training data. The current model is not specific enough to better capture the fine distinctions between the tense categories. The black line being not very smooth is also understandable, given that there are only around 6000 training examples in the newswire v_events dataset.

Figure 4: Learning curves of the artificial neural network model, trained and tested on newswire v_events dataset.

6 Error Analysis

In order to get a better understanding of the use of eventuality type and modality, we look into the error rates for each error type in greater detail. In Table 7, "Pa" stands for "Past", "Pre" is short for "Present", "Fu" is for "Future", and "No" is "None". For each error type, the left-hand side is the gold-standard tense, and the right-hand side is the wrongly assigned label. Statistics are collected on the newswire v_events data test set. Table 7 compares the different error types between the baseline method and the MaxEnt_em method, the best approach for this dataset. We can see that (1) "Present" and "Past" is the most frequently confused tense pair, and (2) eventuality type and modality information help disambiguate "Present" and "Past" events greatly, and reduce the errors due to mis-classifying "Past" as "Future", or "Future" as "Present", or "None" as "Present".

error type	MaxEnt_b	MaxEnt_em
Pre → Pa	11.7%	11.2%
Pa → Pre	9.8%	9.2%
Pa → Fu	2.5%	2.3%
No → Pa	2.0%	2.0%
Fu → Pre	1.9%	1.6%
Pre → Fu	1.4%	1.4%
Fu → Pa	1.4%	1.4%
No → Pre	1.6%	1.2%
No → Fu	0.5%	0.5%
Pa → No	0.3%	0.3%
Pre → No	0.2%	0.2%
Fu → No	0.0%	0.0%

Table 7: Tense inference error rates for different error types on newswire v_events test set.

A closer examination of the sentences in which events are assigned the wrong tense reveals that "Pre → Pa" error is prone to occur on events in relative clauses. The Chinese verb implies a past episodic event, while the event is actually a present state or habitual event. As a good example, the "生产(sheng1chan3)" event in Sentence (3) is wrongly labeled as "Past" by MaxEnt_b but correctly classified as "Present" by MaxEnt_em with eventuality type "Habitual" and modality tag "Actual" (the underlined part in the Chinese sentence is the relative clause). It is also found that most "Pa → Pre" errors occur on events that are more stative. It is reasonable since classifiers tend to assign "Present" to states and "Past" to episodic events. MaxEnt_em managed to correct some with "episodic" as their correct eventuality type.

(3) 目前该区**生产(sheng1chan3)**此疫苗的 普康公司已形成年产五百万人份的生产规模，这对有效地控制甲肝流行具有重大意义。

At present , the Pu Kang Company , which **produces** the vaccine in this zone , has already formed a production scale of 5 million doses per year , which has great significance in effectively controlling the hepatitis A epidemic .

We are also surprised to see that over 2% "Past" events are classified as "Future" events, ranking

third among all error types. This mistake seems very unlikely, but it is still possible when performing tense inference on a language with no grammatical tense at all. Take the following sentence pair (4) as an example. In the Chinese sentence, MaxEnt_b classifies "讨论(tao3lun4)" as "Future" because there is no grammatical indicator in the Chinese sentence implying that the "discussion" has already happened and it is reasonable to assume the "discussion" is in the near future. However, with eventuality type "Episodic" and modality label "Actual", MaxEnt_em classifies it as "Past" correctly, because episodic events tend to occur in the past and future events tend to get "Intended" or "Hypothetical" modality labels.

(4) 他还说，法国政府"甚至指示它的代表，在联合国安理会**讨论(tao3lun4)** 制裁古巴的议案时不要投赞成票"。

He also said, the French government "even directed its representative not to vote Yes when the Security Council **discussed** the resolution on sanctions on Cuba".

7 Conclusion and Future Work

In this paper, we address the problem of automatic inference of Chinese semantic tense. We took advantage of a new corpus annotated with rich linguistic information, and experimented with three approaches. In the first approach, we use two sources of implicit linguistic information, eventuality type and modality, automatically derived, as features in tense inference. We then conducted joint learning on tense and each of these two information types. Finally, we experimented with using artificial neural networks to train models for tense prediction. All three approaches outperformed a strong baseline, a maximum entropy model with extensive engineering. Our future work will include exploring ways to improve automatic eventuality type and modality labeling accuracy to further improve tense inference accuracy.

Abstract

Populating Knowledge Base (KB) with new knowledge facts from reliable text resources usually consists of linking name mentions to KB entities and identifying relationship between entity pairs. However, the task often suffers from errors propagating from upstream entity linkers to downstream relation extractors. In this paper, we propose a novel joint inference framework to allow interactions between the two subtasks and find an optimal assignment by addressing the coherence among preliminary local predictions: whether the types of entities meet the expectations of relations explicitly or implicitly, and whether the local predictions are globally compatible. We further measure the confidence of the extracted triples by looking at the details of the complete extraction process. Experiments show that the proposed framework can significantly reduce the error propagations thus obtain more reliable facts, and outperforms competitive baselines with state-of-the-art relation extraction models.

1 Introduction

Recent advances in natural language processing have made it possible to construct structured KBs from online encyclopedia resources, at an unprecedented scale and much more efficiently than traditional manual edit. However, in those KBs, entities which are popular to the community usually contain more knowledge facts, e.g., the basketball player *LeBron James*, the actor Nicholas Cage, etc., while most other entities often have fewer facts. On the other hand, knowledge facts should be updated as the development of entities, such as changes in the cabinet, a marriage event, or an acquisition between two companies, etc.

In order to address the above issues, we could consult populating existing KBs from reliable text resources, e.g., newswire, which usually involves enriching KBs with new entities and populating KBs with new knowledge facts, in the form of *<Entity, Relation, Entity>* triple. In this paper, we will focus on the latter, identifying relationship between two existing KB entities. This task can be intuitively considered in a pipeline paradigm, that is, name mentions in the texts are first linked to entities in the KB (entity linking, EL), and then the relationship between them are identified (relation extraction, RE). It is worth mentioning that the first task EL is different from the task of named entity recognition (NER) in traditional information extraction (IE) tasks, where NER recognizes and classifies the entity mentions (to several predefined types) in the texts, but EL focuses on linking the mentions to their corresponding entities in the KB. Such pipeline systems often suffer from errors propagating from upstream to downstream, since only the local best results are selected to the next step. One idea to solve the problem is to allow interactions among the local predictions of both subtasks and jointly select an optimal assignment to eliminate possible errors in the pipeline.

Let us first look at an example. Suppose we are extracting knowledge facts from two sentences in Figure 1: in sentence [1], if we are more confident to extract the relation *fb:org.headquarters*[1], we will be then prompted to select *Bryant University*, which indeed favors the RE prediction that requires an organization to be its subject. On the other side, if we are sure to link to *Kobe Bryant* in sentence [2], we will probably select *fb:pro_athlete.teams*, whose subject position expects an athlete, e.g., an NBA player. It is not difficult to see that the argument type expectations of relations can encourage the two subtasks interact with each other and select coherent predictions for

[1]The prefix *fb* means the relations are defined in Freebase.

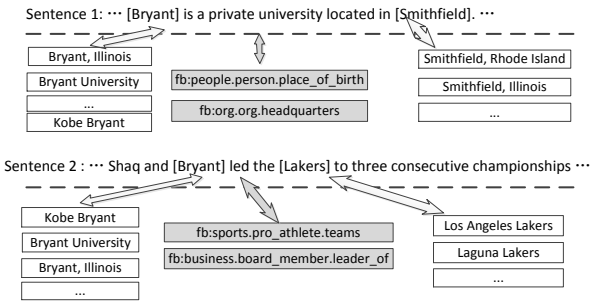

Figure 1: Two example sentences from which we can harvest knowledge facts.

both of them. In KBs with well-defined schemas, such as Freebase, type requirements can be collected and utilized explicitly (Yao et al., 2010). However, in other KBs with less reliable or even no schemas, it is more appropriate to implicitly capture the type expectations for a given relation (Riedel et al., 2013).

Furthermore, previous RE approaches usually process each triple individually, which ignores whether those local predictions are compatible with each other. For example, suppose the local predictions of the two sentences above are *<Kobe Bryant, fb:org.headquarters, Smithfield, Rhode Island>* and *<Kobe Bryant, fb:pro_athlete.teams, Los Angeles Lakers>*, respectively, which, in fact, disagree with each other with respect to the KB, since, in most cases, these two relations cannot share subjects. Now we can see that either the relation predictions or the EL results for "*Bryant*" are incorrect. Those disagreements provide us an effective way to remove the possible incorrect predictions that cause the incompatibilities.

On the other hand, the automatically extracted knowledge facts inevitably contain errors, especially for those triples collected from open domain. Extractions with confidence scores will be more than useful for users to make proper decisions according to their requirements, such as trading recall for precision, or supporting approximate queries.

In this paper, we propose a joint framework to populate an existing KB with new knowledge facts extracted from reliable text resources. The joint framework is designed to address the error propagation issue in a pipeline system, where subtasks are optimized in isolation and locally. We find an optimal configuration from top k results of both subtasks, which maximizes the scores of each step, fulfills the argument type expectations of relations, which can be captured explicitly or implicitly, in the KB, and avoids globally incoherent predictions. We formulate this optimization problem in an Integer Linear Program (ILP) framework, and further adopt a logistic regression model to measure the reliability of the whole process, and assign confidences to all extracted triples to facilitate further applications. The experiments on a real-world case study show that our framework can eliminate error propagations in the pipeline systems by taking relations' argument type expectations and global compatibilities into account, thus outperforms the pipeline approaches based on state-of-the-art relation extractors by a large margin. Furthermore, we investigate both explicit and implicit type clues for relations, and provide suggestions about which to choose according to the characteristics of existing KBs. Additionally, our proposed confidence estimations can help to achieve a precision of over 85% for a considerable amount of high quality extractions.

In the rest of the paper, we first review related work and then define the knowledge base population task that we will address in this paper. Next we detail the proposed framework and present our experiments and results. Finally, we conclude this paper with future directions.

2 Related Work

Knowledge base population (KBP), the task of extending existing KBs with entities and relations, has been studied in the TAC-KBP evaluations (Ji et al., 2011), containing three tasks. The entity linking task links entity mentions to existing KB nodes and creates new nodes for the entities absent in the current KBs, which can be considered as a kind of entity population (Dredze et al., 2010; Tamang et al., 2012; Cassidy et al., 2011). The slot-filling task populates new relations to the KB (Tamang et al., 2012; Roth et al., 2012; Liu and Zhao, 2012), but the relations are limited to a predefined sets of attributes according to the types of entities. In contrast, our RE models only require minimal supervision and do not need well-annotated training data. Our framework is therefore easy to adapt to new scenarios and suits real-world applications. The cold-start task aims at constructing a KB from scratch in a slot-filling style (Sun et al., 2012; Monahan and Carpenter, 2012).

Entity linking is a crucial part in many KB re-

lated tasks. Many EL models explore local contexts of entity mentions to measure the similarity between mentions and candidate entities (Han et al., 2011; Han and Sun, 2011; Ratinov et al., 2011; Cheng and Roth, 2013). Some methods further exploit global coherence among candidate entities in the same document by assuming that these entities should be closely related (Han et al., 2011; Ratinov et al., 2011; Sen, 2012; Cheng and Roth, 2013). There are also some approaches regarding entity linking as a ranking task (Zhou et al., 2010; Chen and Ji, 2011). Lin et al. (2012) propose an approach to detect and type entities that are currently not in the KB.

Note that the EL task in KBP is different from the name entity mention extraction task, mainly in the ACE task style, which mainly identifies the boundaries and types of entity mentions and does not explicitly link entity mentions into a KB (ACE, 2004; Florian et al., 2006; Florian et al., 2010; Li and Ji, 2014), thus are different from our work.

Meanwhile, relation extraction has also been studied extensively in recent years, ranging from supervised learning methods (ACE, 2004; Zhao and Grishman, 2005; Li and Ji, 2014) to unsupervised open extractions (Fader et al., 2011; Carlson et al., 2010). There are also models, with distant supervision (DS), utilizing reliable texts resources and existing KBs to predict relations for a large amount of texts (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). These distantly supervised models can extract relations from texts in open domain, and do not need much human involvement. Hence, DS is more suitable for our task compared to other traditional RE approaches.

Joint inference over multiple local models has been applied to many NLP tasks. Our task is different from the traditional joint IE works based in the ACE framework (Singh et al., 2013; Li and Ji, 2014; Kate and Mooney, 2010), which jointly extract and/or classify named entity mentions to several predefined types in a sentence and identify in a sentence level which relation this specific sentence describes (between a pair of entity mentions in this sentence). Li and Ji (2014) follow the ACE task definitions and present a neat incremental joint framework to simultaneously extract entity mentions and relations by structure perceptron. In contrast, we link entity mentions from a text corpus to their corresponding entities in an existing KB and identify the relations between pairs of entities based on that text corpus. Choi et al. (2006) jointly extracts the expressions and sources of opinion as well as the linking relations (i.e., a source entity expresses an opinion expression) between them, while we focus on jointly modeling EL and RE in open domain, which is a different and challenging task.

Since the automatically extracted knowledge facts inevitably contain errors, many approaches manage to assign confidences for those extracted facts (Fader et al., 2011; Wick et al., 2013). Wick et al. (2013) also point out that confidence estimation should be a crucial part in the automated KB constructions and will play a key role for the wide applications of automatically built KBs. We thus propose to model the reliability of the complete extraction process and take the argument type expectations of the relation, coherence with other predictions and the triples in the existing KB into account for each populated triple.

3 Task definition

We formalize our task as follows. Given a set of entities sampled from an existing KB, $E = \{e_1, e_2, ..., e_{|E|}\}$, a set of canonicalized relations from the same KB, $R = \{r_1, r_2, ..., r_{|R|}\}$, a set of sentences extracted from news corpus, $SN = \{sn_1, sn_2, ..., sn_{|SN|}\}$, each contains two mentions m_1 and m_2 whose candidate entities belong to E, a set of text fragments $\mathcal{T} = \{t_1, t_2, ..., t_{|\mathcal{T}|}\}$, where t_i contains its corresponding target sentence sn_i and acts as its context. Our task is to link those mentions to entities in the given KB, identify the relationship between entity pairs and populate new knowledge facts into the KB.

4 The Framework

We propose to perform joint inference over subtasks involved. For each sentence with two entity mentions, we first employ a preliminary EL model and RE model to obtain entity candidates and possible relation candidates between the two mentions, respectively. Our joint inference framework will then find an optimal assignment by taking the preliminary prediction scores, the argument type expectations of relations and the global compatibilities among the predictions into account. In the task of KBP, an entity pair may appear in multiple sentences as different relation instances, and the crucial point is whether we can identify all the cor-

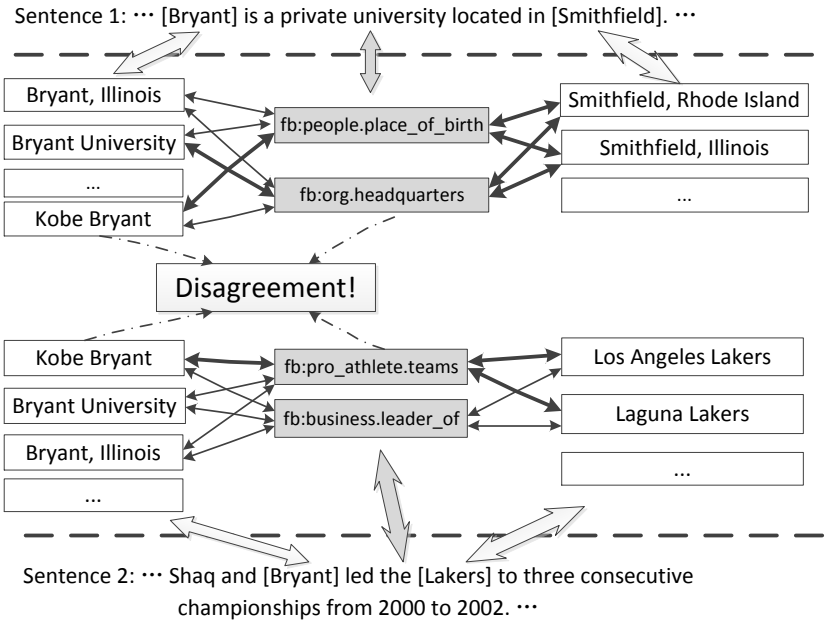

Figure 2: An example of our joint inference framework. The top and bottom are two example sentences with entity mentions in the square brackets, candidate entities in the white boxes, candidate relations in the grey boxes, and the solid lines with arrows between relations and entities represent their preference scores, with thickness indicating the preferences' value.

rect relations for an entity pair. Thus, after finding an optimal sentence-level assignment, we aggregate those local predictions by ORing them into the entity pair level. Finally, we employ a regression model to capture the reliability of the complete extraction process.

4.1 Preliminary Models

Entity Linking The preliminary EL model can be any approach which outputs a score for each entity candidate. Note that a recall-oriented model will be more than welcome, since we expect to introduce more potentially correct local predictions into the inference step. In this paper, we adopt an unsupervised approach in (Han et al., 2011) to avoid preparing training data. Note the challenging NIL problem, i.e., identifying which entity mentions do not have corresponding entities in the KB (labeled as NIL) and clustering those mentions, will be our future work. For each mention we retain the entities with top p scores for the succeeding inference step.

Relation Extraction The choice of RE model is also broad. Any sentence level extractor whose results are easy to be aggregated to entity pair level can be utilized here (again, a recall-oriented version will be welcome), such as Mintz++ mentioned in (Surdeanu et al., 2012), which we adapt into a Maximum Entropy version. We also include a special label, *NA*, to represent the case where there is no predefined relationship between an entity pair. For each sentence, we retain the relations with top q scores for the inference step, and we also call that this sentence **supports** those candidate relations. As for the features of RE models, we use the same features (lexical features and syntactic features) with the previous works (Chen et al., 2014; Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011).

4.2 Relations' Expectations for Argument Types

In most KBs' schemas, canonicalized relations are designed to expect specific types of entities to be their arguments. For example, in Figure 2, it is more likely that an entity *Kobe Bryant* takes the subject position of a relation *fb:pro_athlete.teams*, but it is unlikely for this entity to take the subject position of a relation *fb:org.headquarters*. Making use of these type requirements can encourage the framework to select relation and entity candidates which are coherent with each other, and discard incoherent choices.

In order to obtain the preference scores between

the entities in E and the relations in R, we generate two matrices with $|E|$ rows and $|R|$ columns, whose elements sp_{ij} indicates the preference score of entity i and relation j. The matrix S_{subj} is for relations and their subjects, and the matrix S_{obj} is for relations and their objects. We initialize the two matrices using the KB as follows: for entity i and relation j, if relation j takes entity i as its subject/object in the KB, the element at the position (i, j) of the corresponding matrix will be 1, otherwise it will be 0. Note that in our experiments, we do not count the triples that are evaluated in the testing data, to build the matrices. Now the problem is how we can obtain the unknown elements in the matrices.

Explicit Type Information Intuitively, we should examine whether the explicit types of the entities fulfill the expectations of relations in the KB. For each unknown element $S_{subj}(i, j)$, we first obtain the type of entity i, which is collected from the lowest level of the KB's type hierarchy, and examine whether there is another entity with the same type taking the subject position of relation j in the initial matrix. If such an entity exists, $S_{subj}(i, j) = 1$, otherwise 0. For example, for the subject *Jay Fletcher Vincent* and the relation *fb:pro_athlete.teams*, we first obtain the subject's type *basketball_player*, and then we go through the initial matrix and find another entity *Kobe Bryant* with the same type taking the subject position of *fb:pro_athlete.teams*, indicating that *Jay Fletcher Vincent* may take the relation *fb:pro_athlete.teams*. The matrix S_{obj} is processed in the same way.

Implicit Type Expectations In practice, few KBs have well-defined schemas. In order to make our framework more flexible, we need to come up with an approach to implicitly capture the relations' type expectations, which will also be represented as preference scores.

Inspired by Riedel et al. (2013) who use a matrix factorization approach to capture the association between textual patterns, relations and entities based on large text corpora, we adopt a collaborative filtering (CF) method to compute the preference scores between entities and relations based on the statistics obtained from an existing KB.

In CF, the preferences between customers and items are calculated via matrix factorization over the initial customer-item matrix. In our framework, we compute the preference scores between entities and relations via the same approach over the two initialized matrices S_{subj} and S_{obj}, resulting in two entity-relation matrices with estimated preference values. We use ALS-WR (Zhou et al., 2008) to process the matrices and compute the preference of a relation taking an entity as its subject and object, respectively. We normalize the preference scores of each entity using their means μ and standard deviations σ.

4.3 Compatibilities among Predicted Triples

The second aspect we investigate is whether the extracted triples are compatible with respect to all other knowledge facts. For example, according to the KB, the two relations *fb:org.headquarters* and *fb:pro_athlete.teams* in Figure 2 cannot share the same entity as their subjects. So if such sharing happens, that will indicate either the predictions of the relations or the entities are incorrect. The clues can be roughly grouped into three categories, namely whether two relations can share the same subjects, whether two relations can share the same objects, and whether one relation's subject can be the other relation's object.

Global compatibilities among local predictions have been investigated by several joint models (Li et al., 2011; Li and Ji, 2014; Chen et al., 2014) to eliminate the errors propagating in a pipeline system. Specifically, Chen et al. (2014) utilized the clues with respect to the compatibilities of relations in the task of relation extraction. Following (Li et al., 2011; Chen et al., 2014), we extend the idea of global compatibilities to the entity and relation predictions during knowledge base population. We examine the pointwise mutual information (PMI) between the argument sets of two relations to collect such clues. For example, if we want to learn whether two relations can share the same subject, we first collect the subject sets of both relations from the KB, and then compute the PMI value between them. If the value is lower than a certain threshold (set to -3 in this paper), the clue that *the two relations cannot share the same subject* is added. These clues can be easily integrated into an optimization framework in the form of constraints.

4.4 Integer Linear Program Formulation

Now we describe how we aggregate the above components, and formulate the joint inference problem into an ILP framework. For each candi-

date entity e of mention m in text fragment t, we define a boolean decision variable $d_t^{m,e}$, which denotes whether this entity is selected into the final configuration or not. Similarly, for each candidate relation r of fragment t, we define a boolean decision variable d_t^r. In order to introduce the preference scores into the model, we also need a decision variable $d_t^{r,m,e}$, which denotes whether both relation r and candidate entity e of mention m are selected in t.

We use $s_{el}^{t,m,e}$ to represent the score of mention m in t disambiguated to entity e, which is output by the EL model, $s_{re}^{t,r}$ representing the score of relation r assigned to t, which is output by the RE model, $s_p^{r,e}$ the explicit/implicit preference score between relation r and entity e.

Our goal is to find the best assignment to the variables d_t^r and $d_t^{m,e}$, such that it maximizes the overall scores of the two subtasks and the coherence among the preliminary predictions, while satisfying the constraints between the predicted triples as well. Our objective function can be written as:

$$\max el \times conf^{ent} + re \times conf^{rel} + sp \times coh^{e-r} \tag{1}$$

where el, re and sp are three weighting parameters tuned on development set. $conf^{ent}$ is the overall score of entity linking:

$$conf^{ent} = \sum_t \sum_{m \in M(t)} \sum_{e \in C_e(m)} s_{el}^{t,m,e} d_t^{m,e} \tag{2}$$

where $M(t)$ is the set of mentions in t, $C_e(m)$ is the candidate entity set of the mention m. $conf^{rel}$ represents the overall score of relation extraction:

$$conf^{rel} = \sum_t \sum_{r \in C_r(t)} s_{re}^{t,r} d_t^r \tag{3}$$

where $C_r(t)$ is the set of candidate relations in t. coh^{e-r} is the coherence between the candidate relations and entities in the framework:

$$coh^{e-r} = \sum_t \sum_{r \in C_r(t)} \sum_{m \in M(t)} \sum_{e \in C_e(m)} s_p^{r,e} d_t^{r,m,e} \tag{4}$$

Now we describe the constraints used in our ILP problem. The first kind of constraints is introduced to ensure that each mention should be disambiguated to only one entity:

$$\forall t, \forall m \in M(t), \quad \sum_{e \in C_e(m)} d_t^{m,e} \leq 1 \tag{5}$$

The second type of constraints ensure that each entity mention pair in one sentence can only take one relation label:

$$\forall t, \quad \sum_{r \in C_r(t)} d_r^t \leq 1 \tag{6}$$

The third is introduced to ensure the decision variable $d_t^{r,m,e}$ equals 1 if and only if both the corresponding variables d_t^r and $d_t^{m,e}$ equal 1.

$$\forall t, \forall r \in C_r(t), \forall m \in M(t), \forall e \in C_e(m)$$

$$d_t^{r,m,e} \leq d_t^r \tag{7}$$

$$d_t^{r,m,e} \leq d_t^{m,e} \tag{8}$$

$$d_t^r + d_t^{m,e} \leq d_t^{r,m,e} + 1 \tag{9}$$

As for the compatibility constraints, we need to introduce another type of boolean decision variables. If a mention m_1 in t_1 and another mention m_2 in t_2 share an entity candidate e, we add a variable y for this mention pair, which equals 1 if and only if both $d_{t_1}^{m_1,e}$ and $d_{t_2}^{m_2,e}$ equal 1. So we add the following constraints for each mention pair m_1 and m_2 satisfies the previous condition:

$$y \leq d_{t_1}^{m_1,e} \tag{10}$$

$$y \leq d_{t_2}^{m_2,e} \tag{11}$$

$$d_{t_1}^{m_1,e} + d_{t_2}^{m_2,e} \leq y + 1 \tag{12}$$

Then we further add the following constraints for each mention pair to avoid incompatible predictions:

$$\forall r_1 \in C_r(t_1), r_2 \in C_r(t_2)$$

$$\text{If } (r_1, r_2) \in \mathcal{C}^{sr}, p(m_1) = subj, p(m_2) = subj$$

$$d_{t_1}^{r_1} + d_{t_2}^{r_2} + y \leq 2 \tag{13}$$

$$\text{If } (r_1, r_2) \in \mathcal{C}^{ro}, p(m_1) = obj, p(m_2) = obj$$

$$d_{t_1}^{r_1} + d_{t_2}^{r_2} + y \leq 2 \tag{14}$$

$$\text{If } (r_1, r_2) \in \mathcal{C}^{sro}, p(m_1) = obj, p(m_2) = subj$$

$$d_{t_1}^{r_1} + d_{t_2}^{r_2} + y \leq 2 \tag{15}$$

where $p(m)$ returns the position of mention m, either $subj$ (subject) or obj (object). $\mathcal{C}^{sr}$ is the pairs of relations which cannot share the same subject, $\mathcal{C}^{ro}$ is the pairs of relations which cannot share the same object, $\mathcal{C}^{sro}$ is the pairs of relations in which one relation's subject cannot be the other one's object.

We use IBM ILOG Cplex[2] to solve the above ILP problem.

[2]http://www.cplex.com

Table 1: The features used to calculate the confidence scores.

Type	Feature
Real	The RE score of the relation.
Real	The EL score of the subject.
Real	The EL score of the object.
Real	The preference score between the relation and the subject.
Real	The preference score between the relation and the object.
Real	The ratio of the highest and the second highest relation score in this entity pair.
Real	The ratio of the current relation score and the maximum relation score in this entity pair.
Real	The ratio of the number of sentences supporting the current relation and the total number of sentences in this entity pair.
Real	Whether the extracted triple is coherent with the KB according to the constraints in Section 4.3.

4.5 Confidence Estimation for Extracted Triples

The automatically extracted triples inevitably contain errors and are often considered as with high recall but low precision. Since our aim is to populate the extracted triples into an existing KB, which requires highly reliable knowledge facts, we need a measure of confidence for those extracted triples, so that others can properly utilize them.

Here, we use a logistic regression model to measure the reliability of the process, how the entities are disambiguated, how the relationships are identified, and whether those predictions are compatible. The features we used are listed in Table 1, which are all efficiently computable and independent from specific relations or entities. We manually annotate 1000 triples as correct or incorrect to prepare the training data.

5 Experiments

We evaluate the proposed framework in a real-world scenario: given a set of news texts with entity mentions and a KB, a model should find more and accurate new knowledge facts between pairs of those entities.

5.1 Dataset

We use New York Times dataset from 2005 to 2007 as the text corpus, and Freebase as the KB. We divide the corpus into two equal parts, one for creating training data for the RE models using the distant supervision strategy (we do not need training data for EL), and the other as the testing data. For the convenience of experimentation, we randomly sample a subset of entities for testing. We first collect all sentences containing two mentions which may refer to the sampled entities, and prune them according to: (1)there should be no more than 10 words between the two mentions; (2)the prior probability of the mention referring to the target entity is higher than a threshold (set to 0.1 in this paper), which is set to filter the impossible mappings; (3)the mention pairs should not belong to different clauses. The resulting test set is split into 10 parts and a development set, each with 3500 entity pairs roughly, which leads to averagely 200,000 variables and 900,000 constraints per split and may take 1 hour for Cplex to solve. Note that we do not count the triples that will be evaluated in the testing data when we learn the preferences and the clues from the KB.

5.2 Experimental Setup

We compare our framework with three baselines. The first one, *ME-pl*, is the pipeline system constructed by the entity linker in (Han et al., 2011) and the MaxEnt version of Mintz++ extractor mentioned in (Surdeanu et al., 2012). The second and third baselines are the pipeline systems constructed by the same linker and two state-of-the-art DS approaches, MultiR (Hoffmann et al., 2011) and MIML-RE (Surdeanu et al., 2012), respectively. They are referred to as *MultiR-pl* and *MIML-pl* in the rest of this paper.

We also implement several variants of our framework to investigate the following two components in our framework: whether to use explicit (E) or implicit (I) argument type expectations, whether to take global (G) compatibilities into account, resulting in four variants: *ME-JE*, *ME-JI*, *ME-JEG*, *ME-JIG*.

We tune the parameters in the objective function on the development set to be $re = 1$, $el = 4$, $sp = 1$. The numbers of preliminary results retained to the inference step are set to $p = 2$, $q = 3$. Three metrics used in our experiments include: (1)the precision of extracted triples, which is the ratio of the number of correct triples and the number of total extracted triples; (2)the number of correct triples (NoC); (3)the number of correct triples in the results ranked in top n. The third metric is crucial for KBP, since most users are only interested in the knowledge facts with high confidences. We compare the extracted triples against

Table 2: The results of our joint frameworks and the three baselines.

Approach	Precision	NoC	Top 50	Top 100
ME-pl	28.7 ± 0.8	725 ± 12	38 ± 2	75 ± 4
MultiR-pl	31.0 ± 0.8	647 ± 15	39 ± 2	71 ± 3
MIML-pl	33.2 ± 0.6	608 ± 16	40 ± 3	74 ± 5
ME-JE	32.8 ± 0.7	768 ± 10	46 ± 2	90 ± 3
ME-JEG	34.2 ± 0.5	757 ± 8	46 ± 2	90 ± 3
ME-JI	34.5 ± 1.0	784 ± 9	43 ± 3	88 ± 3
ME-JIG	35.7 ± 1.0	772 ± 8	43 ± 3	88 ± 4

Freebase to compute the precision, which may underestimate the performance since Freebase is incomplete. Since we do not have exact annotations for the EL, it is difficult to calculate the exact recall. We therefore use NoC instead. We evaluate our framework on the 10 subsets of the testing dataset and compute their means and standard deviations.

5.3 Overall Performance

We are interested to find out: **(a)**whether the task benefits from the joint inference i.e., can we collect more and correct facts? Or with a higher precision? **(b)** whether the argument type expectations (explicit and implicit) and global compatibility do their jobs as we expected? And, how do we choose from these components ? **(c)**whether the framework can work with other RE models? **(d)**whether we can find a suitable approach to measure the confidence or uncertainty during the extraction so that users or other applications can better utilize the extracted KB facts?

Let us first look at the performance of the baselines and our framework in Table 2 for an overview. Comparing the three pipeline systems, we can discover that using the same entity linker, *MIML-pl* performs the best in precision with slightly fewer correct triples, while *ME-pl* performs the worst. It is not surprising, *ME-pl*, as a strong and high-recall baseline, outputs the most correct triples. As for the results with high confidences, *MultiR-pl* outputs more correct triples in the top 50 results than *ME-pl*, and *MIML-pl* performs better or comparable than *ME-pl* in top n results.

After performing the joint inference, *ME-JE* improves *ME-pl* with 4.1% in precision and 43 more correct triples averagely, and results in better performance in top n results. By taking global compatibilities into consideration, *ME-JEG* further improve the precision to 34.2% in average with slightly fewer correct triples, indicating that

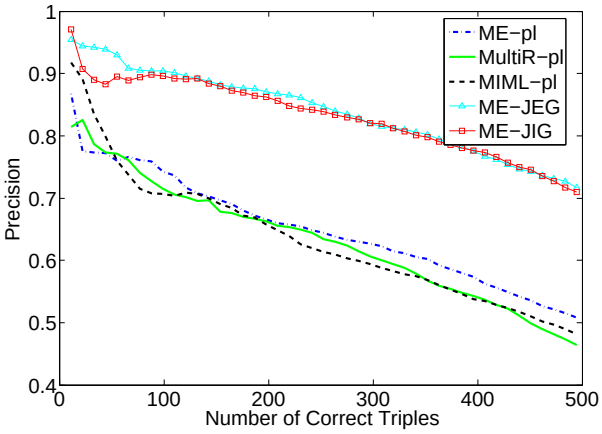

Figure 3: The numbers of correct triples v.s. the precisions for different approaches.

both argument type expectations and global compatibilities are useful in improving the performance: argument type information can help to select the correct and coherent predictions from the candidates EL and RE outputs, while global compatibilities can further prune incorrect triples that cause disagreements, although a few correct ones may be incorrectly eliminated. We can also observe that *ME-JIG* performs even higher than *ME-JEG* in overall precision, but *ME-JEG* collects more correct triples than *ME-JIG* in the top n predictions, showing that explicit type expectations with more accurate type information may perform better in high confidence results.

Furthermore, even though *MultiR-pl* and *MIML-pl* are based on state-of-the-art RE approaches, our model (for example, *ME-JIG*) can still outperform them in terms of all metrics, with 4.7% higher in precision than *MultiR-pl*, 2.5% higher than *MIML-pl*. Our model can extract 125 more correct triples than *MultiR-pl*, 164 more than *MIML-pl*, and perform better in top n results as well.

In previous RE tasks, Precision-Recall curves are mostly used to evaluate the systems' performances. In our task, since it is difficult to calculate the recall exactly, we use the number of correct triples instead, and plot curves of Precision-NoC to show the performance of the competitors and our approaches in more detail. For each value of NoC, the precision is the average of the ten splits of the testing dataset.

As shown in Figure 3, our approaches (*ME-JEG* and *ME-JIG*) obtain higher precisions on each NoC value, and the curves are much smoother than

Table 3: The results of our joint frameworks with MultiR sentence extractor.

Approach	Precision	NoC	Top 50	Top 100
MultiR-pl	31.0 ± 0.8	647 ± 15	39 ± 2	71 ± 3
MultiR-JEG	36.9 ± 0.8	687 ± 15	46 ± 2	88 ± 3
MultiR-JIG	38.5 ± 0.9	700 ± 15	45 ± 2	88 ± 3

the pipeline systems, indicating that our framework is more suitable for harvesting high quality knowledge facts. Comparing the two kinds of type clues, we can see that explicit ones perform better when the confidence control is high and the number of correct triples is small, and then the two are comparable. Since the precision of the triples with high confidences is crucial for the task of KBP, we still suggest choosing the explicit ones when there is a well-defined schema available in the KB, although implicit type expectations can result in higher overall precision.

5.4 Adapting MultiR Sentence Extractor into the Framework

The preliminary relation extractor of our framework is not limited to the MaxEnt[3] extractor. It can be any sentence level recall-oriented relation extractors. To further investigate the generalization of our joint inference framework, we also try to fit other sentence level relation extractors into the framework. Considering that MIML-RE does not output sentence-level results, we only adapt MultiR, with both global compatibilities and explicit/implicit type expectations, named as *MultiR-JEG* and *MultiR-JIG*, respectively. Since the scores output by the original MultiR are unnormalized, which are difficult to directly apply to our framework, we normalize their scores and retune the framework's parameters accordingly. The parameters are set to $re = 1$, $el = 32$, $sp = 16$.

As seen in Table 3, *MultiR-JEG* helps MultiR obtain about 40 more correct triples in average, and achieves 5.9% higher in precision, as well as significant improvements in top n correct predictions. As for *MultiR-JIG*, the improvements are 7.5% in precision and 53 in number of correct triples. In terms of top n results, the explicit and implicit type expectations perform comparable. We also observe that our framework improves MultiR as much as it does to MaxEnt, indicating our joint framework can generalize well in different RE models.

[3] http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.html

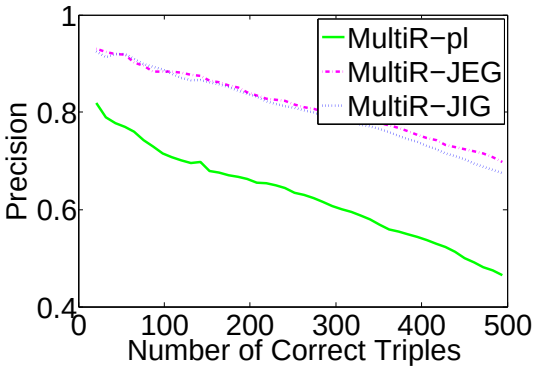

Figure 4: The numbers of correct triples v.s. the precisions for approaches with MultiR extractor.

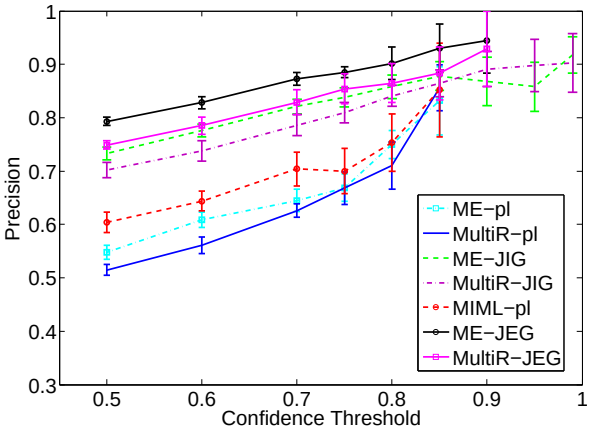

Figure 5: The precisions of different models under different confidence thresholds. The error bars represents the standard deviations of the results.

We further plot Precision-NoC curves for *MultiR-JEG* and *MultiR-JIG* in Figure 4, showing that our framework can result in better performance and smoother curves with MultiR extractor. It is interesting to see that with MultiR extractor, the two kinds of expectations perform comparably.

5.5 Results with Confidence Estimations

Now, we will investigate the results from another perspective with the help of confidence estimations. We calculate the precisions of the competitors and our approaches on different confidence thresholds from 0.5 to 1. The results are summarized in Figure 5. Note that the results across different approaches are not directly comparable, we put them in the same figure only to save space.

In Figure 5, intuitively, as the confidence threshold goes up, the extraction precisions should increase, indicating triples with higher confidences are more likely to be correct. However,

lower thresholds tend to result in estimations with smaller standard derivations due to those precisions are estimated over much more triples than those with higher thresholds, which means the randomness will be smaller.

On the other hand, our joint frameworks provide more evidences that can be used to well capture the reliability of an extraction. For example, the precisions of *Multir-JIG* and *ME-JIG* both stay around 85% when the confidence is higher than 0.85, with about 120 correct triples, indicating that by setting a proper threshold, we can obtain considerable amount of high quality knowledge facts at an acceptable precision, which is crucial for KBP. However, we cannot harvest such amount of high quality knowledge facts from the other three pipeline systems.

6 Conclusions

In this paper, we propose a joint framework for the task of populating KBs with new knowledge facts, which performs joint inference on two subtasks, maximizes their preliminary scores, fulfills the type expectations of relations and avoids global incompatibilities with respect to all local predictions to find an optimal assignment. Experimental results show that our framework can significantly eliminate the error propagations in pipeline systems and outperforms competitive pipeline systems with state-of-the-art RE models. Regarding the explicit argument type expectations and the implicit ones, the latter can result in a higher overall precision, while the former performs better in acquiring high quality knowledge facts with higher confidence control, indicating that if the KB has a well-defined schema we can use explicit type requirements for the KBP task, and if not, our model can still perform well by mining the implicit ones. Our framework can also generalize well with other preliminary RE models. Furthermore, we assign extraction confidences to all extracted facts to facilitate further applications. By setting a suitable threshold, our framework can populate high quality reliable knowledge facts to existing KBs.

For future work, we will address the NIL issue of EL where we currently assume all entities should be linked to a KB. It would be also interesting to jointly model the two subtasks through structured learning, instead of joint inference only. Currently we only use the coherence of extracted triples and the KB to estimate confidences, which would be nice to directly model the issue in a joint model.

Abstract

Information in visually rich formats such as PDF and HTML is often conveyed by a combination of textual and visual features. In particular, genres such as marketing flyers and info-graphics often augment textual information by its color, size, positioning, etc. As a result, traditional text-based approaches to information extraction (IE) could underperform. In this study, we present a supervised machine learning approach to IE from online commercial real estate flyers. We evaluated the performance of SVM classifiers on the task of identifying 12 types of named entities using a combination of textual and visual features. Results show that the addition of visual features such as color, size, and positioning significantly increased classifier performance.

1 Introduction

Since the Message Understanding Conferences in the 1990s (Grishman and Sundheim, 1996; Chinchor and Robinson, 1997), Information Extraction (IE) and Named Entity Recognition (NER) approaches have been applied and evaluated on a variety of domains and textual genres. The majority of the work, however, focuses on the journalistic, scientific, and informal genres (newswires, scientific publications, blogs, tweets, and other social media texts) (Nadeau and Sekine, 2007) and deals with purely textual corpora. As a result, the feature space of NER systems involves purely textual features, typically word attributes and characteristics (orthography, morphology, dictionary lookup, etc.), their contexts and document features (surrounding word window, local syntax, document/corpus word frequencies, etc.) (Nadeau and Sekine, 2007).

At the same time, textual information is often presented in visually rich formats, e.g. HTML and PDF. In addition to text, these formats use a variety of visually salient characteristics, (e.g. color, font size, positioning) to either highlight or augment textual information. In some genres and domains, a textual representation of the data, excluding visual features is often not enough to accurately identify named entities of interest or extract relevant information. Marketing materials, such as online flyers or HTML emails, often contain a plethora of visual features and text-based NER approaches lead to poor results. In this paper, we present a supervised approach that uses a combination of textual and visual features to recognize named entities in online marketing materials.

2 Motivation and Problem Definition

A number of broker-based industries (e.g. commercial real estate, heavy equipment machinery, etc.) lack a centralized searchable database with industry offerings. In particular, the commercial real estate industry (unlike residential real estate) does not have a centralized database or an established source of information. Commercial real estate brokers often need to rely on networking, chance, and waste time with a variety of commercial real estate databases that often present outdated information. While brokers do not often update third party inventory databases, they do create marketing materials (usually PDF flyers) that contain all relevant listing information. Virtually all commercial real estate offerings come with publicly available marketing material that contains all relevant listing information. Our goal is to harness this source of information (the marketing flyer) and use it to extract structured listing information.

Figure 1 shows an example of a commercial real estate flyer. The commercial real estate flyers are often distributed as PDF documents, links to HTML pages, or visually rich HTML-based

Figure 1: An example of a commercial real estate flyer © Kudan Group Real Estate.

emails. They typically contain all relevant listing information such as the address and neighborhood of the offering, the names and contact information of the brokers, the type of space offered (building, land, unit(s) within a building), etc. Similar to other info-graphics, relevant information could be easily pinpointed by visual clues. For example, the listing street address in Figure 1 (*1629 N. Halsted St.*, upper left corner) can be quickly identified and distinguished from the brokerage firm street address (*156 N. Jefferson St.*, upper right corner) due to its visual prominence (font color, size, positioning).

In this study we explored a supervised machine learning approach to the task of identifying listing information from commercial real estate flyers. In particular, we focused on the recognition of 12 types of named entities as described in Table 1 below.

3 Related Work

Nadeau and Satoshi (2007) present a survey of NER and describe the feature space of NER research. While they mention multi-media NER in the context of video/text processing, all described features/approaches focus only on textual representation.

Broker Name Broker Email Broker Phone Company Phone	The contact information of all listing brokers, including full name, email address, phone number. The brokerage company phone number.
Street City Neighborhood State Zip	The address information of the listing address including street or intersection, city, neighborhood, state, and zip code.
Space Size Space Type	Size and attributes of relevant spaces (e.g. *27,042 SF building, 4.44 acres site*, etc.); Mentions of space type descriptors, e.g. building, land/lot, floor, unit. This excludes space type and size information of non-essential listing attributes (e.g. basement size or parking lot size).
Confidential	Any mentions of confidentiality.

Table 1: Types and descriptions of named entities relevant to extracting listing information from commercial real estate flyers.

The literature on Information Extraction from HTML resources is dominated by various approaches based on wrapper induction (Kushmerick, 1997; Kushmerick, 2000). Wrapper inductions rely on common HTML structure (based on the HTML DOM) and formatting features to extract structured information from similarly formatted HTML pages. This approach, however, is not applicable to the genres of marketing materials (PDF and HTML) since they typically do not share any common structure that can be used to identify relevant named entities. Laender et al. (2002) present a survey of data extraction techniques and tools from structured or semi-structured web resources.

Cai et al. (2003) present a vision-based segmentation algorithm of web pages that uses HTML layout features and attempts to partition the page at the semantic level. In (Burget and Rudolfova, 2009) authors propose web-page block classification based on visual features. Yang and Zhang (2001) build a content tree of HTML documents based on *visual consistency* inferred semantics. Burget (2007) proposes a layout based information extraction from HTML documents and states that this visual approach is more robust than traditional DOM-based methods.

Changuel et al.(2009a) describe a system for automatically extracting author information from web-pages. They use spatial information based on the depth of the text node in the HTML DOM tree. In (Changuel et al., 2009b) and (Hu et al., 2006),

the authors proposed a machine learning method for title extraction and utilize format information such as font size, position, and font weight. In (Zhu et al., 2007) authors use layout information based on font size and weight for NER for automated expense reimbursement.

While the idea of utilizing visual features based on HTML style has been previously suggested, this study tackles a non-trivial visually rich dataset that prevents the use of previously suggested simplistic approaches to computing HTML features (such as relying on the HTML DOM tree or simplistic HTML style rendering). In addition, we introduce the use of RGB color as a feature and normalize it approximating human perception.

4 Dataset and Method

The dataset consists of 800 randomly selected commercial real estate flyers spanning 315 US locations, 75 companies, and 730 brokers. The flyers were collected from various online sources and were originally generated using a variety of HTML and PDF creator tools. The collection represents numerous flyer formats and layouts, commercial real estate property types (*industrial, retail, office, land*, etc.), and transactions (*investment, sale, lease*).

All flyers were converted to a common format (HTML)[1]. The HTML versions of all documents were then annotated by 2 annotators. Figure 2 shows an example of an annotated flyer. Annotation guidelines were developed and the 2 annotators were able to achieve an inter-annotator agreement of 91%[2]. The named entities with lowest inter-annotator agreement were entities describing Space Size and Type because of the somewhat complex rules for determining essential listing space information. For example, one of the space size/type rules reads as follows: *If the listing refers to a building and mentions the lot size, include both the land size, the building size, and corresponding space types. Do not include individual parts of the building (e.g. office/basement) as separate spaces. If the listing refers to a UNIT within the building, not the whole building, then DO NOT include the land site as a separate space.*

A supervised machine learning approach was

[1]PDFs were converted to HTML using the PDFTOHTML conversion program `http://pdftohtml.sourceforge.net/`.

[2]The inter-annotator agreement was measured as F1-score using one of the annotator's named entities as the gold standard set and the other as a comparison set.

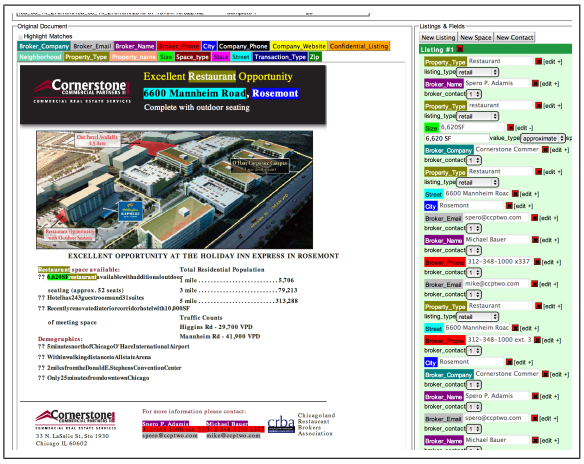

Figure 2: The HTML versions of the flyers were annotated by 2 annotators using a custom web-based annotation tool.

then applied to the task of identifying the 12 named entities shown in Table 1. Flyers were converted to text using an HTML parser while preserving some of the white space formatting. The text was tokenized and the task was then modeled as a **BIO** classification task, classifiers identify the **B**eginning, the **I**nside, and **O**utside of the text segments. We first used a traditional set of text-based features for the classification task. Table 2 lists the various text-based features used. In all cases, a sliding window including the 5 preceding and 5 following tokens was used as features.

Feature Name	Description
Token	A normalized string representation of the token. All tokens were converted to lower case and all digits were converted to a common format.
Token Orth	The token orthography. Possible values are lowercase (all token characters are lower case), all capitals (all token characters are upper case), upper initial (the first token character is upper case, the rest are lower case), mixed (any mixture of upper and lower case letters not included in the previous categories).
Token Kind	Possible values are word, number, symbol, punctuation.
Regex type	Regex-based rules were used to mark chunks as one of 3 regex types: email, phone number, zip code.
Gazetteer	Text chunks were marked as possible US cities or states based on US Census Bureau city and state data. www.census.gov/geo/maps-data/data/gazetteer2013.html.

Table 2: List of text-based features used for the NER task. A sliding window of the 5 preceding and 5 following tokens was used for all features.

As noted previously, human annotators were able to quickly spot named entities of interest solely because of their visual characteristics. For example, a text-only version of the flyer shown in Figure 1, stripped of all rich formatting, will make it quite difficult to distinguish the listing address (shown in prominent size, position, and color) from the brokerage company address, which is rarely prominent as it is not considered important information in the context of the flyer. Similarly, the essential size information for the listing shown on Figure 2 appears prominently on the first page (square footage of the offered restaurant), while non-essential size information, such as the size of the adjacent parking lot or basement, tend to appear in smaller font on subsequent flyer pages.

To account for such visual characteristics we attempted to also include visual features associated with text chunks. We used the computed HTML style attributes for each DOM element containing text. Table 3 lists the computed visual features.

Feature Name	Description
Font Size	The computed *font-size* attribute of the surrounding HTML DOM element, normalized to 7 basic sizes (*xx-small, x-small, small, medium, large, x-large, xx-large*).
Color	The computed *color* attribute of the surrounding HTML DOM element. The RGB values were normalized to a set of 100 basic colors. We converted the RGB values to the YUV color space, and then used Euclidian distance to find the most similar basic color approximating human perception.
Y Coordinate	The computed *top* attribute of the surrounding HTML DOM element, i.e. the y-coordinate in pixels. The pixel locations was normalized to 150 pixel increments (roughly 1/5th of the visible screen for the most common screen resolution.)

Table 3: List of visual features used for the NER task. A sliding window of 5 preceding and 5 following DOM elements were used for all features.

Computing the HTML style attributes is a complex task since they are typically defined by a combination of CSS files, in-lined HTML style attributes, and browser defaults. The complexities of style definition, inheritance, and overwriting are handled by browsers[3]. We used the Chrome browser to compute dynamically the style of each DOM element and output it as inline style attributes. To achieve this we programmatically inserted a javascript snippet that inlines the computed style and saves the new version of the HTML on the local file system utilizing the HTML5 *saveAs* interface[4]. Details on how we normalized the style attribute values for font size, RGB color, and Y coordinate are shown in Table 3.

We then applied Support Vector Machines (SVM) (Vapnik, 2000) on the NER task using the LibSVM library (Chang and Lin, 2011). We chose SVMs as they have been shown to perform well on a variety of NER tasks, for example (Isozaki and Kazawa, 2002; Takeuchi and Collier, 2002; Mayfield et al., 2003; Ekbal and Bandyopadhyay, 2008). We used a linear kernel model with the default parameters. The multi-class problem was converted to binary problems using the one-vs-others scheme. 80% of the documents were used for training, and the remaining 20% for testing.

5 Results

Results are shown in Table 4. We compared classifier performance using only textual features (first 3 columns), versus performance using both textual and visual features (next 3 columns). Results were averaged over 2 runs of randomly selected training/test documents with 80%/20% ratio. We used an exact measure which considers an answer to be correct only if both the entity boundaries and entity type are accurately predicted.

The addition of visual features significantly[5] increased the overall F1-score from 83 to 87%. As expected, performance gains are more significant for named entities that are typically visually salient and are otherwise difficult (or impossible) to identify in a text-only version of the flyers. Named Entities referring to listing address information showed the most significant improvements. In particular, the F1-score for mentions of *Neighborhoods* (typically prominently shown on the first page of the flyers) improved by 19%; F1-score for mentions of the listing *State* improved by 9%; and *Street, City, Zip* by roughly 4% each, all

[3]We attempted to use an HTML renderer from the Cobra java toolkit `http://lobobrowser.org/cobra.jsp` to compute HTML style attributes. However, this renderer produced poor results on our dataset and failed to accurately compute the pixel location of text elements.

Confidential	100	60.0	75.0	75.0	85.7	79.9	N
OVERALL	84.8	81.3	83.0	91.2	83.2	87.0	Y

Table 4: Results from applying SVM using the textual features described in Table 2, as well as both the textual and visual features described in Tables 2 and 3. t=textual features only, v+t=visual + textual features, P=Precision, R=Recall, F=F1-score, S=Significant Difference

statistically significant. Visual clues are also typically used when identifying relevant size information and, as expected, performance improved significantly by roughly 6%. The difference in performance for mentions used to describe confidential information is not statistically significant[6] because such mentions rarely occurred in the dataset. Similarly, performance differences for Company Phone, Broker Phone, Broker Email, and Space Type are not statistically significant. In all of these cases, visual features did not influence performance and text-based features proved adequate predictors.

6 Conclusion

We have shown that information extraction in certain genres and domains spans different media - textual and visual. Ubiquitous online and digital formats such as PDF and HTML often exploit the interaction of textual and visual elements. Information is often augmented or conveyed by non-textual features such as positioning, font size, color, and images. However, traditionally, NER approaches rely exclusively on textual features and as a result could perform poorly in visually rich genres such as online marketing flyers or infographics. We have evaluated the performance gain on the task of NER from commercial real estate flyers by adding visual features to a set of traditional text-based features. We used SVM classifiers for the task of identifying 12 types of named entities. Results show that overall visual features improved performance significantly.

[6] p value = 0.7323% using Z-test on two proportions.

Abstract

Temporal scope adds a time dimension to facts in Knowledge Bases (KBs). These time scopes specify the time periods when a given fact was valid in real life. Without temporal scope, many facts are underspecified, reducing the usefulness of the data for upper level applications such as Question Answering. Existing methods for temporal scope *inference* and *extraction* still suffer from low accuracy. In this paper, we present a new method that leverages temporal profiles augmented with context— Contextual Temporal Profiles (CTPs) of entities. Through change patterns in an entity's CTP, we model the entity's state change brought about by real world events that happen to the entity (e.g, hired, fired, divorced, etc.). This leads to a new formulation of the temporal scoping problem as a *state change detection problem*. Our experiments show that this formulation of the problem, and the resulting solution are highly effective for inferring temporal scope of facts.

1 Introduction

Recent years have seen the emergence of large Knowledge Bases (KBs) of facts (Carlson 2010; Auer 2007; Bollacker 2008; Suchanek 2007). While the wealth of accumulated facts is huge, most KBs are still sparsely populated in terms of temporal scope. Time information is an important dimension in KBs because knowledge is not static, it changes over time: people get divorced; countries elect new leaders; and athletes change teams. This means that facts are not always indefinitely true. Therefore, temporal scope has crucial implications for KB accuracy.

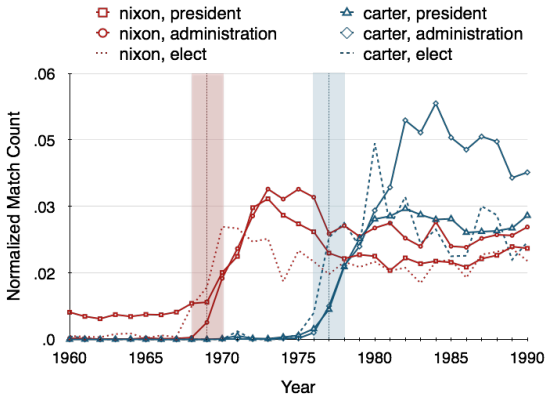

Figure 1: Behavior patterns of context uni-grams for the US presidency state change as seen in the Google Books N-grams corpus: the rise of 'elect', immediately followed by the rise of 'administration' and 'president'.

Towards bridging the time gap in KBs, we propose a new method for temporal scope inference. Our method is based on leveraging aggregate statistics from a time-stamped corpus. First we generate Contextual Temporal Profiles (CTPs) of entities from contexts surrounding mentions of these entities in the corpus. We then detect change patterns in the CTPs. We then use these changes to determine when a given entity undergoes a specific state change caused by real world events. Our main insight is as follows: events that happen to an entity change the entity's state and therefore its facts. Thus by learning *when* a given entity undergoes a specific state change, we can directly infer the time scopes of its facts. For example, in the *divorce event*, the person's state changes from 'married' to 'divorced' hence the *hasSpouse* relation no longer applies to it, signaling the *end* time of its current *hasSpouse* value. In a *country election event*, the country's state changes and it obtains a new value for its *hasPresident* relation.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1930–1936,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

Our method involves learning context units (uni-grams and bi-grams surrounding mentions of an entity) that are relevant to a given state change. For this we use a few seed examples of entities that have gone through the state change. For example, for the US presidency state change denoting the beginning of a US presidency, given seed examples such as *(Richard Nixon, 1969)* and *(Jimmy Carter, 1977)*, relevant context units include unigrams such as 'administration' and 'elect', which are common to both CTPs in 1969 and 1977 respectively. Secondly, we learn the mention behavior of these context units for an entity undergoing a given state change (section 3 has more details). Figure 1 shows a motivating example, we see the behavior patterns of context uni-grams for the US presidency state change: the rise of 'elect' at the beginning of presidencies, immediately followed by the rise of 'administration' and 'president' in the context of the entities, *Nixon* and *Carter*.

2 Related work

Prior work mainly falls into two categories: i) methods that extract temporal scope from text, at the time of fact extraction; ii) methods that infer temporal scope from aggregate statistics in large Web corpora. Early methods mostly fall under category i); Timely YAGO (Wang 2010), TIE (Ling 2010), and PRAVDA (Wang 2011) are three such methods. Timely YAGO applies regular expressions to Wikipedia infoboxes to extract time scopes. It is therefore not applicable to any other corpora but Wikipedia. The TIE (Ling 2010) system produces a maximal set of events and their temporal relations based on the text of a given sentence. PRAVDA uses textual patterns along with a graph-based re-ranking method. Methods falling under category i) have the downside that it is unclear how they can be applied to facts that are already in the knowledge base. Only one other approach learned time scopes from aggregate corpus statistics, a recent system called CoTS (Talukdar 2012b). CoTS uses temporal profiles of facts and how the mentions of such facts rise and fall over time. However, CoTS is based on frequency counts of fact mentions and does not take into account state change inducing context. For example, to find the time scope of Nixon presidency, CoTS uses the rise and fall of the mention 'nixon' and 'president' over time. To improve accuracy, CoTS combined this frequency signal with manually supplied constraints such as the functionality of the US presidency relation to scope the beginning and end of Nixon presidency. In contrast, the proposed system does not require constraints as input.

There have also been tools and competitions developed to facilitate temporal scope extraction. TARSQI (Verhagen 2005) is a tool for automatically annotating time expressions in text. The TempEval (Verhagen 2007) challenge has led to a number of works on temporal relation extraction (Puscasu 2007; Yoshikawa 2009; Bethard 2007).

3 Method

Given an entity and its Contextual Temporal Profile (CTP), we can learn *when* such an entity undergoes a specific state change. We can then directly infer the *begin* or *end* time of the fact associated with the state change.

The CTP of an entity at a given time point t contains the context within which the entity is mentioned at that time. Our method is based on two related insights: i) the context of the entity at time t reflects the events happening to the entity and the state of the entity at time t. ii) the *difference in context* before, at time $t-1$, and after, at time t, reflect the associated state change at time t. However an entity can undergo a multiplicity of changes at the same time. Thus both the contexts and the differences in contexts can contain information pertaining to several state changes. We therefore need a way of determining which part of the context is relevant to a given state change sc_i. To this end, we generate what we refer to as an $aggregate$ state vector, $Vs(\overline{e}, sc_i)$ for a hypothetical average entity $\overline{e}$ undergoing state change sc_i. We generate $Vs(\overline{e}, sc_i)$ from the CTPs of a seed set of entities at the time they undergo state change sc_i.

3.1 Learning State and State Change Vectors

To build CTPs for entities, we use two time-stamped corpora: the Google Books Ngram corpus (Michel 2011); and the English Gigaword (Graff 2003) corpus. The Google Books Ngram corpus contains n-grams for $n = 1-5$; along with occurrence statistics from over about 5 million digitized books. The English Gigaword (Graff

2003) corpus contains newswire text from 1994-2008. From these corpora, we use the time granularity of a year as it is the finest granularity common to both corpora.

Definition 1 (Contextual Temporal Profile) *The Contextual Temporal Profile (CTP) of an entity e at time t, $C_e(t)$, consists of the context within which e is mentioned. Specifically $C_e(t)$ consists of uni-grams and bi-grams generated from the 5-grams(Google Books Ngram) or sentences (Gigaword) that mention e at time t.*

Notice that the CTPs can contain context units (bi-grams or uni-grams) that are simply noise. To filter the noise, we compute *tf-idf* statistics for each contextual unit and only retain the top k ranking units in $C_e(t)$. In our experiments, we used $k = 100$. We compute *tf-idf* by treating each time unit t as a document containing words that occur in the context of e (Wijaya 2011).

Furthermore, CTPs may contain context units attributed to several state changes. We therefore tease apart the CTPs to isolate contexts specific to a given state change. For this, our method takes as input a small set of seed entities, $\mathcal{S}(sc_i)$, for each type of state change. Thus for the US presidency state change that denotes the beginning of a US presidency, we would have seeds as follows: *(Richard Nixon, 1969)*, *(Jimmy Carter, 1977)*. From the CTPs of the seeds for state change sc_i, we generate an aggregate state vector, $Vs(\overline{e}, sc_i)$. To obtain the few dozen seeds required by our method, one can leverage semi-structured sources such as Wikipedia *infoboxes*, where relations e.g., *spouse* often have time information.

Definition 2 (Aggregate State Vector for $\overline{e}$) *The aggregate state vector of a mean entity $\overline{e}$ for state change sc_i, $Vs(\overline{e}, sc_i)$, is made up of the contextual units from the CTPs of entities in the seed set $\mathcal{S}(sc_i)$ that undergo state change sc_i. Thus, we have: $Vs(\overline{e}, sc_i) = \frac{1}{|\mathcal{S}(sc_i)|} \sum_{e,t:(e,t)\in\mathcal{S}(sc_i)} C_e(t)$.*

Thus, the state vector $Vs(\overline{e}, sc_i)$ reflects events happening to $\overline{e}$ and the state of $\overline{e}$ at the time it undergoes the state change sc_i. Additionally, we compute another type of aggregate vector, *aggregate change vector* $\triangle Vs(\overline{e}, sc_i)$ to capture the change patterns in the context units of $\overline{e}$. Recall that context units rise or fall due to state change, as seen earlier in Figure 1.

Definition 3 (Aggregate Change Vector for $\overline{e}$) *The aggregate change vector of a mean entity $\overline{e}$ for state change sc_i, $\triangle Vs(\overline{e}, sc_i)$, is made up of the change in the contextual units of the CTPs of entities in the seed set $\mathcal{S}(sc_i)$ that undergo state change sc_i. Thus, we have: $\triangle Vs(\overline{e}, sc_i) = \frac{1}{|\mathcal{S}(sc_i)|} \sum_{e,t:(e,t)\in\mathcal{S}(sc_i)} C_e(t) - C_e(t-1)$.*

The aggregate state vector $Vs(\overline{e}, sc_i)$ and the aggregate change vector $\triangle Vs(\overline{e}, sc_i)$ are then used to detect state changes.

3.2 Detecting State Changes

To detect state changes in a previously unseen entity e_{new}, we generate its state vector, $C_{e_{new}}(t)$, and its change vector, $\triangle C_{e_{new}}(t)$ = $C_{e_{new}}(t)$ - $C_{e_{new}}(t-1)$, for every time point t. We consider every time point t in the CTP of the new entity to be a candidate for a given state change sc_i, which we seek to determine whether e_{new} goes through and at which time point. We then compare the state vector and change vector of every candidate time point t to the aggregate state and aggregate change vector of state change sc_i. We use cosine similarity to measure similarities between the state vector and the aggregate state vector and between the change vector and the aggregate change vector. To combine these two vector similarities, we sum the state vector and change vector similarities. In future we can explore cross validation and a separate development set to define a weighted sum for combining these two similarities.

The highest ranking candidate time point (most similar to the aggregate state and aggregate change vector) is then considered to be the start of state change sc_i for the new entity e_{new}.

4 Experiments

We carried out experiments to answer the following questions: *Is treating temporal scoping as state change detection in Contextual Temporal Profiles(CTPs) effective? Do CTPs help improve temporal scope extraction over context-unaware temporal profiles?*

4.1 Methods under Comparison

We answer these questions by comparing to the following methods.

1. **CoTS** a state-of-the-art temporal scoping system (Talukdar 2012b)

2. **MaxEnt** a baseline to which CoTS was compared. It is a Maximum Entropy classifier trained separately for each relation using normalized counts and gradients of facts as features. An Integer Linear Program (ILP) is used to predict which facts are active at which times. This is done based on the output of the MAXENT classifier together with temporal intra-relation constraints that regulate the temporal scoping of one or more facsts from a *single* relation (e.g., FUNCTIONAL constraints on US President relation that regulate that at most one fact from the relation can be true at any given time i.e., there is only one US President at any given time).

3. **MaxEnt + Intra Relation Constraints** MaxEnt with cross relation constraints added: constraints that couple facts from *multiple* relations e.g., a constraint that *Al Gore*'s vice presidency is aligned exactly with *Bill Clinton*'s presidency.

We evaluate on the same set of facts as CoTS and its baselines: facts from the US Administration domain (US President, US Vice President, and US Secretary of State); and facts from the Academy Awards domain (Best Director and Best Picture). The number of facts per relation are as follows: US President, 9; US Vice President, 12; US Secretary of State, 13; Best Director, 14; and Best Picture, 14. Our method however is not specific to these relations from these two domains. Since our method does not depend on temporal constraints, the method can work a very different domain, for example one where many facts can exist for any time span without being superseded by another, as long as the entities involved experience a change of state. Thus, it can be applied to relations like *spouse*, even though many people are married in a year as these people change state from *single* or *engaged* to *married*.

Similar to CoTS, the datasets from which the CTPs were generated are as follows: The Google Books Ngram (1960-2008) dataset (Michel 2011) for the US Administration domain and the English Gigaword (1994-2008) dataset (Graff 2003) for Academy Award domain.

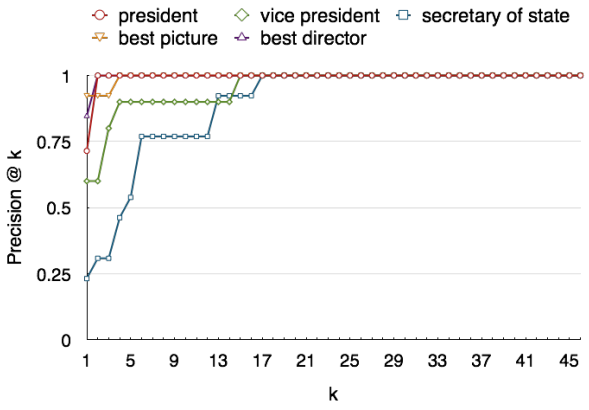

Figure 2: Precision @ k using Contextual Temporal Profiles.

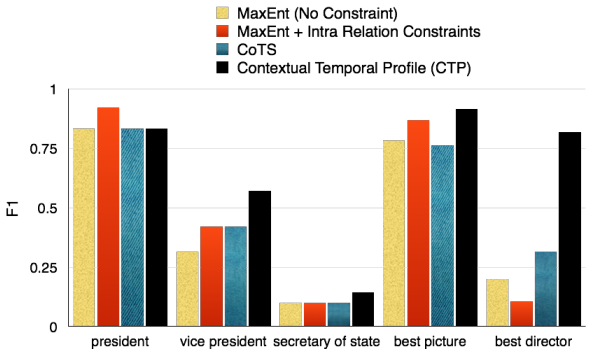

Figure 3: Comparison of F1 scores with CoTS and other baselines.

4.2 CTPs Begin time precision

To compute precision we used cross validation, in particular, leave-one-out cross validation due to the small number of facts per relation.We predict the *begin* time of each fact, the time the fact starts to be valid. True begin times were determined by a human annotator. This human annotated data formed the gold-standard which we used to determine Precision (P), Recall (R), and the F1 measure. All evaluations were performed at the year level, the finest granularity common to the two time-stamped datasets.

For our first experiment, we report the average precision@k, where k=1 to n, where n=47 is the number of years between 1960 to 2008 to select from. As can be seen in Figure 2, precision quickly reaches 1 for most relations. The true begin time is usually found within top k=5 results.

4.3 Comparison to baselines

For our second experiment, we compared to the F1 scores of CoTS and other baselines in (Talukdar 2012b). As can be seen in Figure 3, our CTPs approach gives comparable or better F1 (@k=1) than systems that use only plain temporal profiles, even when these systems are supplemented with many carefully crafted, hand-specified constraints.

We note that the performance on the *US Secretary of State* relation is low in both CoTS (Talukdar 2012b) and in our approach. We found that this was due to few documents mentioning the "secretary of state" in Google Books Ngram dataset. This leads to weak signals for predicting the temporal scope of secretary of state appointments.

We also observe that the uni-grams and bigrams in the train CTPs and change vectors reflect meaningful events and state changes happening to the entities (Table 1). For example, after 'becoming president' and 'taking office', US presidents often see a drop in mentions of their previous (job title state) such as 'senator', 'governor' or 'vice president' as they gain the'president' state.

Relation	CTP State Context	Unigrams and Bigrams in CTP Change Vectors
US President	was elected, took office, became president	vice president (-), by president (+), administration (+), senator (-), governor (-), candidate (-)
Best Picture	nominated for, to win, won the, was nominated	best picture (+), hour minute (-), academy award (+), oscar (+), nominated (+), won (+), star (-), best actress (+), best actor (+), best supporting (+)

Table 1: Example behavior of various contextual units (unigrams and bigrams) automatically learned in the train CTPs and change vector. The *(+)* and *(-)* signs indicate rise and fall in mention frequency, respectively.

4.4 Discussion

Overall, our results show that our method is promising for detecting *begin* time of facts. In its current state, our method performs poorly on inferring *end* times as contexts relevant to a fact often still mentioned with the entity even after the fact ceases to be valid. For example, the entity *Al Gore* is still mentioned a lot with the bi-gram 'vice president' even after he is no longer a vice president. Prior work, CoTS, inferred *end* times by leveraging manually specified constraints, e.g., that there can only be one vice president at a time: the beginning of one signals the end of another (Talukdar 2012b). However such methods do not scale due to the amount of constraints that must be hand-specified. In future, we would like to investigate how to better detect the *end* times of facts.

5 Conclusion

This paper presented a new approach for inferring temporal scopes of facts. Our approach is to reformulate temporal scoping as a state change detection problem. To this end, we introduced Contextual Temporal Profiles (CTPs) which are entity temporal profiles enriched with relevant context. From the CTPs, we learned change vectors that reflect change patterns in context units of CTPs. Our experiments showed that the change patterns are highly relevant for detecting state change, which is an effective way of identifying *begin* times of facts. For future work, we would like to investigate how our method can be improved to dp better at detecting fact *end* times. We also would like to investigate time-stamped corpora of finer-grained granularity such as day. This information can be obtained by subscribing to daily newsfeeds of specific entities.

Noisy Or-based model for Relation Extraction using Distant Supervision

Ajay Nagesh[1,2,3] **Gholamreza Haffari** **Ganesh Ramakrishnan**

Abstract

Distant supervision, a paradigm of relation extraction where training data is created by aligning facts in a database with a large unannotated corpus, is an attractive approach for training relation extractors. Various models are proposed in recent literature to align the facts in the database to their mentions in the corpus. In this paper, we discuss and critically analyse a popular alignment strategy called the *"at least one"* heuristic. We provide a simple, yet effective relaxation to this strategy. We formulate the inference procedures in training as integer linear programming (*ILP*) problems and implement the relaxation to the *"at least one "* heuristic *via* a soft constraint in this formulation. Empirically, we demonstrate that this simple strategy leads to a better performance under certain settings over the existing approaches.

1 Introduction

Although supervised approaches to relation extraction (GuoDong et al., 2005; Surdeanu and Ciaramita, 2007) achieve very high accuracies, they do not scale as they are data intensive and the cost of creating annotated data is quite high. To alleviate this problem, Mintz et al. (2009) proposed relation extraction in the paradigm of *distant supervision*. In this approach, given a database of facts (e.g. Freebase[1]) and an unannotated document collection, the goal is to heuristically align the facts in the database to the sentences in the corpus which contain the entities mentioned in the fact. This is done to create weakly labeled training data to train a classifier for relation extraction. The underlying assumption is that all mentions of an entity pair[2] (i.e. sentences containing the entity pair) in the corpus express the same relation as stated in the database.

The above assumption is a weak one and is often violated in natural language text. For instance, the entity pair, (`Barack Obama`, `United States`) participate in more than one relation: `citizenOf`, `presidentOf`, `bornIn` and every mention expresses either one of these fixed set of relations or none of them.

Consequently, a number of models have been proposed in literature to provide better heuristics for the mapping between the entity pair in the database and its mentions in the sentences of the corpus. Riedel et al. (2010) tightens the assumption of distant supervision in the following manner: "Given a pair of entities and their mentions in sentences from a corpus, *at least one* of the mentions express the relation given in the database". In other words, it models the problem as that of multi-instance (mentions) single-label (relation) learning. Following this, Hoffmann et al. (2011) and Surdeanu et al. (2012) propose models that consider the mapping as that of multi-instance multi-label learning. The instances are the mentions of the entity pair in the sentences of the corpus and the entity pair can participate in more than one relation.

Although, these models work very well in practice, they have a number of shortcomings. One of them is the possibility that during the alignment, a fact in the database might not have an instantiation in the corpus. For instance, if our corpus only contains documents from the years 2000 to 2005, the fact `presidentOf`(`Barack Obama`, `United States`) will not be present in the corpus. In such cases, the distant supervision assumption fails to provide a mapping for the fact in the corpus.

In this paper, we address this situation with a

noisy-or model (Srinivas, 2013) in training the relation extractor by relaxing the *"at least one"* assumption discussed above. Our contributions in this paper are as follows: (i) We formulate the inference procedures in the training algorithm as integer linear programming (*ILP*) problems, (ii) We introduce a soft-constraint in the ILP objective to model noisy-or in training, and (iii) Empirically, our algorithm performs better than Hoffmann et al. (2011) procedure under certain settings on two benchmark datasets.

Our paper is organized as follows. In Section 2, we discuss our methodology. We review the approach of Hoffmann et al. (2011) and explain our modifications to it. In Section 3, we discuss related work. In Section 4, we discuss the experimental setup and our preliminary results. We conclude in Section 4.

2 Methodology

Our work extends the work of Hoffmann et al. (2011). So, we recapitulate Hoffmann's model in the following subsection. Following which our additions to this model is explained in detail.

Hoffmann's model

Hoffmann et al. (2011) present a multi-instance multi-label model for relation extraction through distant supervision. In this model, a pair of entities have multiple mentions (sentence containing the entity pair) in the corpus. An entity pair can have one or more relation labels (obtained from the database).

Objective function

Consider an entity pair (e_1, e_2) denoted by the index i. The set of sentences containing the entity pair is denoted $\mathbf{x_i}$ and the set of relation labels for the entity pair from the database is denoted by $\mathbf{y_i}$. The mention-level labels are denoted by the latent variable $\mathbf{z}$ (there is one variable z_j for each sentence j).

To learn the parameters θ, the training objective to maximize is the likelihood of the facts observed in the database conditioned on the sentences in the text corpus.

$$\theta^* = \arg\max_\theta \prod_i Pr(\mathbf{y_i}|\mathbf{x_i};\theta)$$
$$= \arg\max_\theta \prod_i \sum_z Pr(\mathbf{y_i}, \mathbf{z}|\mathbf{x_i};\theta)$$

The expression $Pr(\mathbf{y_i}, \mathbf{z}|\mathbf{x_i})$ for a given entity pair is defined by two types of factors in the factor graph. They are *extract factors* for each mention and *mention factors* between a relation label and all the mentions.

The *extract factors* capture the local signal for each mention and consists of a bunch of lexical and syntactic features like POS tags, dependency path between the entities and so on (Mintz et al., 2009).

The *mention factors* capture the dependency between relation label and its mentions. Here, the *at least one* assumption that was discussed in Section 1 is modeled. It is implemented as a simple deterministic OR operator as given below:

$$f_{mention}(y_r, \mathbf{z}) = \begin{cases} 1 & \text{if } y_r \text{ is true} \wedge \exists i : z_i = r \\ 0 & \text{otherwise} \end{cases}$$

Training algorithm

The learning algorithm is a perceptron-style parameter update scheme with 2 modifications: i) online learning ii) Viterbi approximation. The inference is shown to reduce to the well-known weighted edge-cover problem which can be solved exactly, although Hoffmann et al. (2011) provide an approximate solution.

Algorithm 1: Hoffmann et al. (2011) : Training

Input : *i*) Σ: set of sentences, *ii*) E: set of entities mentioned in the sentences, *iii*) R: set of relation labels, *iv*) Δ: database of facts
Output: Extraction model : Θ
begin
  for $t \leftarrow 1$ **to** T ; /* training iterations */
  do
    for $i \leftarrow 1$ **to** N ; /* No. of entity pairs */
    do
      $\widehat{\mathbf{y}}, \widehat{\mathbf{z}}, = \arg\max_{\mathbf{y},\mathbf{z}} Pr(\mathbf{y}, \mathbf{z}|\mathbf{x_i};\Theta)$
      if $\widehat{\mathbf{y}}! = \mathbf{y_i}$ **then**
        $\mathbf{z}^* = \arg\max_{\mathbf{z}} Pr(\mathbf{z}|\mathbf{y_i}, \mathbf{x_i};\Theta)$
        $\Theta^{new} = \Theta^{old} + \Phi(\mathbf{x_i}, \mathbf{z}^*) - \Phi(\mathbf{x_i}, \widehat{\mathbf{z}})$
end

Our additions to Hoffmann's model

In the training algorithm described above, there are two MAP inference procedures. Our contributions in this space is two-fold. Firstly, we

have formulated these as ILP problems. As a result of this, the approximate inference therein is replaced by an exact inference procedure. Secondly, we replace the *deterministic-or* by a *noisy-or* which provides a soft-constraint instead of the hard-constraint of Hoffmann. (*"at least one"* assumption)

ILP formulations

Some notations:

- z_{ji} : The mention variable z_j (or jth sentence) taking the relation value i
- s_{ji} : Score for z_j taking the value of i. Scores are computed from the *extract* factors
- y_i : relation label being i
- m : number of mentions (sentences) for the given entity pair
- R: total number of relation labels (excluding the *nil* label)

Deterministic OR

The following is the ILP formulation for the exact inference $\arg\max Pr(\mathbf{y}, \mathbf{z}|\mathbf{x_i})$ in the model based on the *deterministic-or*:

$$\max_{Z,Y} \left\{ \sum_{j=1}^{m} \sum_{i \in \{R,nil\}} \left[z_{ji} s_{ji} \right] \right\}$$

$$\textbf{s.t} \quad 1. \quad \sum_{i \in \{R,nil\}} z_{ji} = 1 \quad \forall j$$

$$2. \quad z_{ji} \leq y_i \quad \forall j, \forall i$$

$$3. \quad y_i \leq \sum_{j=1}^{m} z_{ji} \quad \forall i$$

$$\text{where} \quad z_{ji} \in \{0,1\}, \quad y_i \in \{0,1\}$$

The first constraint restricts a mention to have only one label. The second and third constraints impose the *at least one* assumption. This is the same formulation as Hoffmann but expressed as an ILP problem. However, posing the inference as an ILP allows us to easily add more constraints to it.

Noisy OR

As a case-study, we add the *noisy-or* soft-constraint in the above objective function. The idea is to model the situation where a fact is present in the database but it is not instantiated in the text. This is a common scenario, as the facts populated in the database and the text of the corpus can come from different domains and there might not be a very good match.

$$\max_{Z,Y,\epsilon} \left\{ \left(\sum_{j=1}^{m} \sum_{i \in \{R,nil\}} \left[z_{ji} s_{ji} \right] \right) - \left(\sum_{i \in R} \epsilon_i \right) \right\}$$

$$\textbf{s.t} \quad 1. \quad \sum_{i \in \{R,nil\}} z_{ji} = 1 \quad \forall j$$

$$2. \quad z_{ji} \leq y_i \quad \forall j, \forall i$$

$$3. \quad y_i \leq \sum_{j=1}^{m} z_{ji} + \epsilon_i \quad \forall i$$

$$\text{where} \quad z_{ji} \in \{0,1\}, \quad y_i \in \{0,1\}, \quad \epsilon_i \in \{0,1\}$$

In the above formulation, the objective function is augmented with a soft penalty. Also the third constraint is modified with this penalty term. We call this new term ϵ_i and it is a binary variable to model noise. Through this term we encourage *at least one* type of configuration but will not disallow a configuration that does not conform to this. Essentially, the consequence of this is to allow the case where a fact is present in the database but is not instantiated in the text.

3 Related Work

Relation Extraction in the paradigm of distant supervision was introduced by Craven and Kumlien (1999). They used a biological database as the source of distant supervision to discover relations between biological entities. The progression of models for information extraction using distant supervision was presented in Section 1.

Surdeanu et al. (2012) discuss a noisy-or method for combining the scores of various sentence level models to rank a relation during evaluation. In our approach, we introduce the noisy-or mechanism in the training phase of the algorithm.

Our work is inspired from previous works like Roth and tau Yih (2004). The use of ILP for this problem facilitates easy incorporation of different constraints and to the best of our knowledge, has not been investigated by the community.

4 Experiments

The experimental runs were carried out using the publicly available Stanford's distantly supervised slot-filling system[3] (Surdeanu et al., 2011) and Hoffmann et al. (2011) code-base[4].

[3] http://nlp.stanford.edu/software/mimlre.shtml

[4] http://www.cs.washington.edu/ai/raphaelh/mr/

Datasets and Evaluation

We report results on two standard datasets used as benchmarks by the community namely KBP and Riedel datasets. A complete description of these datasets is provided in Surdeanu et al. (2012).

The evaluation setup and module is the same as that described in Surdeanu et al. (2012). We also use the same set of features used by the various systems in the package to ensure that the approaches are comparable. As in previous work, we report precision/recall (P/R) graphs to evaluate the various techniques.

We used the publicly available *lp_solve* package[5] to solve our inference problems.

Performance of ILP

Use of ILP raises concerns about performance as it is NP-hard. In our problem we solve a separate ILP for every entity pair. The number of variables is limited by the number of mentions for the given entity pair. Empirically, on the KBP dataset (larger of the two datasets), Hoffmann takes around 1hr to run. Our ILP formulation takes around 8.5hrs. However, MIMLRE algorithm (EM-based) takes around 23hrs to converge.

Results

We would primarily like to highlight two settings on which we report the P/R curves and contrast it with Hoffmann et al. (2011). Firstly, we replace the approximate inference in that work with our ILP-based exact inference; we call this setting the *hoffmann-ilp*. Secondly, we replace the deterministic-or in the model with a noisy-or, and call this setting the *noisy-or*. We further compare our approach with Surdeanu et al. (2012). The P/R curves for the various techniques on the two datasets are shown in Figures 1 and 2.

We further report the highest F1 point in the P/R curve for both the datasets in Tables 1 and 2.

Table 1 : Highest F1 point in P/R curve : KBP Dataset

	Precision	Recall	F1
Hoffmann	0.306451619	0.197916672	0.2405063349
MIMLRE	0.28061223	0.286458343	0.2835051518
Noisy-OR	0.297002733	0.189236104	0.2311770916
Hoffmann-ilp	0.293010741	0.189236104	0.2299577976

Discussion

We would like to discuss the results in the above two scenarios.

[5] `http://lpsolve.sourceforge.net/5.5/`

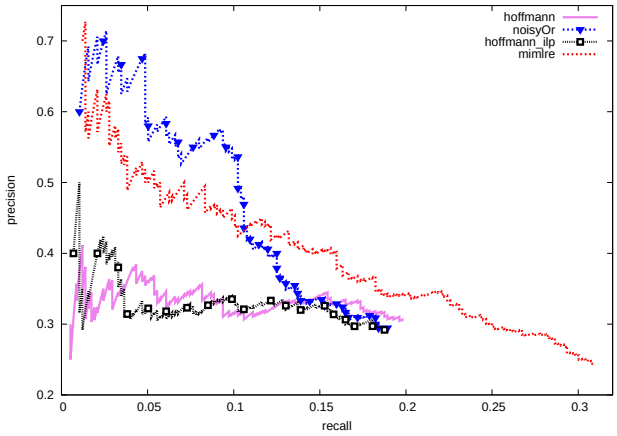

Figure 1: Results : KBP dataset

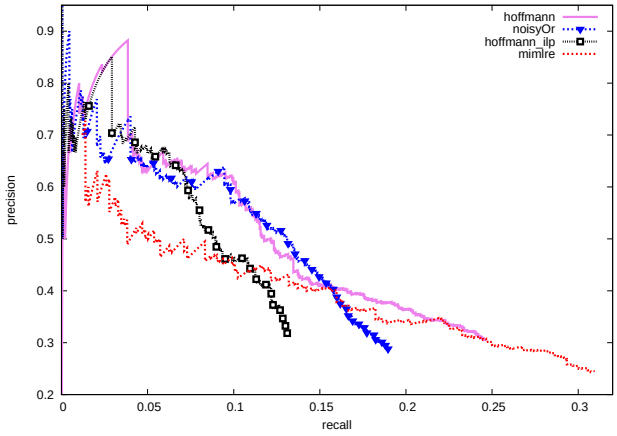

Figure 2: Results : Riedel dataset

1. Performance of *hoffmann-ilp*

   On the KBP dataset, we observe that *hoffmann-ilp* has higher precision in the range of 0.05 to 0.1 at lower recall (0 to 0.04). In other parts of the curve it is very close to the baseline (although hoffmann's algorithm is slightly better). In Table 1, we notice that recall of *hoffmann-ilp* is lower in comparison with hoffmann's algorithm.

   On the Riedel dataset, we observe that *hoffmann-ilp* has better precision (0.15 to 0.2) than MIMLRE within recall of 0.1. At recall > 0.1, precision drops drastically. This is because, *hoffmann-ilp* predicts significantly more nil labels. However, nil labels are not part of the label-set in the P/R curves reported in the community. In Table 2, we see that *hoffmann-ilp* has higher precision (0.04) compared to Hoffmann's algorithm.

2. Performance of *noisy-or*

Table 2 : Highest F1 point in P/R curve : Riedel Dataset			
	Precision	**Recall**	**F1**
Hoffmann	0.32054795	0.24049332	0.27480916
MIMLRE	0.28061223	0.28645834	0.28350515
Noisy-OR	0.317	0.18139774	0.23075178
Hoffmann-ilp	0.36701337	0.12692702	0.18862161

In Figure 1 we see that there is a big jump in precision (around 0.4) of *noisy-or* compared to Hoffmann's model in most parts of the curve on the KBP dataset. However, in Figure 2 (Riedel dataset), we do not see such a trend. Although, we do perform better than MIMLRE (Surdeanu et al., 2012) (precision > 0.15 for recall < 0.15).

On both datasets, *noisy-or* has higher precision than MIMLRE, as seen from Tables 1 and 2. However, the recall reduces. More investigation in this direction is part of future work.

5 Conclusion

In this paper we described an important addition to Hoffmann's model by the use of the *noisy-or* soft constraint to further relax the *at least one* assumption. Since we posed the inference procedures in Hoffmann using ILP, we could easily add this constraint during the training and inference.

Empirically, we showed that the resulting P/R curves have a significant performance boost over Hoffmann's algorithm as a result of this newly added constraint. Although our system has a lower recall when compared to MIMLRE (Surdeanu et al., 2012), it performs competitively w.r.t the precision at low recall.

As part of immediate future work, we would like to improve the system recall. Our ILP formulation provides a good framework to add new type of constraints to the problem. In the future, we would like to experiment with other constraints like modeling the selectional preferences of entity types.

Search-Aware Tuning for Machine Translation

Lemao Liu

liang.huang.sh@gmail.com

Abstract

Parameter tuning is an important problem in statistical machine translation, but surprisingly, most existing methods such as MERT, MIRA and PRO are *agnostic* about search, while search errors could severely degrade translation quality. We propose a search-aware framework to promote *promising* partial translations, preventing them from being pruned. To do so we develop two metrics to evaluate partial derivations. Our technique can be applied to all of the three above-mentioned tuning methods, and extensive experiments on Chinese-to-English and English-to-Chinese translation show up to +2.6 BLEU gains over search-agnostic baselines.

1 Introduction

Parameter tuning has been a key problem for machine translation since the statistical revolution. However, most existing tuning algorithms treat the decoder as a black box (Och, 2003; Hopkins and May, 2011; Chiang, 2012), ignoring the fact that many potentially promising partial translations are pruned by the decoder due to the prohibitively large search space. For example, the popular beam-search decoding algorithm for phrase-based MT (Koehn, 2004) only explores $O(nb)$ items for a sentence of n words (with a beam width of b), while the full search space is $O(2^n n^2)$ or worse (Knight, 1999).

As one of the very few exceptions to the "search-agnostic" majority, Yu et al. (2013) and Zhao et al. (2014) propose a variant of the perceptron algorithm that learns to keep the reference translations in the beam or chart. However, there are several obstacles that prevent their method from becoming popular: First of all, they rely on "forced decoding" to track gold derivations that lead to the reference translation, but in practice only a small portion of (mostly very short) sentence pairs have at least one such derivation. Secondly, they learn the model on the training set, and while this does enable a sparse feature set, it is orders of magnitude slower compared to MERT and PRO.

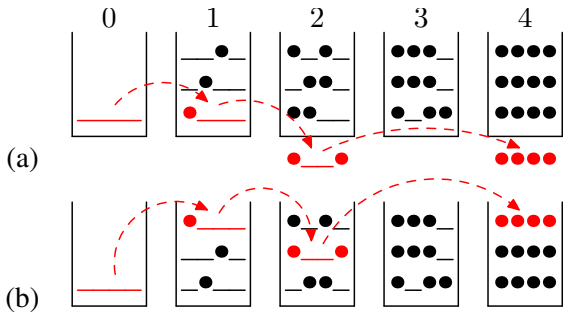

Figure 1: (a) Some potentially promising partial translations (in red) fall out of the beam (bin 2); (b) We identify such partial translations and assign them higher model scores so that they are more likely to survive the search.

We instead propose a very simple framework, **search-aware tuning**, which does not depend on forced decoding, and thus can be trained on all sentence pairs of any dataset. The key idea is that, besides caring about the rankings of the complete translations, we also promote potentially promising partial translations so that they are more likely to survive throughout the search, see **Figure 1** for illustration. We make the following contributions:

- Our idea of search-aware tuning can be applied (as a patch) to all of the three most popular tuning methods (MERT, PRO, and MIRA) by defining a modified objective function (Section 4).
- To measure the "promise" or "potential" of a partial translation, we define a new concept "**potential BLEU**" inspired by future cost in MT decoding (Koehn, 2004) and heuristics in A* search (Hart et al., 1968) (Section 3.2). This work is the first study of evaluating metrics for partial translations.
- Our method obtains substantial and consistent

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1942–1952,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

improvements on both the large-scale NIST Chinese-to-English and English-to-Chinese translation tasks on top of MERT, MIRA, and PRO baselines. This is the first time that consistent improvements can be achieved with a new learning algorithm under dense feature settings (Section 5).

For simplicity reasons, in this paper we use phrase-based translation, but our work has the potential to be applied to other translation paradigms.

2 Review: Beam Search for PBMT Decoding

We review beam search for phrase-based decoding in our notations which will facilitate the discussion of search-aware tuning in Section 4. Following Yu et al. (2013), let $\langle x, y \rangle$ be a Chinese-English sentence pair in the tuning set D, and

$$d = r_1 \circ r_2 \circ \ldots \circ r_{|d|}$$

be a (partial) derivation, where each $r_i = \langle c(r_i), e(r_i) \rangle$ is a rule, i.e., a phrase-pair. Let $|c(r)|$ be the number of Chinese words in rule r, and $e(d) \stackrel{\Delta}{=} e(r_1) \circ e(r_2) \ldots \circ e(r_{|d|})$ be the English prefix (i.e., partial translation) generated so far.

In beam search, each bin $B_i(x)$ contains the best k derivations covering exactly i Chinese words, based on items in previous bins (see Figures 1 and 2):

$$B_0(x) = \{\epsilon\}$$
$$B_i(x) = \mathbf{top}^k_{\mathbf{w}_0}\big(\bigcup_{j=1..i} \{d \circ r \mid d \in B_{i-j}(x), |c(r)| = j\}\big)$$

where r is a rule covering j Chinese words, and $\mathbf{top}^k_{\mathbf{w}_0}(\cdot)$ returns the top k derivations according to the current model $\mathbf{w}_0$. As a special case, note that $\mathbf{top}^1_{\mathbf{w}_0}(S) = \mathbf{argmax}_{d \in S}\, \mathbf{w}_0 \cdot \mathbf{\Phi}(d)$, so $\mathbf{top}^1_{\mathbf{w}_0}(B_{|x|}(x))$ is the final 1-best result.[1] See Figure 2 for an illustration.

3 Challenge: Evaluating Partial Derivations

As mentioned in Section 1, the current mainstream tuning methods such as MERT, MIRA, and PRO are all **search-agnostic**: they only care about the *complete* translations from the last bin, $B_{|x|}(x)$, ignoring all *partial* ones, i.e., $B_i(x)$ for all $i < |x|$. As a result, many potentially promising partial derivations never reach the final bin (See Figure 1).

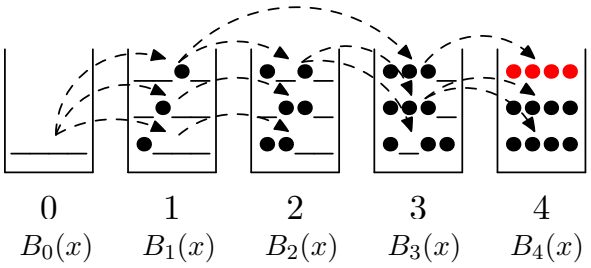

Figure 2: Beam search for phrase-based decoding. The item in red is $\mathbf{top}^1_{\mathbf{w}_0}(B_4(x))$, i.e., the 1-best result. Traditional tuning only uses the final bin $B_4(x)$ while search-aware tuning considers all bins $B_i(x)$ ($i = 1..4$).

To address this problem, our new "search-aware tuning" aims to promote not only the accurate translations in the final bin, but more importantly those potentially promising *partial derivations* in non-final bins. The key challenge, however, is how to evaluate the "promise" or "potential" of a partial derivation. In this Section, we develop two such measures, a simple "partial BLEU" (Section 3.1) and a more principled "potential BLEU" (Section 3.2). In Section 4, we will then adapt traditional tuning methods to their search-aware versions using these partial evaluation metrics.

3.1 Solution 1: Simple and Naive Partial BLEU

Inspired by a trick in (Li and Khudanpur, 2009) and (Chiang, 2012) for oracle or hope extraction, we use a very simple metric to evaluate partial translations for tuning. For a given derivation d, the basic idea is to evaluate the (short) partial translation $e(d)$ against the (full) reference y, but using a "prorated" reference length proportional to $c(d)$ which is the number of Chinese words covered so far in d:

$$|y| \cdot |c(d)|/|x|$$

For example, if d has covered 2 words on a 8-word Chinese sentence with a 12-word English reference, then the "effective reference length" is $12 \times 2/8 = 3$. We call this method "partial BLEU" since it does not complete the translation, and denote it by

$$\bar{\delta}^{|x|}_y(d) = -\delta\big(y, e(d); \text{reflen} = |y| \cdot |c(d)|/|x|\big). \quad (1)$$

[1] Actually $B_{|x|}(x)$ is an approximation to the k-best list since some derivations are merged by dynamic programming; to recover those we can use Alg. 3 of Huang and Chiang (2005).

$$\delta(y, y') = -\text{Bleu}^{+1}(y, y') \quad \text{string distance metric}$$
$$\delta_y(d) = \delta(y, e(d)) \quad \text{full derivations eval}$$
$$\delta_y^x(d) = \begin{cases} \bar{\delta}_y^{|x|}(d) & \text{partial bleu (Sec. 3.1)} \\ \delta(y, \bar{e}_x(d)) & \text{potential bleu (Sec. 3.2)} \end{cases}$$

Table 1: Notations for evaluating full and partial derivations. Functions $\bar{\delta}_y^{|x|}(\cdot)$ and $\bar{e}_x(\cdot)$ are defined by Equations 1 and 3, respectively.

where reflen is the effective length of reference translations, see (Papineni et al., 2002) for details.

3.1.1 Problem with Partial BLEU

Simple as it is, this method does not work well in practice because comparison of partial derivations might be unfair for different derivations covering different set of Chinese words, as it will naturally favor those covering "easier" portions of the input sentence (which we do observe empirically). For instance, consider the following Chinese-to-English example which involves a reordering of the Chinese PP:

(2) *wǒ cóng Shànghǎi fēi dào Běijīng*
I from Shanghai fly to Beijing
"I flew from Shanghai to Beijing"

Partial BLEU will prefer subtranslation "I from" to "I fly" in bin 2 (covering 2 Chinese words) because the former has 2 unigram mathces while the latter only 1, even though the latter is almost identical to the reference and will eventually lead to a complete translation with substantially higher Bleu^{+1} score (matching a 4-gram "from Shanghai to Beijing"). Similarly, it will prefer "I from Shanghai" to "I fly from" in bin 3, without knowing that the former will eventually pay the price of word-order difference. This example suggests that we need a more "global" or less greedy metric (see below).

3.2 Solution 2: Potential BLEU via Extension

Inspired by future cost computation in MT decoding (Koehn, 2004), we define a very simple future string by simply concatenating the best model-score translation (with no reorderings) in each uncovered span. Let $\text{best}_{\mathbf{w}}(x_{[i:j]})$ denote the best monotonic derivation for span $[i:j]$, then

$$future(d, x) = \circ_{[i:j] \in uncov(d,x)} \; e(\text{best}_{\mathbf{w}}(x_{[i:j]}))$$

where $\circ$ is the concatenation operator and $uncov(d, x)$ returns an ordered list of uncovered spans of x. See Figure 3 for an example. This future string resembles (inadmissible) heuristic function (Hart et al., 1968). Now the "extended translation" is simply a concatenation of the existing partial translation $e(d)$ and the future string $future(d, x)$:

$$\bar{e}_x(d) = e(d) \circ future(d, x). \quad (3)$$

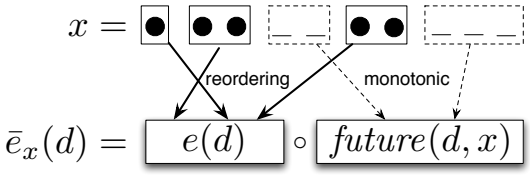

Figure 3: Example of the extension function $\bar{e}_x(\cdot)$ (and future string) on an incomplete derivation d.

Instead of calculating $\text{best}_{\mathbf{w}}(x_{[i:j]})$ on-the-fly for each derivation d, we can precompute it for each span $[i : j]$ during future-cost computation, since the score of $\text{best}_{\mathbf{w}}(x_{[i:j]})$ is context-free (Koehn, 2004). Algorithm 1 shows the pseudo-code of computing $\text{best}_{\mathbf{w}}(x_{[i:j]})$. In practice, since future-cost precomputation already solves the best (monotonic) model-score for each span, is the only extra work for potential BLEU is to record (for each span) the subtranslation that achieves that best score. Therefore, the extra time for potential BLEU is negligible (the time complexity is $O(n^2)$, but just as in future cost, the constant is much smaller than real decoding). The implementation should require minimal hacking on a phrase-based decoder (such as Moses).

To summarize the notation, we use $\delta_y^x(d)$ to denote a generic evaluation function for partial derivation d, which could be instantiated in two ways, partial bleu ($\bar{\delta}_y^{|x|}(d)$) or potential bleu ($\delta(y, \bar{e}_x(d))$). See Table 1 for details. The next Section will only use the generic notation $\delta_y^x(d)$.

Finally, it is important to note that although both partial and potential metrics are not BLEU-specific, the latter is much easier to adapt to other metrics such as TER since it does not change the original Bleu^{+1} definition. By contrast, it is not clear to us at all how to generalize partial BLEU to partial TER.

4 Search-Aware MERT, MIRA, and PRO

Parameter tuning aims to optimize the weight vector $\mathbf{w}$ so that the rankings based on model score defined by $\mathbf{w}$ is positively correlated with those based

Algorithm 1 Computation of best Translations for Potential BLEU.

Input: Source sentence x, a rule set $\mathfrak{R}$ for x, and $\mathbf{w}$.
Output: Best translations $e(\text{best}_{\mathbf{w}}(x[i:j]))$ for all spans $[i:j]$.

for l **in** $(0..|x|)$ **do**
  for i **in** $(0..|x|-l)$ **do**
    $j = i + l + 1$
    best_score $= -\infty$
    if $\mathfrak{R}[i:j] \neq \emptyset$ **then** ▷ $\mathfrak{R}[i:j]$ is a subset of rules $\mathfrak{R}$ for span $[i:j]$.
      $\text{best}_{\mathbf{w}}(x[i:j]) = \mathbf{argmax}_{r \in \mathfrak{R}[i:j]}\, \mathbf{w} \cdot \mathbf{\Phi}(\{r\})$ ▷ $\{r\}$ is a derivation consisting of one rule r.
      best_score $= \mathbf{w} \cdot \mathbf{\Phi}(\text{best}_{\mathbf{w}}(x[i:j]))$
    for k **in** $(i+1\ ..\ i+p)$ **do** ▷ p is the phrase length limit
      if best_score $< \mathbf{w} \cdot \mathbf{\Phi}\Big(\text{best}_{\mathbf{w}}(x[i:k]) \circ \text{best}_{\mathbf{w}}(x[k:j])\Big)$ **then**
        $\text{best}_{\mathbf{w}}(x[i:j]) = \text{best}_{\mathbf{w}}(x[i:k]) \circ \text{best}_{\mathbf{w}}(x[k:j])$
        best_score $= \mathbf{w} \cdot \mathbf{\Phi}(\text{best}_{\mathbf{w}}(x[i:j]))$

on some translation metric (such as BLEU (Papineni et al., 2002)). In other words, for a training sentence pair $\langle x, y \rangle$, if a pair of its translations $y_1 = e(d_1)$ and $y_2 = e(d_2)$ satisfies $\text{BLEU}(y, y_1) > \text{BLEU}(y, y_2)$, then we expect $\mathbf{w} \cdot \mathbf{\Phi}(d_1) > \mathbf{w} \cdot \mathbf{\Phi}(d_2)$ to hold after tuning.

4.1 From MERT to Search-Aware MERT

Suppose D is a tuning set of $\langle x, y \rangle$ pairs. Traditional MERT learns the weight by iteratively reranking the complete translations towards those with higher BLEU in the final bin $B_{|x|}(x)$ for each x in D. Formally, it tries to minimize the document-level error of 1-best translations:

$$\ell_{\text{MERT}}(D, \mathbf{w}) = \bigoplus_{\langle x,y \rangle \in D} \delta_y\Big(\mathbf{top}^1_{\mathbf{w}}(B_{|x|}(x))\Big), \tag{4}$$

where $\mathbf{top}^1_{\mathbf{w}}(S)$ is the best derivation in S under model $\mathbf{w}$, and $\delta.(\cdot)$ is the full derivation metric as defined in Table 1; in this paper we use $\delta_y(y') = -\text{BLEU}(y, y')$. Here we follow Och (2003) and Lopez (2008) to simplify the notations, where the $\oplus$ operator (similar to $\sum$) is an over-simplification for BLEU which, as a document-level metric, is actually not factorizable across sentences.

Besides reranking the complete translations as traditional MERT, our search-aware MERT (SA-MERT) also reranks the partial translations such that potential translations may survive in the middle bins during search. Formally, its objective function is defined as follows:

$$\ell_{\text{SA-MERT}}(D, \mathbf{w}) = \bigoplus_{\langle x,y \rangle \in D} \boxed{\bigoplus_{i=1..|x|}} \boxed{\delta^x_y}\Big(\mathbf{top}^1_{\mathbf{w}}(\boxed{B_i}(x))\Big) \tag{5}$$

where $\mathbf{top}^1_{\mathbf{w}}(\cdot)$ is defined in Eq. (4), and $\delta^x_y(d)$, defined in Table 1, is the generic metric for evaluating a partial derivation d which has two implementations (partial bleu or potential bleu). In order words we can obtain two implementations of search-aware MERT methods, SA-MERT^{par} and SA-MERT^{pot}.

Notice that the traditional MERT is a special case of SA-MERT where i is fixed to $|x|$.

4.2 From MIRA to Search-Aware MIRA

MIRA is another popular tuning method for SMT. It firstly introduced in (Watanabe et al., 2007), and then was improved in (Chiang et al., 2008; Chiang, 2012; Cherry and Foster, 2012). Its main idea is to optimize a weight such that the model score difference of a pair of derivations is greater than their loss difference.

In this paper, we follow the objective function in (Chiang, 2012; Cherry and Foster, 2012), where only the violation between hope and fear derivations is concerned. Formally, we define $d^+(x, y)$ and $d^-(x, y)$ as the hope and fear derivations in the final bin (i.e., complete derivations):

$$d^+(x, y) = \mathop{\mathbf{argmax}}_{d \in B_{|x|}(x)}\ \mathbf{w}_0 \cdot \mathbf{\Phi}(d) - \delta_y(d) \tag{10}$$

$$d^-(x, y) = \mathop{\mathbf{argmax}}_{d \in B_{|x|}(x)}\ \mathbf{w}_0 \cdot \mathbf{\Phi}(d) + \delta_y(d) \tag{11}$$

where $\mathbf{w}_0$ is the current model. The loss function of MIRA is in Figure 4. The update will be between $d^+(x, y)$ and $d^-(x, y)$.

To adapt MIRA to search-aware MIRA (SA-MIRA), we need to extend the definitions of hope

$$\ell_{\text{MIRA}}(D,\mathbf{w}) = \frac{1}{2C}\|\mathbf{w}-\mathbf{w}_0\|^2 + \sum_{\langle x,y\rangle\in D}\left[\Delta\delta_y\big(d^+(x,y),d^-(x,y)\big) - \mathbf{w}\cdot\Delta\boldsymbol{\Phi}\big(d^+(x,y),d^-(x,y)\big)\right]_+ \tag{6}$$

$$\ell_{\text{SA-MIRA}}(D,\mathbf{w}) = \frac{1}{2C}\|\mathbf{w}-\mathbf{w}_0\|^2 + \sum_{\langle x,y\rangle\in D}\sum_{i=1}^{|x|}\left[\Delta\delta_y^x\big(d_i^+(x,y),d_i^-(x,y)\big) - \mathbf{w}\cdot\Delta\boldsymbol{\Phi}\big(d_i^+(x,y),d_i^-(x,y)\big)\right]_+ \tag{7}$$

$$\ell_{\text{PRO}}(D,\mathbf{w}) = \sum_{\langle x,y\rangle\in D}\ \sum_{d_1,d_2\in B_{|x|}(x),\ \Delta\delta_y(d_1,d_2)>0} \log\Big(1+\exp(-\mathbf{w}\cdot\Delta\boldsymbol{\Phi}(d_1,d_2))\Big) \tag{8}$$

$$\ell_{\text{SA-PRO}}(D,\mathbf{w}) = \sum_{\langle x,y\rangle\in D}\sum_{i=1}^{|x|}\ \sum_{d_1,d_2\in B_i(x),\ \Delta\delta_y^x(d_1,d_2)>0} \log\Big(1+\exp(-\mathbf{w}\cdot\Delta\boldsymbol{\Phi}(d_1,d_2))\Big) \tag{9}$$

Figure 4: Loss functions of MIRA, SA-MIRA, PRO, and SA-PRO. The differences between traditional and search-aware versions are highlighted in gray. The hope and fear derivations are defined in Equations 10–13, and we define $\Delta\delta_y(d_1,d_2) = \delta_y(d_1) - \delta_y(d_2)$, and $\Delta\delta_y^x(d_1,d_2) = \delta_y^x(d_1) - \delta_y^x(d_2)$. In addition, $[\theta]_+ = \max\{\theta, 0\}$.

and fear derivations from the final bin to all bins:

$$d_i^+(x,y) = \operatorname*{\mathbf{argmax}}_{d\in B_i(x)}\ \mathbf{w}_0\cdot\boldsymbol{\Phi}(d) - \delta_y(d) \tag{12}$$

$$d_i^-(x,y) = \operatorname*{\mathbf{argmax}}_{d\in B_i(x)}\ \mathbf{w}_0\cdot\boldsymbol{\Phi}(d) + \delta_y(d) \tag{13}$$

The new loss function for SA-MIRA is Eq. 7 in Figure 4. Now instead of one update per sentence, we will perform $|x|$ updates, each based on a pair $d_i^+(x,y)$ and $d_i^-(x,y)$.

4.3 From PRO to Search-Aware PRO

Finally, the PRO algorithm (Hopkins and May, 2011; Green et al., 2013) aims to correlate the ranking under model score and the ranking under BLEU score, among all complete derivations in the final bin. For each preference-pair $d_1, d_2 \in B_{|x|}(x)$ such that d_1 has a higher BLEU score than d_2 (i.e., $\delta_y(d_1) < \delta_y(d_2)$), we add one positive example $\boldsymbol{\Phi}(d_1) - \boldsymbol{\Phi}(d_2)$ and one negative example $\boldsymbol{\Phi}(d_2) - \boldsymbol{\Phi}(d_1)$.

Now to adapt it to search-aware PRO (SA-**PRO**), we will have many more examples to consider: besides the final bin, we will include all preference-pairs in the non-final bins as well. For each bin $B_i(x)$, for each preference-pairs $d_1, d_2 \in B_i(x)$ such that d_1 has a higher partial or potential BLEU score than d_2 (i.e., $\delta_y^x(d_1) < \delta_y^x(d_2)$), we add one positive example $\boldsymbol{\Phi}(d_1) - \boldsymbol{\Phi}(d_2)$ and one negative example $\boldsymbol{\Phi}(d_2) - \boldsymbol{\Phi}(d_1)$. In sum, search-aware PRO has $|x|$ times more examples than traditional PRO. The loss functions of PRO and search-aware PRO are defined in Figure 4.

5 Experiments

We evaluate our new tuning methods on two large scale NIST translation tasks: Chinese-to-English (CH-EN) and English-to-Chinese (EN-CH) tasks.

5.1 System Preparation and Data

We base our experiments on Cubit[2] (Huang and Chiang, 2007), a state-of-art phrase-based system in Python. We set phrase-limit to 7, beam size to 30 and distortion limit 6. We use the 11 dense features from Moses (Koehn et al., 2007), which can lead to good performance and are widely used in almost all SMT systems. The baseline tuning methods MERT (Och, 2003), MIRA (Cherry and Foster, 2012), and PRO (Hopkins and May, 2011) are from the Moses toolkit, which are batch tuning methods based on k-best translations. The search-aware tuning methods are called SA-MERT, SA-MIRA, and SA-PRO, respectively. Their partial BLEU versions are marked with superscript [1] and their potential BLEU versions are marked with superscript [2], as explained in Section 3. All these search-aware tuning methods are implemented on the basis of Moses toolkit. They employ the de-

	Final bin	All bins
MERT	35.5	28.2
SA-MERT	-0.1	+3.1

Table 3: Evaluation on nist02 tuning set using two methods: BLEU is used to evaluate 1-best complete translations in the final bin; while potential BLEU is used to evaluate 1-best partial translations in all bins. The search-aware objective cares about (the potential of) all bins, not just the final bin, which can explain this result.

fault settings following Moses toolkit: for MERT and SA-MERT, the stop condition is defined by the weight difference threshold; for MIRA, SA-MIRA, PRO and SA-PRO, their stop condition is defined by max iteration set to 25; for all tuning methods, we use the final weight for testing.

The training data for both CH-EN and EN-CH tasks is the same, and it is collected from the NIST2008 Open Machine Translation Campaign. It consists of about $1.8M$ sentence pairs, including about $40M/48M$ words in Chinese/English sides. For CH-EN task, the tuning set is nist02 (878 sents), and test sets are nist03 (919 sents), nist04 (1788 sents), nist05 (1082 sents), nist06 (616 sents from news portion) and nist08 (691 from news portion). For EN-CH task, the tuning set is ssmt07 (995 sents)[3], and the test set is nist08 (1859 sents). For both tasks, all the tuning and test sets contain 4 references.

We use GIZA++ (Och and Ney, 2003) for word alignment, and SRILM (Stolcke, 2002) for 4-gram language models with the Kneser-Ney smoothing option. The LM for EN-CH is trained on its target side; and that for CH-EN is trained on the Xinhua portion of Gigaword. We use BLEU-4 (Papineni et al., 2002) with "average ref-len" to evaluate the translation performance for all experiments. In particular, the character-based BLEU-4 is employed for EN-CH task. Since all tuning methods involve randomness, all scores reported are average of three runs, as suggested by Clark et al. (2011) for fairer comparisons.

5.2 Main Results on CH-EN Task

Table 2 depicts the main results of our methods on CH-EN translation task. On all five test sets, our methods consistently achieve substantial improvements with two pruning options: SA-MERT^{pot} gains +1.2 BLEU points over MERT on average; and SA-MIRA^{pot} gains +1.8 BLEU points over MIRA on average as well. SA-PRO^{pot}, however, does not work out of the box when we use the entire nist02 as the tuning set, which might be attributed to the "Monster" behavior (Nakov et al., 2013). To alleviate this problem, we only use the 109 short sentences with less than 10 words from nist02 as our new tuning data. To our supurise, this trick works really well (despite using much less data), and also made SA-PRO^{pot} an order of magnitude faster. This further confirms that our search-aware tuning is consistent across all tuning methods and datasets.

As discussed in Section 3, evaluation metrics of partial derivations are crucial for search-aware tuning. Besides the principled "potential BLEU" version of search-aware tuning (i.e. SA-MERT^{pot}, SA-MIRA^{pot}, and SA-PRO^{pot}), we also run the simple "partial BLEU" version of search-aware tuning (i.e. SA-MERT^{par}, SA-MIRA^{par}, and SA-

[3] On EN-CH task, there is only one test set available for us, and thus we use ssmt07 as the tuning set, which is provided at the Third Symposium on Statistical Machine Translation (http://mitlab.hit.edu.cn/ssmt2007.html).

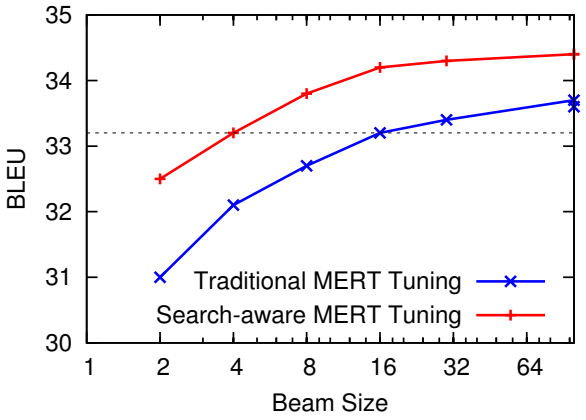

Figure 5: BLEU scores against beam size on nist05. Our search-aware tuning can achieve (almost) the same BLEU scores with much smaller beam size (beam of 4 vs. 16).

	methods	nist02	nist05
1-best	MERT	35.5	33.4
	SA-MERT	-0.1	+0.9
Oracle	MERT	44.3	41.1
	SA-MERT	+0.5	+1.6

Table 4: The k-best oracle BLEU comparison between MERT and SA-MERT.

PRO^{par}). In Table 2, we can see that they may achieve slight improvements over tradition tuning on some datasets, but SA-MERT^{pot}, SA-MIRA^{pot}, and SA-PRO^{pot} using potential BLEU consistently outperform them on all the datasets.

Even though our search-aware tuning gains substantially on all test sets, it does not gain significantly on nist02 tuning set. The main reason is that, search-aware tuning optimizes an objective (i.e. BLEU for all bins) which is different from the objective for evaluation (i.e. BLEU for the final bin), and thus it is not quite fair to evaluate the complete translations for search-aware tuning as the same done for traditional tuning on the tuning set. Actally, if we evaluate the potential BLEU for all partial translations, we find that search-aware tuning gains about 3.0 BLEU on nist02 tuning set, as shown in Table 3.

5.3 Analysis on CH-EN Task

Different beam size. Since our search-aware tuning considers the rankings of partial derivations in the middle bins besides complete ones in the last bin, ideally, if the weight learned by search-aware tuning can exactly evaluate partial derivations, then accurate partial derivations will rank higher according to model score. In this way, even with small beam size, these accurate partial derivations may still survive in the bins. Therefore, it is expected that search-aware tuning can achieve good performance with smaller beam size. To justify our conjecture, we run SA-MERT^{pot} with different beam size (2,4,8,16,30,100), its testing results on nist05 are depicted in Figure 5. our mehtods achieve better trade-off between performance and efficiey. Figure 5 shows that search-aware tuning is consistent with all beam sizes, and as a by-product, search-aware MERT with a beam of 4 can achieve almost identical BLEU scores to MERT with beam of 16.

Diversity	nist02	nist05
MERT	0.216	0.204
SA-MERT	0.227	0.213

Table 5: The diversity comparison based on the k-best list in the final bin on both tuning and nist05 test sets by tuning methods. The higher the metric is, the more diverse the k-best list is.

Oracle BLEU. In addition, we examine the BLEU ponits of oracle for MERT and SA-MERT. We use the weight tuned by MERT and SA-MERT for k-best decoding on nist05 test set, and calculate the oracle over these two k-best lists. The oracle BLEU comparison is shown in Table 4. On nist05 test set, for MERT the oracle BLEU is 41.1; while for SA-MERT its oracle BLEU is 42.7, i.e. with 1.6 BLEU improvements. Although search-aware tuning employs the objective different from the objective of evaluation on nist02 tuning set, it still gains 0.5 BLEU improvements.

Diversity. A k-best list with higher diversity can better represent the entire decoding space, and thus tuning on such a k-best list may lead to better tesing performance (Gimpel et al., 2013). Intuitively, tuning with all bins will encourage the diversity in prefix, infix and suffix of complete translations in the final bin. To testify this, we need a diversity metric.

Indeed, Gimpel et al. (2013) define a diversity metric based on the n-gram matches between two sentences y and y' as follows:

$$d(y, y') = -\sum_{i=1}^{|y|-q} \sum_{j=1}^{|y'|-q} [\![y_{i:i+q} = y'_{j:j+q}]\!]$$

MERT	nist02-r	1	92	1173	31.6	32.7	31.3	29.3	25.9
SA-MERT^{pot}	nist02-r	1	92	1173	33.5	35.0	33.4	31.5	28.0

Table 6: Comparisons with MAXFORCE in terms of BLEU. nist02-px is the non-trivial reachable prefix-data from nist02 via forced decoding; nist02-r is a subset of nist02-px consisting of the fully reachable data; train-r is a subset of fully reachable data from training data that is comparable in size to nist02. All experiments use only dense features.

where $q = n - 1$, and $[\![x]\!]$ equals to 1 if x is true, 0 otherwise. This metric, however, has the following critical problems:

- it is not length-normalized: longer strings will look as if they are more different.
- it suffers from duplicates in n-grams. After normalization, $d(y, y)$ will exceed -1 for any y. In the extreme case, consider y_1 = "the the the the" and y_2 = "the ... the" with 10 the's then will be considered identical after normalization by length.

So we define a balanced metric based on their metric

$$d'(y, y') = 1 - \frac{2 \times d(y, y')}{d(y, y) + d(y', y')}$$

which satisfies the following nice properties:

- $d'(y, y) = 0$ for all y;
- $0 \leq d'(y, y') \leq 1$ for all y, y';
- $d'(y, y') = 1$ if y and y' is completely disjoint.
- it does not suffer from duplicates, and can differentiate y_1 and y_2 defined above.

With this new metric, we evaluate the diversity of k-best lists for both MERT and SA-MERT. As shown in Table 5, on both tuning and test sets the k-best list generated by SA-MERT is more diverse.

5.4 Comparison with Max-Violation Perceptron

Our method considers the rankings of partial derivations, which is simlar to MAXFORCE method (Yu et al., 2013), and thus we re-implement MAXFORCE method. Since the nist02 tuning set contains 4 references and forced decoding is performed for only one reference, we enlarge the nist02 set to a variant set following the transformation in Figure 6, and obtain a variant tuning set denoted as **nist02-px**, which consists of 4-times sentence-pairs. On nist02-px, the non-trivial reachable prefix-data only accounts for 12% sentences and 7% words. Both these sentence-level and the word-level percentages are much lower than those on the training data as shown in Table 3 from (Yu et al., 2013). This is because there are many OOV words on a tuning set. We run the MAXFORCE with dense feature setting on nist02-px and its testing results are shown in Table 6. We can see that on all the test sets, its testing performance is lower than that of SA-MERT^{pot} tuning on nist02 with about 5 BLEU points.

Figure 6: Transformation of a tuning set in forced decoding for MAXFORCE: the original tuning set (on the top) contains 2 source sentences with 2 references for each; while the transformed set (on the bottom) contains 4 source sentences with one reference for each.

For more direct comparisons, we run MERT and SA-MERT^{pot} on a data set similar to nist02-px. We pick up the fully reachable sentences from nist02-px, remove the sentence pairs with the same source side, and get a new tuning set denoted as **nist02-r**. When tuning on nist02-r, we find that MERT is bet-

Methods	tuning-set	nist08
MERT	ssmt07	31.3
MAXFORCE	train-r-part	29.9
SA-MERT^{par}	ssmt07	31.3
SA-MERT^{pot}	ssmt07	**31.7**

Table 7: EN-CH task: BLEU scores on nist08 test set for MERT, SA-MERT, and MAXFORCE on different tuning sets. train-r-part is a part of fully reachable data from training data via forced decoding. All the tuning methods run with dense feature set.

Optimization time	MERT	MIRA	PRO
basline	3	2	2
search-aware	50	7	6

Table 8: Search-aware tuning slows down MERT significantly, and MIRA and PRO moderately. The time (in minutes) is for optimization only (excluding decoding) and measured at the last iteration during the entire tuning (search aware tuning does not increase the number of iterations in our experiments). The decoding time is 20 min. on a single CPU but can be parallelized.

ter than MAXFORCE,[4] and SA-MERT^{pot} are much better than MERT on all the test sets. In addition, we select about $1.2k$ fully reachable sentence pairs from training data, and run the forced decoding on this new tuning data (denoted as **train-r-part**), which is with similar size to nist02. [5] With more tuning data, the performance of max-violation is improved largely, but it is still underperformed by SA-MERT^{pot}.

5.5 Results on EN-CH Translation Task

We also run our search-aware tuning method on EN-CH task. We use SA-MERT as the representative of search-aware tuning methods, and compare its two versions with other tuning methods MERT, MAXFORCE. For MAXFORCE, we first run forced decoding on the training data and then select about $1.2k$ fully reachable sentence pairs as its tuning set (denoted as **train-r-part**). For MERT, SA-MERT^{pot}, and SA-MERT^{par}, their tuning set is ssmt07. Table 7 shows that SA-MERT^{pot} is much better than MAXFORCE, i.e. it achieves 0.4 BLEU improvements over MERT. Finally, comparison between SA-MERT^{pot} and SA-MERT^{par} shows that the potential BLEU is better for evaluation of partial derivations.

5.6 Discussions on Tuning Efficiency

As shown in Figure 2, search-aware tuning considers all partial translations in the middle bins beside all complete translations in the last bin, and thus its total number of training examples is much greater than that of the traditional tuning. In details, suppose the tuning data consists of two sentences with length 10 and 30, respectively. Then, for traditional tuning its number of training examples is 2; but for search-aware tuning, the total number is 40. More training examples makes our search-aware tuning slower than the traditional tuning.

Table 8 shows the training time comparisons between search-aware tuning and the traditional tuning. From this Table, one can see that both SA-MIRA and SA-PRO are with the same order of magtitude as MIRA and PRO; but SA-MERT is much slower than MERT. The main reason is that, as the training examples increase dramatically, the envelope calculation for exact line search (see (Och, 2003)) in MERT is less efficient than the update based on (sub-)gradient with inexact line search in MIRA and PRO.

One possible solution to speed up SA-MERT is the parallelization but we leave it for future work.

6 Related Work

Many tuning methods have been proposed for SMT so far. These methods differ by the objective function or training mode: their objective functions are based on either evaluation-directed loss (Och, 2003; Galley and Quirk, 2011; Galley et al., 2013) or surrogate loss (Hopkins and May, 2011; Gimpel and Smith, 2012; Eidelman et al., 2013); they are either batch (Och, 2003; Hopkins and May, 2011; Cherry and Foster, 2012) or online mode (Watanabe, 2012; Simianer et al., 2012; Flanigan et al., 2013; Green et al., 2013). These methods share a common characteristic: they learn a weight by iteratively reranking a set of *complete* translations represented by k-best (Och, 2003; Watanabe et al., 2007; Chiang et al., 2008) or lattice (hypergraph) (Tromble et al., 2008; Kumar et al., 2009), and they do not care about search errors that potential *partial* translations may be pruned during decoding, even if they agree with

[4] Under the dense feature setting, MAXFORCE is worse than standard MERT. This result is consistent with that in Figure 12 of (Yu et al., 2013).

[5] We run MAXFORCE on train-r-part, i.e. a part of reachable data instead of the entire reachable data, as we found that more tuning data does not necessarily lead to better testing performance under dense feature setting in our internal experiments.

that their decoders are built on the beam pruning based search.

On the other hand, it is well-known that search errors can undermine the standard training for many beam search based NLP systems (Huang et al., 2012). As a result, Collins and Roark (2004) and Huang et al. (2012) propose the early-update and max-violation update to deal with the search errors. Their idea is to update on prefix or partial hypotheses when the correct solution falls out of the beam. This idea has been successfully used in many NLP tasks and improves the performance over the state-of-art NLP systems (Huang and Sagae, 2010; Huang et al., 2012; Zhang et al., 2013).

Goldberg and Nivre (2012) propose the concept of "dynamic oracle" which is the absolute best potential of a partial derivation, and is more akin to a strictly admissible heuristic. This idea inspired and is closely related to our potential BLEU, except that in our case, computing an admissible heuristic is too costly, so our potential BLEU is more like an average potential.

Gesmundo and Henderson (2014) also consider the rankings between *partial* translation pairs as well. However, they evaluate a partial translation through extending it to a complete translation by *re-decoding*, and thus they need many passes of decoding for many partial translations, while ours only need one pass of decoding for all partial translations and thus is much more efficient. In summary, our tuning framework is more general and has potential to be employed over all the state-of-art tuning methods mentioned above, even though ours is only tested on three popular methods.

7 Conclusions and Future Work

We have presented a simple yet powerful approach of "search-aware tuning" by promoting promising partial derivations, and this idea can be applied to all three popular tuning methods. To solve the key challenge of evaluating partial derivations, we develop a concept of "potential BLEU" inspired by future cost in MT decoding. Extensive experiments confirmed substantial BLEU gains with only dense features. We believe our framework can be applied to sparse feature settings and other translation paradigms, and potentially to other structured prediction problems (such as incremental parsing) as well.

Abstract

Data-driven refinement of non-terminal categories has been demonstrated to be a reliable technique for improving monolingual parsing with PCFGs. In this paper, we extend these techniques to learn latent refinements of single-category synchronous grammars, so as to improve translation performance. We compare two estimators for this latent-variable model: one based on EM and the other is a spectral algorithm based on the method of moments. We evaluate their performance on a Chinese–English translation task. The results indicate that we can achieve significant gains over the baseline with both approaches, but in particular the moments-based estimator is both faster and performs better than EM.

1 Introduction

Translation models based on synchronous context-free grammars (SCFGs) treat the translation problem as a context-free parsing problem. A parser constructs trees over the input sentence by parsing with the source language projection of a synchronous CFG, and each derivation induces translations in the target language (Chiang, 2007). However, in contrast to syntactic parsing, where linguistic intuitions can help elucidate the "right" tree structure for a grammatical sentence, no such intuitions are available for synchronous derivations, and so learning the "right" grammars is a central challenge.

Of course, learning synchronous grammars from parallel data is a widely studied problem (Wu, 1997; Blunsom et al., 2008; Levenberg et al., 2012, *inter alia*). However, there has been less exploration of learning rich non-terminal categories, largely because previous efforts to learn such categories have been coupled with efforts to learn derivation structures—a computationally formidable challenge. One popular approach has been to derive categories from source and/or target monolingual grammars (Galley et al., 2004; Zollmann and Venugopal, 2006; Hanneman and Lavie, 2013). While often successful, accurate parsers are not available in many languages: a more appealing approach is therefore to learn the category structure from the data itself.

In this work, we take a different approach to previous work in synchronous grammar induction by assuming that reasonable tree structures for a parallel corpus can be chosen heuristically, and then, fixing the trees (thereby enabling us to sidestep the worst of the computational issues), we learn non-terminal categories as latent variables to explain the distribution of these synchronous trees. This technique has a long history in monolingual parsing (Petrov et al., 2006; Liang et al., 2007; Cohen et al., 2014), where it reliably yields state-of-the-art phrase structure parsers based on generative models, but we are the first to apply it to translation.

We first generalize the concept of latent PCFGs to latent-variable SCFGs (§2). We then follow by a presentation of the tensor-based formulation for our parameters, a representation that makes it convenient to marginalize over latent states. Subsequently, two methods for parameter estimation are presented (§4): a spectral approach based on the method of moments, and an EM-based likelihood maximization. Results on a Chinese–English evaluation set (§5) indicate significant gains over baselines and point to the promise of using latent-variable synchronous grammars in conjunction with a smaller, simpler set of rules instead of unwieldy and bloated grammars extracted via existing heuristics, where a large number of context-independent but un-generalizable rules are utilized. Hence, the hope is that this work pro-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1953–1964,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

motes the move towards translation models that directly model the conditional likelihood of translation rules via (potentially feature-rich) latent-variable models which leverage information contained in the synchronous tree structure, instead of relying on a heuristic set of features based on empirical relative frequencies (Koehn et al., 2003) from non-hierarchical phrase-based translation.

2 Latent-Variable SCFGs

Before discussing parameter learning, we introduce latent-variable synchronous context-free grammars (L-SCFGs) and discuss an inference algorithm for marginalizing over latent states.

We extend the definition of L-PCFGs (Matsuzaki et al., 2005; Petrov et al., 2006) to synchronous grammars as used in machine translation (Chiang, 2007). A latent-variable SCFG (L-SCFG) is a 6-tuple $(\mathcal{N}, m, n_s, n_t, \pi, t)$ where:

- $\mathcal{N}$ is a set of non-terminal (NT) symbols in the grammar. For hierarchical phrase-based translation (HPBT), the set consists of only two symbols, **X** and a goal symbol **S**.
- $[m]$ is the set of possible hidden states associated with NTs. Aligned pairs of NTs across the source and target languages share the same hidden state.
- $[n_s]$ is the set of source side words, i.e., the source-side vocabulary, with $[n_s] \cap \mathcal{N} = \emptyset$.
- $[n_t]$ is the set of target side words, i.e., the target-side vocabulary, with $[n_t] \cap \mathcal{N} = \emptyset$.
- The synchronous production rules compose a set $\mathcal{R} = \mathcal{R}_0 \cup \mathcal{R}_1 \cup \mathcal{R}_2$:
  - Arity 2 (binary) rules ($\mathcal{R}_2$):

    $$a(h_1) \rightarrow \langle \alpha_1 b(h_2) \alpha_2 c(h_3) \alpha_3, \beta_1 b(h_2) \beta_2 c(h_3) \beta_3 \rangle$$

    or

    $$a(h_1) \rightarrow \langle \alpha_1 b(h_2) \alpha_2 c(h_3) \alpha_3, \beta_1 c(h_2) \beta_2 b(h_3) \beta_3 \rangle$$

    where $a, b, c \in \mathcal{N}$, $h_1, h_2, h_3 \in [m]$, $\alpha_1, \alpha_2, \alpha_3 \in [n_s]^*$ and $\beta_1, \beta_2, \beta_3 \in [n_t]^*$.
  - Arity 1 (unary) rules ($\mathcal{R}_1$):

    $$a(h_1) \rightarrow \langle \alpha_1 b(h_2) \alpha_2, \beta_1 b(h_2) \beta_2 \rangle$$

    where $a, b \in \mathcal{N}$, $h_1, h_2 \in [m]$, $\alpha_1, \alpha_2 \in [n_s]^*$ and $\beta, \beta_2 \in [n_t]^*$.
  - Pre-terminal rules ($\mathcal{R}_0$): $a(h_1) \rightarrow \langle \alpha, \beta \rangle$ where $a \in \mathcal{N}$, $\alpha \in [n_t]^*$ and $\beta \in [n_s]^*$.

  Each of these rules is associated with a probability $t(a(h_1) \rightarrow \gamma | a, h_1)$ where γ is the right-hand side (RHS) of the rule.
- For $a \in \mathcal{N}$, $h \in [m]$, $\pi(a, h)$ is a parameter specifying the root probability of $a(h)$.

A skeletal tree (s-tree) for a sentence is the set of rules in the synchronous derivation of that sentence, without any additional latent state information or decoration. A full tree consists of an s-tree $r_1, \ldots, r_N$ together with values $h_1, \ldots, h_N$ for every NT in the tree. An important point to keep in mind in comparison to L-PCFGs is that the right-hand side (RHS) non-terminals of synchronous rules are aligned pairs across the source and target languages.

In this work, we refine the one-category grammar introduced by Chiang (2007) for HPBT in order to learn additional latent NT categories. Thus, the following discussion is restricted to these kinds of grammars, although the method is equally applicable in other scenarios, e.g., the extended tree-to-string transducer (**xRs**) formalism (Huang et al., 2006; Graehl et al., 2008) commonly used in syntax-directed translation, and phrase-based MT (Koehn et al., 2003).

Marginal Inference with L-SCFGs. For a parameter t of rule r, the latent state h_1 attached to the left-hand side (LHS) NT of r is associated with the outside tree for the sub-tree rooted at the LHS, and the states attached to the RHS NTs are associated with the inside trees of that NT. Since we do not assume conditional independence of these states, we need to consider all possible interactions, which can be compactly represented as a 3rd-order tensor in the case of a binary rule, a matrix (i.e., a 2nd-order tensor) for unary rules, and a vector for pre-terminal (lexical) rules. Preferences for certain outside-inside tree combinations are reflected in the values contained in these tensor structures. In this manner, we intend to capture interactions between non-local context of a phrase, which can typically be represented via features defined over outside trees of the node spanning the phrase, and the interior context, correspondingly defined via features over the inside trees. We refer to these tensor structures collectively as C^r for rules $r \in \mathcal{R}$, which encompass the parameters t.

For $r \in \mathcal{R}_0 : C^r \in \mathbb{R}^{m \times 1}$; similarly for $r \in \mathcal{R}_1 : C^r \in \mathbb{R}^{m \times m}$ and $r \in \mathcal{R}_2 : C^r \in \mathbb{R}^{m \times m \times m}$. We also maintain a vector $C^{\mathbf{S}} \in \mathbb{R}^{1 \times m}$ corresponding to the parameters $\pi(\mathbf{S}, h)$ for the

Inputs: Sentence $f_1 \dots f_N$, L-SCFG $(\mathcal{N}, S, m, n)$, parameters $C^r \in \mathbb{R}^{(m \times m \times m)}$, $\in \mathbb{R}^{(m \times m)}$, or $\in \mathbb{R}^{(m \times 1)}$ for all $r \in \mathcal{R}$, $C^{\mathbf{S}} \in \mathbb{R}^{(1 \times m)}$, hypergraph $\mathcal{H}$.
Data structures:
For each node $q \in \mathcal{H}$:

- $\boldsymbol{\alpha}(q) \in \mathbb{R}^{m \times 1}$ is a column vector of inside terms.
- $\boldsymbol{\beta}(q) \in \mathbb{R}^{1 \times m}$ is a row vector of outside terms.
- For each incoming edge $e \in \mathbf{B}(q)$ to node q, $\mu(e)$ is a marginal probability for edge (rule) e.

Algorithm:
▷ *Inside Computation*
For nodes q in topological order in $\mathcal{H}$,
  $\boldsymbol{\alpha}(q) = \mathbf{0}$
  For each incoming edge $e \in \mathbf{B}(q)$,
    tail = **t**(e), rule = **r**(e)
    if |tail| $= 0$, then $\boldsymbol{\alpha}(q) = \boldsymbol{\alpha}(q) + C^{\text{rule}}$
    else if |tail| $= 1$, then $\boldsymbol{\alpha}(q) = \boldsymbol{\alpha}(q) + C^{\text{rule}} \times_1 \boldsymbol{\alpha}(\text{tail}_0)$
    else if |tail| $= 2$, then $\boldsymbol{\alpha}(q) = \boldsymbol{\alpha}(q) + C^{\text{rule}} \times_2 \boldsymbol{\alpha}(\text{tail}_1) \times_1 \boldsymbol{\alpha}(\text{tail}_0)$
▷ *Outside Computation*
For $q \in \mathcal{H}$,
  $\boldsymbol{\beta}(q) = \mathbf{0}$
$\boldsymbol{\beta}(\text{goal}) = C^{\mathbf{S}}$
For q in reverse topological order in $\mathcal{H}$,
  For each incoming edge $e \in \mathbf{B}(q)$,
    tail = **t**(e), rule = **r**(e)
    if |tail| $= 1$, then
      $\boldsymbol{\beta}(\text{tail}_0) = \boldsymbol{\beta}(\text{tail}_0) + \boldsymbol{\beta}(q) \times_0 C^{\text{rule}}$
    else if |tail| $= 2$, then
      $\boldsymbol{\beta}(\text{tail}_0) = \boldsymbol{\beta}(\text{tail}_0) + \boldsymbol{\beta}(q) \times_0 C^{\text{rule}} \times_2 \boldsymbol{\alpha}(\text{tail}_1)$
      $\boldsymbol{\beta}(\text{tail}_1) = \boldsymbol{\beta}(\text{tail}_1) + \boldsymbol{\beta}(q) \times_0 C^{\text{rule}} \times_1 \boldsymbol{\alpha}(\text{tail}_0)$
▷*Edge Marginals*
Sentence probability $g = \boldsymbol{\alpha}(\text{goal}) \times \boldsymbol{\beta}(\text{goal})$
For edge $e \in \mathcal{H}$,
  head = **h**(e), tail = **t**(e), rule = **r**(e)
  if |tail| $= 0$, then $\mu(e) = (\boldsymbol{\beta}(\text{head}) \times_0 C^{\text{rule}})/g$
  else if |tail| $= 1$, then $\mu(e) = (\boldsymbol{\beta}(\text{head}) \times_0 C^{\text{rule}} \times_1 \boldsymbol{\alpha}(\text{tail}_0))/g$
  else if |tail| $= 2$, then $\mu(e) = (\boldsymbol{\beta}(\text{head}) \times_0 C^{\text{rule}} \times_2 \boldsymbol{\alpha}(\text{tail}_1) \times_1 \boldsymbol{\alpha}(\text{tail}_0))/g$

Figure 1: The tensor form of the hypergraph inside-outside algorithm, for calculation of rule marginals $\mu(e)$. A slight simplification in the marginal computation yields NT marginals for spans $\mu(\mathbf{X}, i, j)$. **B**(q) returns the incoming hyperedges for node q, and **h**(e), **t**(e), **r**(e) return the head node, tail nodes, and rule for hyperedge e.

goal node (root). These parameters participate in tensor-vector operations: a 3rd-order tensor C^{r_2} can be multiplied along each of its three modes ($\times_0, \times_1, \times_2$), and if multiplied by an $m \times 1$ vector, will produce an $m \times m$ matrix.[1] Note that matrix multiplication can be represented by $\times_1$ when multiplying on the right and $\times_0$ when multiplying on the left of the matrix. The decoder computes marginal probabilities for each skeletal rule in the parse forest of a source sentence by marginalizing over the latent states, which in practice corresponds to simple tensor-vector products. This operation is not dependent on the manner in which the parameters were estimated.

Figure 1 presents the tensor version of the inside-outside algorithm for decoding L-SCFGs. The algorithm takes as input the parse forest of the source sentence represented as a hypergraph (Klein and Manning, 2001), which is computed using a bottom-up parser with Earley-style rules similar to the algorithm in Chiang (2007). Hypergraphs are a compact way to represent a forest of multiple parse trees. Each node in the hypergraph corresponds to an NT span, and can have multiple incoming and outgoing hyperedges. Hyperedges, which connect one or more tail nodes to a single head node, correspond exactly to rules, and tail or head nodes correspond to children (RHS NTs) or parent (LHS NT). The function **B**(q) returns all incoming hyperedges to a node q, i.e., all rules such that the LHS NT of the rule corresponds to the NT span of the node q. The algorithm computes inside and outside probabilities over the hypergraph using the tensor representations, and converts these probabilities to marginal rule probabilities. It is similar to the version presented in Cohen et al. (2014), but adapted to hypergraph parse forests.

The complexity of this decoding algorithm is $\mathcal{O}(n^3 m^3 |G|)$ where n is the length of the input sentence, m is the number of latent states, and $|G|$ is the number of production rules in the grammar *without* latent-variable annotations (i.e., $m = 1$).[2] The bulk of the computation is a series of tensor-vector products of relatively small size (each dimension is of length m), which can be computed very quickly and in parallel. The tensor computations can be significantly sped up using techniques described by Cohen and Collins (2012), so that they are linear in m and not cubic.

3 Derivation Trees for Parallel Sentences

To estimate the parameters t and π of an L-SCFG (discussed in detail in the next section), we assume the existence of a dataset composed of synchronous s-trees, which can be acquired from word alignments. Normally in phrase-based translation models, we consider all possible phrase

[1] This operation is sometimes called a contraction.

[2] In practice, the term $m^3|G|$ can be replaced with a smaller term, which separates the rules in G by the number of NTs on the RHS. This idea relates to the notion of "effective grammar size" which we discuss in §5.

pairs consistent with the word alignments and estimate features based on surface statistics associated with the phrase pairs or rules. The weights of these features are then learned using a discriminative training algorithm (Och, 2003; Chiang, 2012, *inter alia*). In contrast, in this work we restrict the number of possible synchronous derivations for each sentence pair to just one; thus, derivation forests do not have to be considered, making parameter estimation more tractable.[3]

To achieve this objective, for each sentence in the training data we extract the **minimal** set of synchronous rules consistent with the word alignments, as opposed to the **composed** set of rules (Galley et al., 2006). Composed rules are ones that can be formed from smaller rules in the grammar; with these rules, there are multiple synchronous trees consistent with the alignments for a given sentence pair, and thus the total number of applicable rules can be combinatorially larger than if we just consider the set of rules that cannot be formed from other rules, namely the minimal rules. The rule types across all sentence pairs are combined to form a minimal grammar.[4] To extract a set of minimal rules, we use the linear-time extraction algorithm of Zhang et al. (2008). We give a rough description of their method below, and refer the reader to the original paper for additional details.

The algorithm returns a complete minimal derivation tree for each word-aligned sentence pair, and generalizes an approach for finding all common intervals (pairs of phrases such that no word pair in the alignment links a word inside the phrase to a word outside the phrase) between two permutations (Uno and Yagiura, 2000) to sequences with many-to-many alignment links between the two sides, as in word alignment. The key idea is to encode all phrase pairs of a sentence alignment in a tree of size proportional to the source sentence length, which they call the normalized decomposition tree. Each node corresponds to a phrase pair, with larger phrase spans represented by higher nodes in the tree. Constructing the tree is analogous to finding common intervals in two permutations, a property that they leverage to propose a linear-time algorithm for tree extraction. Converting the tree to a set of minimal SCFG rules for the sentence pair is straightforward, by replacing nodes corresponding to spans with lexical items or NTs in a bottom-up manner.[5]

By using minimal rules as a starting point instead of the traditional heuristically-extracted rules (Chiang, 2007) or arbitrary compositions of minimal rules (Galley et al., 2006), we are also able to explore the transition from minimal rules to composed ones in a principled manner by encoding contextual information through the latent states. Thus, a beneficial side effect of our refinement process is the creation of more context-specific rules without increasing the overall size of the baseline grammar, instead holding this information in our parameters C^r.

4 Parameter Estimation for L-SCFGs

We explore two methods for estimating the parameters C^r of the model: a likelihood-maximization approach based on EM (Dempster et al., 1977), and a spectral approach based on the method of moments (Hsu et al., 2009; Cohen et al., 2014), where we identify a subspace using a singular value decomposition (SVD) of the cross-product feature space between inside and outside trees and estimate parameters in this subspace.

Figure 2 presents a side-by-side comparison of the two algorithms, which we discuss in this section. In the spectral approach, we base our parameter estimates on low-rank representations of moments of features, while EM explicitly maximizes a likelihood criterion. The parameter estimation algorithms are relatively similar, but in lieu of sparse feature functions in the spectral case, EM uses partial counts estimated with the current set of parameters. The nature of EM allows it to be susceptible to local optima, while the spectral approach comes with guarantees on obtaining the global optimum (Cohen et al., 2014). Lastly, computing the SVD and estimating parameters in the low-rank space is a one-shot operation, as opposed to the iterative procedure of EM, and therefore is much more computationally efficient.

4.1 Estimation with Spectral Method

We generalize the parameter estimation algorithm presented in Cohen et al. (2013) to the syn-

[3] For future work, we will consider efficient algorithms for parameter estimation over derivation forests, since there may be multiple valid ways to explain the sentence pair via a synchronous tree structure.

[4] Table 2 presents a comparison of grammar sizes for our experiments (§5.1).

[5] We filtered rules with arity 3 and above (i.e., containing more than 3 NTs on the RHS). While the L-SCFG formalism is perfectly capable of handling such cases, it would have resulted in higher order tensors for our parameter structures.

Inputs:
Training examples $(r^{(i)}, t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}, b^{(i)})$ for $i \in \{1 \dots M\}$, where $r^{(i)}$ is a context free rule; $t^{(i,1)}$, $t^{(i,2)}$, and $t^{(i,3)}$ are inside trees; $o^{(i)}$ is an outside tree; and $b^{(i)} = 1$ if the rule is at the root of tree, 0 otherwise. A function ϕ that maps inside trees t to feature-vectors $\phi(t) \in \mathbb{R}^d$. A function ψ that maps outside trees o to feature-vectors $\psi(o) \in \mathbb{R}^{d'}$.

Algorithm:

▷ *Step 0: Singular Value Decomposition*

- Compute the SVD of Eq. 1 to calculate matrices $\hat{U} \in \mathbb{R}^{(d \times m)}$ and $\hat{V} \in \mathbb{R}^{(d' \times m)}$.

▷ *Step 1: Projection*

$$Y(t) = U^\top \phi(t)$$
$$Z(o) = \Sigma^{-1} V^\top \psi(o)$$

▷ *Step 2: Calculate Correlations*

$$\hat{E}^r = \begin{cases} \frac{\sum_{o \in Q^r} Z(o)}{|Q^r|} & \text{if } r \in \mathcal{R}_0 \\ \frac{\sum_{(o,t) \in Q^r} Z(o) \otimes Y(t)}{|Q^r|} & \text{if } r \in \mathcal{R}_1 \\ \frac{\sum_{(o,t^2,t^3) \in Q^r} Z(o) \otimes Y(t^2) \otimes Y(t^3)}{|Q^r|} & \text{if } r \in \mathcal{R}_2 \end{cases}$$

Q^r is the set of outside-inside tree triples for binary rules, outside-inside tree pairs for unary rules, and outside trees for pre-terminals.

▷ *Step 3: Compute Final Parameters*

- For all $r \in \mathcal{R}$,
$$\hat{C}^r = \frac{\text{count}(r)}{M} \times \hat{E}^r$$
- For all $r^{(i)} \in \{1, \dots, M\}$ such that $b^{(i)}$ is 1,
$$\hat{C}^{\mathbf{S}} = \hat{C}^{\mathbf{S}} + \frac{Y(t^{(i,1)})}{|Q^{\mathbf{S}}|}$$

$Q^{\mathbf{S}}$ is the set of trees at the root.

(a) The spectral learning algorithm for estimating parameters of an L-SCFG.

Inputs:
Training examples $(r^{(i)}, t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}, b^{(i)})$ for $i \in \{1 \dots M\}$, where $r^{(i)}$ is a context free rule; $t^{(i,1)}$, $t^{(i,2)}$, and $t^{(i,3)}$ are inside trees; $o^{(i)}$ is an outside tree; $b^{(i)} = 1$ if the rule is at the root of tree, 0 otherwise; and MAX_ITERATIONS.

Algorithm:

▷ *Step 0: Parameter Initialization*

For rule $r \in \mathcal{R}$,

- if $r \in \mathcal{R}_0$: initialize $\hat{C}^r \in \mathbb{R}^{m \times 1}$
- if $r \in \mathcal{R}_1$: initialize $\hat{C}^r \mathbb{R}^{m \times m}$
- if $r \in \mathcal{R}_2$: initialize $\hat{C}^r \mathbb{R}^{m \times m \times m}$

Initialize $\hat{C}^{\mathbf{S}} \in \mathbb{R}^{m \times 1}$
$\hat{C}^r_0 = \hat{C}^r, \hat{C}^{\mathbf{S}}_0 = \hat{C}^{\mathbf{S}}$
For iteration $t = 1, \dots,$ MAX_ITERATIONS,

- Expectation Step:

  ▷ *Estimate Y and Z*

  Compute partial counts and total tree probabilities g for all t and o using Fig. 1 and parameters $\hat{C}^r_{t-1}, \hat{C}^{\mathbf{S}}_{t-1}$.

  ▷ *Calculate Correlations*

$$\hat{E}^r = \begin{cases} \sum_{o,g \in Q^r} \frac{Z(o)}{g} & \text{if } r \in \mathcal{R}_0 \\ \sum_{(o,t,g) \in Q^r} \frac{Z(o) \otimes Y(t)}{g} & \text{if } r \in \mathcal{R}_1 \\ \sum_{(o,t^2,t^3,g) \in Q^r} \frac{Z(o) \otimes Y(t^2) \otimes Y(t^3)}{g} & \text{if } r \in \mathcal{R}_2 \end{cases}$$

  ▷ *Update Parameters*

  For all $r \in \mathcal{R}$, $\hat{C}^r_t = \hat{C}^r_{t-1} \odot \hat{E}^r$

  For all $r^{(i)} \in \{1, \dots, M\}$ such that $b^{(i)}$ is 1, $\hat{C}^{\mathbf{S}}_t = \hat{C}^{\mathbf{S}}_t + (\hat{C}^{\mathbf{S}}_{t-1} \odot Y(r^{(i)}))/g$

  $Q^{\mathbf{S}}$ is the set of trees at the root.

- Maximization Step

  if $r \in \mathcal{R}_0$: $\forall h_1 : \hat{C}^r(h_1) = \frac{\hat{C}^r(h_1)}{\sum_{r'=r} \sum_{h_1} \hat{C}^{r'}(h_1)}$

  if $r \in \mathcal{R}_1$: $\forall h_1, h_2 : \hat{C}^r(h_1, h_2) = \frac{\hat{C}^r(h_1, h_2)}{\sum_{r'=r} \sum_{h_2} \hat{C}^{r'}(h_1, h_2)}$

  if $r \in \mathcal{R}_2$: $\forall h_1, h_2, h_3 : \hat{C}^r(h_1, h_2, h_3) = \frac{\hat{C}^r(h_1, h_2, h_3)}{\sum_{r'=r} \sum_{h_2, h_3} \hat{C}^{r'}(h_1, h_2, h_3)}$

  if LHS$(r) = \mathbf{S}$: $\forall h_1 : \hat{C}^r(h_1) = \frac{\hat{C}^r(h_1)}{\sum_{r'=r} \sum_{h_1} \hat{C}^{r'}(h_1)}$

(b) The EM-based algorithm for estimating parameters of an L-SCFG.

Figure 2: The two parameter estimation algorithms proposed for L-SCFGs; (**a**) method of moments; (**b**) expectation maximization. $\odot$ is the element-wise multiplication operator.

chronous or bilingual case. The central concept of the spectral parameter estimation algorithm is to learn an m-dimensional representation of inside and outside trees by defining these trees in terms of features, in combination with a projection step (SVD), with the hope being that the lower-dimensional space captures the syntactic and semantic regularities among rules from the sparse feature space. Every NT in an s-tree has an associated inside and outside tree; the inside tree contains the entire sub-tree at and below the NT, and the outside tree is everything else in the synchronous s-tree except the inside tree. The inside feature function ϕ maps the domain of inside tree

fragments to a d-dimensional Euclidean space, and the outside feature function ψ maps the domain of outside tree fragments to a d'-dimensional space. The specific features we used are discussed in §5.2.

Let $\mathcal{O}$ be the set of all tuples of inside-outside trees in our training corpus, whose size is equivalent to the number of rule tokens (occurrences in the corpus) M, and let $\phi(t) \in \mathbb{R}^{d\times 1}$, $\psi(o) \in \mathbb{R}^{d'\times 1}$ be the inside and outside feature functions for inside tree t and outside tree o. By computing the outer product $\otimes$ between the inside and outside feature vectors for each pair and aggregating, we obtain the empirical inside-outside feature covariance matrix:

$$\hat{\Omega} = \frac{1}{|\mathcal{O}|} \sum_{(o,t)\in\mathcal{O}} \phi(t) \left(\psi(o)\right)^{\top} \qquad (1)$$

If m is the desired latent space dimension, we compute an m-rank truncated SVD of the empirical covariance matrix $\hat{\Omega} \approx U\Sigma V^{\top}$, where $U \in \mathbb{R}^{d\times m}$ and $V \in \mathbb{R}^{d'\times m}$ are the matrices containing the left and right singular vectors, and $\Sigma \in \mathbb{R}^{m\times m}$ is a diagonal matrix containing the m-largest singular values along its diagonal.

Figure 2a provides the remaining steps in the algorithm. The M training examples are obtained by considering all nodes in all of the synchronous s-trees given as input. In step 1, for each inside and outside tree, we project its high-dimensional representation to the m-dimensional latent space. Using the m-dimensional representations for inside and outside trees, in step 2 for each rule type r we compute the covariance between the inside tree vectors and the outside tree vector using the *tensor product*, a generalized outer product to compute covariances between more than two random vectors. For binary rules, with two child inside vectors and one outside vector, the result $\hat{E}^r$ is a 3-mode tensor; for unary rules, a regular matrix, and for pre-terminal rules with no right-hand side non-terminals, a vector. The final parameter estimate is then the associated tensor/matrix/vector, scaled by the maximum likelihood estimate of the rule r, as in step 3.

The corresponding theoretical guarantees from Cohen et al. (2014) can also be generalized to the synchronous case. $\hat{\Omega}$ is an empirical estimate of the true covariance matrix Ω, and if Ω has rank m, then the marginals computed using the spectrally-estimated parameters will converge to the true marginals, with the sample complexity for convergence inversely proportional to a polynomial function of the m^{th} largest singular value of Ω.

4.2 Estimation with EM

A likelihood maximization approach can also be used to learn the parameters of an L-SCFG. Parameters are initialized by sampling each parameter value $\hat{C}^r(h_1, h_2, h_3)$ from the interval $[0, 1]$ uniformly at random.[6] We first decode the training corpus using an existing set of parameters to compute the inside and outside probability vectors associated with NTs for every rule in each s-tree, constrained to the tree structure of the training example. These probabilities can be computed using the decoding algorithm in Figure 1 (where $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ correspond to the inside and outside probabilities respectively), except the parse forest consists of a single tree only. These vectors represent partial counts over latent states. We then define functions Y and Z (analogous to the spectral case) which map inside and outside tree instances to m-dimensional vectors containing these partial counts. In the spectral case, Y and Z are estimated just once, while in the case of EM they have to be re-estimated at each iteration.

The expectation step thus consists of computing the partial counts of inside and outside trees t and o, i.e., recovering the functions Y and Z, and updating parameters C^r by computing correlations, which involves summing over partial counts (across all occurrences of a rule in the corpus). Each partial count's contribution is divided by a normalization factor g, which is the total probability of the tree which t or o is part of. Note that unlike the spectral case, there is a specific normalization factor for each inside-outside tuple. Lastly, the correlations are scaled by the existing parameter estimates.

To obtain the next set of parameters, in the maximization step we normalize $\hat{C}^r$ for $r \in \mathcal{R}$ such that for every h_1, $\sum_{r'=r,h_2,h_3} \hat{C}^{r'}(h_1, h_2, h_3) = 1$ for $r \in \mathcal{R}_2$, $\sum_{r'=r,h_2} \hat{C}^{r'}(h_1, h_2) = 1$ for $r \in \mathcal{R}_1$, and $\sum_{r'=r,h_2} \hat{C}^{r'}(h_2) = 1$ for $r \in \mathcal{R}_0$. We also normalize the root rule parameters $\hat{C}^r$ where $\text{LHS}(r) = \mathbf{S}$. It is also possible to add sparse, overlapping features to an EM-based estimation

[6] In our experiments, we also tried the initialization scheme described in Matsuzaki et al. (2005), but found that it provided little benefit.

procedure (Berg-Kirkpatrick et al., 2010) and we leave this extension for future work.

5 Experiments

The goal of the experimental section is to evaluate the performance of the latent-variable SCFG in comparison to a baseline without any additional NT annotations (MIN-GRAMMAR), and to compare the performance of the two parameter estimation algorithms. We also compare L-SCFGs to a HIERO baseline (Chiang, 2007). The language pair of evaluation is Chinese–English (ZH-EN).

We score translations using BLEU (Papineni et al., 2002). The latent-variable model is integrated into the standard MT pipeline by computing marginal probabilities for each rule in the parse forest of a source sentence using the algorithm in Figure 1 with the parameters estimated through the algorithms in Figure 2, and is added as a feature for the rule during MERT (Och, 2003). These probabilities are conditioned on the LHS (**X**), and are thus joint probabilities for a source-target RHS pair. We also write out as features the conditional relative frequencies $\hat{P}(e|f)$ and $\hat{P}(f|e)$ as estimated by our latent-variable model, i.e., conditioned on the source and target RHS.

Overall, we find that both the spectral and the EM-based estimators improve upon a minimal grammar baseline with only a single category, but the spectral approach does better. In fact, it matches the performance of the standard HIERO baseline, despite learning on top of a minimal grammar.

5.1 Data and Baselines

The ZH-EN data is the BTEC parallel corpus (Paul, 2009); we combine the first and second development sets in one, and evaluate on the third development set. The development and test sets are evaluated with 16 references. Statistics for the data are shown in Table 1. We used the CDEC decoder (Dyer et al., 2010) to extract word alignments and the baseline hierarchical grammars, MERT tuning, and decoding. We used a 4-gram language model built from the target-side of the parallel training data. The Python-based implementation of the tensor-based decoder, as well as the parameter estimation algorithms is available at `github.com/asaluja/spectral-scfg/`.

The baseline HIERO system uses a grammar extracted by applying the commonly used heuristics (Chiang, 2007). Each rule is decorated with two lexical and phrasal features corresponding to the forward $(e|f)$ and backward $(f|e)$ conditional log frequencies, along with the log joint frequency (e, f), the log frequency of the source phrase (f), and whether the phrase pair or the source phrase is a singleton. Weights for the language model (and language model OOV), glue rule, and word penalty are also tuned. The MIN-GRAMMAR baseline[7] maintains the same set of weights.

	ZH-EN
TRAIN (SRC)	334K
TRAIN (TGT)	366K
DEV (SRC)	7K
DEV (TGT)	7.6K
TEST (SRC)	3.8K
TEST (TGT)	3.9K

Table 1: Corpus statistics (in words). For the target DEV and TEST statistics, we take the first reference.

Grammar	Number of Rules
HIERO	1.69M
MIN-GRAMMAR	59K
LV $m = 1$	27.56K
LV $m = 8$	3.18M
LV $m = 16$	22.22M

Table 2: Grammar sizes for the different systems; for the latent-variable models, effective grammar sizes are provided.

Grammar sizes are presented in Table 2. For the latent-variable models, we provide the effective grammar size, where the number of NTs on the RHS of a rule is taken into account when computing the grammar size, by assuming each possible latent variable configuration amongst the NTs generates a different rule. Furthermore, all singletons are mapped to the OOV rule, while we include singletons in MIN-GRAMMAR.[8] Hence, effective grammar size can be computed as $m(1 + |\mathcal{R}_0^{>1}|) + m^2|\mathcal{R}_1| + m^3|\mathcal{R}_2|$, where $\mathcal{R}_0^{>1}$ is the set of pre-terminal rules that occur more than once.

5.2 Spectral Features

We use the following set of sparse, binary features in the spectral learning process:

[7] Code to extract the minimal derivation trees is available at `www.cs.rochester.edu/u/gildea/mt/`.

[8] This OOV mapping is done so that the latent-variable model can handle unknown tokens.

- **Rule Indicator.** For the inside features, we consider the rule production containing the current non-terminal on the left-hand side, as well as the rules of the children (distinguishing between left and right children for binary rules). For the outside features, we consider the parent rule production along with the rule production of the sibling (if it exists).
- **Lexical.** for both the inside and outside features, any lexical items that appear in the rule productions are recorded. Furthermore, we consider the first and last words of spans (left and right child spans for inside features, distinguishing between the two if both exist, and sibling span for outside features). Source and target words are treated separately.
- **Length.** the span length of the tree and each of its children for inside features, and the span length of the parent and sibling for outside features.

In our experiments, we instantiated a total of 170,000 rule indicator features, 155,000 lexical features, and 80 length features.

5.3 Chinese–English Experiments

Table 3 presents a comprehensive evaluation of the ZH-EN experimental setup. The first section consists of the various baselines we consider. In addition to the aforementioned baselines, we evaluated a setup where the spectral parameters simply consist of the joint maximum likelihood estimates of the rules. This baseline should perform *en par* with MIN-GRAMMAR, which we see is the case on the development set. The performance on the test set is better though, primarily because we also include the reverse log relative frequency $(f|e)$ computed from the latent-variable model as an additional feature in MERT. Furthermore, in line with previous work (Galley et al., 2006) which compares minimal and composed rules, we find that minimal grammars take a hit of more than 2.5 BLEU points on the development set, compared to composed (HIERO) grammars. The $m = 1$ spectral baseline with only rule indicator features performs slightly better than the minimal grammar baseline, since it overtly takes into account inside-outside tree combination preferences in the parameters, but improvement is minimal with one latent state naturally and the performance on the test set is in line with the MLE baseline.

On top of the baselines, we looked at a number of feature combinations and latent states for the spectral and EM-estimated latent-variable models. For the spectral models, we tuned MERT parameters separately for each rank on a set of parameters estimated from rule indicator features only; subsequent variations within a given rank, e.g., the addition of lexical or length features or smoothing, were evaluated with the same set of rank-specific weights from MERT. For EM, we ran parameter estimation with 5 randomly initialized starting points for 50 iterations; we tuned the MERT parameters with EM parameters obtained after 25$^{\text{th}}$ iterations. Similar to the spectral experiments, we fixed the MERT weight values and evaluated BLEU performance with parameters after every 5 iterations and chose the iteration with the highest score on the development set. The results are averaged over the 5 initializations, with standard deviation in parentheses.

Firstly, we can see a clear dependence on rank, with peak performance for the spectral and EM models occurring at $m = 16$. In this instance, the spectral model roughly matches the performance of the HIERO baseline, but it only uses rules extracted from a minimal grammar, whose size is a fraction of the HIERO grammar. The gains seem to level off at this rank; additional ranks seem to add noise to the parameters. Feature-wise, additional lexical and length features add little, prob-

		BLEU	
	Setup	Dev	Test
Baselines	HIERO	46.08	55.31
	MIN-GRAMMAR	43.38	51.78
	MLE	43.24	52.80
Spectral	$m = 1$ RI	44.18	52.62
	$m = 8$ RI	44.60	53.63
	$m = 16$ RI	46.06	55.83
	m=16 RI+Lex+Sm	46.08	55.22
	m=16 RI+Lex+Len	45.70	55.29
	m=24 RI+Lex	43.00	51.28
	m=32 RI+Lex	43.06	52.16
EM	$m = 8$	40.53 (0.2)	49.78 (0.5)
	$m = 16$	42.85 (0.2)	52.93 (0.9)
	$m = 32$	41.07 (0.4)	49.95 (0.7)

Table 3: Results for the ZH-EN corpus, comparing across the baselines and the two parameter estimation techniques. RI, Lex, and Len correspond to the rule indicator, lexical, and length features respectively, and Sm denotes smoothing. For the EM experiments, we selected the best scoring iteration by tuning weights for parameters obtained after 25 iterations and evaluating other parameters with these weights. Results for EM are averaged over 5 starting points, with standard deviation given in parentheses. Spectral, EM, and MLE performances compared to the MIN-GRAMMAR baseline are statistically significant ($p < 0.01$).

ably because much of this information is encapsulated in the rule indicator features. For EM, $m = 16$ outperforms the minimal grammar baseline, but is not at the level of the spectral results. All EM, spectral, and MLE results are statistically significant ($p < 0.01$) with respect to the MIN-GRAMMAR baseline (Zhang et al., 2004), and the improvement over the HIERO baseline achieved by the $m = 16$ rule indicator configuration is also statistically significant.

The two estimation algorithms differ significantly in their estimation time. Given a feature covariance matrix, the spectral algorithm (SVD, which was done with Matlab, and correlation computation steps) for $m = 16$ took 7 minutes, while the EM algorithm took 5 minutes for *each* iteration with this rank.

5.4 Analysis

Figure 3 presents a comparison of the non-terminal span marginals for two sentences in the development set. We visualize these differences through a heat map of the CKY parse chart, where the starting word of the span is on the rows, and the span end index is on the columns. Each cell is shaded to represent the marginal of that particular non-terminal span, with higher likelihoods in blue and lower likelihoods in red.

For the most part, marginals at the leaves (i.e., pre-terminal marginals) tend to score relatively similarly across different setups. Higher up in the chart, the latent SCFG marginals look quite different than the MLE parameters. Most noticeably, spans starting at the beginning of the sentence are much more favored. It is these rules that allow the right translation to be preferred since the MLE chooses not to place the object of the sentence in the subject's span. However, the spectral parameters seem to discriminate between these higher-level rules better than EM, which scores spans starting with the first word uniformly highly. Another interesting point is that the range of likelihoods is much larger in the EM case compared to the MLE and spectral variants. For the second sentence (row), the 1-best hypothesis produced by all systems are the same, but the heat map accentuates the previous observation.

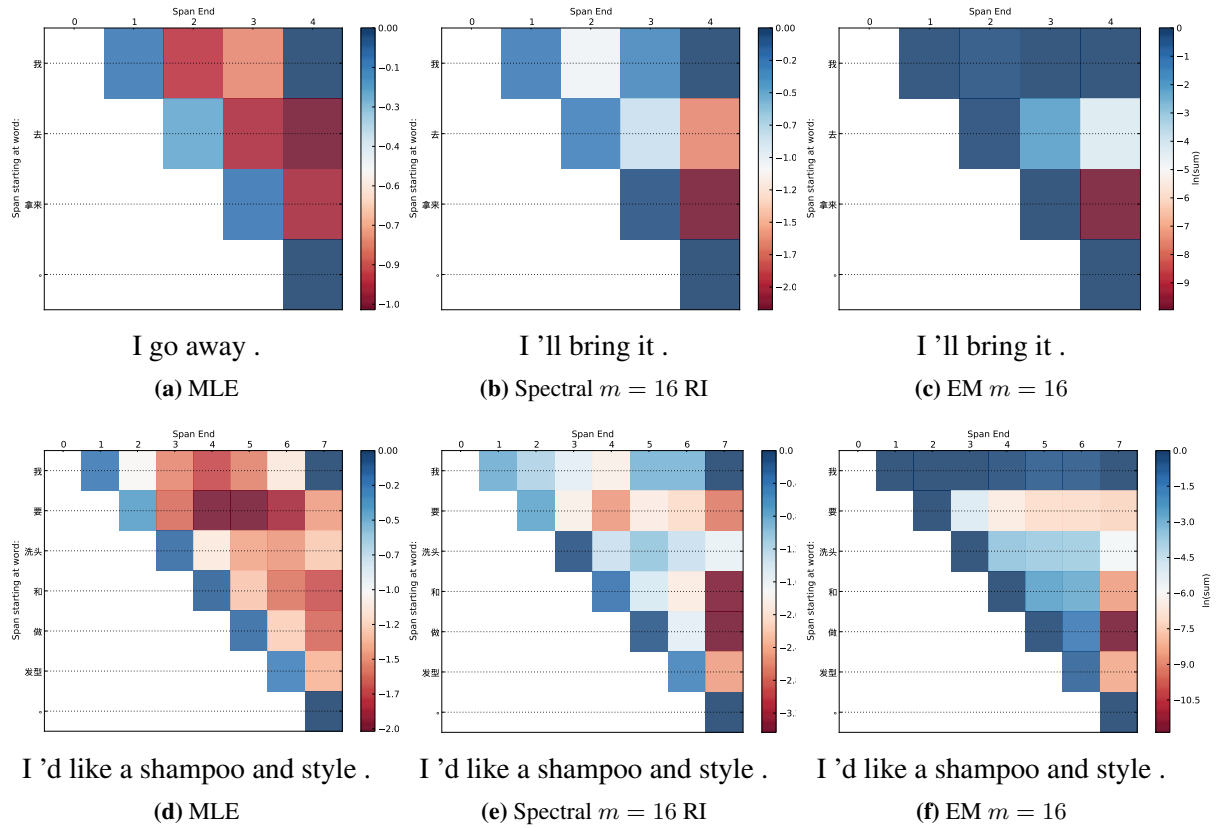
6 Related Work

The goal of refining single-category HPBT grammars or automatically learning the NT categories in a grammar, instead of relying on noisy parser outputs, has been explored from several different angles in the MT literature. Blunsom et al. (2008) present a Bayesian model for synchronous grammar induction, and place an appropriate nonparametric prior on the parameters. However, their starting point is to estimate a synchronous grammar with multiple categories from parallel data (using the word alignments as a prior), while we aim to refine a fixed grammar with additional latent states. Furthermore, their estimation procedure is extremely expensive and is restricted to learning up to five NT categories, via a series of mean-field approximations.

Another approach is to explicitly attach a real-valued vector to each NT: Huang et al. (2010) use an external source-language parser for this purpose and score rules based on the similarity between a source sentence parse and the information contained in this vector, which explicitly requires the integration of a good-quality source-language parser. The EM-based algorithm that we propose here is similar to what they propose, except that we need to handle tensor structures. Mylonakis and Sima'an (2011) select among linguistically motivated non-terminal labels with a cross-validated version of EM. Although they consider a restricted hypothesis space, they do marginalize over different derivations therefore their inside-outside algorithm is $\mathcal{O}(n^6)$. In the syntax-directed translation literature, there have been efforts to relax or coarsen the hard labels provided by a syntactic parser in an automatic manner to promote parameter sharing (Venugopal et al., 2009; Hanneman and Lavie, 2013), which is the complement of our aim in this paper.

The idea of automatically learned grammar refinements comes from the monolingual parsing literature, where phenomena like head lexicalization can be modeled through latent variables. Matsuzaki et al. (2005) look at a likelihood-based method to split the NT categories of a grammar into a fixed number of sub-categories, while Petrov et al. (2006) learn a variable number of sub-categories per NT. The latter's extension may be useful for finding the optimal number of latent states from the data in our case.

The question of whether we can incorporate additional contextual information in minimal rule grammars in MT via auxiliary models instead of using longer, composed rules has been investigated before as well. n-gram translation mod-



(a) MLE **(b)** Spectral $m = 16$ RI **(c)** EM $m = 16$

Higher likelihoods are in blue, lower likelihoods in red. The hypotheses produced by each setup are below the heat maps.

els (Mariño et al., 2006; Durrani et al., 2011) seek to model long-distance dependencies and reorderings through n-grams. Similarly, Vaswani et al. (2011) use a Markov model in the context of tree-to-string translation, where the parameters are smoothed with absolute discounting (Ney et al., 1994), while in our instance we capture this smoothing effect through low rank or latent states. Feng and Cohn (2013) also utilize a Markov model for MT, but learn the parameters through a more sophisticated estimation technique that makes use of Pitman-Yor hierarchical priors.

Hsu et al. (2009) presented one of the initial efforts at spectral-based parameter estimation (using SVD) of observed moments for latent-variable models, in the case of Hidden Markov models. This idea was extended to L-PCFGs (Cohen et al., 2014), and our approach can be seen as a bilingual or synchronous generalization.

7 Conclusion

In this work, we presented an approach to refine synchronous grammars used in MT by inferring the latent categories for the single non-terminal in our grammar rules, and proposed two algorithms to estimate parameters for our latent-variable model. By fixing the synchronous derivations of each parallel sentence in the training data, it is possible to avoid many of the computational issues associated with synchronous grammar induction. Improvements over a minimal grammar baseline and equivalent performance to a hierarchical phrase-based baseline are achieved by the spectral approach. For future work, we will seek to relax this consideration and jointly reason about non-terminal categories and derivation structures.

Abstract

We investigate the interaction of power, gender, and language use in the Enron email corpus. We present a freely available extension to the Enron corpus, with the gender of senders of 87% messages reliably identified. Using this data, we test two specific hypotheses drawn from the sociolinguistic literature pertaining to gender and power: women managers use face-saving communicative strategies, and women use language more explicitly than men to create and maintain social relations. We introduce the notion of "gender environment" to the computational study of written conversations; we interpret this notion as the gender makeup of an email thread, and show that some manifestations of power differ significantly between gender environments. Finally, we show the utility of gender information in the problem of automatically predicting the direction of power between pairs of participants in email interactions.

1 Introduction

It has long been observed that men and women communicate differently in different contexts. This phenomenon has been studied by sociolinguists, who typically rely on case studies or surveys. The availability of large corpora of naturally occurring social interactions has given us the opportunity to study language use at a broader level than before. In this paper, we use the Enron Corpus of work-related emails to examine written communication in a corporate setting. We investigate three factors that affect choices in communication: the writer's gender, the gender of his or her fellow discourse participants (what we call the "gender environment"), and the relations of organizational power he or she has to the discourse participants. We concentrate on modeling the writer's choices related to discourse structure, rather than lexical choice. Specifically, our goal is to show that gender, gender environment, and power all affect individuals' choices in complex ways, resulting in patterns in the discourse that reveal the underlying factors.

This paper makes three major contributions. First, we introduce an extension to the well-known Enron corpus of emails: we semi-automatically identify the sender's gender of 87% of email messages in the corpus. This extension will be made publicly available. Second, we use this enriched version of the corpus to investigate the interaction of hierarchical power and gender. We formalize the notion of "gender environment", which reflects the gender makeup of the discourse participants of a particular conversation. We study how gender, power, and gender environment influence discourse participants' choices in dialog. We investigate two specific hypotheses from the sociolinguistic literature, relating to face-saving use of language, and to the use of language to strengthen social relations. This contribution does not exhaust the possibilities of our corpus, but it shows how social science can benefit from advanced natural language processing techniques in analyzing corpora, allowing social scientists to tackle corpora such as the Enron corpus which cannot be examined in its entirety by hand. Third, we show that the gender information in the enriched corpus can be useful for computational tasks, specifically for training a system that predicts the direction of hierarchical power between participants in an interaction. Our use of the gender-based features boosts the accuracy of predicting the direction of power between pairs of email interactants from 68.9% to 70.2% on an unseen test set.

The paper is structured as follows. We review related work in Section 2. We present the Gender Identified Enron Corpus (our first contribution) in Section 3. Section 4 defines the problem of predicting power and the various dimensions of interaction we analyze. We turn to our second contribution, the analysis of the data, in Sections 5 and 6. Section 7 describes our third contribution, the machine learning experiments using gender-related features in the prediction of hierarchical power. We then conclude and discuss future work.

2 Related Work

There is much sociolinguistic background related to gender and language use, some of it specifically related to language use in the work environment (Kendall and Tannen, 1997; Holmes and Stubbe, 2003; Kendall, 2003; Herring, 2008). We do not provide a full discussion of this work for lack of space, but single out one paper which has particularly influenced our work. Holmes and Stubbe (2003) provide two case studies that do not look at the differences between male and female managers' communication, but at the difference between female managers' communication in more heavily female vs. more heavily male environments. They find that, while female managers tend to break many stereotypes of "feminine" communication, they have different strategies in connecting with employees and exhibiting power in the two gender environments. This work has inspired us to look at this phenomenon by including "Gender Environment" in our study. By finding the ratios of males to females on a thread, we can look at whether indicators change within a more heavily male or female thread. This notion of gender environment is supported by an idea in recent Twitter-based sociolinguistic research on gender identity and lexical variation (Bamman et al., 2014). One of the many insights from their work is that gendered linguistic behavior is oriented by a number of factors, one of which includes the speaker's audience. Their work looks at Twitter users whose linguistic style fails to identify their gender in classification experiments, and finds that the linguistic gender norms can be influenced by the style of their interlocutors.

Within the NLP community, there has been substantial research exploring language use and power. A large number of these studies are performed in the domain of organizational email where the notion of power is well defined in terms of organizational hierarchy. It is also aided by the availability of the moderately large Enron email corpus which captures email interactions in an organizational setting. Earlier approaches used simple lexical features alone (e.g. (Bramsen et al., 2011; Gilbert, 2012)) as a means to predict power. Later studies have used more complex linguistic and structural features, such as formality (Peterson et al., 2011), dialog acts (Prabhakaran and Rambow, 2013), and thread structure (Prabhakaran and Rambow, 2014). Our work is also on the Enron email corpus, and our baseline features are derived from some of this prior work. Researchers have also studied power and influence in other genres of interactions, such as online forums (Danescu-Niculescu-Mizil et al., 2012; Biran et al., 2012), multi-party chats (Strzalkowski et al., 2012) and off-line interactions such as presidential debates (Nguyen et al., 2013; Prabhakaran et al., 2013; Prabhakaran et al., 2014).

There is also some work within the NLP field on analyzing language use in relation to gender. Mohammad and Yang (2011) analyzed the way gender affects the expression of sentiments in text, while we are interested in how gender relates to manifestations of organizational power. For their study, they assigned gender for the core employees in the Enron email corpus based on whether the first name of the person was easily gender identifiable or not. If the person had an unfamiliar name or a name that could be of either gender, they marked his/her gender as *unknown* and excluded them from their study.[1] For example, the gender of the employee Kay Mann was marked as *unknown* in their gender assignment. However, in our work, we manually research and determine the gender of every core employee.

Researchers have also attempted to automatically predict the gender of email senders using supervised learning techniques based on linguistic features (Corney et al., 2002; Cheng et al., 2011; Deitrick et al., 2012), a task we do not address in this paper. These studies use datasets that are relatively smaller in size. Corney et al. (2002) use around 4K emails from 325 gender identified authors. Cheng et al. (2011) use around 9K emails from 108 gender identified authors. Deitrick et al. (2012) use around 18K emails from 144 gender

[1] http://www.saifmohammad.com/WebDocs/dir-email-gender.txt

identified authors. The dataset we offer is much larger in size, with around 97K emails whose authors are gender identified. We believe that our resource will aid further research in this area.

3 Gender Identified Enron Corpus

3.1 Enron Corpus

In our work, we use the version of Enron email corpus released by Yeh and Harnly (2006). The corpus contains emails from the mailboxes of 145 core employees who held top managerial positions within Enron at the time of bankruptcy. Yeh and Harnly (2006) preprocessed the corpus to combine multiple email addresses belonging to the same entity and identify each entity in the corpus with a unique identifier. The corpus contains a total of 111,933 messages. This version of the corpus has been enriched later by Agarwal et al. (2012) with gold organizational power relations, manually determined using information from Enron organizational charts. It includes relations of 1,518 employees and captures dominance relations between 13,724 pairs of them. This information enables us to study the manifestations of power in these interactions, in relation to gender.

In this version of the corpus, the thread structure of email messages is reconstructed, with the missing messages restored from other emails in which they were quoted. This allows us to go beyond isolated messages and study the dialog structure within email threads. There were 34,156 unique discourse participants across all the email threads present in the corpus. Manually determining the gender of all the discourse participants in the corpus is not feasible. Hence, we adopt a two-step approach through which we reliably identify the gender of a large majority of entities in the email threads within the corpus. We manually determine the gender of the 145 core employees who have a bigger representation in the corpus, and we systemically determine the gender of the rest of the discourse participants using the Social Security Administration's baby names database. We adopt a conservative approach so that we assign a gender only when the name of the participant meets a very low ambiguity threshold.

3.2 Manual Gender Assignment

We researched each of the 145 core employees using web search and found public records about them or articles referring to them. In order to make sure that the results are about the same person we want, we added the word 'enron' to the search queries. Within the public records returned for each core employee, we looked for instances in which they were being referred to either using a gender revealing pronoun (*he*/*him*/*his* vs. *she*/*her*) or using a gender revealing addressing form (*Mr.* vs. *Mrs.*/*Ms.*/*Miss*). Since these employees held top managerial positions within Enron at the time of bankruptcy, it was fairly easy to find public records or articles referring to them. For example, the page we found for Kay Mann clearly identifies her gender.[2] We were able to correctly determine the gender of each of the 145 core employees in this manner. A benefit of manually determining the gender of these core employees is that it ensures a high coverage of 100% confident gender assignments in the corpus.

3.3 Automatic Gender Assignment

As mentioned in Section 3.1, our corpus contains a large number of discourse participants in addition to the 145 core employees for which we manually identified the gender. To attempt to find the gender of these other discourse participants, we first determine their first names and then find how ambiguous the names are by querying the Social Security Administration's (SSA) baby names dataset. We first describe how we calculate an ambiguity score for a name using the SSA dataset and then describe how we use it to determine the gender of discourse participants in our corpus.

3.3.1 SSA Names and Gender Dataset

The US Social Security Administration maintains a dataset of baby names, gender, and name count for each year starting with the 1880s, for names with at least five counts.[3] We used this dataset in order to determine the gender ambiguity of a name. The Enron data set contains emails from 1998 to 2001. We estimate the common age range for a large, corporate firm like Enron at 24-67,[4] so we used the SSA data from 1931-1977 to calculate ambiguity scores for our purposes.

For each name n in the database, let $mp(n)$ and $fp(n)$ denote the percentages of males and females with the name n. Then, we calculate the ambiguity score $AS(n)$ as $100 - |mp(n) - fp(n)|$.

[2] http://www.prnewswire.com/news-releases/kay-mann-joins-noble-as-general-counsel-57073687.html

[3] http://www.ssa.gov/oact/babynames/limits.html

[4] http://www.bls.gov/cps/demographics.htm

The value of $AS(n)$ varies between 0 and 100. A name that is 'perfectly unambiguous' would have an ambiguity score of 0, while a 'perfectly ambiguous' name (i.e., 50%/50% split between genders) would have an ambiguity score of 100. We assign the likely gender of the name to be the one with the higher percentage, if the ambiguity score is below a threshold AS_T.

$$G(n) = \begin{cases} M, & \text{if } AS(n) \leq AS_T \text{ and } mp(n) > fp(n) \\ F, & \text{if } AS(n) \leq AS_T \text{ and } mp(n) \leq fp(n) \\ I, & \text{if } AS(n) > AS_T \end{cases}$$

Around 88% of the names in the SSA dataset have $AS(n) = 0$. We choose a very conservative threshold of $AS_T = 10$ for our gender assignments, which assigns gender to around 93% names in the SSA dataset.[5]

3.3.2 Identifying the First Name

Each discourse participant in our corpus has at least one email address and zero or more names associated with it. The name field is automatically assembled by Yeh and Harnly (2006), where they captured the different names from email headers, which are populated from individual email clients and do not follow a standard format. Not all discourse participants are human; some may refer to organizational groups (e.g., HR Department) or anonymous corporate email accounts (e.g., a webmaster account, do-not-reply address etc.). The name field may sometimes be empty, contain multiple names, contain an email address, or show other irregularities. Hence, it is nontrivial to determine the first name of our discourse participants. We used the heuristics below to extract the most likely first name for each discourse participant.

- If the name field contains two words, pick the second or first word, depending on whether a comma separates them or not.
- If the name field contains three words and a comma, choose the second and third words (a likely first and middle name, respectively). If the name field contains three words but no comma, choose the first and second words (again, a likely first and middle name).
- If the name field contains an email address, pick the portion from the beginning of the string to a '.','_' or '-'; if the email address is in camel case, take portion from the beginning of the string to the first upper case letter.
- If the name field is empty, apply the above rule to the email address field to pick a name.

The above heuristics create a list of candidate names for each discourse participant which we then query for an ambiguity score (Section 3.3.1) and the likely gender. We find the candidate name with the lowest ambiguity score that passes the threshold and assign the associated gender to the discourse participant. If none of the candidate names for a discourse participant passes the threshold, we assign the gender to be 'I' (Indeterminate). We also assign the gender to be 'I', if none of the candidate names is present in the SSA dataset. This will occur if the name is a first name that is not in the database (an unusual or international name; e.g., *Vladi*), or if no true first name was found (e.g., the name field was empty and the email address was only a pseudonym). This will also include most of the cases where the discourse participant is not a human.

3.3.3 Coverage and Accuracy

We evaluated the coverage and accuracy of our gender assignment system on the manually assigned gender data of the 145 core people. We obtained a coverage of 90.3%, i.e., for 14 of the 145 core people, the ambiguity score was higher than the threshold. Of the 131 people the system assigned a gender to, we obtained an accuracy of 89.3% in correctly identifying the gender. We investigated the errors and found that all errors were caused due to incorrectly identifying the first name. These errors arise because the name fields are automatically populated and sometimes the core discourse participants' name fields include their secretaries. While this is common for people in higher managerial positions, we expect this not to happen in the middle management and below, to which most of the automatically gender-assigned discourse participants belong.

3.4 Corpus Statistics and Divisions

We apply the gender assignment system described above to all discourse participants of all email threads in the entire Enron corpus described in Section 3.1. Table 1 shows the coverage of gender assignment in our corpus at different levels: unique discourse participants, messages and threads. In Table 2, we show the male/female percentage split of all unique discourse participants, as well as the split at the level of messages (i.e., messages sent by males vs. females).

[5] In the corpus that will be released, we retain the $AS(n)$ of each name, so that the users of this resource can decide the threshold that suit their needs.

	Count (%)
Total unique discourse participants	34,156
- gender identified	23,009 (67.3%)
Total messages	111,933
- senders gender identified	97,255 (86.9%)
Total threads	36,615
- all senders gender identified	26,015 (71.1%)
- all participants gender identified	18,030 (49.2%)

Table 1: Coverage of Gender Identification at various level: unique discourse participants, messages and threads

	Male	Female
Unique Discourse Participants	66.1%	33.9%
Message Senders	58.2%	41.8%

Table 2: Male/Female split across a) all unique participants who were gender identified, b) all messages whose senders were gender identified

We divide the entire corpus into Train, Dev and Test sets at the thread level, through random sampling, with a distribution of 50%, 25% and 25% each. The number of threads and messages in each subdivision is shown in Table 3.

	Total	**Train**	**Dev**	**Test**
Threads	36,615	18,498	8,973	9,144
Messages	111,933	56,447	27,565	27,921

Table 3: Train/Test/Dev breakup of the entire corpus

We also create a sub-corpus of the threads called *All Participants Gender Identified* (APGI), containing the 18,030 threads for which the gender assignment system succeeded in assigning the genders of all participants, including senders and all recipients (To and CC). For the analysis and experiments presented in the rest of this paper, we use 17,788 threads from this APGI subset, excluding the remaining 242 threads that were used for previous manual annotation efforts.

4 Manifestations of Power

We use the gender information of the participants to investigate how the gender of the sender and recipients affect the manifestations of hierarchical power in interactions. In order to do this, we use the interaction analysis framework from our prior work (Prabhakaran and Rambow, 2014). In this section, we give a brief overview of the problem formulation and the structural features we used.

4.1 Hierarchically Related Interacting Pairs

Let t denote an email thread and M_t denote the set of all messages in t. Also, let P_t be the set of all participants in t, i.e., the union of senders and recipients (*To* and *CC*) of all messages in M_t. We are interested in analyzing the power relations between pairs of participants who interact within a given email thread. Not every pair of participants $(p_1, p_2) \in P_t \times P_t$ interact with one another within t. Let $IM_t(p_1, p_2)$ denote the set of *Interaction Messages* — non-empty messages in t in which either p_1 is the sender and p_2 is one of the recipients or vice versa. We call the set of (p_1, p_2) such that $|IM_t(p_1, p_2)| > 0$ the *interacting participant pairs* of t (IPP_t). For every $(p_1, p_2) \in IPP_t$, we query the set of dominance relations in the gold hierarchy and assign their hierarchical power relation ($HP(p_1, p_2)$) to be *superior* if p_1 dominates p_2, and *subordinate* if p_2 dominates p_1. We exclude pairs that do not exist in the gold hierarchy from our analysis and call the remaining set *related interacting participant pairs* ($RIPP_t$). Table 4 shows the total number of pairs in IPP_t and $RIPP_t$ from all the threads in the APGI subset of our corpus and across Train, Dev and Test sets.

Description	**Total**	**Train**	**Dev**	**Test**
# of threads	17,788	8,911	4,328	4,549
$\sum_t \lvert IPP_t \rvert$	74,523	36,528	18,540	19,455
$\sum_t \lvert RIPP_t \rvert$	4,649	2,260	1,080	1,309

Table 4: Data Statistics
Row 1 presents the total number of threads in different subsets of the corpus. Row 2 and 3 present the number of interacting participant pairs (IPP) and related interacting participant pairs ($RIPP$) in those subsets.

4.2 Structural Features

Now, we describe various features that capture the structure of interaction between the pairs of participants in a thread. Each feature f is extracted with respect to a person p over a reference set of messages M (denoted f^p_M). For a pair (p_1, p_2), we extract 4 versions of each feature f: $f^{p_1}_{IM_t(p_1,p_2)}$, $f^{p_2}_{IM_t(p_1,p_2)}$, $f^{p_1}_{M_t}$ and $f^{p_2}_{M_t}$. The first two capture behavior of each person of the pair in interactions between themselves, while the third and fourth capture their overall behavior in the entire thread. We group our features into three categories — THR^{STR}, THR^{META} and DIA. THR^{STR} captures the thread structure in terms of verbosity and

positional features of messages (e.g., how many emails did a person send). THR$^{\text{META}}$ contain email header meta-data based features that capture the thread structure (e.g., how many recipients were there). Both sets of features do not perform any NLP analysis on the the content of the emails. DIA captures the pragmatics of the dialog and requires a deeper analysis of the email content (e.g., did they issue any requests).

THR$^{\text{STR}}$: This feature set includes two kinds of features — positional and verbosity. The positional features are a boolean feature to denote whether p sent the first message (Initiate), and the relative positions of p's first and last messages (FirstMsgPos and LastMsgPos) in M. The verbosity features are p's message count (MsgCount), message ratio (MsgRatio), token count (TokenCount), token ratio (TokenRato) and tokens per message (TokenPerMsg), all calculated over M.

THR$^{\text{META}}$: This feature set includes the average number of recipients (AvgRecipients) and *To* recipients (AvgToRecipients) in emails sent by p, the percentage of emails p received in which he/she was in the *To* list (InToList%), boolean features denoting whether p added or removed people when responding to a message (AddPerson and RemovePerson), average number of replies received per message sent by p (ReplyRate) and average number of replies received from the other person of the pair to messages where he/she was a *To* recipient (ReplyRateWithinPair). ReplyRateWithinPair applies only to $IM_t(p_1, p_2)$.

DIA: We use dialog acts (DA) and overt displays of power (ODP) tags to model the structure of interactions within the message content. We obtain DA and ODP tags using automatic taggers trained on manual annotations. The DA tagger (Omuya et al., 2013) obtained an accuracy of 92%. The ODP tagger (Prabhakaran et al., 2012) obtained an accuracy of 96% and F-measure of 54%. The DA tagger labels each sentence to be one of the 4 dialog acts: Request Action, Request Information, Inform, and Conventional. The ODP Tagger identifies sentences (mostly requests) that express additional constraints on their addressee, beyond those introduced by the dialog act. For example, the sentence "Please come to my office right now" is considered as an ODP, while "It would be great if you could come to my office now" is not, even though both issue the same request. For more details on ODP, we refer the reader to (Prabhakaran et al., 2012). We use 5 features: ReqAction, ReqInform, Inform, Conventional, and ODPCount to capture the number of sentences in messages sent by p that have each of these labels. We also use a feature to capture the number of p's messages with a request that did not get a reply, i.e., dangling request percentage (DanglingReq%), over all messages sent by p.

5 Gender and Power

In this subsection, we analyze the impact of gender on the expression of power in email. We perform an ANOVA test on all features described in Section 4.2 keeping both Hierarchical Power and Gender as independent variables. We perform this on the Train subset of the APGI subset of our corpus. Table 5 shows the results for thread level version of the features (we obtain similar significance results at the interaction level as well). As can be seen from the ANOVA results, the mean values of many features differ significantly for the factorial

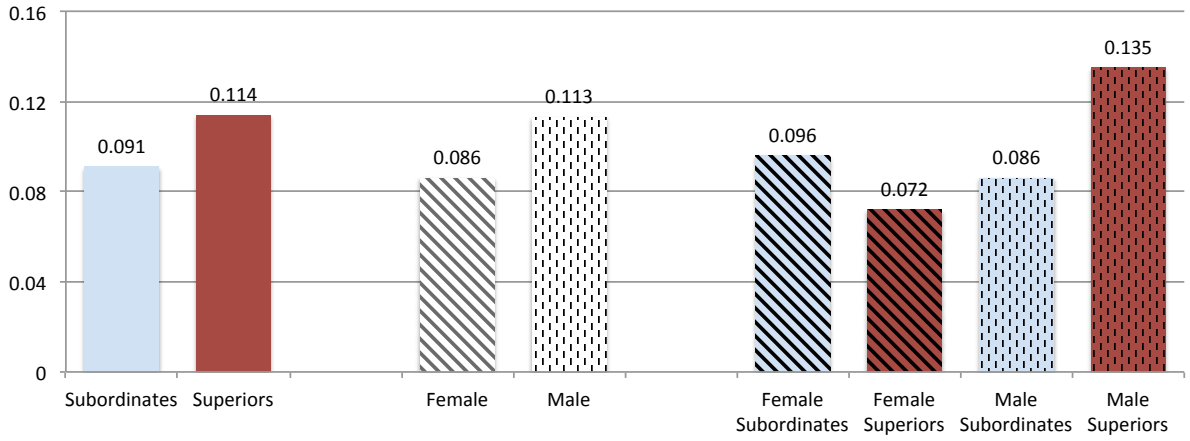

Figure 1: Mean values of ODPCounts in different groups: Subordinates vs. Superiors; Female vs. Male; across all combinations of Hierarchical Power and Gender.

groups of Hierarchical Power and Gender. For example, ReplyRate was highly significant; female superiors obtain the highest reply rate.

It is crucial to note that ANOVA only determines that there is a significant difference between groups, but does not tell which groups are significantly different. In order to ascertain that, we must use the Tukey's HSD (Honest Significant Difference) Test. We do not describe the analysis of all our features to that depth in this paper due to space limitations. Instead, we investigate specific hypotheses which we have derived from sociolinguistic literature. The first hypothesis we investigate is:

- **Hypothesis 1**: Female superiors tend to use "face-saving" strategies at work that include conventionally polite requests and impersonalized directives, and that avoid imperatives (Herring, 2008).

As a stand-in for a face-threatening communicative strategy, we use our "Overt Display of Power" feature (ODP). An ODP limits the addressee's range of possible responses, and thus threatens his or her (negative) face.[6] We thus reformulate our hypothesis as follows: the use of ODP by superiors changes when looking at the splits by gender, with female superiors using fewer ODPs than male superiors. We look further into the ANOVA analysis of the thread-level ODPCount treating Hierarchical Power and Gender as independent variables. Figure 1 shows the mean values of ODP counts in each group of participants. A summary of the results follows.

Hierarchical Power was significant. Subordinates had an average of 0.091 ODP counts and Superiors had an average of 0.114 ODP counts. Gender was also significant; Females had an average of 0.086 ODP counts and Males had an average of 0.113 ODP counts. When looking at the factorial groups of Hierarchical Power and Gender, however, several results were very highly significant. The significantly different pairs of groups, as per the Tukey's HSD test, are Male Superiors/Male Subordinates, Male Superiors/Female Superiors, and Male Superiors/Female Subordinates. Male Superiors used the most ODPs, with an average of 0.135 counts. Somewhat surprisingly, Female Superiors used the *least* of the entire group, with an average of 0.072 counts. Among Subordinates, Females actually used slightly more ODP, with an average of 0.096 counts. Male Subordinates had an average of 0.086 ODP counts. However, the differences among these three groups (Female Superiors, Female Subordinates, and Male Subordinates) are not significant.

The results confirm our hypothesis: female superiors use fewer ODPs than male superiors. However, we also see that among women, there is no significant difference between superiors and subordinates, and the difference between superiors and subordinates in general (which is significant) is entirely due to men. This in fact shows that a more specific (and more interesting) hypothesis than our original hypothesis is validated: only male superiors use more ODPs than subordinates.

[6]For a discussion of the notion of "face", see (Brown and Levinson, 1987).

6 Gender Environment and Power

We now turn to gender environments and their relation to the expression of power in written dialogs. We again start with a hypothesis based on the sociolinguistic literature.

- **Hypothesis 2**: Women use language to create and maintain social relations, for example, they use more small talk (based on a reported "stereotype" in (Holmes and Stubbe, 2003)).

We first define more formally what we mean by "gender environment" (Section 6.1), and then investigate our hypothesis (Section 6.2).

6.1 The Notion of "Gender Environment"

The notion of "gender environment" refers to the gender composition of a group who are communicating. In the sociolinguistic studies we have consulted (Holmes and Stubbe, 2003; Herring, 2008), the notion refers to a stable work group who interact regularly. Since we are interested in studying email conversations (threads), we adapt the notion to refer to a single thread at a time. Furthermore, we assume that a discourse participant makes communicative decisions based on (among other factors) his or her own gender, and based on the genders of the people he or she is communicating with in a given conversation (i.e., email thread). We therefore consider the "gender environment" to be specific to each discourse participant and to describe the other participants from his or her point of view. Put differently, we use the notion of "gender environment" to model a discourse participant's (potential) audience in a conversation. For example, a conversation among five women and one man looks like an all-female audience from the man's point of view, but a majority-female audience from the women's points of view.

We define the gender environment of a discourse participant p in a thread t as follows. As discussed, we assume that the gender environment is a property of each discourse participant p in thread t. We take the set of all discourse participants of the thread t, P_t (see Section 4.1), and exclude p from it: $P_t \setminus \{p\}$. We then calculate the percentage of women in this set.[7] We obtain three groups by setting thresholds on these percentages. Finer-grained gender environments resulted in partitions of the data with very few instances, since most of our data involves fairly balanced gender ratios. The three gender environments we use are the following:

- **Female Environment**: if the percentage of women in $P_t \setminus \{p\}$ is above 66.7%.
- **Mixed Environment**: if the percentage of women in $P_t \setminus \{p\}$ is between 33.3% and 66.7%.
- **Male Environment**: if the percentage of women in $P_t \setminus \{p\}$ is below 33.3%

Across all threads and discourse participants in the threads, we have 791 female, 2087 mixed and 1642 male gender environments.

6.2 Gender Environment and Conventional Dialog Acts

We now turn to testing Hypothesis 2. We have at present no way of testing for "small talk" as opposed to work-related talk, so we instead test Hypothesis 2 by asking how many conventional dialog acts a person performs. Conventional dialog acts serve not to convey information or requests (both of which would typically be work-related in the Enron corpus), but to establish communication (greetings) and to manage communication (sign-offs); since communication is an important way of creating and maintaining social relations, we can say that conventional dialog acts serve the purpose of easing conversations and thus of maintaining social relations. Since this aspect of language is specifically dependent on a group of people (it is an inherently social function), we assume that the relevant feature is not simply Gender, but Gender Environment. Specifically, we make our Hypothesis 2 more precise by saying that a higher number of conventional dialog acts is used in Female Environments. We use the thread level version of the feature ConventionalCount.

Figure 2 shows the mean values of ConventionalCount in each sub-group of participants. Hierarchical Power was highly significant as per ANOVA results. Subordinates use conventional language more (0.60 counts) than Superiors (0.52). Gender is a very highly significant variable; Males use 0.60 counts on average, whereas

[7] We note that one could also define the notion of gender environment at the level of individual emails: not all emails in a thread involve the same set of participants. We leave this to future work.

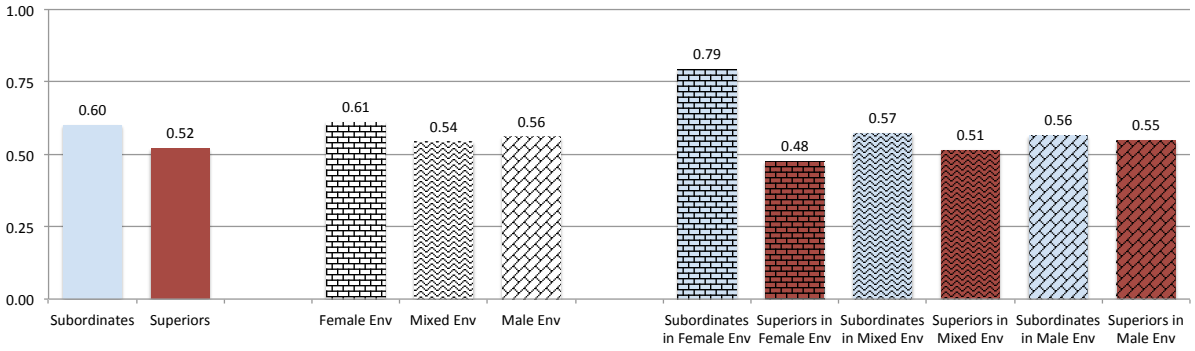

Figure 2: Mean values of Conventional Counts: Subordinates vs. Superiors; across all Gender Environments; across all combinations of Hierarchical Power and Gender Environments.

Females use 0.50. This result is somewhat surprising, but does not invalidate our Hypothesis 2, since our hypothesis is not formulated in terms of Gender, but in terms of Gender Environment. The analysis of Gender Environment at first appears to be a negative result: while the averages by Gender Environment differ, the differences are not significant. However, the groups defined by both Hierarchical Power *and* Gender Environment have highly significant differences. Subordinates in Female Environments use the most conventional language of all six groups, with an average of 0.79. Superiors in Female Environments use the least, with an average of 0.48. Mixed Environments and Male Environments differ, but are more similar to each other than to Female Environments. In fact, in the Tukey HSD test, the only significant pairs are exactly the set of subordinates in Female Environments paired with each other group (Superiors in Female Environments, and Subordinates and Superiors in Mixed Environments and Male Environments). That is, Subordinates in Female environments use significantly more conventional language than any other group, but the remaining groups do not differ significantly from each other.

Our hypothesis is thus only partially verified: while gender environment is a crucial aspect of the use of conventional DAs, we also need to look at the power status of the writer. In fact only subordinates in female environments use more conventional DAs than any other group (as defined by power status and gender environment). While our hypothesis is not fully verified, we interpret the results to mean that subordinates are more comfortable in female environments to use a style of communication which includes more conventional DAs than outside the female environments.

7 Predicting Power in Participant Pairs

In this section, we use the formulation of the power prediction problem presented in our prior work (Prabhakaran and Rambow, 2014). Given a thread t and a pair of participants $(p_1, p_2) \in RIPP_t$, we want to automatically detect $HP(p_1, p_2)$. We use the SVM-based supervised learning system from (Prabhakaran and Rambow, 2014) that can predict $HP(p_1, p_2)$ to be either *superior* or *subordinate* based on the interaction within a thread t for any pair of participants $(p_1, p_2) \in RIPP_t$. The order of participants in (p_1, p_2) is fixed such that p_1 is the sender of the first message in $IM_t(p_1, p_2)$. The power prediction system is built using the ClearTK (Ogren et al., 2008) wrapper for SVMLight (Joachims, 1999) package. It uses a quadratic kernel to capture feature-feature interactions, which is very important as we see in Section 5 and 6. We use the Train, Dev and Test subsets of the APGI subset of our corpus for our experiments. We use the related interacting participant pairs in threads from the Train set to train our models and optimize our performance on those from the Dev set. We report results on both Dev and Test sets.

In addition to the features described in Section 4.2, the power prediction system presented in (Prabhakaran and Rambow, 2014) uses a lexical feature set (LEX) that captures word ngrams, POS (part of speech) ngrams and mixed ngrams, since lexical features have been established to be very useful for power prediction. Mixed ngrams are word ngrams where words belonging to open classes are replaced with their POS tags. We add two gender-based feature sets: GEN containing the gender of both persons of the pair and ENV containing the gender environment feature.

Table 6 presents the results obtained using various feature combinations. We experimented using all subsets of {LEX, THR^{STR}, THR^{META}, DIA, GEN, ENV } on the Dev set; we report the most interesting results here. The majority baseline (*subordinate*) obtains an accuracy of 55.8%. Using the gender-based features alone performs only slightly better than the majority baseline. We use the best performing feature subset from (Prabhakaran and Rambow, 2014) (LEX + THR^{META}) as another baseline, which obtains an accuracy of 68.2%. Adding the GEN features improves the performance to 70.6%. Further adding the ENV features improves the performance, but only marginally to 70.7% (our overall best result, an improvment of 2.4% points). The best performing feature set without using LEX was the combination of DIA, THR^{META} and GEN (67.3%). Removing the gender features from this reduced the performance to 64.6%. Similarly, the best performing feature set which do not use the content of emails at all was THR^{STR} + THR^{META} + GEN (66.6). Removing the gender features decreases the accuracy by a larger margin (5.4% accuracy reduction to 63.0).

We interpret the differences in absolute improvement as follows: the gender-based features on their own are not very useful, and gain predictive value only when paired with other features. This is because the other features in fact make quite different predictions depending on gender and/or gender environment. However, the content features (and in particular the lexical features) are so powerful on their own that the relative contribution of the gender-based features decreases again. Nonetheless, we take these results as validation of the claim that gender-based features enhance the value of other features in the task of predicting power relations.

We performed another experiment where we partitioned the data into two subsets according to the gender of the first person of the pair and trained two separate models to predict power. At test time, we chose the appropriate model based on the gender of the first person of the pair. However, this did not improve the performance.

On our blind test set, the majority baseline obtains an accuracy of 57.9% and the (Prabhakaran and Rambow, 2014) baseline obtains an accuracy of 68.9%. On adding the gender-based features, the accuracy of the system improves to 70.2%.

Description	**Accuracy**
Majority (Always Subordinate)	55.83
GEN	57.59
GEN + ENV	57.59
Baseline (LEX + THR^{META})	68.24
Baseline (LEX + THR^{META}) + GEN	70.56
Baseline (LEX + THR^{META}) + GEN + ENV	**70.74**
DIA + THR^{META} + GEN	67.31
DIA + THR^{META}	64.63
THR^{STR} + THR^{META} + GEN	66.57
THR^{STR} + THR^{META}	62.96

Table 6: Accuracies on feature subsets (Dev set). THR^{META}: meta-data; THR^{STR}: structural; DIA: dialog-act; GEN: gender; ENV: gender environment; LEX: ngrams;

8 Conclusion

We presented a new, freely available resource: the Gender Identified Enron Corpus, and explored the relation between power, gender, and language using this resource. We also introduced the notion of gender environment, and showed that the manifestations of power differ significantly between gender environments. We also showed that the gender-related features helps in improving power prediction. In future work, we will explore machine learning algorithms which capture the interactions between features better than our SVM with quadratic kernel.

We expect our corpus to be a rich resource for social scientists interested in the effect of power and gender on language use. We will investigate several other sociolinguistic-inspired research questions; for example, do the strategies managers use for "effectiveness" of communication differ based on gender environments?

While our findings pertain to the Enron data set, we believe that the insights and techniques from this study can be extended to other genres in which there is an independent notion of hierarchical power, such as moderated online forums.

Online Topic Model for Twitter Considering Dynamics of User Interests and Topic Trends

Abstract

Latent Dirichlet allocation (LDA) is a topic model that has been applied to various fields, including user profiling and event summarization on Twitter. When LDA is applied to tweet collections, it generally treats all aggregated tweets of a user as a single document. Twitter-LDA, which assumes a single tweet consists of a single topic, has been proposed and has shown that it is superior in topic semantic coherence. However, Twitter-LDA is not capable of online inference. In this study, we extend Twitter-LDA in the following two ways. First, we model the generation process of tweets more accurately by estimating the ratio between topic words and general words for each user. Second, we enable it to estimate the dynamics of user interests and topic trends online based on the topic tracking model (TTM), which models consumer purchase behaviors.

1 Introduction

Microblogs such as Twitter, have prevailed rapidly in our society recently. Twitter users post a message using 140 characters, which is called a tweet. The characters limit allows users to post tweets easily about not only personal interest or real life but also public events such as traffic accidents or earthquakes. There have been many studies on how to extract and utilize such information on tweets (Diao et al., 2012; Pennacchiotti and Popescu, 2011; Sakaki et al., 2010; Weng et al., 2010).

Topic models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003) are widely used to identify latent topic structure in large collections of documents. Recently, some studies have applied LDA to Twitter for user classification (Pennacchiotti and Popescu, 2011), detection of influential users (Weng et al., 2010), and so on. LDA is a generative document model, which assumes that each document is represented as a probability distribution over some topics, and that each word has a latent topic. When we apply LDA to tweets, each tweet is treated as a single document. This direct application does not work well because a tweet is very short compared with traditional media such as newspapers. To deal with the shortness of a tweet, some studies aggregated all the tweets of a user as a single document (Hong and Davison, 2010; Pennacchiotti and Popescu, 2011; Weng et al., 2010). On the other hand, Zhao et al. (2011) proposed "Twitter-LDA," which is a model that considers the shortness of a tweet. Twitter-LDA assumes that a single tweet consists of a single topic, and that tweets consist of topic and background words. Zhao et al. (2011) show that it works well at the point of semantic coherence of topics compared with LDA. However, as with the case of LDA, Twitter-LDA cannot consider a sequence of tweets because it assumes that samples are exchangeable. In Twitter, user interests and topic trends are dynamically changing. In addition, when new data comes along, a new model must be generated again with all the data in Twitter-LDA because it does not assume online inference. Therefore, it cannot efficiently analyze the large number of tweets generated everyday. To overcome these difficulties, a model that considers the time sequence and has the capability of online inference is required.

In this study, we first propose an improved model based on Twitter-LDA, which assumes that the ratio between topic and background words differs for each user. This study evaluates the proposed method based on perplexity and shows the efficacy of the new assumption in the improved model. Second, we propose a new topic model called "Twitter-TTM" by extending the improved

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1977–1985,

model based on the topic tracking model (TTM) (Iwata et al., 2009), which models the purchase behavior of consumers and is capable of online inference. Finally, we demonstrate that Twitter-TTM can effectively capture the dynamics of user interests and topic trends in Twitter.

2 Improvement of Twitter-LDA

2.1 Improved-Model

Figure 1(a) shows the graphical representation of Twitter-LDA based on the following assumptions. There are K topics in Twitter and each topic is represented by a topic word distribution. Each user has his/her topic interests ϕ_u represented by a distribution over K topics. Topic k is assigned to each tweet of user u depending on the topic interests ϕ_u. Each word in the tweet assigned by topic k is generated from a background word distribution θ_B or a topic word distribution θ_k. Whether the word is a background word or a topic word is determined by a latent value y. When $y = 0$, the word is generated from the background word distribution θ_B, and from the topic word distribution θ_k when $y = 1$. The latent value y is chosen according to a distribution π. In other words, the ratio between background and topic words is determined by π.

In Twitter-LDA, π is common for all users, meaning that the rate between background and topic words is the same for each user. However, this assumption could be incorrect, and the rate could differ for each user. Thus, we develop an improved model based on Twitter-LDA, which assumes that π is different for each user, as shown in Figure 1(b). In the improved model, the rate between background and topic words for user u is determined by a user-specific distribution π_u. The improved model is expected to infer the generative process of tweets more efficiently.

2.2 Experiment for Improved Model

We performed an experiment to compare the predictive performances of LDA, TTM, and the improved model shown in Section 2.1. In this experiment, LDA was applied as the method to aggregate all tweets of a user as a single document. The original Twitter data set contains 14,305 users and 292,105 tweets collected on October 18, 2013. We then removed words that occurred less than 20 times and stop words. Retweets[1] were treated as the same as other general tweets because they reflected the user's interests. After the above preprocessing, we obtained the final dataset with 14,139 users, 252,842 tweets, and 7,763 vocabularies. Each model was inferred with collapsed Gibbs sampling (Griffiths and Steyvers, 2004) and the iteration was set at 500. For a fair comparison, the hyper parameters in these models were optimized in each Gibbs sampling iteration by maximizing likelihood using fixed iterations (Minka, 2000).

This study employs perplexity as the evaluation index, which is the standard metric in information retrieval literature. The perplexity of a held-out test set is defined as

$$perplexity = exp\Big(-\frac{1}{N}\sum_{u}\log p(\mathbf{w_u})\Big) \quad (1)$$

where $\mathbf{w_u}$ represents words are contained in the tweets of user u and N is the number of words in the test set. A lower perplexity means higher predictive performance. We set the number of topics K at 50, 100, 150, 200, and 250 and evaluated the perplexity for each model in each K via a 10-fold cross-validation.

The results are shown in Table 1, which shows that the improved model performs better than the other models for any K. Therefore, the new assumption of the improved model, that the rate between background and topic words is different for each user, could be more appropriate. LDA performance worsens with an increase in K because the aggregated tweets of a single user neglect the topic of each tweet.

Table 2 shows examples of the tweets of users with high and low rates of background words. The users with a high background words rate tend to use basic words that are often used in any topics, such as "like," "about," and "people," and they tend to tweet about their personal lives. On the other hand, for users with a low background words rate, topical words are often used such as "Arsenal," "Justin," and "Google". They tend to tweet about their interests, including music, sports, and movies.

3 Twitter-TTM

3.1 Model Extension based on Topic Tracking Model

We extend the improved model shown in Section 2.1 considering the time sequence and capabil-

[1] Republishing a tweet written by another Twitter user.

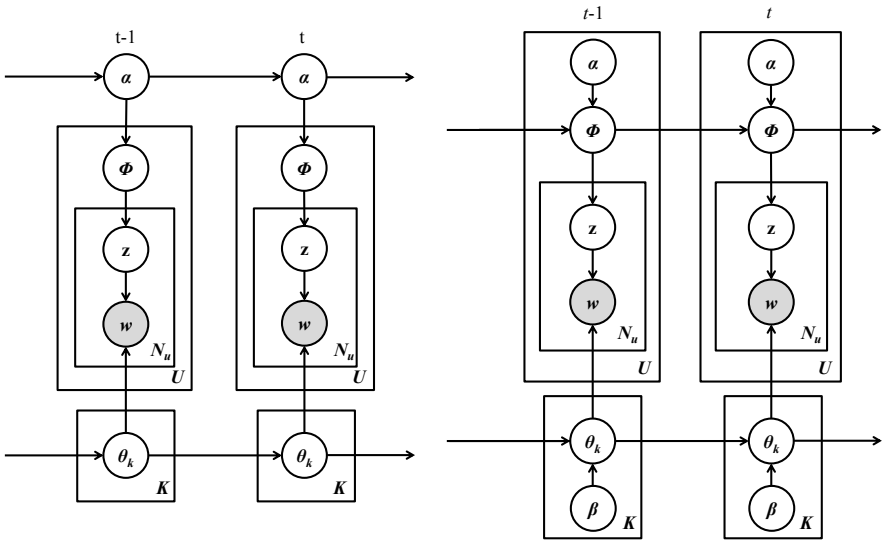
All need your support please	Google nexus briefly appears in Google play store

ity of online inference based on TTM (Iwata et al., 2009). TTM is a probabilistic consumer purchase behavior model based on LDA for tracking the interests of each user and the trends in each topic. Other topic models considering the dynamics of topics include the dynamic topic model (DTM) (Blei and Lafferty, 2006) and topic over time (ToT) (Wang and McCallum, 2006). DTM is a model for analyzing the time evolution of topics in time-ordered document collections. It does not track the interests of each user as shown in Figure 2(a) because it assumes that a user (document) has only one time stamp. ToT requires all the data over time for inference, thus, it is not appropriate for application to continuously generated data such as Twitter. We consider a model must be capable of online inference and track the dynamics of user interests and topic trends for modeling tweets. Since TTM has these abilities, we adapt it to the improved model described in Section 2.

Figure 2(b) shows the graphical representation of TTM. TTM assumes that the mean of user interests at the current time is the same as that at the previous time, unless new data is observed. Formally, the current interest $\phi_{t,u}$ are drawn from the following Dirichlet distribution in which the mean is the previous interest $\hat{\phi}_{t-1,u}$ and the precision is



(a) DTM (b) TTM

Figure 2: Graphical representation of DTM and TTM

$\alpha_{t,u}$

$$p(\phi_{t,u}|\hat{\phi}_{t-1,u},\alpha_{t,u}) \propto \prod_k \phi_{t,u,k}^{\alpha_{t,u}\hat{\phi}_{t-1,u,k}-1} \quad (2)$$

where $\phi_{t,u,k}$ represents the probability that user u is interested in topic k at time t. t is a discrete variable and can be arbitrarily set as the unit time interval, e.g., at one day or one week. The precision $\alpha_{t,u}$ represents the interest persistence of how consistently user u maintains his/her interests at time t compared with the previous time $t-1$. $\alpha_{t,u}$ is estimated for each time period and each user because interest persistence depends on both time and users. As mentioned above, the current topic trend $\theta_{t,k}$ is drawn from the following Dirichlet distribution with the previous trend $\hat{\theta}_{t-1,k}$

$$p(\theta_{t,k}|\hat{\theta}_{t-1,k},\beta_{t,k}) \propto \prod_v \theta_{t,k,v}^{\beta_{t,k}\hat{\theta}_{t-1,k,v}-1} \quad (3)$$

where $\theta_{t,k,v}$ represents the probability that word v is chosen in topic k at time t.

Here our proposed Twitter-TTM adapts the above TTM assumptions to the improved model. That is, we extend the improved model whereby user interest $\phi_{t,u}$ and topic trend $\theta_{t,k}$ depend on previous states. Time dependency is not considered on θ_B and π_u because they can be regarded as being independent of time.

Figures 3 and 4 show the generative process and a graphical representation of Twitter-TTM, respectively. Twitter-TTM can capture the dynamics of user interests and topic trends in Twitter considering the features of tweets online. Moreover, Twitter-TTM can be extended to capture long-term dependences, as described in Iwata et al. (2009).

3.2 Model Inference

We use a stochastic expectation-maximization algorithm for Twitter-TTM inference, as described in Wallach (2006) in which Gibbs sampling of latent values and maximum joint likelihood estimation of parameters are alternately iterated. At time t, we estimate user interests $\mathbf{\Phi}_t = \{\hat{\phi}_{t,u}\}_{u=1}^U$, topic trends $\mathbf{\Theta}_t = \{\hat{\theta}_{t,k}\}_{k=1}^K$, background word distribution $\theta_{t,B}$, word usage rate distribution $\pi_{t,u}$, interest persistence parameters $\boldsymbol{\alpha_t} = \{\alpha_{t,u}\}_{u=1}^U$, and trend persistence parameters $\boldsymbol{\beta_t} = \{\beta_{t,k}\}_{k=1}^K$ using the previous time interests $\hat{\mathbf{\Phi}}_{t-1}$ and trends $\hat{\mathbf{\Theta}}_{t-1}$.

We employ collapsed Gibbs sampling to infer the latent variables. Let D_t be a set of tweets and Z_t, Y_t be a set of latent variables z, y at time t. We can integrate the parameters in the joint distribu-

tion as follows:

$$
\begin{aligned}
&p(D_t, Y_t, Z_t | \hat{\boldsymbol{\Phi}}_{t-1}, \hat{\boldsymbol{\Theta}}_{t-1}, \boldsymbol{\alpha_t}, \boldsymbol{\beta_t}, \lambda, \gamma) \\
&= \Big(\frac{\Gamma(2\gamma)}{\Gamma(\gamma)^2}\Big)^U \prod_u \frac{\Gamma(\gamma + n_{t,u,B})\Gamma(\gamma + n_{t,u,K})}{\Gamma(2\gamma + n_{t,u})} \\
&\times \frac{\Gamma(V\lambda)}{\Gamma(\lambda)^V} \frac{\prod_v \Gamma(n_{t,B,v} + \lambda)}{\Gamma(n_{t,B} + V\lambda)} \\
&\times \prod_k \frac{\Gamma(\beta_{t,k})}{\Gamma(n_{t,k} + \beta_{t,k})} \prod_v \frac{\Gamma(n_{t,k,v} + \beta_{t,k}\hat{\theta}_{t-1,k,v})}{\Gamma(\beta_{t,k}\hat{\theta}_{t-1,k,v})} \\
&\times \prod_u \frac{\Gamma(\alpha_{t,u})}{\Gamma(c_{t,u} + \alpha_{t,u})} \prod_k \frac{\Gamma(c_{t,u,k} + \alpha_{t,u}\hat{\phi}_{t-1,u,k})}{\Gamma(\alpha_{t,u}\hat{\phi}_{t-1,u,k})},
\end{aligned} \tag{4}
$$

where $n_{t,u,B}$ and $n_{t,u,K}$ are the number of background and topic words of user u at time t, $n_{t,B,v}$ is the number of times that word v is assigned as a background word at time t, $n_{t,k,v}$ is the number of times that word v is assigned to topic k at time t, $c_{t,u,k}$ is the number of tweets assigned to topic k for user u at time t. In addition, $n_{t,u} = n_{t,u,B} + n_{t,uK}$, $n_{t,B} = \sum_v n_{t,B,v}$, $n_{t,K} = \sum_k n_{t,k} = \sum_k \sum_v n_{t,k,v}$, $n_{t,u} = \sum_k n_{t,u,k}$, and $c_{t,u} = \sum_k c_{t,u,k}$.

Given the assignment of all other latent variables, we derive the following formula calculated from eq.(4) to infer a latent topic,

$$
\begin{aligned}
&p(z_i = k | D_t, Y_t, Z_{t\backslash i}, \hat{\boldsymbol{\Phi}}_{t-1}, \hat{\boldsymbol{\Theta}}_{t-1}, \boldsymbol{\alpha_t}, \boldsymbol{\beta_t}) \\
&\propto \frac{c_{t,u,k\backslash i} + \alpha_{t,u}\hat{\phi}_{t-1,u,k}}{c_{t,u\backslash i} + \alpha_{t,u}} \frac{\Gamma(n_{t,k\backslash i} + \beta_{t,k})}{\Gamma(n_{t,k} + \beta_{t,k})} \\
&\times \prod_v \frac{\Gamma(n_{t,k,v} + \beta_{t,k}\hat{\theta}_{t-1,k,v})}{\Gamma(n_{t,k,v\backslash i} + \beta_{t,k}\hat{\theta}_{t-1,k,v})},
\end{aligned} \tag{5}
$$

where $i = (t, u, s)$, thus z_i represents a topic assigned to the s-th tweet of user u at time t, and $\backslash i$ represents a count excluding the i-th tweet.

Then, when $z_i = k$ is given, we derive the following formula to infer a latent variable y_j,

$$
\begin{aligned}
&p(y_j = 0 | D_t, Y_{t\backslash j}, Z_t, \lambda, \gamma) \\
&\propto \frac{n_{t,B,v\backslash j} + \lambda}{n_{t,B\backslash j} + V\lambda} \frac{n_{t,u,B\backslash j} + \gamma}{n_{t,u\backslash j} + 2\gamma},
\end{aligned} \tag{6}
$$

$$
\begin{aligned}
&p(y_j = 1 | D_t, Y_{t\backslash j}, Z_t, \hat{\boldsymbol{\Theta}}_{t-1}, \boldsymbol{\beta_t}, \gamma) \\
&\propto \frac{n_{t,k,v\backslash j} + \beta_{t,k}\hat{\theta}_{t-1,k,v}}{n_{t,k\backslash j} + \beta_{t,k}} \frac{n_{t,u,K\backslash j} + \gamma}{n_{t,u\backslash j} + 2\gamma},
\end{aligned} \tag{7}
$$

where $j = (t, u, s, n)$, thus y_j represents a latent variable assigned to the n-th word in the s-th tweet of user u at time t, and $\backslash j$ represents a count excluding the j-th word.

The persistence parameters $\boldsymbol{\alpha_t}$ and $\boldsymbol{\beta_t}$ are estimated by maximizing the joint likelihood eq.(4), using a fixed point iteration (Minka, 2000). The update formulas are as follows:

$$
\alpha_{t,u}^{new} = \alpha_{t,u} \frac{\sum_k \hat{\phi}_{t-1,u,k} A_{t,u,k}}{\Psi(c_{t,u} + \alpha_{t,u}) - \Psi(\alpha_{t,u})}, \tag{8}
$$

where $A_{t,u,k} = \Psi(c_{t,u,k} + \alpha_{t,u}\hat{\phi}_{t-1,u,k}) - \Psi(\alpha_{t,u}\hat{\phi}_{t-1,u,k})$, and

$$
\beta_{t,k}^{new} = \beta_{t,k} \frac{\sum_v \hat{\theta}_{t-1,k,v} B_{t,k,v}}{\Psi(n_{t,k} + \beta_{t,k}) - \Psi(\beta_{t,k})}, \tag{9}
$$

where $B_{t,k,v} = \Psi(n_{t,k,v} + \beta_{t,k}\hat{\theta}_{t-1,k,v}) - \Psi(\beta_{t,k}\hat{\theta}_{t-1,k,v})$. We can estimate latent variables Z_t, Y_t, and parameters $\boldsymbol{\alpha_t}$ and $\boldsymbol{\beta_t}$ by iterating Gibbs sampling with eq.(5), eq.(6), and eq.(7) and maximum joint likelihood with eq.(8) and eq.(9). After the iterations, the means of $\phi_{t,u,k}$ and $\theta_{t,k,v}$ are obtained as follows.

$$
\hat{\phi}_{t,u,k} = \frac{c_{t,u,k} + \alpha_{t,u}\hat{\phi}_{t-1,u,k}}{c_{t,u} + \alpha_{t,u}}, \tag{10}
$$

$$
\hat{\theta}_{t,k,v} = \frac{n_{t,k,v} + \beta_{t,k}\hat{\theta}_{t-1,k,v}}{n_{t,k} + \beta_{t,k}}. \tag{11}
$$

These estimates are used as the hyper parameters of the prior distributions at the next time period $t + 1$.

4 Related Work

Recently, topic models for Twitter have been proposed. Diao et al. (2012) proposed a topic model that considers both the temporal information of tweets and user's personal interests. They applied their model to find bursty topics from Twitter. Yan et al. (2013) proposed a biterm topic model (BTM), which assumes that a word-pair is independently drawn from a specific topic. They demonstrated that BTM can effectively capture the topics within short texts such as tweets compared with LDA. Chua and Asur (2013) proposed two topic models considering time order and tweet intervals to extract the tweets summarizing a given event. The models mentioned above do not consider the dynamics of user interests, nor

1. Draw $\theta_{t,B}$ ∼Dirichlet(λ)
2. For each topic $k = 1, ..., K$,
   (a) draw $\theta_{t,k}$ ∼Dirichlet($\beta_{t,k}\hat{\theta}_{t-1,k}$)
3. For each user $u = 1, ..., U$,
   (a) draw $\phi_{t,u}$ ∼Dirichlet($\alpha_{t,u}\hat{\phi}_{t-1,u}$)
   (b) draw $\pi_{t,u}$ ∼Beta(γ)
   (c) for each tweet $s = 1, ..., N_u$
      i. draw $z_{t,u,s}$ ∼Multinomial($\phi_{t,u}$)
      ii. for each word $n = 1, ..., N_{u,s}$
         A. draw $y_{t,u,s,n}$ ∼Bernoulli($\pi_{t,u}$)
         B. draw $w_{t,u,s,n}$ ∼ Multinomial($\theta_{t,B}$) if $y_{t,u,s,n} = 0$ or Multinomial($\theta_{t,z_{t,u,s}}$) if $y_{t,u,s,n} = 1$

Figure 3: Generative process of tweets in Twitter-TTM

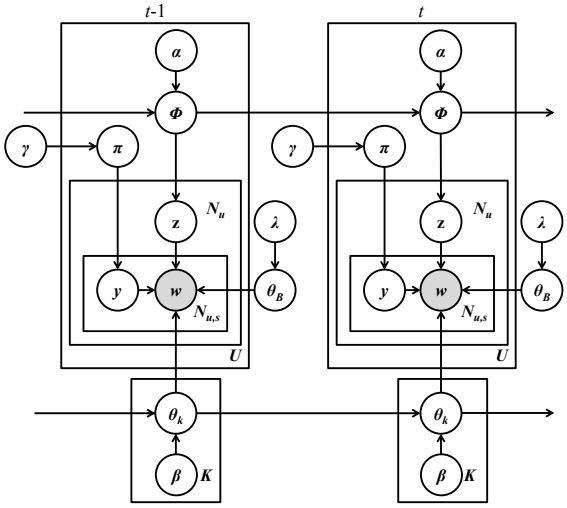


Figure 4: Graphical model of Twitter-TTM

do they have the capability of online inference; thus, they cannot efficiently model the large number of tweets generated everyday, whereas Twitter-TTM can capture the dynamics of user interests and topic trends and has the capability of online inference.

Some online topic models have also been proposed. TM-LDA was proposed by Wang et al. (2012), which can efficiently model online the topics and topic transitions that naturally arise in a tweet stream. Their model learns the transition parameters among topics by minimizing the prediction error on topic distribution in subsequent tweets. However, the TM-LDA does not consider dynamic word distributions. In other words, their model can not capture the dynamics of topic trends. Lau et al. (2012) proposed a topic model implementing a dynamic vocabulary based on online LDA (OLDA) (AlSumait et al., 2008) and applied it to track emerging events on Twitter. An online variational Bayes algorithm for LDA is also proposed (Hoffman et al., 2010). However, these methods are based on LDA and do not consider the shortness of a tweet. Twitter-TTM tackles the shortness of a tweet by assuming that a single tweet consists of a single topic. This assumption is based on the following observation: a tweet is much shorter than a normal document, so a single tweet rarely contains multiple topics but rather a single one.

5 Experiment

5.1 Setting

We evaluated the effectiveness of the proposed Twitter-TTM using an actual Twitter data set. The original Twitter data set contains 15,962 users and 4,146,672 tweets collected from October 18 to 31, 2013. We then removed words that occurred less than 30 times and stop words. After this preprocessing, we obtained the final data set with 15,944 users, 3,679,481 tweets, and 30,096 vocabularies.

We compared the predictive performance of Twitter-TTM with LDA, TTM, Twitter-LDA, Twitter-LDA+TTM, and the improved model based on the perplexity for the next time tweets. Twitter-LDA+TTM is a combination of Twitter-LDA and TTM. It is equivalent to Twitter-TTM, except that the rate between background and topic words is different for each user. We set the number of topics K at 100, the iteration of each model at 500, and the unit time interval at one day. The hyper parameters in these models were optimized in each Gibbs sampling iteration by maximizing likelihood using fixed iterations (Minka, 2000). The inferences of LDA, Twitter-LDA, and the improved model were made for current time tweets.

5.2 Result

Figure 5 shows the perplexity of each model for each time, where $t = 1$ in the horizontal axis represents October 18, $t = 2$ represents October 19, ..., and $t = 13$ represents October 31. The perplexity at time t represents the predictive performance of each model inferred by previous time tweets to

the current time tweets. Note that at $t = 1$, the performance of LDA and TTM, that of Twitter-LDA and Twitter-LDA+TTM, and that of Twitter-TTM and the improved model were found to be equivalent.

As shown in Figure 5(a), the proposed Twitter-TTM shows lower perplexity compared with conventional models, such as LDA, Twitter-LDA, and TTM at any time, which implies that Twitter-TTM can appropriately model the dynamics of user interests and topic trends in Twitter. TTM could not have perplexity lower than LDA although it considers the dynamics. If LDA could not appropriately model the tweets, then the user interests $\hat{\mathbf{\Phi}}_{t-1}$ and topic trends $\hat{\mathbf{\Theta}}_{t-1}$ in the previous time are not estimated well in TTM. Figure 5(b) shows the perplexities of the improved model and Twitter-TTM. From $t = 2$, Twitter-TTM shows lower perplexity than the improved model for each time. The reason for the high perplexity of the improved model is that it does not consider the dynamics. Twitter-TTM also shows lower perplexity than Twitter-LDA+TTM for each time, as shown in Figure 5(c), because Twitter-TTM's assumption that the rate between background and topic words is different for each user is more appropriate, as demonstrated in Section 2.2. These results imply that Twitter-TTM also outperforms other conventional methods, such as DTM, OLDA, and TM-LDA, which do not consider the shortness of a tweet or the dynamics of user interests or topic trends .

Table 3 shows two topic examples of the topic evolution analyzed by Twitter-TTM, and Figure 6 shows the trend persistence parameters β of each topic at each time. The persistence parameters of the topic "Football" are lower than those of "Birthday" because it is strongly affected by trends in the real world. In fact, the top words in "Football" change more dynamically than those of "Birthday." For example, in the "Football" topic, though 'Arsenal' is usually popular, 'Madrid' becomes more popular on October 24.

Figure 5: Perplexity for each time

6 Conclusion

We first proposed an improved model based on Twitter-LDA, which estimates the rate between background and topic words for each user. We demonstrated that the improved model could model tweets more efficiently than LDA and Twitter-LDA. Next we proposed a novel probabilistic topic model for Twitter, called Twitter-TTM, which can capture the dynamics of user interests and topic trends and is capable of online inference. We evaluated Twitter-TTM using an actual Twitter data set and demonstrated that it could model more accurately tweets than conventional

methods.

The proposed method currently needs to predetermine the number of topics each time, and it is fixed. In future work, we plan to extend the proposed method to capture the birth and death of topics along the timeline with a variable number of topics, such as the model proposed by Ahmed (Ahmed and Xing, 2010). We also plan to apply the proposed method to content recommendations and trend analysis in Twitter to investigate this method further.

Abstract

Self-disclosure, the act of revealing oneself to others, is an important social behavior that strengthens interpersonal relationships and increases social support. Although there are many social science studies of self-disclosure, they are based on manual coding of small datasets and questionnaires. We conduct a computational analysis of self-disclosure with a large dataset of naturally-occurring conversations, a semi-supervised machine learning algorithm, and a computational analysis of the effects of self-disclosure on subsequent conversations. We use a longitudinal dataset of 17 million tweets, all of which occurred in conversations that consist of five or more tweets directly replying to the previous tweet, and from dyads with twenty of more conversations each. We develop self-disclosure topic model (SDTM), a variant of latent Dirichlet allocation (LDA) for automatically classifying the level of self-disclosure for each tweet. We take the results of SDTM and analyze the effects of self-disclosure on subsequent conversations. Our model significantly outperforms several comparable methods on classifying the level of self-disclosure, and the analysis of the longitudinal data using SDTM uncovers significant and positive correlation between self-disclosure and conversation frequency and length.

1 Introduction

Self-disclosure is an important and pervasive social behavior. People disclose personal information about themselves to improve and maintain relationships (Jourard, 1971; Joinson and Paine, 2007). A common instance of self-disclosure is the start of a conversation with an exchange of names and additional self-introductions. Another example of self-disclosure, shown in Figure 1c, where the information disclosed about a family member's serious illness, is much more personal than the exchange of names. In this paper, we seek to understand this important social behavior using a large-scale Twitter conversation data, automatically classifying the level of self-disclosure using machine learning and correlating the patterns with conversational behaviors which can serve as proxies for measuring intimacy between two conversational partners.

Twitter conversation data, explained in more detail in section 4.1, enable an extremely large scale study of naturally-occurring self-disclosure behavior, compared to traditional social science studies. One challenge of such large scale study, though, remains in the lack of labeled ground-truth data of self-disclosure level. That is, naturally-occurring Twitter conversations do not come tagged with the level of self-disclosure in each conversation. To overcome that challenge, we propose a semi-supervised machine learning approach using probabilistic topic modeling. Our self-disclosure topic model (SDTM) assumes that self-disclosure behavior can be modeled using a combination of simple linguistic features (e.g., pronouns) with automatically discovered semantic themes (i.e., topics). For instance, an utterance "I am finally through with this disastrous relationship" uses a first-person pronoun and contains a topic about personal relationships.

In comparison with various other models, SDTM shows the highest accuracy, and the resulting conversation frequency and length patterns on self-disclosure are shown different over time. Our contributions to the research community include the following:

*This work was done when JinYeong Bak was a visiting student at Microsoft Research, Beijing, China.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 1986–1996,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

- We present key features and prior knowledge for identifying self-disclosure level, and show relevance of it with experiment results (Sec. 2).
- We present a topic model that explicitly includes the level of self-disclosure in a conversation using linguistic features and the latent semantic topics (Sec. 3).
- We collect a large dataset of Twitter conversations over three years and annotate a small subset with self-disclosure level (Sec. 4).
- We compare the classification accuracy of SDTM with other models and show that it performs the best (Sec. 5).
- We correlate the self-disclosure patterns and conversation behaviors to show that there is significant relationship over time (Sec. 6).

A fabio capello is the manager are u sure its someone else whos playing lol
B common you guys England manager is Roy Hodgson
A noooooo we mean the manager before!
B haha!! the manager before Roy was Fabio yes, Roy became Manager in May after Fabio resigned in February
A ohhhhhhhhhhh we learn something new everyday! Haha

(a) A G level Twitter conversation

A Today's my mother's birthday and she was extremely happy when I informed her I'm applying for Phoenix soon. Happy Bi rthday mom! :D
B HAHA, nice! Tell her I said Happy Birthday and give her a ki ss and hug for me! :3
A that is a bit problematic. My mommy is not here lol
B HAHA! I figured that'd be the case. Well I'm off tomorrow so I guess I'll do it myself tomorrow. XP
A lol She gets home around 6 or 6:30

(b) A M level Twitter conversation

A My mom has just been taken to the hospital by ambulance. Please pray for her. Thank you
B Hugs **A**. Glad your mom is doing better.
A thanks, she is in hospital & is very disoriented.
B My dad was like that when he was in the hospital. Talked to ppl who had been dead for years.
A yeah, she did that too.
it is so scary to see her that way....
B Extra hugs sweetie. I am glad it wasn't a stroke.

(c) A H level Twitter conversation

Figure 1: An example of a Twitter conversation (from annotated dataset) with G, M and H level of self-disclosure.

2 Self-Disclosure

In this section, we look at social science literature for definition of the levels of self-disclosure. Using that definition, we devise an approach to automatically identify the levels of self-disclosure in a large corpus of OSN conversations. We discuss three approaches, first, using first-person pronoun features, and second, extracting seed words and phrases from the Twitter conversation corpus, and third, extracting seed words and phrases from an external corpus of anonymously posted secrets, and we demonstrate the efficacy of those approaches with an annotated corpus.

2.1 Self-disclosure (*SD*) level

To analyze self-disclosure, researchers categorize self-disclosure language into three levels: G (general) for no disclosure, M for medium disclosure, and H for high disclosure (Vondracek and Vondracek, 1971; Barak and Gluck-Ofri, 2007). Utterances that contain general (non-sensitive) information about the self or someone close (e.g., a family member) are categorized as M. Examples are personal events, past history, or future plans. Utterances about age, occupation and hobbies are also included. Utterances that contain sensitive information about the self or someone close are categorized as H. Sensitive information includes personal characteristics, problematic behaviors, physical appearance and wishful ideas. Generally, these are thoughts and information that one would keep as secrets to himself. All other utterances, those that do not contain information about the self or someone close are categorized as G. Examples include gossip about celebrities or factual discourse about current events. Figure 1 shows Twitter conversation examples with G, M and H levels from annotated dataset (see Section 4.2 for a detailed description of the annotated dataset).

2.2 G Level of Self-Disclosure

An obvious clue of self-disclosure is the use of first-person pronouns. For example, phrases such as 'I live' or 'My name is' indicate that the utterance contains personal information. In previous research, the simple method of counting first-person pronouns was used to measure the degree of self-disclosure (Joinson, 2001; Barak and Gluck-Ofri, 2007). Consequently, the absence of a first-person pronoun signals that the utterance belongs in the G level of self-disclosure. We verify this pattern with a dataset of Tweets annotated with G, M, and H levels. We divide the annotated Tweets into two classes, G and M/H. Then we compute mutual information of each unigram, bigram, or trigram feature to see which features are most discriminative. As Table 1 shows, 18 out of 30

Category	Words/Expressions
Unigram	my, I, I'm, I'll, but, was, I've, love, dad, have
Bigram	I love, I was, I have, my dad, go to, my mom, with my, have to, to go, my mum
Trigram	I have a, is going to, to go to, want to go, and I was, going to miss, I love him, I think I, I was like, I wish I

Table 1: High ranked words and expressions by mutual information between G and M/H level in annotated conversations.

Category	Words - SECRET	Words - Annotated
physical appearance	acne, hair, overweight, stomach, chest, hand, scar, thighs, chubby	ankle, face, toe, skin
mental/ physical condition	addicted, bulimia, doctor, illness, alcoholic, disease, drugs, pills	ache, epilepsy, pain, chiropractor, codeine

Table 3: Example words for identifying H level of SD from secret posts (2nd column) and annotated data (3rd column). Categories are hand-labeled.

most highly ranked discriminative features contain a first-person pronoun.

2.3 M Level of Self-Disclosure

Utterances with M level include two types: 1) information related with past events and future plans, and 2) general information about self (Barak and Gluck-Ofri, 2007). For the former, we add as seed trigrams 'I have been' and 'I will'. For the latter, we use seven types of information generally accepted to be personally identifiable information (McCallister, 2010), as listed in the left column of Table 2. To find the appropriate trigrams for those, we take Twitter conversation data (described in Section 4.1) and look for trigrams that begin with 'I' and 'my' and occur more than 200 times. We then check each one to see whether it is related with any of the seven types listed in the table. As a result, we find 57 seed trigrams for M level. Table 2 shows several examples.

Type	Trigram
Name	My name is, My last name
Birthday	My birthday is, My birthday party
Location	I live in, I lived in, I live on
Contact	My email address, My phone number
Occupation	My job is, My new job
Education	My high school, My college is
Family	My dad is, My mom is, My family is

Table 2: Example seed trigrams for identifying M level of SD. There are 51 of these used in SDTM.

2.4 H Level of Self-Disclosure

Utterances with H level express secretive wishes or sensitive information that exposes self or someone close (Barak and Gluck-Ofri, 2007). These are generally kept as secrets. With this intuition, we crawled 26,523 posts from *Six Billion Secrets*[1] site where users post secrets anonymously[2]. We call this external dataset SECRET. Unlike G and M levels, evidence of H level of self-disclosure tends to be topical, such as physical appearance, mental and physical illnesses, and family problems, so we take an approach of fitting a topic model driven by seed words. A similar approach has been successful in sentiment classification (Jo and Oh, 2011; Kim et al., 2013).

A critical component of this approach is the set of seed words with which to drive the discovery of topics that are most indicative of H level self-disclosure. To extract the seed words that express secretive personal information, we compute mutual information (Manning et al., 2008) with SECRET and 24,610 randomly selected tweets. We select 1,000 words with high mutual information and filter out stop words. Table 3 shows some of these words. To extract seed trigrams of secretive wishes, we again look for trigrams that start with 'I' or 'my', occur more than 200 times, and select trigrams of wishful thinking, such as 'I want to', and 'I wish I'. In total, there are 88 seed words and 8 seed trigrams for H.

Since SECRET is quite different from Twitter, we must show that posts in SECRET are semantically similar to the H level Tweets. Rather than directly comparing SECRET posts and Tweets, we use the same method of extracting discriminative word features from the annotated H level Tweets (see Section 4.2). Table 3 shows the seed words extracted from SECRET as well as the annotated Tweets. Because the annotated dataset consists of only 200 conversations, the coverage of the topics seems narrower than the much larger SECRETS, but both datasets show similarities in the topics. This, combined with the results of the model with the two sets of seed words (see Section 5 for the results), shows that SECRETS is an effective and simple-to-obtain substitute for an annotated corpus of H level of self-disclosure.

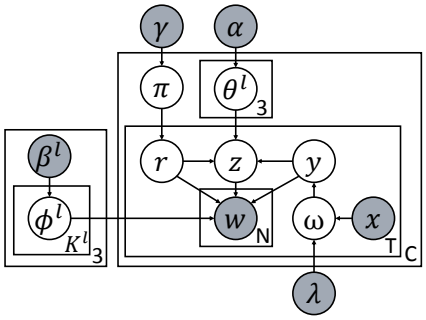

Figure 2: Graphical model of SDTM

Notation	Description
G; M; H	{general; medium; high} SD level
C; T; N	Number of conversations; tweets; words
K^G; K^M; K^H	Number of topics for {G; M; H}
c; ct	Conversation; tweet in conversation c
y_{ct}	SD level of tweet ct, G or M/H
r_{ct}	SD level of tweet ct, M or H
z_{ct}	Topic of tweet ct
w_{ctn}	n^{th} word in tweet ct
$\boldsymbol{\lambda}$	Learned Maximum entropy parameters
$\boldsymbol{x}_{ct}$	First-person pronouns features
$\boldsymbol{\omega}_{ct}$	Distribution over SD level of tweet ct
$\boldsymbol{\pi}_c$	SD level proportion of conversation c
$\boldsymbol{\theta}_c^G$; $\boldsymbol{\theta}_c^M$; $\boldsymbol{\theta}_c^H$	Topic proportion of {G; M; H} in conversation c
$\boldsymbol{\phi}^G$; $\boldsymbol{\phi}^M$; $\boldsymbol{\phi}^H$	Word distribution of {G; M; H}
$\boldsymbol{\alpha}$; $\boldsymbol{\gamma}$	Dirichlet prior for θ; π
$\boldsymbol{\beta}^G$, $\boldsymbol{\beta}^M$; $\boldsymbol{\beta}^H$	Dirichlet prior for ϕ^G; ϕ^M; ϕ^H
n_{cl}	Number of tweets assigned SD level l in conversation c
n_{ck}^l	Number of tweets assigned SD level l and topic k in conversation c
n_{kv}^l	Number of instances of word v assigned SD level l and topic k
m_{ctkv}	Number of instances of word v assigned topic k in tweet ct

Table 4: Summary of notations used in SDTM

3 Self-Disclosure Topic Model

This section describes our model, the self-disclosure topic model (SDTM), for classifying self-disclosure level and discovering topics for each self-disclosure level.

3.1 Model

In section 2, we discussed different approaches to identifying each level of self-disclosure, based on social science literature, annotated and unannotated Tweets, and an external corpus of secret posts. In this section, we describe our self-disclosure topic model, based on the widely used latent Dirichlet allocation (Blei et al., 2003), which incorporates those approaches.

Figure 2 illustrates the graphical model of

1. For each level $l \in \{\texttt{G}, \texttt{M}, \texttt{H}\}$:
   For each topic $k \in \{1, \ldots, K^l\}$:
   Draw $\boldsymbol{\phi}_k^l \sim Dir(\boldsymbol{\beta}^l)$
2. For each conversation $c \in \{1, \ldots, C\}$:
   (a) Draw $\boldsymbol{\theta}_c^G \sim Dir(\boldsymbol{\alpha})$
   (b) Draw $\boldsymbol{\theta}_c^M \sim Dir(\boldsymbol{\alpha})$
   (c) Draw $\boldsymbol{\theta}_c^H \sim Dir(\boldsymbol{\alpha})$
   (d) Draw $\boldsymbol{\pi}_c \sim Dir(\boldsymbol{\gamma})$
   (e) For each message $t \in \{1, \ldots, T\}$:
      i. Observe first-person pronouns features $\boldsymbol{x}_{ct}$
      ii. Draw $\boldsymbol{\omega}_{ct} \sim MaxEnt(\boldsymbol{x}_{ct}, \boldsymbol{\lambda})$
      iii. Draw $y_{ct} \sim Bernoulli(\boldsymbol{\omega}_{ct})$
      iv. If $y_{ct} = 0$ which is G level:
         A. Draw $z_{ct} \sim Mult(\boldsymbol{\theta}_c^G)$
         B. For each word $n \in \{1, \ldots, N\}$:
            Draw word $w_{ctn} \sim Mult(\boldsymbol{\phi}_{z_{ct}}^G)$
      Else which can be M or H level:
         A. Draw $r_{ct} \sim Mult(\boldsymbol{\pi}_c)$
         B. Draw $z_{ct} \sim Mult(\boldsymbol{\theta}_c^{r_{ct}})$
         C. For each word $n \in \{1, \ldots, N\}$:
            Draw word $w_{ctn} \sim Mult(\boldsymbol{\phi}_{z_{ct}}^{r_{ct}})$

Figure 3: Generative process of SDTM.

SDTM and how those approaches are embodied in it. The first approach based on the first-person pronouns is implemented by the observed variable $\boldsymbol{x}_{ct}$ and the parameters $\boldsymbol{\lambda}$ from a maximum entropy classifier for G vs. M/H level. The approach of seed words and phrases for levels M and H is implemented by the three separate word-topic probability vectors for the three levels of SD: $\boldsymbol{\phi}^l$ which has a Bayesian informative prior $\boldsymbol{\beta}^l$ where $l \in \{G, M, H\}$, the three levels of self-disclosure. Table 4 lists the notations used in the model and the generative process, and Figure 3 describes the generative process.

3.2 Classifying G vs M/H levels

Classifying the SD level for each tweet is done in two parts, and the first part classifies G vs. M/H levels with first-person pronouns (*I, my, me*). In the graphical model, y is the latent variable that represents this classification, and $\boldsymbol{\omega}$ is the distribution over y. x is the observation of the first-person pronoun in the tweets, and $\boldsymbol{\lambda}$ are the parameters learned from the maximum entropy classifier. With the annotated Twitter conversation dataset (described in Section 4.2), we experimented with several classifiers (Decision tree, Naive Bayes) and chose the maximum entropy classifier because it performed the best, similar to other joint topic models (Zhao et al., 2010; Mukherjee et al., 2013).

3.3 Classifying M vs H levels

The second part of the classification, the M and the H level, is driven by informative priors with seed words and seed trigrams. In the graphical model, r is the latent variable that represents this classification, and $\boldsymbol{\pi}$ is the distribution over r. $\boldsymbol{\gamma}$ is a non-informative prior for $\boldsymbol{\pi}$, and $\boldsymbol{\beta}^l$ is an informative prior for each SD level by seed words. For example, we assign a high value for the seed word 'acne' for $\boldsymbol{\beta}^H$, and a low value for 'My name is'. This approach is the same as joint models of topic and sentiment (Jo and Oh, 2011; Kim et al., 2013).

3.4 Inference

For posterior inference of SDTM, we use collapsed Gibbs sampling which integrates out latent random variables $\boldsymbol{\omega}, \boldsymbol{\pi}, \boldsymbol{\theta}$, and $\boldsymbol{\phi}$. Then we only need to compute $\boldsymbol{y}, \boldsymbol{r}$ and $\boldsymbol{z}$ for each tweet. We compute full conditional distribution $p(y_{ct} = j', r_{ct} = l', z_{ct} = k' | \boldsymbol{y}_{-ct}, \boldsymbol{r}_{-ct}, \boldsymbol{z}_{-ct}, \boldsymbol{w}, \boldsymbol{x})$ for tweet ct as follows:

$$p(y_{ct} = 0, z_{ct} = k' | \boldsymbol{y}_{-ct}, \boldsymbol{r}_{-ct}, \boldsymbol{z}_{-ct}, \boldsymbol{w}, \boldsymbol{x}) \propto \frac{exp(\boldsymbol{\lambda}_0 \cdot \boldsymbol{x}_{ct})}{\sum_{j=0}^{1} exp(\boldsymbol{\lambda}_j \cdot \boldsymbol{x}_{ct})} \, g(c, t, l', k'),$$

$$p(y_{ct} = 1, r_{ct} = l', z_{ct} = k' | \boldsymbol{y}_{-ct}, \boldsymbol{r}_{-ct}, \boldsymbol{z}_{-ct}, \boldsymbol{w}, \boldsymbol{x}) \propto \frac{exp(\boldsymbol{\lambda}_1 \cdot \boldsymbol{x}_{ct})}{\sum_{j=0}^{1} exp(\boldsymbol{\lambda}_j \cdot \boldsymbol{x}_{ct})} (\gamma_{l'} + n_{cl'}^{(-ct)}) \, g(c, t, l', k'),$$

where $\boldsymbol{z}_{-ct}, \boldsymbol{r}_{-ct}, \boldsymbol{y}_{-ct}$ are $\boldsymbol{z}, \boldsymbol{r}, \boldsymbol{y}$ without tweet ct, $m_{ctk'(\cdot)}$ is the marginalized sum over word v of $m_{ctk'v}$ and the function $g(c, t, l', k')$ as follows:

$$g(c, t, l', k') = \frac{\Gamma(\sum_{v=1}^{V} \beta_v^{l'} + n_{k'v}^{l'-(ct)})}{\Gamma(\sum_{v=1}^{V} \beta_v^{l'} + n_{k'v}^{l'-(ct)} + m_{ctk'(\cdot)})} \left(\frac{\alpha_{k'} + n_{ck'}^{l'(-ct)}}{\sum_{k=1}^{K} \alpha_k + n_{ck}^{l'}} \right) \prod_{v=1}^{V} \frac{\Gamma(\beta_v^{l'} + n_{k'v}^{l'-(ct)} + m_{ctk'v})}{\Gamma(\beta_v^{l'} + n_{k'v}^{l'-(ct)})}.$$

4 Data Collection and Annotation

To test our self-disclosure topic model, we use a large dataset of conversations consisting of Tweets over three years such that we can analyze the relationship between self-disclosure behavior and conversation frequency and length over time. We chose to crawl Twitter because it offers a practical and large source of conversations (Ritter et al., 2010). Others have also analyzed Twitter conversations for natural language and social media research (boyd et al., 2010; Danescu-Niculescu-Mizil et al., 2011), but we collect conversations from the same set of dyads over several months for a unique longitudinal dataset. We also make sure that each conversation is at least five tweets, and that each dyad has at least twenty conversations.

Users	Dyads	Conv's	Tweets
101,686	61,451	1,956,993	17,178,638

Table 5: Dataset of Twitter conversations. We chose conversations consisting of five or more tweets each. We chose dyads with twenty or more conversations.

4.1 Collecting Twitter conversations

We define a Twitter conversation as a chain of tweets where two users are consecutively replying to each other's tweets using the Twitter reply button. We initialize the set of users by randomly sampling thirteen users who reply to other users in English from the Twitter public streams[3]. Then we crawl each user's public tweets, and look at users who are mentioned in those tweets. It is a breadth-first search in the network defined by users as nodes and edges as conversations. We run this search for dyads until the depth of four, and filter out users who tweet in a non-English language. We use an open source tool for detecting English tweets[4]. To protect users' privacy, we replace Twitter userid, usernames and url in tweets with random strings. This dataset consists of 101,686 users, 61,451 dyads, 1,956,993 conversations and 17,178,638 tweets which were posted between August 2007 to July 2013. Table 5 summarizes the dataset.

4.2 Annotating self-disclosure level

To measure the accuracy of our model, we randomly sample 301 conversations, each with ten or fewer tweets, and ask three judges, fluent in English and graduate students/researchers, to annotate each tweet with the level of self-disclosure. Judges first read and discussed the definitions and examples of self-disclosure level shown in (Barak and Gluck-Ofri, 2007), then they worked separately on a Web-based platform.

As a result of annotation, there are 122 G level converstaions, 147 M level and 32 H level con-

[3] https://dev.twitter.com/docs/api/streaming

[4] https://github.com/shuyo/ldig

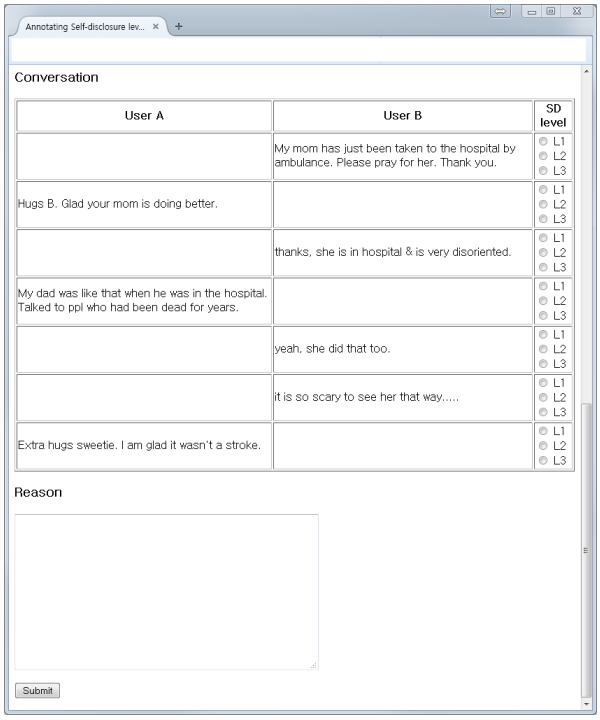

Figure 4: Screenshot of annotation web-based platform. Annotators read a Twitter conversation and annotate self-disclosure level to each tweet.

versations, and inter-rater agreement using Fleiss kappa (Fleiss, 1971) is 0.68, which is substantial agreement result (Landis and Koch, 1977).

5 Classification of Self-Disclosure Level

This section describes experiments and results of SDTM as well as several other methods for classification of self-disclosure level.

We first start with the annotated dataset in section 4.2 in which each tweet is annotated with SD level. We then aggregate all of the tweets of a conversation, and we compute the proportions of tweets in each SD level. When the proportion of tweets at `M` or `H` level is equal to or greater than 0.2, we take the level of the larger proportion and assign that level to the conversation. When the proportions of tweets at `M` or `H` level are both less than 0.2, we assign `G` to the SD level. The reason for setting 0.2 as the threshold is that a conversation containing tweets with `H` or `M` level of self-disclosure usually starts with a greeting or a general comment, and contains one or more questions or comments before or after the self-disclosure tweet.

We compare SDTM with the following methods for classifying conversations for SD level:

- LDA (Blei et al., 2003): A Bayesian topic model. Each conversation is treated as a document. Used in previous work (Bak et al., 2012).
- MedLDA (Zhu et al., 2012): A supervised topic model for document classification. Each conversation is treated as a document and response variable can be mapped to a SD level.
- LIWC (Tausczik and Pennebaker, 2010): Word counts of particular categories[5]. Used in previous work (Houghton and Joinson, 2012).
- Bag of Words + Bigrams + Trigrams (BOW+): A bag of words, bigram and trigram features. We exclude features that appear only once or twice.
- Seed words and trigrams (SEED): Occurrences of seed words/trigrams from SECRET which are described in section 3.3.
- SDTM with seed words from annotated Tweets (SDTM−): To compare with SDTM below using seed words from SECRET, this uses seed words from the annotated data described in section 2.4.
- ASUM (Jo and Oh, 2011): A joint model of sentiments and topics. We map each SD level to one sentiment and use the same seed words/trigrams from SECRET as in SDTM below. Used in previous work (Bak et al., 2012).
- First-person pronouns (FirstP): Occurrence of first-person pronouns which are described in section 3.2. To identify first-person pronouns, we tagged parts of speech in each tweet with the Twitter POS tagger (Owoputi et al., 2013).
- First-person pronouns + Seed words/trigrams (FP+SE1): First-person pronouns and seed words/trigrams from SECRET.
- Two stage classifier with First-person pronouns + Seed words/trigrams (FP+SE2): A

[5]personal pronouns, 3rd person singular words, family words, human words, sexual words, etc

Method	*Acc*	G F_1	M F_1	H F_1	*Avg* F_1
LDA	49.2	0.00	0.65	0.05	0.23
MedLDA	43.3	0.41	0.52	0.09	0.34
LIWC	49.2	0.34	0.61	0.18	0.38
BOW+	54.1	0.50	0.59	0.15	0.41
SEED	54.4	0.52	0.60	0.14	0.42
ASUM	56.6	0.32	0.70	0.38	0.47
SDTM−	60.4	0.57	0.70	0.14	0.47
FirstP	63.2	0.63	0.69	0.10	0.47
FP+SE1	61.0	0.61	0.67	0.16	0.48
FP+SE2	60.4	**0.64**	0.69	0.17	0.50
SDTM	**64.5**	0.61	**0.71**	**0.43**	**0.58**

Table 6: SD level classification accuracies and F-measures using annotated data. *Acc* is accuracy, and G F_1 is F-measure for classifying the G level. *Avg* F_1 is the macroaveraged value of G F_1, M F_1 and H F_1. SDTM outperforms all other methods compared. The difference between SDTM and FirstP is statistically significant (p-value < 0.05 for accuracy, < 0.0001 for *Avg* F_1).

two stage classifier with first-person pronouns and seed words/trigrams from SECRET. In the first stage, the classifier identifies G with first-person pronouns. Then in the second stage, the classifier uses seed words and trigrams to identify M and H levels.

- SDTM: Our model with first-person pronouns and seed words/trigrams from SECRET.

SEED, LIWC, LDA and FirstP cannot be used directly for classification, so we use Maximum entropy model with outputs of each of those models as features[6]. BOW+ uses SVM with a radial basis kernel which performs better than all other settings tried including maximum entropy. We split the data randomly into 80/20 for train/test. We run MedLDA, ASUM and SDTM 20 times each and compute the average accuracies and F-measure for each level. We run LDA and MedLDA with various number of topics from 80 to 140, and 120 topics shows best outputs. So we set 120 topics for LDA, MedLDA and ASUM, 60; 40; 40 topics for SDTM K^G, K^M and K^H respectively which is best perform from 40; 40; 40 to 60; 60; 60 topics. We assume that a conversation has few topics and self-disclosure levels, so we set $\alpha = \gamma = 0.1$ (Tang et al., 2014). To incorporate the seed words and trigrams into ASUM and SDTM, we initialize $\boldsymbol{\beta}^G, \boldsymbol{\beta}^M$ and $\boldsymbol{\beta}^H$ differently. We assign a high value of 2.0 for each seed word and trigram for that level, and a low value of 10^{-6} for each word that is a seed word for another level, and a default value of 0.01 for all other words. This approach is the same as previous papers (Jo and Oh, 2011; Kim et al., 2013).

As Table 6 shows, SDTM performs better than the other methods for accuracy as well as F-measure. LDA and MedLDA generally show the lowest performance, which is not surprising given these models are quite general and not tuned specifically for this type of semi-supervised classification task. BOW which is simple word features also does not perform well, showing especially low F-measure for the H level. LIWC and SEED perform better than LDA, but these have quite low F-measure for G and H levels. ASUM shows better performance for classifying H level than others, confirming the effectiveness of a topic modeling approach to this difficult task, but not as well as SDTM. FirstP shows good F-measure for the G level, but the H level F-measure is quite low, even lower than SEED. Combining first-person pronouns and seed words and trigrams (FP+SE1) shows better than each feature alone, and the two stage classifier (FP+SE2) which is a similar approach taken in SDTM shows better results. Finally, SDTM classifies G and M level at a similar accuracy with FirstP, FP+SE1 and FP+SE2, but it significantly improves accuracy for the H level compared to all other methods.

6 Relations of Self-Disclosure and Conversation Behaviors

In this section, we investigate whether there is a relationship between self-disclosure and conversation behaviors over time. Self-disclosure is one way to maintain and improve relationships (Jourard, 1971; Joinson and Paine, 2007). So two people's intimacy changes over time has relationship with self-disclosure in their conversation. However, it is hard to identify intimacy between users in large scale online social network. So we choose conversation behaviors such as conversation frequency and length which can be treated as proxies for measuring intimacy between two people (Emmers-Sommer, 2004; Bak et al., 2012).

[6]It performs better than other classifiers (C4.5, Naive-Bayes, SVM with linear kernel, polynomial kernel and radial basis)

With SDTM, we can automatically classify the SD level of a large number of conversations, so we investigate whether there is a similar relationship between self-disclosure in conversations and subsequent conversation behaviors with the same partner on Twitter.

For comparing conversation behaviors over time, we divided the conversations into two sets for each dyad. For the $initial$ period, we include conversations from the dyad's first conversation to 20 days later. And for the $subsequent$ period, we include conversations during the subsequent 10 days. We compute proportions of conversation for each SD level for each dyad in the $initial$ and $subsequent$ periods.

More specifically, we ask the following three questions:

1. If a dyad shows high conversation frequency at a particular time period, would they display higher SD in their subsequent conversations?

2. If a dyad displays high SD level in their conversations at a particular time period, would their subsequent conversations be longer?

3. If a dyad displays high overall SD level, would their conversations increase in length over time more than dyads with lower overall SD level?

6.1 Experiment Setup

We first run SDTM with all of our Twitter conversation data with 150; 120; 120 topics for SDTM K^G, K^M and K^H respectively. The hyper-parameters are the same as in section 5. To handle a large dataset, we employ a distributed algorithm (Newman et al., 2009), and run with 28 threads.

Table 7 shows some of the topics that were prominent in each SD level by KL-divergence. As expected, `G` level includes general topics such as food, celebrity, soccer and IT devices, `M` level includes personal communication and birthday, and finally, `H` level includes sickness and profanity.

We define a new measurement, SD level score for a dyad in the period, which is a weighted sum of each conversation with SD levels mapped to 1, 2, and 3, for the levels `G`, `M`, and `H`, respectively.

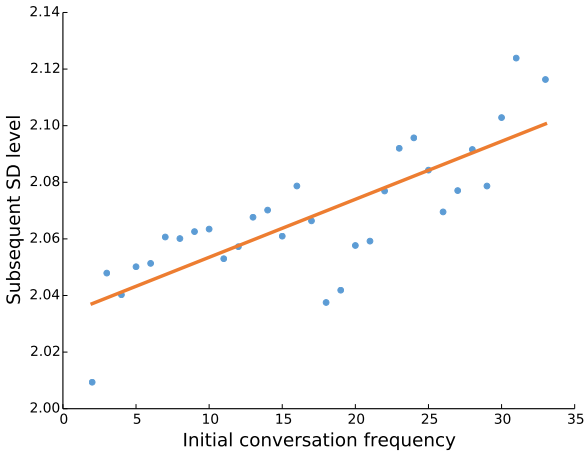

Figure 5: Relationship between initial conversation frequency and subsequent SD level. The solid line is the linear regression line, and the coefficient is 0.0020 with $p < 0.0001$, which shows a significant positive relationship.

6.2 Does high frequency of conversation lead to more self-disclosure?

We investigate whether the $initial$ conversation frequency is correlated with the SD level in the $subsequent$ period. We run linear regression with the initial conversation frequency as the independent variable, and SD level in the subsequent period as the dependent variable.

The regression coefficient is 0.0020 with low p-value ($p < 0.0001$). Figure 5 shows the scatter plot. We can see that the slope of the regression line is positive.

6.3 Does high self-disclosure lead to longer conversations?

Now we investigate the effect of the self-disclosure level to conversation length. We run linear regression with the intial SD level score as the independent variable, and the rate of change in conversation length between $initial$ period and $subsequent$ period as the dependent variable. Conversation length is measured by the number of tweets in a conversation.

The result of regression is that the independent variable's coefficient is 0.048 with a low p-value ($p < 0.0001$). Figure 6 shows the scatter plot with the regression line, and we can see that the slope of regression line is positive.

G level			M level			H level		
101	184	176	36	104	82	113	33	19

Table 7: High ranked topics in each level by comparing KL-divergence with other level's topics

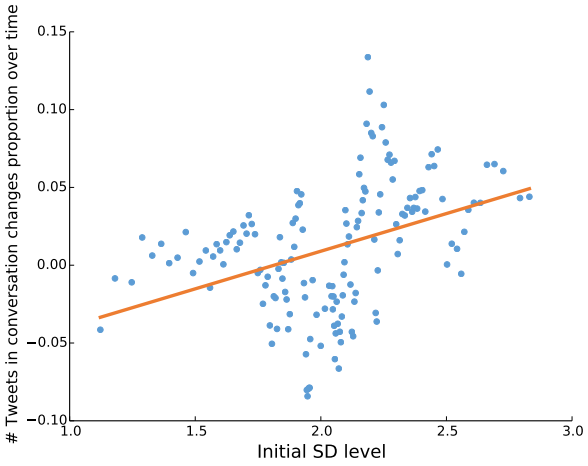

Figure 6: Relationship between initial SD level and conversation length changes over time. The solid line is the linear regression line, and the coefficient is 0.048 with $p < 0.0001$, which shows a significant positive relationship.

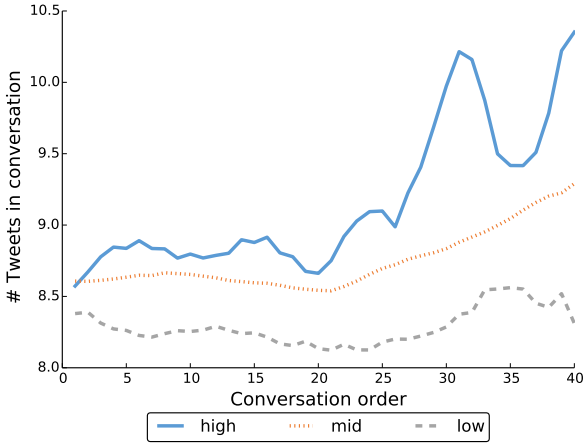

Figure 7: Changes in conversation length over time. We divide dyads into three groups by SD level score as low, medium, and high. Conversation length noticeably increases over time in the medium and high groups, but only slight in the low group.

6.4 Is there a difference in conversation length patterns over time depending on overall SD level?

Now we investigate the conversation length changes over time with three groups, low, medium, and high, by overall SD level. Then we investigate changes in conversation length over time.

Figure 7 shows the results of this investigation. First, conversations are generally lengthier when SD level is high. This phenomenon is also observed in figure 6, but here we can see it as a long-term persistent pattern. Second, conversation length increases consistently and significantly for the high and medium groups, but for the low SD group, there is not a significant increase of conversation length over time.

7 Related Work

Prior work on quantitatively analyzing self-disclosure has relied on user surveys (Ledbetter et

al., 2011; Trepte and Reinecke, 2013) or human annotation (Barak and Gluck-Ofri, 2007; Courtney Walton and Rice, 2013). These methods consume much time and effort, so they are not suitable for large-scale studies. In prior work closest to ours, Bak et al. (2012) showed that a topic model can be used to identify self-disclosure, but that work applies a two-step process in which a basic topic model is first applied to find the topics, and then the topics are post-processed for binary classification of self-disclosure. We improve upon this work by applying a single unified model of topics and self-disclosure for high accuracy in classifying the three levels of self-disclosure.

Subjectivity which is aspect of expressing opinions (Pang and Lee, 2008; Wiebe et al., 2004) is related with self-disclosure, but they are different dimensions of linguistic behavior. Because there indeed are many high self-disclosure tweets that are subjective, but there are also counter examples in annotated dataset. The tweet "England manager is Roy Hodgson." is low self-disclosure and low subjectivity, "I have barely any hair left." is high self-disclosure but low subjectivity, and "Senator stop lying!" is low self-disclosure but high subjectivity.

8 Conclusion and Future Work

In this paper, we have presented the self-disclosure topic model (SDTM) for discovering topics and classifying SD levels from Twitter conversation data. We devised a set of effective seed words and trigrams, mined from a dataset of secrets. We also annotated Twitter conversations to make a ground-truth dataset for SD level. With annotated data, we showed that SDTM outperforms previous methods in classification accuracy and F-measure. We publish the source code of SDTM and the dataset include annotated Twitter conversations and SECRET publicly[7].

We also analyzed the relationship between SD level and conversation behaviors over time. We found that there is a positive correlation between initial SD level and subsequent conversation length. Also, dyads show higher level of SD if they initially display high conversation frequency. Finally, dyads with overall medium and high SD level will have longer conversations over time. These results support previous results in social psychology research with more robust results from a large-scale dataset, and show the effectiveness of computationally analyzing at SD behavior.

There are several future directions for this research. First, we can improve our modeling for higher accuracy and better interpretability. For instance, SDTM only considers first-person pronouns and topics. Naturally, there are other linguistic patterns that can be identified by humans but not captured by pronouns and topics. Second, the number of topics for each level is varied, and so we can explore nonparametric topic models (Teh et al., 2006) which infer the number of topics from the data. Third, we can look at the relationship between self-disclosure behavior and general online social network usage beyond conversations. We will explore these directions in our future work.

Abstract

Social media websites provide a platform for anyone to describe significant events taking place in their lives in realtime. Currently, the majority of personal news and life events are published in a textual format, motivating information extraction systems that can provide a structured representations of major life events (weddings, graduation, etc...). This paper demonstrates the feasibility of accurately extracting major life events. Our system extracts a fine-grained description of users' life events based on their published tweets. We are optimistic that our system can help Twitter users more easily grasp information from users they take interest in following and also facilitate many downstream applications, for example realtime friend recommendation.

1 Introduction

Social networking websites such as Facebook and Twitter have recently challenged mainstream media as the freshest source of information on important news events. In addition to an important source for breaking news, social media presents a unique source of information on private events, for example a friend's engagement or college graduation (examples are presented in Figure 1). While a significant amount of previous work has investigated event extraction from Twitter (e.g., (Ritter et al., 2012; Diao et al., 2012)), existing approaches mostly focus on public bursty event extraction, and little progress has been made towards the problem of automatically extracting the major life events of ordinary users.

A system which can automatically extract major life events and generate fine-grained descriptions as in Figure 1 will not only help Twitter users with the problem of information overload by summarizing important events taking place in their friends lives, but could also facilitate downstream applications such as friend recommendation (e.g., friend recommendation in realtime to people who were just admitted into the same university, get the same jobs or internships), targeted online advertising (e.g., recommend baby care products to newly expecting mothers, or wedding services to new couples), information extraction, etc.

Before getting started, we first identify a number of key challenges in extracting significant life events from user-generated text, which account the reason for the lack of previous work in this area:

Challenge 1: Ambiguous Definition for Major Life Events Major life event identification is an open-domain problem. While many types of events (e.g., marriage, engagement, finding a new job, giving birth) are universally agreed to be important, it is difficult to robustly predefine a list of characteristics for important life events on which algorithms can rely for extraction or classification.

Challenge 2: Noisiness of Twitter Data: The user-generated text found in social media websites such as Twitter is extremely noisy. The language used to describe life events is highly varied and ambiguous and social media users frequently discuss public news and mundane events from their daily lives, for instance what they ate for lunch.

Even for a predefined life event category, such as marriage, it is still difficult to accurately identify mentions. For instance, a search for the keyphrase "get married" using Twitter Search[1] results in a large number of returned results that do not correspond to a personal event:

- I want to **get married** once. No divorce & no cheating, just us two till the end.
  (error: wishes)

[1]https://twitter.com/search?q=get~married

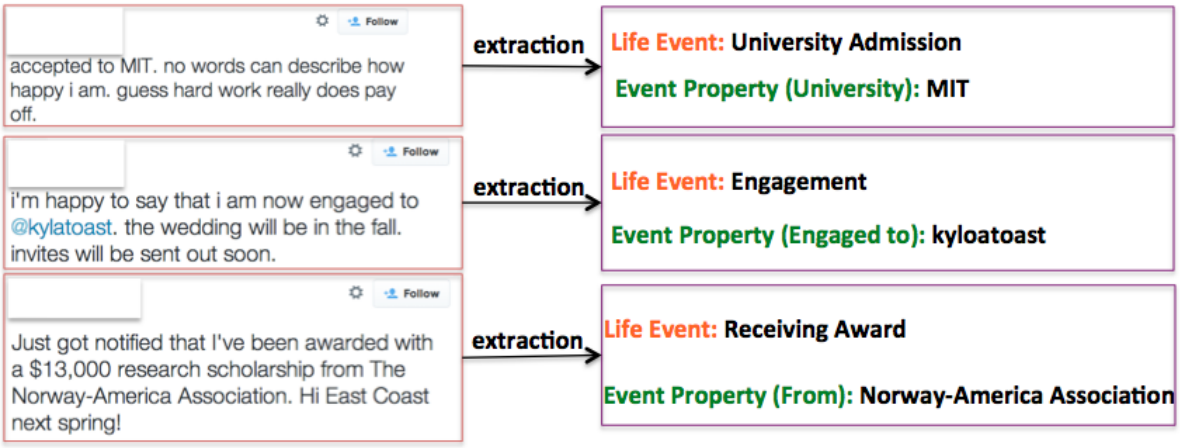

Figure 1: Examples of users mentioning personal life events on Twitter.

- Can Adam Sandler and Drew Barrymore just drop the pretense and **get married** already? (error: somebody else)
- I **got married** and had kids on purpose (error: past)

Challenge 3: the Lack of Training Data Collecting sufficient training data in this task for machine learning models is difficult for a number of reasons: (1) A traditional, supervised learning approach, requires explicit annotation guidelines for labeling, though it is difficult to know which categories are most representative in the data apriori. (2) Unlike public events which are easily identified based on message volume, significant private events are only mentioned by one or several users directly involved in the event. Many important categories are relatively infrequent, so even a large annotated dataset may contain just a few or no examples of these categories, making classification difficult.

In this paper, we present a pipelined system that addresses these challenges and extracts a structured representation of individual life events based on users' Twitter feeds. We exploit the insight to automatically gather large volumes of major life events which can be used as training examples for machine learning models. Although personal life events are difficult to identify using traditional approaches due to their highly diverse nature, we noticed that users' followers often directly reply to such messages with CONGRATULATIONS or CONDOLENCES speech acts, for example:

User1: *I got accepted into Harvard !*
User2: *Congratulations !*

These speech acts are easy to identify with high precision because the possible ways to express them are relatively constrained. Instead of directly inspecting tweets to determine whether they correspond to major life events, we start by identifying replies corresponding to CONGRATULATIONS or CONDOLENCES, and then retrieve the message they are in response to, which we assume refer to important life events.

The proposed system automatically identifies major life events and then extracts correspondent event properties. Through the proposed system, we demonstrate that it is feasible to automatically reconstruct a detailed list of individual life events based on users' Twitter streams. We hope that work presented in this paper will facilitate downstream applications and encourage follow-up work on this task.

2 System Overview

An overview of the components of the system is presented in Figure 2. **Pipeline1** first identifies the major life event category the input tweet talks about and filters out the irrelevant tweets and will be described in Section 4. Next, **Pipeline2**, as, demonstrated in Section 5, identifies whether the speaker is directly involved in the life event. Finally, **Pipeline3** extracts the property of event and will be illustrated in Section 6.

Section 3 serves as the preparing step for the pipelined system, describing how we collect training data in large-scale. The experimental evaluation regarding each pipeline of the system is presented in the corresponding section (i.e., Section 4,5,6) and the end-to-end evaluation will be pre-

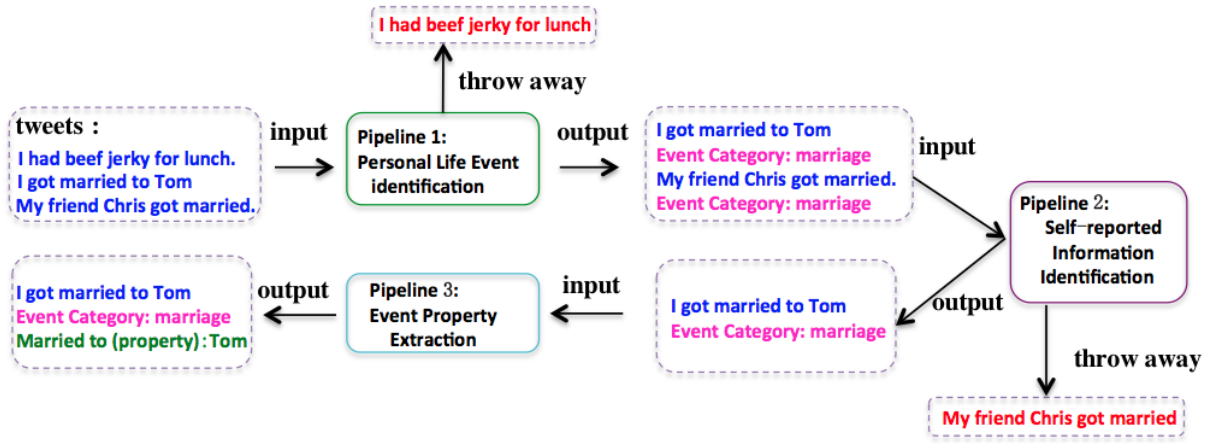

Figure 2: System Overview. Blue: original input tweets. Red: filtered out tweets. Magenta: life event category. Green: life event property. **Pipeline 1** identifies the life category the input tweet talks about (e.g., marriage, graduation) and filter out irrelevant tweets (e.g., I had beef stick for lunch). **Pipeline 2** identifies whether the speaker is directly involved in the event. It will preserve self-reported information (i.e. "I got married") and filtered out unrelated tweets (e.g., "my friend Chris got married"). **Pipeline 3** extracts the property of event (e.g. to whom the speaker married or the speaker admitted by which university).

sented in Section 7.

3 Personal Life Event Clustering

In this section, we describe how we identify common categories of major life events by leveraging large quantities of unlabeled data and obtain a collection of tweets corresponding to each type of identified event.

3.1 Response based Life Event Detection

While not all major life events will elicit CONGRATULATIONS or CONDOLENCES from a user's followers, this technique allows us to collect large volumes of high-precision personal life events which can be used to train models to recognize the diverse categories of major life events discussed by social media users.

3.2 Life Event Clustering

Based on the above intuition, we develop an approach to obtain a list of individual life event clusters. We first define a small set of seed responses which capture common CONGRATULATIONS and CONDOLENCES, including the phrases: "Congratulations", "Congrats", "Sorry to hear that", "Awesome", and gather tweets that were observed with seed responses. Next, an LDA (Blei et al., 2003)[2] based topic model is used to cluster the gathered tweets to automatically identify important categories of major life events in an unsupervised way. In our approach, we model the whole conversation dialogue as a document[3] with the response seeds (e.g., congratulation) masked out. We furthermore associate each sentence with a single topic, following strategies adopted by (Ritter et al., 2010; Gruber et al., 2007). We limit the words in our document collection to verbs and nouns which we found to lead to clearer topic representations, and used collapsed Gibbs Sampling for inference (Griffiths and Steyvers, 2004).

Next one of the authors manually inspected the resulting major life event types inferred by the model, and manually assigned them labels such as "getting a job", "graduation" or "marriage" and discarded incoherent topics[4]. Our methodology is inspired by (Ritter et al., 2012) that uses a LDA-CLUSTERING+HUMAN-IDENTIFICATION strategy to identify public events from Twitter. Similar strategies have been widely used in unsupervised information extraction (Bejan et al., 2009; Yao et al., 2011) and selectional preference

[2]Topic Number is set to 120.

[3]Each whole conversation usually contains multiple tweets and users.

[4]While we applied manual labeling and coherence evaluation in this work, an interesting direction for future work is automatically labeling major life event categories following previous work on labeling topics in traditional document-based topic models (Mimno et al., 2011; Newman et al., 2010).

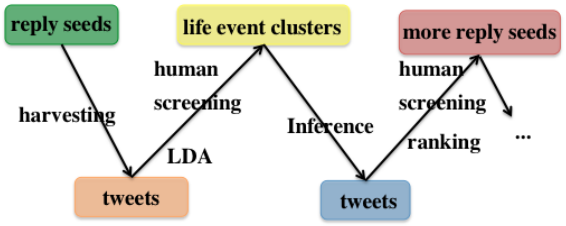

Figure 3: Illustration of bootstrapping process.

Input: Reply seed list $E = \{e\}$, Tweet conversation collection $T = \{t\}$, Retrieved Tweets Collection $D = \phi$. Identified topic list L=ϕ
Begin
While not stopping:

1. For unprocessed conversation $t \in T$ if t contains reply $e \in E$,
   - add t to D: $D = D + t$.
   - remove t from T: $T = T - t$
2. Run streaming LDA (Yao et al., 2009) on newly added tweets in D.
3. Manually Identify meaningful/trash topics, giving label to meaningful topics.
4. Add newly detected meaningful topic l to L.
5. For conversation t belonging to trash topics
   - remove t from D: $D = D - t$
6. Harvest more tweets based on topic distribution.
7. Manually identify top 20 responses to tweets harvested from Step 6.
8. Add meaningful responses to E.

End
Output: Identified topic list L. Tweet collection D.

Figure 4: Bootstrapping Algorithm for Response-based Life event identification.

modeling (Kozareva and Hovy, 2010a; Roberts and Harabagiu, 2011).

Conversation data was extracted from the CMU Twitter Warehouse of 2011 which contains a total number of 10% of all published tweets in that year.

3.3 Expanding dataset using Bootstrapping

While our seed patterns for identifying messages expressing CONGRATULATIONS and CONDOLENCES are very high precision, they don't cover all the possible ways these speech acts can be expressed. We therefore adopt a semi-supervised bootstrapping approach to expand our reply seeds and event-related tweets. Our bootstrapping approach is related to previous work on semi-supervised information harvesting (e.g., (Kozareva and Hovy, 2010b; Davidov et al., 2007)). To preserve the labeled topics from the first iteration, we apply a streaming approach to inference (Yao et al., 2009) over unlabeled tweets (those which did not match one of the response

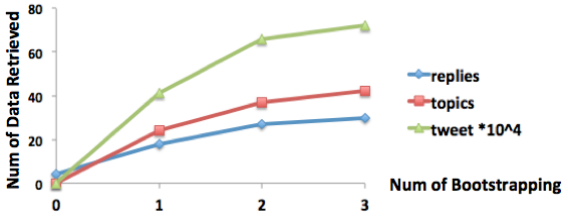

Figure 5: Illustration of data retrieved in each step of bootstrapping.

congratulations (cong, congrats); (that's) fantastic; (so) cool; (I'm) (very) sorry to hear that; (that's) great (good) new; awesome; what a pity; have fun; great; that sucks; too bad; (that's) unfortunate; how sad; fabulous; (that's) terrific; (that's) (so) wonderful; my deepest condolences;

Table 1: Responses retrieved from Bootstrapping.

seeds). We collect responses to the newly added tweets, then select the top 20 frequent replies[5]. Next we manually inspect and filter the top ranked replies, and use them to harvest more tweets. This process is then repeated with another round of inference in LDA including manual labeling of newly inferred topics, etc... An illustration of our approach is presented in Figure 3 and the details are presented in Figure 4. The algorithm outputs a collection of personal life topics L, and a collection of retrieved tweets D. Each tweet $d \in D$ is associated with a life event topic l, $l \in L$.

We repeat the bootstrapping process for 4 iterations and end up with 30 different CONGRATULATIONS and CONDOLENCES patterns (shown in Table 1) and 42 coherent event types which refer to significant life events (statistics for harvested data from each step is shown in Figure 5). We show examples of the mined topics with correspondent human labels in Table 3, grouped according to a specific kind of resemblance.

3.4 Summary and Discussion

The objective of this section is (1) identifying a category of life events (2) identifying tweets associated with each event type which can be used as candidates for latter self reported personal information and life event category identification.

We understand that the event list retrieved from our approach based on replies in the conversation is far from covering all types of personal events (especially the less frequent life events). But our

[5]We only treat the first sentence that responds to the beginning of the conversation as replies.

Life Event	Proportion

Table 2: List of automatically discovered life event types with percentage (%) of data covered.

list is still able to cover a large proportion of IMPORTANT and COMMON life events. Our latter work is focused on given a random tweet, identifying whether it corresponds to one of the 42 types of life events in our list.

Another thing worth noting here is that, while current section is not focused on self-reported information identification, we have already obtained a relatively clean set of data with a large proportion of non self-reported information related tweets being screened: people do not usually respond to non self-reported information with commonly used replies, or in other words, with replies that will pass our next step human test[6]. These non self-reported tweets would therefore be excluded from training data.

4 Life Event Identification

In this section, we focused on deciding whether a given tweet corresponds to one of the 42 predefined life events.

Our training dataset consists of approximately 72,000 tweets from 42 different categories of life events inferred by our topic model as described in Section 3. We used the top 25% of tweets for which our model assigned highest probability to each topic. For sparsely populated topics we used the top 50% of tweets to ensure sufficient coverage.

We further collected a random sample of about 10 million tweets from Twitter API[7] as non-life

[6]For example, people don't normally respond to "I want to **get married** once" (example in Challenge 2, Section 1) with "Congratulations".

Human Label	Top words
Wedding &engagement	wedding, love, ring, engagement, engaged, bride, video, marrying
Relationship Begin	boyfriend, girlfriend, date, check, relationship, see, look
Anniversary	anniversary, years, year, married, celebrating, wife, celebrate, love
Relation End/ Devoice	relationship, ended, hurt, hate, devoice, blessings, single
Graduation	graduation, school, college, graduate, graduating, year, grad
Admission	admitted, university, admission, accepted, college, offer, school
Exam	passed, exam, test, school, semester, finished, exams, midterms
Research	research, presentation, journalism, paper, conference, go, writing
Essay & Thesis	essay, thesis, reading, statement, dissertation, complete, project
Job	job, accepted, announce, join, joining, offer, starting, announced, work
Interview& Internship	interview, position, accepted, internship, offered, start, work
Moving	house, moving, move, city, home, car, place, apartment, town, leaving
Travel	leave, leaving, flight, home, miss, house, airport, packing, morning
Vacation	vocation, family, trip, country, go, flying, visited, holiday, Hawaii
Winning Award	won, award, support, awards, winning, honor, scholarship, prize
Election/ Promotion/ Nomination	president, elected, run, nominated, named, promotion, cel, selected, business, vote
Publishing	book, sold, writing, finished, read, copy, review, release, books, cover
Contract	signed, contract, deal, agreements, agreed, produce, dollar, meeting
song/ video/ album release	video, song, album, check, show, see, making, radio, love
Acting	play, role, acting, drama, played, series, movie, actor, theater
Death	dies, passed, cancer, family, hospital, dad, grandma, mom, grandpa
Give Birth	baby, born, boy, pregnant, girl, lbs, name, son, world, daughter, birth
Illness	ill, hospital, feeling, sick, cold, flu, getting, fever, doctors, cough
Surgery	surgery, got, test, emergency, blood, tumor, stomachs, hospital, pain, brain
Sports	win, game, team, season, fans, played, winning, football, luck
Running	run, race, finished, race, marathon, ran, miles, running, finish, goal
New Car	car, buy, bought, cars, get, drive, pick, seat, color, dollar, meet
Lost Weight	weight, lost, week, pounds, loss, weeks, gym, exercise, running
Birthday	birthday, come, celebrate, party, friends, dinner, tonight, friend
Lawsuit	sue, sued, file, lawsuit, lawyer, dollars, illegal, court, jury.

Table 3: Example event types with top words discovered by our model.

event examples and trained a 43-class maximum entropy classifier based on the following features:

- **Word**: The sequence of words in the tweet.
- **NER**: Named entity Tag.
- **Dictionary**: Word matching a dictionaries of the top 40 words for each life event category (automatically inferred by the topic model). The feature value is the term's probability generated by correspondent event.
- **Window**: If a dictionary term exists, left and right context words within a window of 3 words and their part-of-speech tags.

Name entity tag is assigned from Ritter et al's Twitter NER system (Ritter et al., 2011). Part-of-Speech tags are assigned based on Twitter POS package (Owoputi et al., 2013) developed by CMU ARK Lab. **Dictionary** and **Window** are constructed based on the topic-term distribution obtained from the previous section.

The average precision and recall are shown in Table 4. And as we can observe, the dictionary (with probability) contributes a lot to the performance and by taking into account a more comprehensive set of information around the key word, classifier on **All** feature setting generate significantly better performance, with 0.382 prevision and 0.48 recall, which is acceptable considering (1) This is is a 43-way classification with much more negative data than positive (2) Some types of events are very close to each other (e.g., Leaving and Vocation). Note that recall is valued more than precision here as false-positive examples will be further screened in self-reported information identification process in the following section.

Feature Setting	Precision	Recall
Word+NER	0.204	0.326
Word+NER+Dictionary	0.362	0.433
All	0.382	0.487

Table 4: Average Performance of Multi-Class Classifier on Different Feature Settings. Negative examples (non important event type) are not considered.

5 Self-Reported Information Identification

Although a message might refer to a topic corresponding to a life event such as marriage, the event still might be one in which the speaker is not directly involved. In this section we describe the self reported event identification portion of our pipeline, which takes output from Section 4 and further identifies whether each tweet refers to an event directly involving the user who publishes it.

Direct labeling of randomly sampled Twitter messages is infeasible for the following reasons: (1) Class imbalance: self-reported events are relatively rare in randomly sampled Twitter messages. (2) A large proportion of self-reported information refers to mundane, everyday topics (e.g., "I just finished dinner!"). Fortunately, many of the tweets retrieved from Section 3 consist of self-reported information and describe major life events. The candidates for annotation are therefore largely narrowed down.

We manually annotated 800 positive examples of self-reported events distributed across the event categories identified in Section 3. We ensured good coverage by first randomly sampling 10 examples from each category, the remainder were sampled from the class distribution in the data. Negative examples of self-reported information consisted of a combination of examples from the original dataset[8] and randomly sampled messages gathered by searching for the top terms in each of the pre-identified topics using the Twitter Search interface [9]. Due to great varieties of negative scenarios, the negative dataset constitutes about 2500 tweets.

5.1 Features

Identifying self-reported tweet requires sophisticated feature engineering. Let u denote the term within the tweet that gets the highest possibility generated by the correspondent topic. We experimented with combinations of the following types of features (results are presented in Table **??**):

- **Bigram**: Bigrams within each tweet (punctuation included).
- **Window**: A window of $k \in \{0, 1, 2\}$ words adjacent to u and their part-of-speech tags.
- **Tense**: A binary feature indicating past tense identified in by the presence of past tense verb (VBD).
- **Factuality**: Factuality denotes whether one expression is presented as corresponding to real situations in the world (Saurí and Pustejovsky, 2007). We use Stanford PragBank[10],

[8] Most tweets in the bootstrapping output are positive.

[9] The majority of results returned by Twitter Search are negative examples.

[10] http://compprag.christopherpotts.net/factbank.html

an extension of FactBank (Saurí and Pustejovsky, 2009) which contains a list of modal words such as "might", "will", "want to" etc[11].

- **I**: Whether the subject of the tweet is first person singular.
- **Dependency**: If the subject is first person singular and the u is a verb, the dependency path between the subject and u (or non-dependency).

Tweet dependency paths were obtained from (Kong et al., 2014). As the tweet parser we use only supports one-to-one dependency path identification but no dependency properties, **Dependency** is a binary feature. The subject of each tweet is determined by the dependency link to the root of the tweet from the parser.

Among the features we explore, **Word** encodes the general information within the tweet. **Window** addresses the information around topic key word. The rest of the features specifically address each of the negative situations described in Challenge 2, Section 1: **Tense** captures past event description, **Factuality** filters out wishes or imagination, **I** and **Dependency** correspond to whether the described event involves the speaker. We built a linear SVM classifier using SVM$_{light}$ package (Joachims, 1999).

5.2 Evaluation

Feature Setting	Acc	Pre	Rec
Bigram+Window	0.76	0.47	0.44
Bigram+Window +Tense+Factuality	0.77	0.47	0.46
all	0.82	0.51	0.48

Table 5: Performance for self-report information identification regarding different feature settings.

We report performance on the task of identifying self-reported information in this subsection. We employ 5-fold cross validation and report Accuracy (Accu), Prevision (Prec) and Recall (Rec) regarding different feature settings. The **Tense**, **Factuality**, **I** and **Dependency** features positively contribute to performance respectively and the best performance is obtained when all types of features are included.

[11]Due to the colloquial property of tweets, we also introduced terms such as "gonna", "wanna", "bona".

precision	recall	F1
0.82	0.86	0.84

Table 7: Performance for identifying properties.

6 Event Property Extraction

Thus far we have described how to automatically identify tweets referring to major life events. In addition, it is desirable to extract important properties of the event, for example the name of the university the speaker was admitted to (See Figure 1). In this section we take a supervised approach to event property extraction, based on manually annotated data for a handfull of the major life event categories automatically identified by our system. While this approach is unlikely to scale to the diversity of important personal events Twitter users are discussing, our experiments demonstrate that event property extraction is indeed feasible.

We cast the problem of event property extraction as a sequence labeling task, using Conditional Random Fields (Lafferty et al., 2001) for learning and inference. To make best use of the labeled data, we trained a unified CRF model for closely related event categories which often share properties; the full list is presented in Table 6 and we labeled 300 tweets in total. Features we used include:

- word token, capitalization, POS
- left and right context words within a window of 3 and the correspondent part-of-speech tags
- word shape, NER
- a gazetteer of universities and employers borrowed from NELL[12].

We use 5-fold cross-validation and report results in Table 7.

7 End-to-End Experiment

The evaluation for each part of our system has been demonstrated in the corresponding section. We now present a real-world evaluation: to what degree can our trained system automatically identify life events in real world.

7.1 Dataset

We constructed a gold-standard life event dataset using annotators from Amazon's Mechanical Turk (Snow et al., 2008) using 2 approaches:

[12]http://rtw.ml.cmu.edu/rtw/kbbrowser/

Life Event	Property
(a) Acceptance, Graduation	Name of University/College
(b) Wedding, Engagement, Falling love	Name of Spouse/ partner/ bf/ gf
(c) Getting a job, interview, internship	Name of Enterprise
(d) Moving to New Places, Trip, Vocation, Leaving	Place, Origin, Destination
(e) Winning Award	Name of Award, Prize

Table 6: Labeling Event Property.

- Ask Twitter users to label their own tweets (Participants include friends, colleagues of the authors and Turkers from Amazon Mechanical Turk[13]).
- Ask Turkers to label other people's tweets.

For option 1, we asked participants to directly label their own published tweets. For option 2, for each tweet, we employed 2 Turkers. Due to the ambiguity in defining life events, the value cohen's kappa[14] as a measure of inter-rater agreement is 0.54; this does not show significant inter-annotator agreement. The authors examined disagreements and also verified all positively labeled tweets. The resulting dataset contains around 900 positive tweets and about 60,000 negative tweets.

To demonstrate the advantage of leveraging large quantities of unlabeled data, the first baseline we investigate is a **Supervised** model which is trained on the manually annotated labeled dataset, and evaluated using 5 fold cross validation. Our **Supervised** baseline consists of a linear SVM classifier using bag of words, NER and POS features. We also tested a second baseline that combines **Supervised** algorithm with an our self-reported information classifier, denoted as **Supervised+Self**.

Results are reported in Table 8; as we can observe, the fully supervised approach is not suitable for this task with only one digit F1 score. The explanations are as follows: (1) the labeled data can only cover a small proportion of life events (2) supervised learning does not separate important event categories and will therefore classify any tweet with highly weighted features (e.g., the mention of "I" or "marriage") as positive. By using an additional self-reported information classifier in **Supervised+Self**, we get a significant boost in precision with a minor recall loss.

[13] https://www.mturk.com/mturk/welcome

[14] http://en.wikipedia.org/wiki/Cohen's_kappa

Approach	Precision	Recall
Our approach	0.62	0.48
Supervised	0.13	0.20
Supervised+Self	0.25	0.18

Table 8: Performance for different approaches for identifying life events in real world.

Approach	Precision	Recall
Step 1	0.65	0.36
Step 2	0.64	0.43
Step 3	0.62	0.48

Table 9: Performance for different steps of bootstrapping for identifying life events in real world.

Another interesting question is to what degree the bootstrapping contributes to the final results. We keep the self-reported information classifier fixed (though it's based the ultimate identified data source), and train the personal event classifier based on topic distributions identified from each of the three steps of bootstrapping[15]. Precision and recall at various stages of bootstrapping are presented in Table 9. As bootstrapping continues, the precision remains roughly constant, but recall increases as more life events and CONGRATULATIONS and CONDOLENCES are discovered.

8 Related Work

Our work is related to three lines of NLP researches. (1) user-level information extraction on social media (2) public event extraction on social media. (3) Data harvesting in Information Extraction, each of which contains large amount of related work, to which we can not do fully justice.

User Information Extraction from Twitter Some early approaches towards understanding user level information on social media is focused on user profile/attribute prediction (e.g.,(Ciot et al., 2013)) user-specific content extraction (Diao

[15] which are 24, 38, 42-class classifiers, where 24, 38, 42 denoted the number of topics discovered in each step of bootstrapping (see Figure 5).

et al., 2012; Diao and Jiang, 2013; Li et al., 2014) or user personalization (Low et al., 2011) identification.

The problem of user life event extraction was first studied by Li and Cardie's (2014). They attempted to construct a chronological timeline for Twitter users from their published tweets based on two criterion: a personal event should be personal and time-specific. Their system does not explicitly identify a global category of life events (and tweets discussing correspondent event) but identifies the topics/events that are personal and time-specific to a given user using an unsupervised approach, which helps them avoids the nuisance of explicit definition for life event characteristics and acquisition of labeled data. However, their system has the short-coming that each personal topic needs to be adequately discussed by the user and their followers in order to be detected[16].

Public Event Extraction from Twitter Twitter serves as a good source for event detection owing to its real time nature and large number of users. These approaches include identifying bursty public topics (e.g.,(Diao et al., 2012)), topic evolution (Becker et al., 2011) or disaster outbreak (Sakaki et al., 2010; Li and Cardie, 2013) by spotting the increase/decrease of word frequency. Some other approaches are focused on generating a structured representation of events (Ritter et al., 2012; Benson et al., 2011).

Data Acquisition in Information Extraction Our work is also related with semi-supervised data harvesting approaches, the key idea of which is that some patterns are learned based on seeds. They are then used to find additional terms, which are subsequently used as new seeds in the patterns to search for additional new patterns (Kozareva and Hovy, 2010b; Davidov et al., 2007; Riloff et al., 1999; Igo and Riloff, 2009; Kozareva et al., 2008). Also related approaches are distant or weakly supervision (Mintz et al., 2009; Craven et al., 1999; Hoffmann et al., 2011) that rely on available structured data sources as a weak source of supervision for pattern extraction from related text corpora.

[16]The reason is that topic models use word frequency for topic modeling.

9 Conclusion and Discussion

In this paper, we propose a pipelined system for major life event extraction from Twitter. Experimental results show that our model is able to extract a wide variety of major life events.

The key strategy adopted in this work is to obtain a relatively clean training dataset from large quantity of Twitter data by relying on minimum efforts of human supervision, and sometimes is at the sacrifice of recall. To achieve this goal, we rely on a couple of restrictions and manual screenings, such as relying on replies, LDA topic identification and seed screening. Each part of system depends on the early steps. For example, topic clustering in Section 3 not only offers training data for event identification in Section 4, but prepares the training data for self-information identification in Section 5. .

We acknowledge that our approach is not perfect due to the following ways: (1) The system is only capable of discovering a few categories of life events with many others left unidentified. (2) Each step of the system will induce errors and negatively affected the following parts. (3) Some parts of evaluations are not comprehensive due to the lack of gold-standard data. (4) Among all pipelines, event property identification in Section 6 still requires full supervision in CRF model, making it hard to scale to every event type[17]. How to address these aspects and generate a more accurate, comprehensive and fine-grained life event list for Twitter users constitute our further work.

Acknowledgements

A special thanks is owned to Myle Ott for suggestions on bootstrapping procedure in data harvesting. The authors want to thank Noah Smith, Chris Dyer and Alok Kothari for useful comments, discussions and suggestions regarding different steps of the system and evaluations. We thank Lingpeng Kong and members of Noah's ARK group at CMU for providing the tweet dependency parser. All data used in this work is extracted from CMU Twitter Warehouse maintained by Brendan O'Connor, to whom we want to express our gratitude.

[17]We view weakly supervised life event property extraction as an interesting direction for future work.

Brighter than Gold: Figurative Language in User Generated Comparisons

Vlad Niculae and **Cristian Danescu-Niculescu-Mizil**
MPI-SWS
Cornell University
vniculae@mpi-sws.org, cristian@mpi-sws.org

Abstract

Comparisons are common linguistic devices used to indicate the likeness of two things. Often, this likeness is not meant in the literal sense—for example, "I slept like a log" does not imply that logs actually sleep. In this paper we propose a computational study of figurative comparisons, or *similes*. Our starting point is a new large dataset of comparisons extracted from product reviews and annotated for figurativeness. We use this dataset to characterize figurative language in naturally occurring comparisons and reveal linguistic patterns indicative of this phenomenon. We operationalize these insights and apply them to a new task with high relevance to text understanding: distinguishing between figurative and literal comparisons. Finally, we apply this framework to explore the social context in which figurative language is produced, showing that similes are more likely to accompany opinions showing extreme sentiment, and that they are uncommon in reviews deemed helpful.

1 Introduction

> *In argument similes are like songs in love; they describe much, but prove nothing.*
>
> — Franz Kafka

Comparisons are fundamental linguistic devices that express the likeness of two things—be it entities, concepts or ideas. Given that their working principle is to emphasize the relation between the shared properties of two arguments (Bredin, 1998), comparisons can synthesize important semantic knowledge.

Often, comparisons are not meant to be understood literally. Figurative comparisons are an important figure of speech called *simile*. Consider the following two examples paraphrased from Amazon product reviews:

(1) Sterling is much cheaper than gold.

(2) Her voice makes this song shine brighter than gold.

In (1) the comparison draws on the relation between the price property shared by the two metals, *sterling* and *gold*. While (2) also draws on a common property (*brightness*), the polysemantic use (vocal timbre vs. light reflection) makes the comparison figurative.

Importantly, there is no general rule separating literal from figurative comparisons. More generally, the distinction between figurative and literal language is blurred and subjective (Hanks, 2006). Multiple criteria for delimiting the two have been proposed in the linguistic and philosophical literature—for a comprehensive review, see Shutova (2010)—but they are not without exceptions, and are often hard to operationalize in a computational framework. When considering the specific case of comparisons, such criteria cannot be directly applied.

Recently, the simile has received increasing attention from linguists and lexicographers (Moon, 2008; Moon, 2011; Hanks, 2013) as it became clearer that similes need to be treated separately from metaphors since they operate on fundamentally different principles (Bethlehem, 1996). Metaphors are linguistically simple structures hiding a complex mapping between two domains, through which many properties are transferred. For example the conceptual metaphor of *life as a journey* can be instantiated in many particular ways: *being at a fork in the road*, *reaching the end of the line* (Lakoff and Johnson, 1980). In contrast, the semantic context of similes tends to be very shallow, transferring a single property (Hanks, 2013). Their more explicit syntactic structure allows, in exchange, for more lexical creativity. As Hanks (2013) puts it, similes "tend to license all

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2008–2018,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

sorts of logical mayhem." Moreover, the overlap between the expressive range of similes and metaphors is now known to be only partial: there are similes that cannot be rephrased as metaphors, and the other way around (Israel et al., 2004). This suggests that figurativeness in similes should be modeled differently than in metaphors. To further underline the necessity of a computational model for similes, we give the first estimate of their frequency in the wild: over 30% of comparisons are figurative.[1] We also confirm that a state of the art metaphor detection system performs poorly when applied directly to the task of detecting similes.

In this work we propose a computational study of figurative language in comparisons. To this end, we build the first large collection of naturally occurring comparisons with figurativeness annotation, which we make publicly available. Using this resource we explore the linguistic patterns that characterize similes, and group them in two conceptually distinctive classes. The first class contains cues that are agnostic of the context in which the comparison appears (domain-agnostic cues). For example, we find that the higher the semantic similarity between the two arguments, the less likely it is for the comparison to be figurative—in the examples above, *sterling* is semantically very similar to *gold*, both being metals, but *song* and *gold* are semantically dissimilar. The second type of cues are domain-specific, drawing on the intuition that the domain in which a comparison is used is a factor in determining its figurativeness. We find, for instance, that the less specific a comparison is to the domain in which it appears, the more likely it is to be used in a figurative sense (e.g., in example (2), *gold* is very unexpected in the musical domain).

We successfully exploit these insights in a new prediction task relevant to text understanding: discriminating figurative comparisons from literal ones. Encouraged by the high accuracy of our system—which is within 10% of that obtained by human annotators—we automatically extend the figurativeness labels to 80,000 comparisons occurring in product reviews. This enables us to conduct a fine-grained analysis of how comparison usage interacts with their social context, opening up a research direction with applications in sentiment analysis and opinion mining. In particular we find that figurative comparisons are more likely to accompany reviews showing extreme sentiment, and that they are uncommon in opinions deemed as being helpful. To the best of our knowledge, this is the first time figurative language is tied to the social context in which it appears.

To summarize, the main contributions of this work are as follows:

- it introduces the first large dataset of comparisons with figurativeness annotations (Section 3);
- it unveils new linguistic patterns characterizing figurative comparisons (Section 4);
- it introduces the task of distinguishing figurative from literal comparisons (Section 5);
- it establishes the relation between figurative language and the social context in which it appears (Section 6).

2 Further Related Work

Corpus studies on figurative language in comparisons are scarce, and none directly address the distinction between figurative and literal comparisons. Roncero et al. (2006) observed, by searching the web for several stereotypical comparisons (e.g., *education is like a stairway*), that similes are more likely to be accompanied by explanations than equivalent metaphors (e.g., *education is a stairway*). Related to figurativeness is irony, which Veale (2012a) finds to often be lexically marked. By using a similar insight to filter out ironic comparisons, and by assuming that the rest are literal, Veale and Hao (2008) learn stereotypical knowledge about the world from frequently compared terms. A similar process has been applied to both English and Chinese by Li et al. (2012), thereby encouraging the idea that the trope behaves similarly in different languages. A related system is the *Jigsaw Bard* (Veale and Hao, 2011), a thesaurus driven by figurative conventional similes extracted from the Google N-grams. This system aims to build and generate canned expressions by using items frequently associated with the simile pattern above. An extension of the principles of the *Jigsaw Bard* is found in *Thesaurus Rex* (Veale and Li, 2013), a data-driven partition of words into ad-hoc categories. *Thesaurus Rex* is constructed using simple comparison and hypernym patterns

[1] This estimate is based on the set of noun-noun comparisons with non-identical arguments collected for this study from Amazon.com product reviews.

and is able to provide weighted lists of categories for given words.

In text understanding systems, literal comparisons are used to detect analogies between related geographical places (Lofi et al., 2014). Tandon et al. (2014) use relative comparative patterns (e.g., *X is heavier than Y*) to enrich a common-sense knowledge base. Jindal and Liu (2006) extract graded comparisons from various sources, with the objective of mining consumer opinion about products. They note that identifying objective vs. subjective comparisons—related to literality—is an important future direction. Given that many comparisons are figurative, a system that discriminates literal from figurative comparisons is essential for such text understanding and information retrieval systems.

The vast majority of previous work on figurative language focused on metaphor detection. Tsvetkov et al. (2014a) propose a cross-lingual system based on word-level conceptual features and they evaluate it on Subject-Verb-Object triples and Adjective-Noun pairs. Their features include and extend the idea of abstractness used by Turney et al. (2011) for Adjective-Noun metaphors. Hovy et al. (2013) contribute an unrestricted metaphor corpus and propose a method based on tree kernels. Bridging the gap between metaphor identification and interpretation, Shutova and Sun (2013) proposed an unsupervised system to learn source-target domain mappings. The system fits conceptual metaphor theory (Lakoff and Johnson, 1980) well, at the cost of not being able to tackle figurative language in general, and similes in particular, as similes do not map entire domains to one another. Since similes operate on fundamentally different principles than metaphors, our work proposes a computational approach tailored specifically for comparisons.

3 Background and Data

3.1 Structure of a comparison

Unlike metaphors, which are generally unrestricted, comparisons are more structured but also more lexically and semantically varied. This enables a more structured computational representation of which we take advantage. The constituents of a comparison according to Hanks (2012) are:

- the TOPIC, sometimes called tenor: it is usually a noun phrase and acts as logical subject;
- the VEHICLE: it is the object of the comparison and is also usually a noun phrase;
- the shared PROPERTY or ground: it expresses what the two entities have in common—it can be explicit but is often implicit, left for the reader to infer;
- the EVENT (eventuality or state): usually a verb, it sets the frame for the observation of the common property;
- the COMPARATOR: commonly a preposition (*like*) or part of an adjectival phrase (*better than*), it is the trigger word or phrase that marks the presence of a comparison.

The literal example (1) would be segmented as:

> [Sterling /TOPIC] [is /EVENT] much [cheaper /PROPERTY] [than /COMPARATOR] [gold /VEHICLE]

3.2 Annotation

People resort to comparisons often when making descriptions, as they are a powerful way of expressing properties by example. For this reason we collect a dataset of user-generated comparisons in Amazon product reviews (McAuley and Leskovec, 2013), where users have to be descriptive and precise, but also to express personal opinion. We supplement the data with a smaller set of comparisons from WaCky and WaCkypedia (Baroni et al., 2009) to cover more genres. In preliminary work, we experimented with dependency parse tree patterns for extracting comparisons and labeling their parts (Niculae, 2013). We use the same approach, but with an improved set of patterns, to extract comparisons with the COMPARATORS *like*, *as* and *than*.[2] We keep only the matches where the TOPIC and the VEHICLE are nouns, and the PROPERTY, if present, is an adjective, which is the typical case. Also, the head words of the constituents are constrained to occur in the distributional resources used (Baroni and Lenci, 2010; Faruqui and Dyer, 2014).[3]

[2] We process the review corpus with part-of-speech tagging using the IRC model for *TweetNLP* (Owoputi et al., 2013; Forsyth and Martell, 2007) and dependency parsing using the *TurboParser* standard model (Martins et al., 2010).

[3] Due to the strong tendency of comparisons with the same TOPIC and VEHICLE to be trivially literal in the WaCky examples, we filtered out such examples from the Amazon product reviews. We also filtered proper nouns using a capitalization heuristic.

We proceed to validate and annotate for figurativeness a random sample of the comparisons extracted using the automated process described above. The annotation is performed using crowdsourcing on the Amazon Mechanical Turk platform, in two steps. First, the annotators are asked to determine whether a displayed sentence is indeed a comparison between the highlighted words (TOPIC and VEHICLE). Sentences qualified by two out of three annotators as comparisons are used in the second round, where the task is to rate how metaphorical a comparison is. We use a scale of 1 to 4 following Turney et al. (2011), and then binarize to consider scores of 1–2 as literal and 3–4 as figurative. Finally, in this work we only consider comparisons where all three annotators agree on this binary notion of figurativeness. For both tasks, we provide guidelines mostly in the form of examples and intuition, motivated on one hand by the annotators not having specialized knowledge, and on the other hand by the observation that the literal-figurative distinction is subjective. All annotators have the *master worker* qualification, reside in the U.S. and completed a linguistic background questionnaire that verifies their experience with English. In both tasks, control sentences with confidently known labels are used to filter low quality answers; in addition, we test annotators with a simple paraphrasing task shown to be effective for eliciting and verifying linguistic attention (Munro et al., 2010). Both tasks seem relatively difficult for humans, with inter-annotator agreement given by Fleiss' k of 0.48 for the comparison identification task and of 0.54 for the figurativeness annotation after binarization. This is comparable to 0.57 reported by Hovy et al. (2013) for general metaphor labeling. We show some statistics about the collected data in Table 1. Overall, this is a costly process: out of 2400 automatically extracted comparison candidates, about 60% were deemed by the annotators to be actual comparisons and only 12% end up being selected confidently enough as figurative comparisons.

Our dataset of human-filtered comparisons, with the scores given by the three annotators, is made publicly available to encourage further work.[4] This also includes about 400 comparisons where the annotators do not agree perfectly on binary figurativeness. Such cases can be interesting to other analyses, even if we don't consider them in our experiments. It is worth noting that the existing corpora annotated for metaphor cannot be directly used to study comparisons. For example, in TroFi (Birke and Sarkar, 2006), a corpus of 6436 sentences annotated for figurativeness, we only find 42 noun-noun comparisons with sentence-level (thus noisy) figurativeness labels.

Domain	fig.	lit.	% fig.
Books	177	313	36%
Music	45	68	40%
Electronics	23	105	18%
Jewelery	9	126	7%
WaCky	19	79	19%
Total	273	609	31%

Table 1: Figurativeness annotation results. Only comparisons where all three annotators agree are considered.

4 Linguistic Insights

We now proceed to exploring the linguistic patterns that discriminate figurative from literal comparisons. We consider two broad classes of cues, which we discuss next.

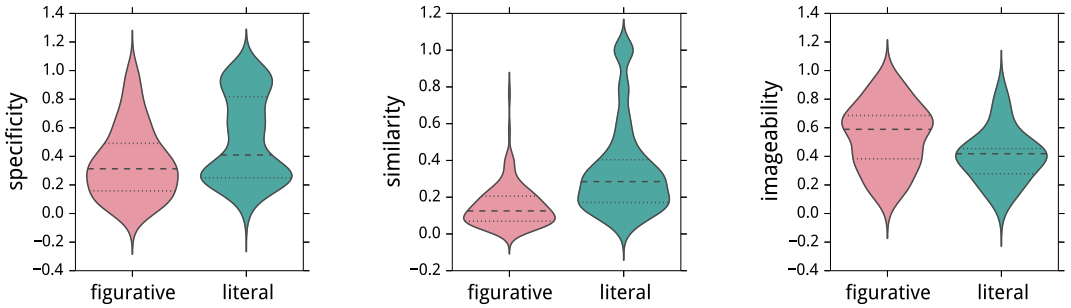
4.1 Domain-specific cues

Figurative language is often used for striking effects, and comparisons are used to describe new things in terms of something given (Hanks, 2013). Since the norms that define what is surprising and what is well-known vary across domains, we expect that such contextual information should play an important role in figurative language detection. This is a previously unexplored dimension of figurative language, and Amazon product reviews offer a convenient testbed for this intuition since category information is provided.

Specificity To estimate whether a comparison can be considered striking in a particular domain—whether it references images or ideas that are unexpected in its context—we employ a simple measure of word *specificity* with respect to a domain: the ratio of the word frequency within the domain and the word frequency in all domains being considered.[5] It should be noted that specificity is not purely a function of the word, but

[4] http://vene.ro/figurative-comparisons/

[5] We measure specificity for the VEHICLE, PROPERTY and EVENT.



(a) VEHICLE specificity. (b) TOPIC-VEHICLE similarity. (c) Imageability of the PROPERTY.

Figure 1: Distribution of some of the features we use, across literal and figurative comparisons in the test set. The profile of the plot is a kernel density estimation of the distribution, and the markers indicate the median and the first and third quartiles.

of the word and the context in which it appears. A comparison in the *music* domain that involves melodies is not surprising:

> But the title song really feels like a pretty bland vocal **melody** [...]

But the same word can play a very different role in another context, for example, *book* reviews:

> Her books are like sweet **melodies** that flow through your head.

Indeed, the word *melody* has a specificity of 96% in the *music* domain and only of 3% in the *books* domain.

An analysis on the labeled data confirms that literal comparisons do indeed tend to have more domain-specific VEHICLES (Mann-Whitney U test, $p < 0.01$) than figurative ones. Furthermore, the distribution of specificity across both types of comparisons, as shown in Figure 1a, has the appearance of a mixture model of general and specific words. Figurative comparison VEHICLES largely exhibit only the general component of the mixture.[6]

Domain label An analysis of the annotation results reveals that the percentage of comparisons that are figurative differs widely across domains, as indicated in the last column in Table 1. This suggests that simply knowing the domain of a text can serve to adjust some prior expectation about figurative language presence and therefore improve detection. We test this hypothesis using a Z-test comparing all Amazon categories. With the exception of *books* and *music* reviews, that have similar ratios, all other pairs of categories show significantly different proportions of figurative comparisons ($p < 0.01$).

4.2 Domain-agnostic cues

Linguistic studies of figurative language suggest that there is a fundamental generic notion of figurativeness. We attempt to capture this notion in the context of comparisons using syntactic and semantic information.

Topic-Vehicle similarity The default role of literal comparisons is to assert similarity of things. Therefore, we expect that a high semantic similarity between the TOPIC and the VEHICLE of a comparison is a sign of literal usage, as we previously hypothesized in preliminary work (Niculae, 2013). To test this hypothesis, we compute TOPIC-VEHICLE similarity using Distributional Memory (Baroni and Lenci, 2010), a freely available distributional semantics resource that captures word relationships through grammatical role co-occurrence.

By applying this measure to our data, we find that there is indeed an important difference between the distributions of TOPIC-VEHICLE similarity in figurative and literal comparisons (shown in Figure 1b); the means of the two distributions are significantly different (Mann-Whitney $p < 0.01$).

Metaphor-inspired features We also seek to understand to what extent insights provided by computational work on metaphor detection can be

[6]The mass around 0.25 in Figure 1a is largely explained by generic words such as *thing, others, nothing, average* and barely specific words like *veil, reputation, dream, garbage*.

	more concrete	less concrete
more imageable	*cinnamon, kiss*	*devil, happiness*
less imageable	*casque, pugilist*	*aspect, however*

Table 2: Examples of words with high and low concreteness and imageability scores from the MRC Psycholinguistic Database.

applied in the context of comparisons. To that end we consider features shown to provide state of the art performance in the task of metaphor detection (Tsvetkov et al., 2014a): abstractness, imageability and supersenses.

Abstractness and imageability features are derived from the MRC Psycholinguistic Database (Coltheart, 1981), a dictionary based on manually annotated datasets of psycholinguistic norms. Imageability is the property of a word to arouse a mental image, be it in the form of a mental picture, sound or any other sense. Concreteness is defined as "any word that refers to objects, materials or persons," while abstractness, at the other end of the spectrum, is represented by words that cannot be usually experienced by the senses (Paivio et al., 1968). Table 2 shows a few examples of words with high and low concreteness and imageability scores. Supersenses are a very coarse form of meaning representation. Tsvetkov et al. (2014a) used WordNet (Miller, 1995) semantic classes for nouns and verbs, for example *noun.body*, *noun.animal*, *verb.consumption*, or *verb.motion*. For adjectives, Tsvetkov et al. (2014b) developed and made available a novel classification in the same spirit.[7] We compute abstractness, imageability and supersenses for the TOPIC, VEHICLE, EVENT, and PROPERTY.[8] We concatenate these features with the raw vector representations of the constituents, following Tsvetkov et al. (2014a).

We find that such features relate to figurative comparisons in a meaningful way. For example, out of all comparisons with explicit properties, figurative comparisons tend to have properties that are more imageable (Mann-Whitney $p < 0.01$), as illustrated by Figure 1c. This is in agreement with Hanks (2005), who observed that similes are characterized by their appeal to sensory imagination.

Definiteness We introduce another simple but effective syntactic cue that relates to concreteness: the presence of a definite article versus an indefinite one (or none at all). We search for the indefinite articles *a* and *an* and the definite article *the* in each component of a comparison.

We find that similes tend to have indefinite articles in the VEHICLE more often and definite articles less often (Mann-Whitney $p < 0.01$). In particular, 59% of comparisons where the VEHICLE has a indefinite article are figurative, as opposed to 13% of the comparisons where VEHICLE has a definite article.

5 Prediction Task

We now turn to the task of predicting whether a comparison is figurative or literal. Not only does this task allow us to assess and compare the efficiency of the linguistic cues we discussed, but it is also highly relevant in the context of natural language understanding systems.

We conduct a logistic regression analysis, and compare the efficiency of the features derived from our analysis to a **bag of words** baseline. In addition to the features inspired by the previously described linguistic insights, we also try to computationally capture the lexical usage patterns of comparisons using a version of bag of words adapted to the comparison structure. In this **slotted bag of words** system, features correspond to occurrence of words within constituents (e.g., *bright* $\in$ PROPERTY).

We perform a stratified split of our comparison dataset into equal train and test sets (each set containing 408 comparisons, out of which 134 are figurative),[9] and use a 5-fold stratified cross validation over the training set to choose the optimal value for the logistic regression regularization parameter and the type of regularization (ℓ_1 or ℓ_2) for each feature set.[10]

[7] Following Tsvetkov et al. (2014a) we train a classifier to predict these features from a vector space representation of a word. We use the same cross-lingually optimized representation from Faruqui and Dyer (2014) and a simpler classifier, a logistic regression, which we find to perform as well as the random forests used in Tsvetkov et al. (2014a). We treat supersense prediction as a multi-label problem and apply a one-versus-all transformation, effectively learning a linear classifier for each supersense.

[8] If the PROPERTY is implicit, all corresponding features are set to zero. An extra binary feature indicates whether the PROPERTY is explicit or implicit.

[9] The entire analysis described in Section 4 is only conducted on the training set. Also, in order to ensure that we are assessing the performance of the classifier on unseen comparisons, we discard from our dataset all those with the same TOPIC and VEHICLE pair.

[10] We use the logistic regression implementation of `liblinear` (Fan et al., 2008) wrapped by the `scikit-learn` library (Pedregosa et al., 2011).

Model	# features	Acc.	P	R	F_1	AUC
Bag of words	1970	0.79	0.63	0.84	0.72	0.87
Slotted bag of words	1840	0.80	0.64	0.90	0.75	0.89
Domain-agnostic cues	357	0.81	0.70	0.74	0.72	0.90
only metaphor inspired	345	0.75	0.60	0.72	0.65	0.84
Domain-specific cues	8	0.69	0.51	0.81	0.63	0.76
All linguistic insight cues	365	0.86	0.76	0.83	0.79	0.92
Full	2202	0.88	0.80	0.84	0.82	0.94
Human	-	0.96	0.92	0.96	0.94	-

Table 3: Classification performance on the test set for the different sets of features we considered; human performance is shown for reference.

Classifier performance The performance on the classification task is summarized in Table 3. We note that the **bag of words** baseline is remarkably strong, because of common idiomatic similes that can be captured through keywords. Our **full** system (which relies on our linguistically inspired cues discussed in Section 4 in addition to slotted bag of words) significantly outperforms the bag of words baseline and the slotted bag of words system in terms of accuracy, F_1 score and AUC ($p < 0.05$),[11] suggesting that linguistic insights complement idiomatic simile matching. Importantly, a system using only our **linguistic insight cues** also significantly improves over the baseline in terms of accuracy and AUC and it is not significantly different from the full system in terms of performance, in spite of having about an order of magnitude fewer features. It is also worth noting that the **domain-specific cues** play an important role in bringing the performance to this level by capturing a different aspect of what it means for a comparison to be figurative.

The features used by the state of the art metaphor detection system of Tsvetkov et al. (2014a), adapted to the comparison structure, perform poorly by themselves and do not improve significantly over the baseline. This is consistent with the theoretical motivation that figurativeness in comparisons requires special computational treatment, as discussed in Section 1. Furthermore, the linguistic insight features not only significantly outperform the metaphor inspired features ($p < 0.05$), but are also better at exploiting larger amounts of data, as shown in Figure 2.

[11] All statistical significance results in this paragraph are obtained from 5000 bootstrap samples.

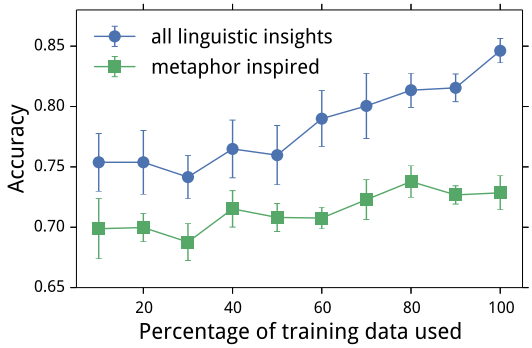


Figure 2: Learning curves. Each point is obtained by fitting a model on 10 random subsets of the training set. Error bars show 95% confidence intervals.

Comparison to human performance To gauge how well humans would perform at the classification task on the actual test data, we perform another Amazon Mechanical Turk evaluation on 140 examples from the test set. For the evaluation, we use majority voting between the three annotators,[12] and compare to the agreed labels in the dataset. Estimated human accuracy is 96%, placing our full system within 10% of human accuracy.

Feature analysis The predictive analysis we perform allows us to investigate to what extent the features inspired by our linguistic insights have discriminative power, and whether they actually cover different aspects of figurativeness.

[12] Majority voting helps account for the noise inherent to crowdsourced annotation, which is less accurate than professional annotation. Taking the less optimistic invididual turker answers, human performance is on the same level as our full system.

Feature	Coef.	Example where the feature is positively activated
TOPIC-VEHICLE similarity	−11.3	the older *man* was wiser and stronger than the *boy*
VEHICLE specificity	−5.8	the cord is more durable than the *adapter* [Electronics]
VEHICLE imageability	4.9	the explanations are as clear as *mud*
VEHICLE communication supersense	−4.6	the book reads like six short *articles*
VEHICLE indefiniteness	4.0	his fame drew foreigners to him like *a* magnet
life ∈ VEHICLE	7.1	the hero is truly larger than *life*: godlike, yet flawed
picture ∈ VEHICLE	−6.0	the necklace looks just like the *picture*
other ∈ VEHICLE	−5.9	this one is just as nice as the *other*
others ∈ VEHICLE	−5.5	some songs are more memorable than *others*
crap ∈ VEHICLE	4.7	the headphones sounded like *crap*

Table 4: Top 5 linguistic insight features (top) and slotted bag of words features (bottom) in the full model and their logistic regression coefficients. A positive coefficient means the feature indicates figurativeness.

Table 4 shows the best linguistic insight and slotted bag of words features selected by the full model. The strongest feature by far is the semantic similarity between the TOPIC and the VEHICLE. By itself, this feature gets 70% accuracy and 61% F_1 score.

The rest of the top features involve mostly the VEHICLE. This suggests that the VEHICLE is the most informative element of a comparison when it comes to figurativeness. Features involving other constituents also get selected, but with slightly lower weights, not making it to the top.

VEHICLE specificity is one of the strongest features, with positive values indicating literal comparisons. This confirms our intuition that domain information is important to discriminate figurative from literal language.

Of the adapted metaphor features, the noun communication supersense and the imageability of the VEHICLE make it to the top. Nouns with low communication rating occurring in the training set include *puddles, arrangements, carbohydrates* while nouns with high communication rating include *languages* and *subjects*.

Presence of an indefinite article in the VEHICLE is a strong indicator of figurativeness. By themselves, the definiteness and indefiniteness features perform quite well, attaining 78% accuracy and 67% F_1 score.

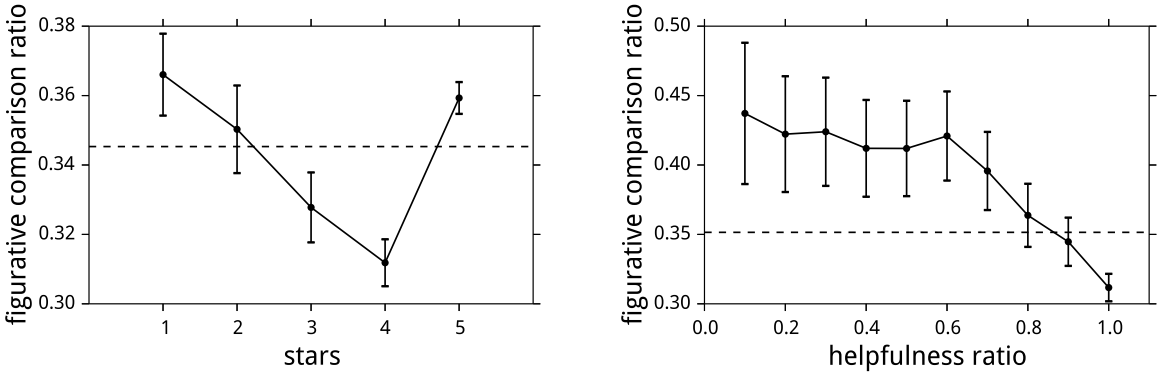
The salient bag of words features correspond to specific types of comparisons. The words *other* and *others* in the VEHICLE indicate comparisons between the same kind of arguments, for example *some songs are more memorable than others,* and these are likely to be literal. The word *picture* is specific to the review setting, as products are accompanied by photos, and for certain kinds of products, the resemblance of the product with the image is an important factor for potential buyers.[13] The bag of words systems are furthermore able to learn idiomatic comparisons by identifying common figurative VEHICLES such as *life* and *crap*, corresponding to fixed expressions such as *larger than life*.

Error analysis Many of the errors made by our full system involve indirect semantic mechanisms such as metonymy. For example, the false positive *the typeface was larger than most books* really means *larger than the typefaces found in most books*, but without the implicit expansion the meaning can appear figurative. A similar kind of ellipsis makes the example *a lot [of songs] are even better than sugar* be wrongly classified as literal. Another source of error is polysemy. Examples like *the rejuvelac formula is about 10 times better than yogurt* are misclassified because of the multiple meanings of the word *formula*, one being closely related to yogurt and food, but the more common ones being general and abstract, suggesting figurativeness.

6 Social Correlates

The advantage of studying comparisons situated in a social context is that we can understand how their usage interacts with internal and external human factors. An internal factor is the sentiment of

[13] This feature is highly correlated with the domain: it appears 25 times in the training set, 24 of which in the *jewelery* domain and once in *book* reviews.



(a) Figurative comparisons are more likely to be found in reviews with strongly polarized sentiment.

(b) Helpful reviews are less likely to contain figurative comparisons.

Figure 3: Interaction between figurative language and social context aspects. Error bars show 95% confidence intervals. The dashed horizontal line marks the average proportion of figurative comparisons. In Figure 3b the average proportion is different because we only consider reviews rated by at least 10 readers.

the user towards the reviewed product, indicated by the star rating of the review. An external factor present in the data is how helpful the review is perceived by other users. In this section we analyze how these factors interact with figurative language in comparisons.

To gain insight about fine grained interactions with human factors at larger scale, we use our classifier to find over 80,000 figurative and literal comparisons from the same four categories. The trends we reveal also hold significantly on the manually annotated data.

Sentiment While it was previously noted that similes often transmit strong affect (Hanks, 2005; Veale, 2012a; Veale, 2012b), the connection between figurativeness and sentiment was never empirically validated. The setting of product reviews is convenient for investigating this issue, since the star ratings associated with the reviews can be used as sentiment labels. We find that comparisons are indeed significantly more likely to be figurative when the users express strong opinions, i.e., in one-star or five-star reviews (Mann-Whitney $p < 0.02$ on the manually annotated data). Figure 3a shows how the proportion of figurative comparisons varies with the polarity of the review.

Helpfulness It is also interesting to understand to what extent figurative language relates to the external perception of the content in which it appears. We find that comparisons in helpful reviews[14] are less likely to be figurative. Figure 3b shows a near-constant high ratio of figurative comparisons among unhelpful and average reviews; as helpfulness increases, figurative comparisons become less frequent. We further validate that this effect is not a confound of the distribution of helpfulness ratings across reviews of different polarity by controlling for the star rating: given a fixed star rating, the proportion of figurative comparisons is still lower in helpful (helpfulness over 50%) than in unhelpful (helpfulness under 50%) reviews; this difference is significant (Mann-Whitney $p < 0.01$) for all classes of ratings except one-star. The size of the manually annotated data does not allow for star rating stratification, but the overall difference is statistically significant (Mann-Whitney $p < 0.01$). This result encourages further experimentation to determine whether there is a causal link between the use of figurative language in user generated content and its external perception.

7 Conclusions and Future Work

This work proposes a computational study of figurative language in comparisons. Starting from a new dataset of naturally occurring comparisons with figurativeness annotation (which we make publicly available) we explore linguistic patterns that are indicative of similes. We show that these

[14] In order to have reliable helpfulness scores, we only consider reviews that have been rated by at least by ten readers.

insights can be successfully operationalized in a new prediction task: distinguishing literal from figurative comparisons. Our system reaches accuracy that is within 10% of human performance, and is outperforming a state of the art metaphor detection system, thus confirming the need for a computational approach tailored specifically to comparisons. While we take a data-driven approach, our annotated dataset can be useful for more theoretical studies of the kinds of comparisons and similes people use.

We discover that domain knowledge is an important factor in identifying similes. This suggests that future work on automatic detection of figurative language should consider contextual parameters such as the topic and community where the content appears.

Furthermore, we are the first to tie figurative language to the social context in which it is produced and show its relation to internal and external human factors such as opinion sentiment and helpfulness. Future investigation into the causal effects of these interactions could lead to a better understanding of the role of figurative language in persuasion and rhetorics.

In our work, we consider common noun TOPICS and VEHICLES and adjectival PROPERTIES. This is the most typical case, but supporting other parts of speech—such as proper nouns, pronouns, and adverbs—can make a difference in many applications. Capturing compositional interaction between the parts of the comparison could lead to more flexible models that give less weight to the VEHICLE.

This study is also the first to estimate how prevalent similes are in the wild, and reports that about one third of the comparisons we consider are figurative. This is suggestive of the need to build systems that can properly process figurative comparisons in order to correctly harness the semantic information encapsulated in comparisons.

Acknowledgements

We would like to thank Yulia Tsvetkov for constructive discussion about figurative language and about her and her co-authors' work. We are grateful for the suggestions of Patrick Hanks, Constantin Orăsan, Sylviane Cardey, Izabella Thomas, Ekaterina Shutova, Tony Veale, and Niket Tandon. We extend our gratitude to Julian McAuley for preparing and sharing the Amazon review dataset. We are thankful to the anonymous reviewers, whose comments were *like a breath of fresh air*. We acknowledge the help of the Amazon Mechanical Turk annotators and of the MPI-SWS students involved in pilot experiments.

Abstract

We describe an algorithm for automatic classification of idiomatic and literal expressions. Our starting point is that words in a given text segment, such as a paragraph, that are high-ranking representatives of a common topic of discussion are less likely to be a part of an idiomatic expression. Our additional hypothesis is that contexts in which idioms occur, typically, are more affective and therefore, we incorporate a simple analysis of the intensity of the emotions expressed by the contexts. We investigate the bag of words topic representation of one to three paragraphs containing an expression that should be classified as idiomatic or literal (a target phrase). We extract topics from paragraphs containing idioms and from paragraphs containing literals using an unsupervised clustering method, Latent Dirichlet Allocation (LDA) (Blei et al., 2003). Since idiomatic expressions exhibit the property of non-compositionality, we assume that they usually present different semantics than the words used in the local topic. We treat idioms as semantic outliers, and the identification of a semantic shift as outlier detection. Thus, this topic representation allows us to differentiate idioms from literals using local semantic contexts. Our results are encouraging.

1 Introduction

The definition of what is literal and figurative is still object of debate. Ariel (2002) demonstrates that literal and non-literal meanings cannot always be distinguished from each other. Literal meaning is originally assumed to be conventional, compositional, relatively context independent, and truth conditional. The problem is that the boundary is not clear-cut, some figurative expressions are compositional – metaphors and many idioms; others are conventional – most of the idioms. Idioms present great challenges for many Natural Language Processing (NLP) applications. They can violate selection restrictions (Sporleder and Li, 2009) as in *push one's luck* under the assumption that only concrete things can normally be pushed. Idioms can disobey typical subcategorization constraints (e.g., *in line* without a determiner before line), or change the default assignments of semantic roles to syntactic categories (e.g., in *X breaks something with Y*, Y typically is an instrument but for the idiom *break the ice*, it is more likely to fill a patient role as in *How to break the ice with a stranger*). In addition, many potentially idiomatic expressions can be used either literally or figuratively, depending on the context. This presents a great challenge for machine translation. For example, a machine translation system must translate *held fire* differently in *Now, now, hold your fire until I've had a chance to explain. Hold your fire, Bill. You're too quick to complain.* and *The sergeant told the soldiers to hold their fire. Please hold your fire until I get out of the way*. In fact, we tested the last two examples using the Google Translate engine and we got proper translations of the two neither into Russian nor into Hebrew, Spanish, or Chinese. Most current translation systems rely on large repositories of idioms. Unfortunately, these systems are not capable to tell apart literal from figurative usage of the same expression in context. Despite the common perception that phrases that can be idioms are mainly used in their idiomatic sense, Fazly et al. (2009)'s analysis of 60 idioms has shown that close to half of these also have a clear literal meaning; and of those with a literal meaning, on average around 40% of their usages are literal.

In this paper we describe an algorithm for automatic classification of idiomatic and literal expressions. Our starting point is that words in a given text segment, such as a paragraph, that are high-ranking representatives of a common topic of discussion are less likely to be a part of an idiomatic expression. Our additional hypothesis is that contexts in which idioms occur, typically, are more affective and therefore, we incorporate a simple analysis of the intensity of the emotions expressed by the contexts. We investigate the bag of words *topic* representation of one to three paragraphs containing an expression that should be classified as idiomatic or literal (a target phrase). We extract topics from paragraphs containing idioms and from paragraphs containing literals using an unsupervised clustering method, Latent Dirichlet Allocation (LDA) (Blei et al., 2003). Since idiomatic expressions exhibit the property of non-compositionality, we assume that they usually present different semantics than the words used

in the local topic. We treat idioms as semantic outliers, and the identification of semantic shift as outlier detection. Thus, this topic representation allows us to differentiate idioms from literals using the local semantics.

The paper is organized as follows. Section 2 briefly describes previous approaches to idiom recognition or classification. In Section 3 we describe our approach in detail, including the hypothesis, the topic space representation, and the proposed algorithm. After describing the preprocessing procedure in Section 4, we turn to the actual experiments in Sections 5 and 6. We then compare our approach to other approaches (Section 7) and discuss the results (Section 8).

2 Previous Work

Previous approaches to idiom detection can be classified into two groups: 1) Type-based extraction, i.e., detecting idioms at the type level; 2) token-based detection, i.e., detecting idioms in context. Type-based extraction is based on the idea that idiomatic expressions exhibit certain linguistic properties that can distinguish them from literal expressions (Sag et al. (2002); Fazly et al. (2009)), among many others, discuss various properties of idioms. Some examples of such properties include 1) lexical fixedness: e.g., neither 'shoot the wind' nor 'hit the breeze' are valid variations of the idiom shoot the breeze and 2) syntactic fixedness: e.g., *The guy kicked the bucket* is potentially idiomatic whereas *The bucket was kicked* is not idiomatic anymore; and of course, 3) non-compositionality. Thus, some approaches look at the tendency for words to occur in one particular order, or a fixed pattern. Hearst (1992) identifies lexico-syntactic patterns that occur frequently, are recognizable with little or no precoded knowledge, and indicate the lexical relation of interest. Widdows and Dorow (2005) use Hearst's concept of lexicosyntactic patterns to extract idioms that consist of fixed patterns between two nouns. Basically, their technique works by finding patterns such as "thrills and spills", whose reversals (such as "spills and thrills") are never encountered.

While many idioms do have these properties, many idioms fall on the continuum from being compositional to being partly unanalyzable to completely non-compositional (Cook et al. (2007)). Fazly et al. (2009); Li and Sporleder (2010), among others, notice that type-based approaches do not work on expressions that can be interpreted idiomatically or literally depending on the context and thus, an approach that considers tokens in context is more appropriate for the task of idiom recognition.

A number of token-based approaches have been discussed in the literature, both supervised (Katz and Giesbrech (2006)), weakly supervised (Birke and Sarkar (2006)) and unsupervised (Sporleder and Li (2009); Fazly et al. (2009)). Fazly et al. (2009) develop statistical measures for each linguistic property of idiomatic expressions and use them both in a type-based classification task and in a token identification task, in which they distinguish idiomatic and literal usages of potentially idiomatic expressions in context. Sporleder and Li (2009) present a graph-based model for representing the lexical cohesion of a discourse. Nodes represent tokens in the discourse, which are connected by edges whose value is determined by a semantic relatedness function. They experiment with two different approaches to semantic relatedness: 1) Dependency vectors, as described in Pado and Lapata (2007); 2) Normalized Google Distance (Cilibrasi and Vitányi (2007)). Sporleder and Li (2009) show that this method works better for larger contexts (greater than five paragraphs). Li and Sporleder (2010) assume that literal and figurative data are generated by two different Gaussians, literal and non-literal and the detection is done by comparing which Gaussian model has a higher probability to generate a specific instance. The approach assumes that the target expressions are already known and the goal is to determine whether this expression is literal or figurative in a particular context. The important insight of this method is that figurative language in general exhibits less semantic cohesive ties with the context than literal language.

Feldman and Peng (2013) describe several approaches to automatic idiom identification. One of them is idiom recognition as outlier detection. They apply principal component analysis for outlier detection – an approach that does not rely on costly annotated training data and is not limited to a specific type of a syntactic construction, and is generally language independent. The quantitative analysis provided in their work shows that the outlier detection algorithm performs better and seems promising. The qualitative analysis also shows that their algorithm has to incorporate several important properties of the idioms: (1) Idioms are relatively non-compositional, comparing to literal expressions or other types of collocations. (2) Idioms violate local cohesive ties, as a result, they are semantically distant from the local topics. (3) While not all semantic outliers are idioms, non-compositional semantic outliers are likely to be idiomatic. (4) Idiomaticity is not a binary property. Idioms fall on the continuum from being compositional to being partly unanalyzable to completely non-compositional.

The approach described below is taking Feldman and Peng (2013)'s original idea and is trying to address (2) directly and (1) indirectly. Our approach is also somewhat similar to Li and Sporleder (2010) because it also relies on a list of potentially idiomatic expressions.

3 Our Hypothesis

Similarly to Feldman and Peng (2013), out starting point is that idioms are semantic outliers that violate cohesive structure, especially in local contexts. However, our task is framed as supervised classification and we rely on data annotated for idiomatic and literal expressions. We hypothesize that words in a given text

segment, such as a paragraph, that are high-ranking representatives of a common topic of discussion are less likely to be a part of an idiomatic expression in the document.

3.1 Topic Space Representation

Instead of the simple bag of words representation of a target document (segment of three paragraphs that contains a target phrase), we investigate the bag of words topic representation for target documents. That is, we extract topics from paragraphs containing idioms and from paragraphs containing literals using an unsupervised clustering method, Latent Dirichlet Allocation (LDA) (Blei et al., 2003). The idea is that if the LDA model is able to capture the semantics of a target document, an idiomatic phrase will be a "semantic" outlier of the themes. Thus, this topic representation will allow us to differentiate idioms from literals using the semantics of the local context.

Let $d = \{w_1, \cdots, w_N\}^t$ be a segment (document) containing a target phrase, where N denotes the number of terms in a given corpus, and t represents transpose. We first compute a set of m topics from d. We denote this set by

$$T(d) = \{t_1, \cdots, t_m\},$$

where $t_i = (w_1, \cdots, w_k)^t$. Here w_j represents a word from a vocabulary of W words. Thus, we have two representations for d: (1) d, represented by its original terms, and (2) $\hat{d}$, represented by its topic terms. Two corresponding term by document matrices will be denoted by M_D and $M_{\hat{D}}$, respectively, where D denotes a set of documents. That is, M_D represents the original "text" term by document matrix, while $M_{\hat{D}}$ represents the "topic" term by document matrix.

Figure 1 shows the potential benefit of topic space representation. In the figure, text segments containing target phrase "blow whistle" are projected on a two dimensional subspace. The left figure shows the projection in the "text" space, represented by the term by document matrix M_D. The middle figure shows the projection in the topic space, represented by $M_{\hat{D}}$. The topic space representation seems to provide a better separation.

We note that when learning topics from a small data sample, learned topics can be less coherent and interpretable, thus less useful. To address this issue, regularized LDA has been proposed in the literature (Newman et al., 2011). A key feature is to favor words that exhibit short range dependencies for a given topic. We can achieve a similar effect by placing restrictions on the vocabulary. For example, when extracting topics from segments containing idioms, we may restrict the vocabulary to contain words from these segments only. The middle and right figures in Figure 1 illustrate a case in point. The middle figure shows a projection onto the topic space that is computed with a restricted vocabulary, while the right figure shows a projection when we place no restriction on the vocabulary. That is, the vocabulary includes terms from documents that contain both idioms and literals.

Note that by computing $M_{\hat{D}}$, the topic term by document matrix, from the training data, we have created a vocabulary, or a set of "features" (i.e., topic terms) that is used to directly describe a query or test segment. The main advantage is that topics are more accurate when computed by LDA from a large collection of idiomatic or literal contexts. Thus, these topics capture more accurately the semantic contexts in which the target idiomatic and literal expressions typically occur. If a target query appears in a similar semantic context, the topics will be able to describe this query as well. On the other hand, one might similarly apply LDA to a given query to extract query topics, and create the query vector from the query topics. The main disadvantage is that LDA may not be able to extract topic terms that match well with those in the training corpus, when applied to the query in isolation.

3.2 Algorithm

The main steps of the proposed algorithm, called **TopSpace**, are shown below.

Input: $D = \{d_1, \cdots, d_k, d_{k+1}, \cdots, d_n\}$: training documents of k idioms and $n-k$ literals.
$Q = \{q_1, \cdots, q_l\}$: l query documents.

1. Let $DicI$ be the vocabulary determined solely from idioms $\{d_1, \cdots, d_k\}$. Similarly, let $DicL$ be the vocabulary obtained from literals $\{d_{k+1}, \cdots, d_n\}$.
2. For a document d_i in $\{d_1, \cdots, d_k\}$, apply LDA to extract a set of m topics $T(d_i) = \{t_1, \cdots, t_m\}$ using $DicI$. For $d_i \in \{d_{k+1}, \cdots, d_n\}$, $DicL$ is used.
3. Let $\hat{D} = \{\hat{d}_1, \cdots, \hat{d}_k, \hat{d}_{k+1}, \cdots, \hat{d}_n\}$ be the resulting topic representation of D.
4. Compute the term by document matrix $M_{\hat{D}}$ from $\hat{D}$, and let $DicT$ and gw be the resulting dictionary and global weight (idf), respectively.
5. Compute the term by document matrix M_Q from Q, using $DicT$ and gw from the previous step.

Output: $M_{\hat{D}}$ and M_Q

To summarize, after splitting our corpus (see section 4) into paragraphs and preprocessing it, we extract topics from paragraphs containing idioms and from paragraphs containing literals. We then compute a term by document matrix, where terms are topic terms and documents are topics extracted from the paragraphs. Our test data are represented as a term-by-document matrix as well (See the details in section 5).

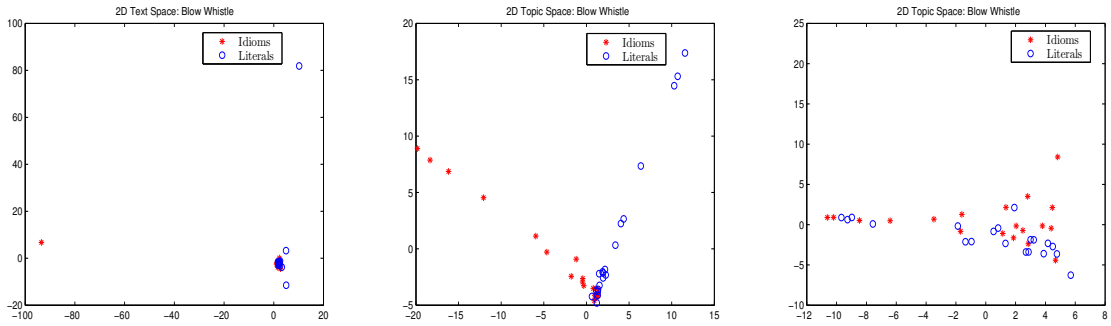

Figure 1: 2D projection of text segments containing "blow whistle." Left panel: Original text space. Middle panel: Topic space with restricted vocabulary. Right panel: Topic space with enlarged vocabulary.

3.3 Fisher Linear Discriminant Analysis

Once $M_{\hat{D}}$ and M_Q are obtained, a classification rule can be applied to predict idioms vs. literals. The approach we are taking in this work for classifying idioms vs. literals is based on Fisher's discriminant analysis (FDA) (Fukunaga, 1990). FDA often significantly simplifies tasks such as regression and classification by computing low-dimensional subspaces having statistically uncorrelated or discriminant variables. In language analysis, statistically uncorrelate or discriminant variables are extracted and utilized for description, detection, and classification. Woods et al. (1986), for example, use statistically uncorrelated variables for language test scores. A group of subjects is scored on a battery of language tests, where the subtests measure different abilities such as vocabulary, grammar or reading comprehension. Horvath (1985) analyzes speech samples of Sydney speakers to determine the relative occurrence of five different variants of each of five vowels sounds. Using this data, the speakers cluster according to such factors as gender, age, ethnicity and socio-economic class.

A similar approach has been discussed in Peng et al. (2010). FDA is a class of methods used in machine learning to find the linear combination of features that best separate two classes of events. FDA is closely related to principal component analysis (PCA), where a linear combination of features that best explains the data. Discriminant analysis explicitly exploits class information in the data, while PCA does not.

Idiom classification based on discriminant analysis has several advantages. First, as has been mentioned, it does not make any assumption regarding data distributions. Many statistical detection methods assume a Gaussian distribution of normal data, which is far from reality. Second, by using a few discriminants to describe data, discriminant analysis provides a compact representation of the data, resulting in increased computational efficiency and real time performance.

In FDA, within-class, between-class, and mixture scatter matrices are used to formulate the criteria of class separability. Consider a J class problem, where m_0 is the mean vector of all data, and m_j is the mean vector of jth class data. A within-class scatter matrix characterizes the scatter of samples around their respective class mean vector, and it is expressed by

$$S_w = \sum_{j=1}^{J} p_j \sum_{i=1}^{l_j} (x_i^j - m_j)(x_i^j - m_j)^t, \qquad (1)$$

where l_j is the size of the data in the jth class, p_j ($\sum_j p_j = 1$) represents the proportion of the jth class contribution, and t denotes the transpose operator. A between-class scatter matrix characterizes the scatter of the class means around the mixture mean m_0. It is expressed by

$$S_b = \sum_{j=1}^{J} p_j (m_j - m_0)(m_j - m_0)^t. \qquad (2)$$

The mixture scatter matrix is the covariance matrix of all samples, regardless of their class assignment, and it is given by

$$S_m = \sum_{i=1}^{l} (x_i - m_0)(x_i - m_0)^t = S_w + S_b. \qquad (3)$$

The Fisher criterion is used to find a projection matrix $W \in \Re^{q \times d}$ that maximizes

$$J(W) = \frac{|W^t S_b W|}{|W^t S_w W|}. \qquad (4)$$

In order to determine the matrix W that maximizes $J(W)$, one can solve the generalized eigenvalue problem: $S_b w_i = \lambda_i S_w w_i$. The eigenvectors corresponding to the largest eigenvalues form the columns of W. For a two class problem, it can be written in a simpler form: $S_w w = m = m_1 - m_2$, where m_1 and m_2 are the means of the two classes.

4 Data preprocessing

4.1 Verb-noun constructions

For our experiments we use the British National Corpus (BNC, Burnard (2000)) and a list of verb-noun constructions (VNCs) extracted from BNC by Fazly et al.

(2009); Cook et al. (2008) and labeled as L (Literal), I (Idioms), or Q (Unknown). The list contains only those VNCs whose frequency was greater than 20 and that occurred at least in one of two idiom dictionaries (Cowie et al., 1983; Seaton and Macaulay, 2002). The dataset consists of 2,984 VNC tokens. For our experiments we only use VNCs that are annotated as I or L.

4.2 Lemmatization

Instead of dealing with various forms of the same root, we use lemmas provided by the BNC XML annotation, so our corpus is lemmatized. We also apply the (modified) Google stop list before extracting the topics. The reason we modified the stop list is that some function words can potentially be idiom components (e.g., certain prepositions).

4.3 Paragraphs

We use the original SGML annotation to extract paragraghs from BNC. We only kept the paragraphs that contained VNCs for our experiments. We experimented with texts of one paragraph length (single paragraph contexts) and of three-paragraph length (multi-paragraph contexts). An example of multi-paragraph contexts is shown below:

So, reluctantly, I joined Jack Hobbs in not rocking the boat, reporting the play and the general uproar with perhaps too much impartiality. My reports went to all British newspapers, with special direct services by me to India, South Africa and West Indies; even to King George V in Buckingham Palace, who loved his cricket. In other words, I was to some extent leading the British public astray.

I regret I can shed little new light on the mystery of who **blew the whistle** *on the celebrated dressing-room scene after Woodfull was hit. while he was lying on the massage table after his innings waiting for a doctor, Warner and Palairet called to express sympathy.*

Most versions of Woodfull's reply seem to agree that he said. There are two teams out there on the oval. One is playing cricket, the other is not. This game is too good to be spoilt. It is time some people got out of it. Warner and Palairet were too taken aback to reply. They left the room in embarrassment.

Single paragraph contexts simply consist of the middle paragraph.

5 Experiments

5.1 Methods

We have carried out an empirical study evaluating the performance of the proposed algorithm. For comparison, the following methods are evaluated. (1) The proposed algorithm **TopSpace** (1), where the data are represented in topic space. (2) **TexSpace** algorithm, where the data are represented in original text space. For each representation, two classification schemes are applied: a) FDA (Eq. 4), followed by the nearest neighbor rule. b) SVMs with Gaussian kernels (Cristianini and Shawe-Taylor (2000)). For the nearest neighbor rule, the number of nearest neighbors is set to $\lceil n/5 \rceil$, where n denotes the number of training examples. For SVMs, kernel width and soft margin parameters are set to default values.

5.2 Data Sets

The following data sets are used to evaluate the performance of the proposed technique. These data sets have enough examples from both idioms and literals to make our results meaningful. On average, the training data is 6K word tokens. Our test data is of a similar size.

BlowWhistle: This data set has 78 examples, 27 of which are idioms and the remaining 51 are literals. The training data for **BlowWhistle** consist of 40 randomly chosen examples (20 paragraphs containing idioms and 20 paragraphs containing literals). The remaining 38 examples (7 idiomatic and 31 literals) are used as test data.

MakeScene: This data set has 50 examples, 30 of which are paragraphs containing idioms and the remaining 20 are paragraphs containing literals. The training data for **MakeScene** consist of 30 randomly chosen examples, 15 of which are paragraphs containing *make scene* as an idiom and the rest 15 are paragraphs containing *make scene* as a literal. The remaining 20 examples (15 idiomatic paragraphs and 5 literals) are used as test data.

LoseHead: This data set has 40 examples, 21 of which are idioms and the remaining 19 are literals. The training data for **LoseHead** consist of 30 randomly chosen examples (15 idiomatic and 15 literal). The remaining 10 examples (6 idiomatic and 4 literal) are used as test data.

TakeHeart: This data set has 81 examples, 61 of which are idioms and the remaining 20 are literals. The training data for **TakeHeart** consist of 30 randomly chosen examples (15 idiomatic and 15 literals). The remaining 51 examples (46 idiomatic and 5 literals) are used as test data.

5.3 Adding affect

Nunberg et al. (1994) notice that "idioms are typically used to imply a certain evaluation or affective stance toward the things they denote". Language users usually choose an idiom in non-neutral contexts. The situations that idioms describe can be positive or negative; however, the polarity of the context is not as important as the strength of the emotion expressed. So, we decided to incorporate the knowledge about the emotion strength into our algorithm. We use a database of word norms collected by Warriner et al. (2013). This database contains almost 14,000 English lemmas annotated with three components of emotions: valence (the pleasantness of a stimulus), arousal (the intensity of emotion provoked by a stimulus), and dominance

Table 1: Average accuracy of competing methods on four datasets in single paragraph contexts: A = Arousal

(the degree of control exerted by a stimulus). These components were elicited from human subjects via an Amazon Mechanical Turk crowdsourced experiment. We only used the arousal feature in our experiments because we were interested in the intensity of the emotion rather than its valence.

For a document $d = \{w_1, \cdots, w_N\}^t$, we calculate the corresponding arousal value a_i for each w_i, obtaining $d_A = \{a_1, \cdots, a_N\}^t$. Let m_A be the average arousal value calculated over the entire training data. The centered arousal value for a training document is obtained by subtracting m_A from d_A, i.e., $\bar{d}_A = d_A - m_A = \{a_1 - m_A, \cdots, a_N - m_A\}^t$. Similarly, the centered arousal value for a query is computed according to $\bar{q}_A = q_A - m_A = \{q_1 - m_A, \cdots, q_N - m_A\}^t$. That is, the training arousal mean is used to center both training and query arousal values. The corresponding arousal matrices for D, $\hat{D}$, and Q are A_D, $A_{\hat{D}}$, A_Q, respectively. To incorporate the arousal feature, we simply compute

$$\Theta_D = M_D + A_D, \tag{5}$$

and

$$\Theta_{\hat{D}} = M_{\hat{D}} + A_{\hat{D}}. \tag{6}$$

The arousal feature can be similarly incoporated into query $\Theta_Q = M_Q + A_Q$.

6 Results

Table 1 shows the average precision, recall, and accuracy of the competing methods on the four data sets over 10 runs in simple paragraph contexts. Table 2 shows the results for the multi-paragraph contexts. Note that for single paragraph contexts, we chose two topics, each having 10 terms. For multi-paragrah contexts, we had four topics, with 10 terms per topic. No optimization was made for selecting the number of topics as well as the number of terms per topic. In the tables, the best performance in terms of the sum of precision, recall and accuracy is given in boldface.

The results show that the topic representation achieved the best performance in 6 out of 8 cases. Figure 2 plots the overall aggregated performance in terms of topic vs text representations across the entire data sets, regardless of the classifiers used. Everything else being equal, this clearly shows the advantage of topics over simple text representation.

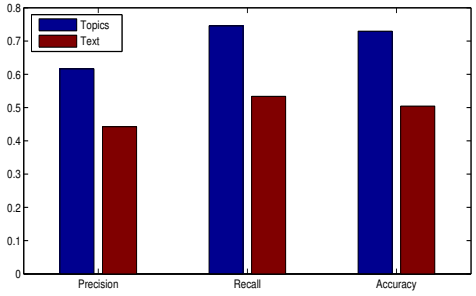

Figure 2: Aggregated performance: Topic vs text representations.

The arousal feature (Eqs 5 and 6) also improved the overall performance, particularly in text representation (Eq. 5). This can be seen in the top panel in Figure 3. In fact, in 2/8 cases, text representation coupled with the arousal feature achieved the best performance. One possible explanation is that the LDA model already performed "feature" selection (choosing topic terms), to the extent possible. Thus, any additional information such as arousal only provides marginal improvement at the best (bottom panel in Figure 3). On the other hand, original text represents "raw" features, whereby arousal information helps provide better contexts, thus improving overall performance.

Figure 4 shows a case in point: the average (sorted) arousal values of idioms and literals of the target phrase "lose head." The upper panel plots arousal values in the text space, while lower panel plots arousal values in the topic space. The plot supports the results shown in Tables 1 and 2, where the arousal feature generally improves text representation.

7 Comparisons with other approaches

Even though we used Fazly et al. (2009)'s dataset for these experiments, the direct comparison with their method is impossible here because our task is formulated differently and we do not use the full dataset for the experiments. Fazly et al. (2009)'s unsupervised

model that relies on the so-called canonical forms gives 72.4% (macro-)accuracy on the extraction of idiomatic tokens when evaluated on their test data.

We cannot compare our method directly with the other methods discussed in section 2 either because each uses a different dataset or formulates the task differently (detection vs. recognition vs. identification). However, we can compare the method presented here with Feldman and Peng (2013) who also experiment with LDA, use similar data, and frame the problem as classification. Their goal, however, is to classify *sentences* as either idiomatic or literal. To obtain a discriminant subspace, they train their model on a small number of randomly selected idiomatic and non-idiomatic sentences. They then project both the training and the test data on the chosen subspace and use the three nearest neighbor (3NN) classifier to obtain accuracy. The average accuracy they report is 80%. Our method clearly outperforms the Feldman and Peng (2013) approach (at least on the dataset we use).

8 Discussion and Conclusion

We have described an algorithm for automatic classification of idiomatic and literal expressions. We have investigated the bag of words topic representation for target documents (segments of one or three paragraphs that contains a target phrase). The approach definitely outperforms the baseline model that is based on the simple bag of words representation, but it also outperforms approaches previously discussed in the literature. Our model captures the local semantics and thus is capable to identify semantic outliers (=idioms).

While we realize that the data set we use is small, the results are encouraging. We notice that using 3 paragraphs for local contexts improves the performance of the classifiers. The reason is that some paragraphs are

relatively short. A larger context provides more related terms, which gives LDA more opportunities to sample these terms.

Idioms are also relatively non-compositional. While we do not measure their non-compositionality in this approach, we indirectly touch upon this property by hypothesizing that non-compositional idiomatic expressions are likely to be far from the local topics.

We feel that incorporating the intensity of emotion expressed by the context into our model improves performance, in particular, in text representation. When we performed a qualitative analysis of the results trying to determine the causes of false positives and negatives, we noticed that there were quite a number of cases that improved after incorporating the arousal feature into the model. For example, the FDA:topic classifier labels "blow the whistle" as literal in the following context, but FDA:topics+A marks this expression as idiomatic (italicized words indicate words with relatively high arousal values):

Peter thought it all out very *carefully*. He decided the *wisest* course was to pool all he had made over the last two years, enabling Julian to purchase the lease of a high street property. This would enable them to set up a business on a more *settled* and *permanent* trading basis. Before long they opened a grocery-cum-delicatessen in a *good* position as far as passing trade was concerned. Peter's investment was not misplaced. The business did very well with the two lads greatly *appreciated* locally for their *hard* work and quality of service. The range of goods they were able to carry was *welcomed* in the area, as well as lunchtime sandwich facilities which had previously been missing in the neighbourhood.

Success was the fruit of some three years' *strenuous* work. But it was more than a *shock* when Julian admitted to Peter that he had been running up *huge debts* with their bank. Peter knew that Julian *gambled*, but he hadn't expected him to *gamble* to that level, and certainly not to use the shop as security. With continual borrowing over two years, the bank had **blown the whistle**. Everything was gone. Julian was *bankrupt.* Even if they'd had a formal partnership, which they didn't, it would have made no difference. Peter *lost* all he'd made, and with it his *chance* to help his parents and his younger brother and sister, Toby and Laura.

Peter was *heartbroken*. His father had said all along: neither a lender nor a borrower. Peter had found out the *hard* way. But as his mother observed, he was the same Peter, he'd pick himself up somehow. Once again, Peter was resolute. He made up his mind he'd never make the same *mistake* twice. It wasn't just the money or the hard work, though the waste of that was *difficult* enough to accept. Peter had been working a *debt* of *love*. He'd done all this for his parents, particularly for his father, whose *dedication* to his children had always *impressed* Peter and moved him *deeply*. And now it had all come to nothing.

Therefore, we think that idioms have the tendency to appear in more affective contexts; and we think that incorporating more sophisticated sentiment analysis into our model will improve the results.

Learning Spatial Knowledge for Text to 3D Scene Generation

Angel X. Chang, Manolis Savva and Christopher D. Manning

Abstract

We address the grounding of natural language to concrete spatial constraints, and inference of implicit pragmatics in 3D environments. We apply our approach to the task of text-to-3D scene generation. We present a representation for common sense spatial knowledge and an approach to extract it from 3D scene data. In text-to-3D scene generation, a user provides as input natural language text from which we extract explicit constraints on the objects that should appear in the scene. The main innovation of this work is to show how to augment these explicit constraints with learned spatial knowledge to infer missing objects and likely layouts for the objects in the scene. We demonstrate that spatial knowledge is useful for interpreting natural language and show examples of learned knowledge and generated 3D scenes.

1 Introduction

To understand language, we need an understanding of the world around us. Language describes the world and provides symbols with which we represent meaning. Still, much knowledge about the world is so obvious that it is rarely explicitly stated. It is uncommon for people to state that chairs are usually on the floor and upright, and that you usually eat a cake from a plate on a table. Knowledge of such common facts provides the context within which people communicate with language. Therefore, to create practical systems that can interact with the world and communicate with people, we need to leverage such knowledge to interpret language in context.

Spatial knowledge is an important aspect of the world and is often not expressed explicitly in natural language. This is one of the biggest challenges in grounding language and enabling natural communication between people and intelligent systems. For instance, if we want a robot that can follow commands such as "bring me a piece of cake", it needs to be imparted with an understanding of likely locations for the cake in the kitchen and that the cake should be placed on a plate.

Figure 1: Generated scene for "There is a room with a chair and a computer." Note that the system infers the presence of a desk and that the computer should be supported by the desk.

The pioneering WordsEye system (Coyne and Sproat, 2001) addressed the text-to-3D task and is an inspiration for our work. However, there are many remaining gaps in this broad area. Among them, there is a need for research into learning spatial knowledge representations from data, and for connecting them to language. Representing unstated facts is a challenging problem unaddressed by prior work and the focus of our contribution. This problem is a counterpart to the image description problem (Kulkarni et al., 2011; Mitchell et al., 2012; Elliott and Keller, 2013), which has so far remained largely unexplored by the community.

We present a representation for this form of spatial knowledge that we learn from 3D scene data and connect to natural language. We will show how this representation is useful for grounding language and for inferring unstated facts, i.e., the pragmatics of language describing physical environments. We demonstrate the use of this representation in the task of text-to-3D scene genera-

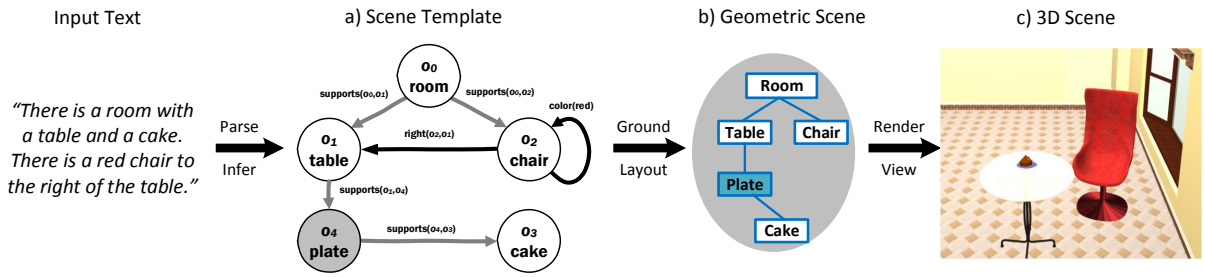

Figure 2: Overview of our spatial knowledge representation for text-to-3D scene generation. We parse input text into a scene template and infer implicit spatial constraints from learned priors. We then ground the template to a geometric scene, choose 3D models to instantiate and arrange them into a final 3D scene.

tion, where the input is natural language and the desired output is a 3D scene.

We focus on the text-to-3D task to demonstrate that extracting spatial knowledge is possible and beneficial in a challenging scenario: one requiring the grounding of natural language and inference of rarely mentioned implicit pragmatics based on spatial facts. Figure 1 illustrates some of the inference challenges in generating 3D scenes from natural language: the desk was not explicitly mentioned in the input, but we need to infer that the computer is likely to be supported by a desk rather than directly placed on the floor. Without this inference, the user would need to be much more verbose with text such as "There is a room with a chair, a computer, and a desk. The computer is on the desk, and the desk is on the floor. The chair is on the floor."

Contributions We present a spatial knowledge representation that can be learned from 3D scenes and captures the statistics of what objects occur in different scene types, and their spatial positions relative to each other. In addition, we model spatial relations (left, on top of, etc.) and learn a mapping between language and the geometric constraints that spatial terms imply. We show that using our learned spatial knowledge representation, we can infer implicit constraints, and generate plausible scenes from concise natural text input.

2 Task Definition and Overview

We define text-to-scene generation as the task of taking text that describes a scene as input, and generating a plausible 3D scene described by that text as output. More concretely, based on the input text, we select objects from a dataset of 3D models and arrange them to generate output scenes.

The main challenge we address is in transforming a scene template into a physically realizable 3D scene. For this to be possible, the system must be able to automatically specify the objects present and their position and orientation with respect to each other as constraints in 3D space. To do so, we need to have a representation of scenes (§3). We need good priors over the arrangements of objects in scenes (§4) and we need to be able to ground textual relations into spatial constraints (§5). We break down our task as follows (see Figure 2):

Template Parsing (§6.1): Parse the textual description of a scene into a set of constraints on the objects present and spatial relations between them.

Inference (§6.2): Expand this set of constraints by accounting for implicit constraints not specified in the text using learned spatial priors.

Grounding (§6.3): Given the constraints and priors on the spatial relations of objects, transform the scene template into a geometric 3D scene with a set of objects to be instantiated.

Scene Layout (§6.4): Arrange the objects and optimize their placement based on priors on the relative positions of objects and explicitly provided spatial constraints.

3 Scene Representation

To capture the objects present and their arrangement, we represent scenes as graphs where nodes are objects in the scene, and edges are semantic relationships between the objects.

We represent the semantics of a scene using a *scene template* and the geometric properties using a *geometric scene*. One critical property which is captured by our scene graph representation is that of a static support hierarchy, i.e., the order in which bigger objects physically support smaller ones: the floor supports tables, which support plates, which can support cakes. Static support and other constraints on relationships between objects are represented as edges in the scene graph.

Figure 3: Probabilities of different scene types given the presence of "knife" and "table".

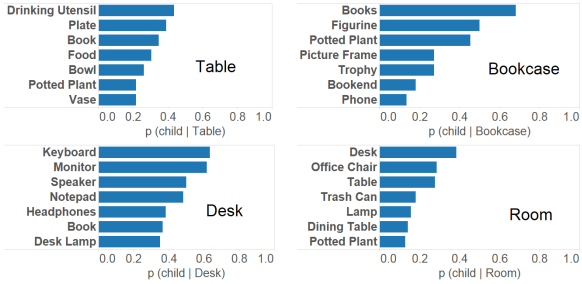

Figure 4: Probabilities of support for some most likely child object categories given four different parent object categories, from top left clockwise: dining table, bookcase, room, desk.

3.1 Scene Template

A scene template $\mathcal{T} = (\mathcal{O}, \mathcal{C}, C_s)$ consists of a set of object descriptions $\mathcal{O} = \{o_1, \ldots, o_n\}$ and constraints $\mathcal{C} = \{c_1, \ldots, c_k\}$ on the relationships between the objects. A scene template also has a scene type C_s.

Each object o_i, has properties associated with it such as category label, basic attributes such as color and material, and number of occurrences in the scene. For constraints, we focus on spatial relations between objects, expressed as predicates of the form *supported_by*(o_i, o_j) or *left*(o_i, o_j) where o_i and o_j are recognized objects.[1] Figure 2a shows an example scene template. From the scene template we instantiate concrete geometric 3D scenes. To infer implicit constraints on objects and spatial support we learn priors on object occurrences in 3D scenes (§4.1) and their support hierarchies (§4.2).

3.2 Geometric Scene

We refer to the concrete geometric representation of a scene as a "geometric scene". It consists of a set of 3D model instances – one for each object – that capture the appearance of the object. A transformation matrix that represents the position, orientation, and scaling of the object in a scene is also necessary to exactly position the object. We generate a geometric scene from a scene template by selecting appropriate models from a 3D model database and determining transformations that optimize their layout to satisfy spatial constraints. To inform geometric arrangement we learn priors on the types of support surfaces (§4.2) and the relative positions of objects (§4.4).

4 Spatial Knowledge

Our model of spatial knowledge relies on the idea of abstract scene types describing the occurrence and arrangement of different categories of objects within scenes of that type. For example, kitchens typically contain kitchen counters on which plates and cups are likely to be found. The type of scene and category of objects condition the spatial relationships that can exist in a scene.

We learn spatial knowledge from 3D scene data, basing our approach on that of Fisher et al. (2012) and using their dataset of 133 small indoor scenes created with 1723 Trimble 3D Warehouse models (Fisher et al., 2012).

4.1 Object Occurrence Priors

We learn priors for object occurrence in different scene types (such as kitchens, offices, bedrooms).

$$P_{occ}(C_o|C_s) = \frac{count(C_o \text{ in } C_s)}{count(C_s)}$$

This allows us to evaluate the probability of different scene types given lists of object occurring in them (see Figure 3). For example given input of the form "there is a knife on the table" then we are likely to generate a scene with a dining table and other related objects.

4.2 Support Hierarchy Priors

We observe the static support relations of objects in existing scenes to establish a prior over what objects go on top of what other objects. As an example, by observing plates and forks on tables most of the time, we establish that tables are more likely to support plates and forks than chairs. We estimate the probability of a parent category C_p supporting a given child category C_c as a simple conditional probability based on normalized observation counts.[2]

$$P_{support}(C_p|C_c) = \frac{count(C_c \text{ on } C_p)}{count(C_c)}$$

We show a few of the priors we learn in Figure 4 as likelihoods of categories of child objects being statically supported by a parent category object.

[1] Our representation can also support other relationships such as $larger(o_i, o_j)$.

[2] The support hierarchy is explicitly modeled in the scene dataset we use.

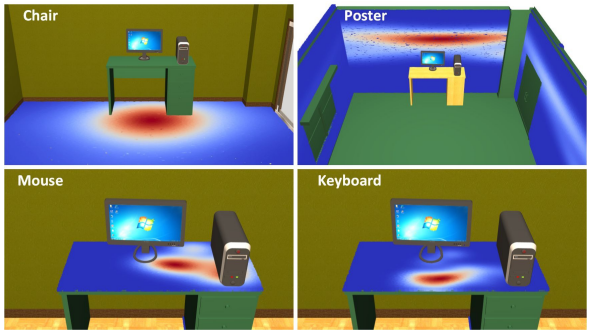

Figure 5: Predicted positions using learned relative position priors for *chair* given *desk* (top left), *poster-room* (top right), *mouse-desk* (bottom left), *keyboard-desk* (bottom right).

4.3 Support Surface Priors

To identify which surfaces on parent objects support child objects, we first segment parent models into planar surfaces using a simple region-growing algorithm based on (Kalvin and Taylor, 1996). We characterize support surfaces by the direction of their normal vector, limited to the six canonical directions: *up, down, left, right, front, back*. We learn a probability of supporting surface normal direction S_n given child object category C_c. For example, posters are typically found on walls so their support normal vectors are in the horizontal directions. Any unobserved child categories are assumed to have $P_{surf}(S_n = up|C_c) = 1$ since most things rest on a horizontal surface (e.g., floor).

$$P_{surf}(S_n|C_c) = \frac{count(C_c \text{ on surface with } S_n)}{count(C_c)}$$

4.4 Relative Position Priors

We model the relative positions of objects based on their object categories and current scene type: i.e., the relative position of an object of category C_{obj} is with respect to another object of category C_{ref} and for a scene type C_s. We condition on the relationship R between the two objects, whether they are siblings ($R = Sibling$) or child-parent ($R = ChildParent$).

$$P_{relpos}(x, y, \theta|C_{obj}, C_{ref}, C_s, R)$$

When positioning objects, we restrict the search space to points on the selected support surface. The position x, y is the centroid of the target object projected onto the support surface in the semantic frame of the reference object. The θ is the angle between the front of the two objects. We represent these relative position and orientation priors by performing kernel density estimation on the observed samples. Figure 5 shows predicted positions of objects using the learned priors.

Relation	$P(relation)$
inside(A,B)	$\frac{Vol(A \cap B)}{Vol(A)}$
outside(A,B)	1 - $\frac{Vol(A \cap B)}{Vol(A)}$
left_of(A,B)	$\frac{Vol(A \cap \text{left\_of}(B))}{Vol(A)}$
right_of(A,B)	$\frac{Vol(A \cap \text{right\_of}(B))}{Vol(A)}$
near(A,B)	$\mathbb{1}(dist(A, B) < t_{near})$
faces(A,B)	$\cos(front(A), c(B) - c(A))$

Table 1: Definitions of spatial relation using bounding boxes. Note: $dist(A, B)$ is normalized against the maximum extent of the bounding box of B. $front(A)$ is the direction of the front vector of A and $c(A)$ is the centroid of A.

Table 2: Map of top keywords to spatial relations (appropriate mappings in **bold**).

5 Spatial Relations

We define a set of formal spatial relations that we map to natural language terms (§5.1). In addition, we collect annotations of spatial relation descriptions from people, learn a mapping of spatial keywords to our formal spatial relations, and train a classifier that given two objects can predict the likelihood of a spatial relation holding (§5.2).

5.1 Predefined spatial relations

For spatial relations we use a set of predefined relations: *left_of, right_of, above, below, front, back, supported_by, supports, next_to, near, inside, outside, faces, left_side, right_side*.[3] These are measured using axis-aligned bounding boxes from the viewer's perspective; the involved bounding boxes are compared to determine volume overlap or closest distance (for proximity relations; see Table 1).

[3] We distinguish *left_of(A,B)* as A being left of the left edge of the bounding box of B vs *left_side(A,B)* as A being left of the centroid of B.

Feature	#	*Description*
$delta(A, B)$	3	Delta position (x, y, z) between the centroids of A and B
$dist(A, B)$	1	Normalized distance (wrt B) between the centroids of A and B
$overlap(A, f(B))$	6	Fraction of A inside left/right/front/back/top/bottom regions wrt B: $\frac{Vol(A \cap f(B))}{Vol(A)}$
$overlap(A, B)$	2	$\frac{Vol(A \cap B)}{Vol(A)}$ and $\frac{Vol(A \cap B)}{Vol(B)}$
$support(A, B)$	2	$supported\_by(A, B)$ and $supports(A, B)$

Table 3: Features for trained spatial relations predictor.

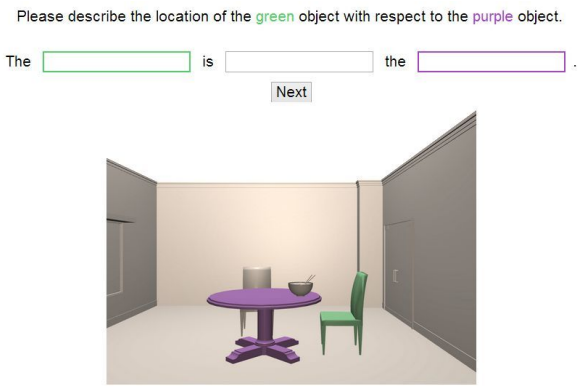

Figure 6: Our data collection task.

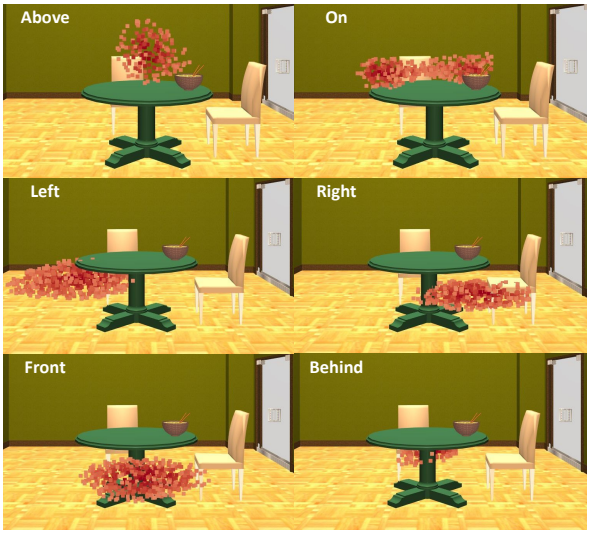

Figure 7: High probability regions where the center of another object would occur for some spatial relations with respect to a table: *above* (top left), *on* (top right), *left* (mid left), *right* (mid right), *in front* (bottom left), *behind* (bottom right).

Since these spatial relations are resolved with respect to the view of the scene, they correspond to view-centric definitions of spatial concepts.

5.2 Learning Spatial Relations

We collect a set of text descriptions of spatial relationships between two objects in 3D scenes by running an experiment on Amazon Mechanical Turk. We present a set of screenshots of scenes in our dataset that highlight particular pairs of objects and we ask people to fill in a spatial relationship of the form "The __ is __ the __" (see Fig 6). We collected a total of 609 annotations over 131 object pairs in 17 scenes. We use this data to learn priors on view-centric spatial relation terms and their concrete geometric interpretation.

For each response, we select one keyword from the text based on length. We learn a mapping of the top 15 keywords to our predefined set of spatial relations. We use our predefined relations on annotated spatial pairs of objects to create a binary indicator vector that is set to 1 if the spatial relation holds, or zero otherwise. We then create a similar vector for whether the keyword appeared in the annotation for that spatial pair, and then compute the cosine similarity of the two vectors to obtain a score for mapping keywords to spatial relations. Table 2 shows the obtained mapping. Using just the top mapping, we are able to map 10 of the 15 keywords to an appropriate spatial relation. The 5 keywords that are not well mapped are proximity relations that are not well captured by our predefined spatial relations.

Using the 15 keywords as our spatial relations, we train a log linear binary classifier for each keyword over features of the objects involved in that spatial relation (see Table 3). We then use this model to predict the likelihood of that spatial relation in new scenes.

Figure 7 shows examples of predicted likelihoods for different spatial relations with respect to an anchor object in a scene. Note that the learned spatial relations are much stricter than our predefined relations. For instance, "above" is only used to referred to the area directly above the table, not to the region above and to the left or above and in front (which our predefined classifier will all consider to be above). In our results, we show we have more accurate scenes using the trained spatial relations than the predefined ones.

Dependency Pattern	*Example Text*
`{tag:VBN}=verb >nsubjpass {}=nsubj >prep ({}=prep >pobj {}=pobj)`	The chair$_{\texttt{[nsubj]}}$ is made$_{\texttt{[verb]}}$ of$_{\texttt{[prep]}}$ wood$_{\texttt{[pobj]}}$.
attribute`(verb,pobj)(nsubj,pobj)`	`material(chair,wood)`
`{}=dobj >cop {} >nsubj {}=nsubj`	The chair$_{\texttt{[nsubj]}}$ is red$_{\texttt{[dobj]}}$.
attribute`(dobj)(nsubj,dobj)`	`color(chair,red)`
`{}=dobj >cop {} >nsubj {}=nsubj >prep ({}=prep >pobj {}=pobj)`	The table$_{\texttt{[nsubj]}}$ is next$_{\texttt{[dobj]}}$ to$_{\texttt{[prep]}}$ the chair$_{\texttt{[pobj]}}$.
spatial`(dobj)(nsubj, pobj)`	`next_to(table,chair)`
`{}=nsubj >advmod ({}=advmod >prep ({}=prep >pobj {}=pobj))`	There is a table$_{\texttt{[nsubj]}}$ next$_{\texttt{[advmod]}}$ to$_{\texttt{[prep]}}$ a chair$_{\texttt{[pobj]}}$.
spatial`(advmod)(nsubj, pobj)`	`next_to(table,chair)`

Table 4: Example dependency patterns for extracting attributes and spatial relations.

6 Text to Scene generation

We generate 3D scenes from brief scene descriptions using our learned priors.

6.1 Scene Template Parsing

During scene template parsing we identify the scene type, the objects present in the scene, their attributes, and the relations between them. The input text is first processed using the Stanford CoreNLP pipeline (Manning et al., 2014). The scene type is determined by matching the words in the utterance against a list of known scene types from the scene dataset.

To identify objects, we look for noun phrases and use the head word as the category, filtering with WordNet (Miller, 1995) to determine which objects are visualizable (under the physical object synset, excluding locations). We use the Stanford coreference system to determine when the same object is being referred to.

To identify properties of the objects, we extract other adjectives and nouns in the noun phrase. We also match dependency patterns such as "X is made of Y" to extract additional attributes. Based on the object category and attributes, and other words in the noun phrase mentioning the object, we identify a set of associated keywords to be used later for querying the 3D model database.

Dependency patterns are also used to extract spatial relations between objects (see Table 4 for some example patterns). We use Semgrex patterns to match the input text to dependencies (Chambers et al., 2007). The attribute types are determined from a dictionary using the text expressing the attribute (e.g., *attribute*(red)=color, *attribute*(round)=shape). Likewise, spatial relations are looked up using the learned map of keywords to spatial relations.

As an example, given the input "There is a room with a desk and a red chair. The chair is to the left of the desk." we extract the following objects and spatial relations:

Objects	category	attributes	keywords
o_0	room		room
o_1	desk		desk
o_2	chair	*color*:red	chair, red

Relations: $\mathit{left}(o_2, o_1)$

6.2 Inferring Implicits

From the parsed scene template, we infer the presence of additional objects and support constraints.

We can optionally infer the presence of additional objects from object occurrences based on the scene type. If the scene type is unknown, we use the presence of known object categories to predict the most likely scene type by using Bayes' rule on our object occurrence priors P_{occ} to get $P(C_s|\{C_o\}) \propto P_{occ}(\{C_o\}|C_s)P(C_s)$. Once we have a scene type C_s, we sample P_{occ} to find objects that are likely to occur in the scene. We restrict sampling to the top $n = 4$ object categories.

We can also use the support hierarchy priors $P_{support}$ to infer implicit objects. For instance, for each object o_i we find the most likely supporting object category and add it to our scene if not already present.

After inferring implicit objects, we infer the support constraints. Using the learned text to predefined relation mapping from §5.2, we can map the keywords "on" and "top" to the *supported_by* relation. We infer the rest of the support hierarchy by selecting for each object o_i the parent object o_j that maximizes $P_{support}(C_{o_j}|C_{o_i})$.

6.3 Grounding Objects

Once we determine from the input text what objects exist and their spatial relations, we select 3D models matching the objects and their associated properties. Each object in the scene template is grounded by querying a 3D models database with

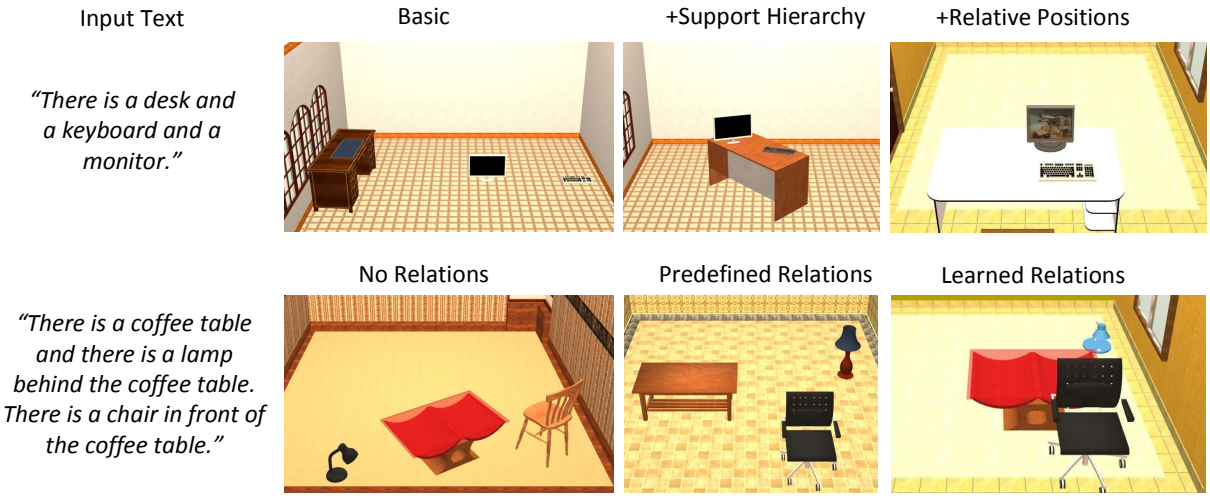

Figure 8: **Top** Generated scenes for randomly placing objects on the floor (*Basic*), with inferred *Support Hierarchy*, and with priors on *Relative Positions*. **Bottom** Generated scenes with no understanding of spatial relations (*No Relations*), scoring using *Predefined Relations* and *Learned Relations*.

the appropriate category and keywords.

We use a 3D model dataset collected from Google 3D Warehouse by prior work in scene synthesis and containing about 12490 mostly indoor objects (Fisher et al., 2012). These models have text associated with them in the form of names and tags. In addition, we semi-automatically annotated models with object category labels (roughly 270 classes). We used model tags to set these labels, and verified and augmented them manually.

In addition, we automatically rescale models so that they have physically plausible sizes and orient them so that they have a consistent up and front direction (Savva et al., 2014). We then indexed all models in a database that we query at run-time for retrieval based on category and tag labels.

6.4 Scene Layout

Once we have instantiated the objects in the scene by selecting models, we aim to optimize an overall layout score $\mathcal{L} = \lambda_{obj}\mathcal{L}_{obj} + \lambda_{rel}\mathcal{L}_{rel}$ that is a weighted sum of object arrangement $\mathcal{L}_{obj}$ score and constraint satisfaction $\mathcal{L}_{rel}$ score:

$$\mathcal{L}_{obj} = \sum_{o_i} P_{surf}(S_n|C_{o_i}) \sum_{o_j \in F(o_i)} P_{relpos}(\cdot)$$

$$\mathcal{L}_{rel} = \sum_{c_i} P_{rel}(c_i)$$

where $F(o_i)$ are the sibling objects and parent object of o_i. We use $\lambda_{obj} = 0.25$ and $\lambda_{rel} = 0.75$ for the results we present.

We use a simple hill climbing strategy to find a reasonable layout. We first initialize the positions of objects within the scene by traversing the support hierarchy in depth-first order, positioning the children from largest to first and recursing. Child nodes are positioned by first selecting a supporting surface on a candidate parent object through sampling of P_{surf}. After selecting a surface, we sample a position on the surface based on P_{relpos}. Finally, we check whether collisions exist with other objects, rejecting layouts where collisions occur. We iterate by randomly jittering and repositioning objects. If there are any spatial constraints that are not satisfied, we also remove and randomly reposition the objects violating the constraints, and iterate to improve the layout. The resulting scene is rendered and presented to the user.

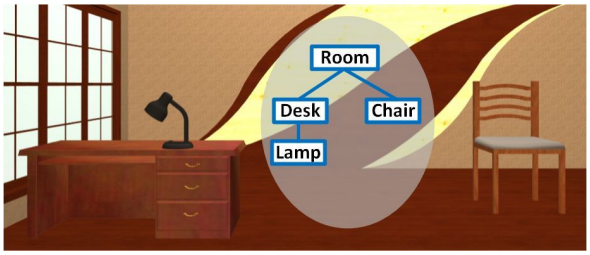

Figure 9: Generated scene for "There is a room with a desk and a lamp. There is a chair to the right of the desk." The inferred scene hierarchy is overlayed in the center.

7 Results and Discussion

We show examples of generated scenes, and compare against naive baselines to demonstrate learned priors are essential for scene generation. We

Figure 10: Generated scene for "There is a room with a poster bed and a poster."

Figure 11: Generated scene for "living room".

also discuss interesting aspects of using spatial knowledge in view-based object referent resolution (§7.2) and in disambiguating geometric interpretations of "on" (§7.3).

Model Comparison Figure 8 shows a comparison of scenes generated by our model versus several simpler baselines. The top row shows the impact of modeling the support hierarchy and the relative positions in the layout of the scene. The bottom row shows that the learned spatial relations can give a more accurate layout than the naive predefined spatial relations, since it captures pragmatic implicatures of language, e.g., left is only used for directly left and not top left or bottom left (Vogel et al., 2013).

Figure 12: **Left**: chair is selected using "the chair to the right of the table" or "the object to the right of the table". Chair is not selected for "the cup to the right of the table". **Right**: Different view results in different chair being selected for the input "the chair to the right of the table".

7.1 Generated Scenes

Support Hierarchy Figure 9 shows a generated scene along with the input text and support hierarchy. Even though the spatial relation between lamp and desk was not mentioned, we infer that the lamp is supported by the top surface of the desk.

Disambiguation Figure 10 shows a generated scene for the input "There is a room with a poster bed and a poster". Note that the system differentiates between a "poster" and a "poster bed" – it correctly selects and places the bed on the floor, while the poster is placed on the wall.

Inferring objects for a scene type Figure 11 shows an example of inferring all the objects present in a scene from the input "living room". Some of the placements are good, while others can clearly be improved.

7.2 View-centric object referent resolution

After a scene is generated, the user can refer to objects with their categories and with spatial relations between them. Objects are disambiguated by both category and view-centric spatial relations. We use the WordNet hierarchy to resolve hyponym or hypernym referents to objects in the scene. In Figure 12 (left), the user can select a chair to the right of the table using the phrase "chair to the right of the table" or "object to the right of the table". The user can then change their viewpoint by rotating and moving around. Since spatial relations are resolved with respect to the current viewpoint, a different chair is selected for the same phrase from a different viewpoint in the right screenshot.

7.3 Disambiguating "on"

As shown in §5.2, the English preposition "on", when used as a spatial relation, corresponds strongly to the *supported_by* relation. In our trained model, the *supported_by* feature also has a high positive weight for "on".

Our model for supporting surfaces and hierarchy allows interpreting the placement of "A on B" based on the categories of A and B. Figure 13 demonstrates four different interpretations for "on". Given the input "There is a cup on the table" the system correctly places the cup on the top surface of the table. In contrast, given "There is a cup on the bookshelf", the cup is placed on a supporting surface of the bookshelf, but not necessarily the top one which would be fairly high.

Figure 13: From top left clockwise: "There is a cup on the table", "There is a cup on the bookshelf", "There is a poster on the wall", "There is a hat on the chair". Note the different geometric interpretations of "on".

Given the input "There is a poster on the wall", a poster is pasted on the wall, while with the input "There is a hat on the chair" the hat is placed on the seat of the chair.

7.4 Limitations

While the system shows promise, there are still many challenges in text-to-scene generation. For one, we did not address the difficulties of resolving objects. A failure case of our system stems from using a fixed set of categories to identify visualizable objects. For example, the sense of "top" referring to a spinning top, and other uncommon object types, are not handled by our system as concrete objects. Furthermore, complex phrases including object parts such as "there's a coat on the seat of the chair" are not handled. Figure 14 shows some example cases where the context is important in selecting an appropriate object and the difficulties of interpreting noun phrases.

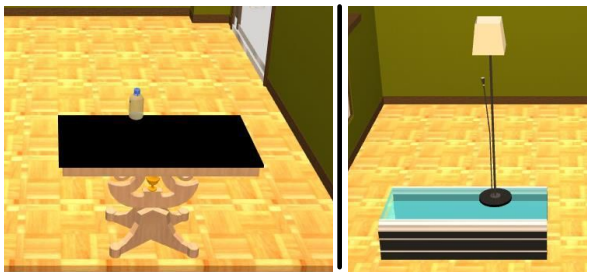

Figure 14: **Left**: A water bottle instead of wine bottle is selected for "There is a bottle of wine on the table in the kitchen". In addition, the selected table is inappropriate for a kitchen. **Right**: A floor lamp is incorrectly selected for the input "There is a lamp on the table".

In addition, we rely on a few dependency patterns for extracting spatial relations so robustness to variations in spatial language is lacking. We only handle binary spatial relations (e.g., "left", "behind") ignoring more complex relations such as "around the table" or "in the middle of the room". Though simple binary relations are some of the most fundamental spatial expressions and a good first step, handling more complex expressions will do much to improve the system.

Another issue is that the interpretation of sentences such as "the desk is covered with paper", which entails many pieces of paper placed on the desk, is hard to resolve. With a more data-driven approach we can hope to link such expressions to concrete facts.

Finally, we use a traditional pipeline approach for text processing, so errors in initial stages can propagate downstream. Failures in dependency parsing, part of speech tagging, or coreference resolution can result in incorrect interpretations of the input language. For example, in the sentence "there is a desk with a chair in front of it", "it" is not identified as coreferent with "desk" so we fail to extract the spatial relation `front_of(chair, desk)`.

8 Related Work

There is related prior work in the topics of modeling spatial relations, generating 3D scenes from text, and automatically laying out 3D scenes.

8.1 Spatial knowledge and relations

Prior work that required modeling spatial knowledge has defined representations specific to the task addressed. Typically, such knowledge is manually provided or crowdsourced – not learned from data. For instance, WordsEye (Coyne et al., 2010) uses a set of manually specified relations. The NLP community has explored grounding text to physical attributes and relations (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013), generating text for referring to objects (FitzGerald et al., 2013) and connecting language to spatial relationships (Vogel and Jurafsky, 2010; Golland et al., 2010; Artzi and Zettlemoyer, 2013). Most of this work focuses on learning a mapping from text to formal representations, and does not model

implicit spatial knowledge. Many priors on real world spatial facts are typically unstated in text and remain largely unaddressed.

8.2 Text to Scene Systems

Early work on the SHRDLU system (Winograd, 1972) gives a good formalization of the linguistic manipulation of objects in 3D scenes. By restricting the discourse domain to a micro-world with simple geometric shapes, the SHRDLU system demonstrated parsing of natural language input for manipulating scenes. However, generalization to more complex objects and spatial relations is still very hard to attain.

More recently, a pioneering text-to-3D scene generation prototype system has been presented by WordsEye (Coyne and Sproat, 2001). The authors demonstrated the promise of text to scene generation systems but also pointed out some fundamental issues which restrict the success of their system: much spatial knowledge is required which is hard to obtain. As a result, users have to use unnatural language (e.g., "the stool is 1 feet to the south of the table") to express their intent. Follow up work has attempted to collect spatial knowledge through crowd-sourcing (Coyne et al., 2012), but does not address the learning of spatial priors.

We address the challenge of handling natural language for scene generation, by learning spatial knowledge from 3D scene data, and using it to infer unstated implicit constraints. Our work is similar in spirit to recent work on generating 2D clipart for sentences using probabilistic models learned from data (Zitnick et al., 2013).

8.3 Automatic Scene Layout

Work on scene layout has focused on determining good furniture layouts by optimizing energy functions that capture the quality of a proposed layout. These energy functions are encoded from design guidelines (Merrell et al., 2011) or learned from scene data (Fisher et al., 2012). Knowledge of object co-occurrences and spatial relations is represented by simple models such as mixtures of Gaussians on pairwise object positions and orientations. We leverage ideas from this work, but they do not focus on linking spatial knowledge to language.

9 Conclusion and Future Work

We have demonstrated a representation of spatial knowledge that can be learned from 3D scene data and how it corresponds to natural language. We also showed that spatial inference and grounding is critical for achieving plausible results in the text-to-3D scene generation task. Spatial knowledge is critically useful not only in this task, but also in other domains which require an understanding of the pragmatics of physical environments.

We only presented a deterministic approach for mapping input text to the parsed scene template. An interesting avenue for future research is to automatically learn how to parse text describing scenes into formal representations by using more advanced semantic parsing methods.

We can also improve the representation used for spatial priors of objects in scenes. For instance, in this paper we represented support surfaces by their orientation. We can improve the representation by modeling whether a surface is an interior or exterior surface.

Another interesting line of future work would be to explore the influence of object identity in determining when people use ego-centric or object-centric spatial reference models, and to improve resolution of spatial terms that have different interpretations (e.g., "the chair to the left of John" vs "the chair to the left of the table").

Finally, a promising line of research is to explore using spatial priors for resolving ambiguities during parsing. For example, the attachment of "next to" in "Put a lamp on the table next to the book" can be readily disambiguated with spatial priors such as the ones we presented.

A Model of Coherence Based on Distributed Sentence Representation

Jiwei Li[1] **and Eduard Hovy**[3]
[1]Computer Science Department, Stanford University, Stanford, CA 94305, USA

jiweil@stanford.edu ehovy@andrew.cmu.edu

Abstract

Coherence is what makes a multi-sentence text meaningful, both logically and syntactically. To solve the challenge of ordering a set of sentences into coherent order, existing approaches focus mostly on defining and using sophisticated features to capture the cross-sentence argumentation logic and syntactic relationships. But both argumentation semantics and cross-sentence syntax (such as coreference and tense rules) are very hard to formalize. In this paper, we introduce a neural network model for the coherence task based on distributed sentence representation. The proposed approach learns a syntactico-semantic representation for sentences automatically, using either recurrent or recursive neural networks. The architecture obviated the need for feature engineering, and learns sentence representations, which are to some extent able to capture the 'rules' governing coherent sentence structure. The proposed approach outperforms existing baselines and generates the state-of-art performance in standard coherence evaluation tasks[1].

1 Introduction

Coherence is a central aspect in natural language processing of multi-sentence texts. It is essential in generating readable text that the text planner compute which ordering of clauses (or sentences; we use them interchangeably in this paper) is likely to support understanding and avoid confusion. As Mann and Thompson (1988) define it,

> A text is coherent when it can be explained what role each clause plays with regard to the whole.

Several researchers in the 1980s and 1990s addressed the problem, the most influential of which include: Rhetorical Structure Theory (RST; (Mann and Thompson, 1988)), which defined about 25 relations that govern clause interdependencies and ordering and give rise to text tree structures; the stepwise assembly of semantic graphs to support adductive inference toward the best explanation (Hobbs et al., 1988); Discourse Representation Theory (DRT; (Lascarides and Asher, 1991)), a formal semantic model of discourse contexts that constrain coreference and quantification scoping; the model of intention-oriented conversation blocks and their stack-based queueing to model attention flow (Grosz and Sidner, 1986), and more recently an inventory of a hundred or so binary inter-clause relations and associated annotated corpus (Penn Discourse Treebank. Work in text planning implemented some of these models, especially operationalized RST (Hovy, 1988) and explanation relations (Moore and Paris, 1989) to govern the planning of coherent paragraphs. Other computational work defined so called schemas (McKeown, 1985), frames with fixed sequences of clause types to achieve stereotypical communicative intentions.

Little of this work survives. Modern research tries simply to order a collection of clauses or sentences without giving an account of which order(s) is/are coherent or what the overall text structure is. The research focuses on identifying and defining a set of increasingly sophisticated features by which algorithms can be trained to propose orderings. Features being explored include the clause entities, organized into a grid (Lapata and Barzilay, 2005; Barzilay and Lapata, 2008), coreference clues to ordering (Elsner and Charniak, 2008), named-entity categories (Eisner and Charniak, 2011), syntactic features (Louis and Nenkova, 2012), and others. Besides being time-intensive (feature engineering usually requites considerable

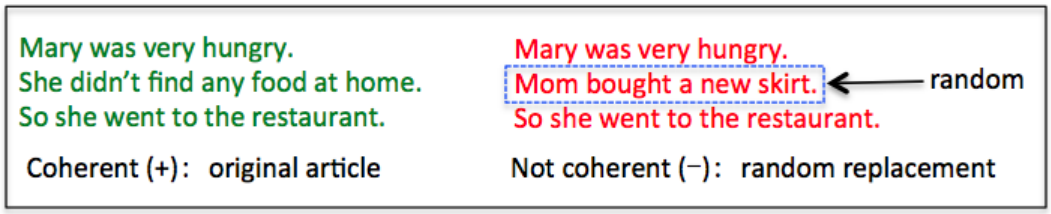

Figure 1: Illustrations of coherent (positive) vs not-coherent (negative) training examples.

effort and can depend greatly on upstream feature extraction algorithms), it is not immediately apparent which aspects of a clause or a coherent text to consider when deciding on ordering. More importantly, the features developed to date are still incapable of fully specifying the acceptable ordering(s) within a context, let alone describe why they are coherent.

Recently, deep architectures, have been applied to various natural language processing tasks (see Section 2). Such deep connectionist architectures learn a dense, low-dimensional representation of their problem in a hierarchical way that is capable of capturing both semantic and syntactic aspects of tokens (e.g., (Bengio et al., 2006)), entities, N-grams (Wang and Manning, 2012), or phrases (Socher et al., 2013). More recent researches have begun looking at higher level distributed representations that transcend the token level, such as sentence-level (Le and Mikolov, 2014) or even discourse-level (Kalchbrenner and Blunsom, 2013) aspects. Just as words combine to form meaningful sentences, can we take advantage of distributional semantic representations to explore the composition of sentences to form coherent meanings in paragraphs?

In this paper, we demonstrate that it is feasible to discover the coherent structure of a text using distributed sentence representations learned in a deep learning framework. Specifically, we consider a WINDOW approach for sentences, as shown in Figure 1, where positive examples are windows of sentences selected from original articles generated by humans, and negatives examples are generated by random replacements[2]. The semantic representations for terms and sentences are obtained through optimizing the neural network framework based on these positive vs negative examples and the proposed model produces state-of-art performance in multiple standard evaluations for coherence models (Barzilay and Lee, 2004).

The rest of this paper is organized as follows: We describe related work in Section 2, then describe how to obtain a distributed representation for sentences in Section 3, and the window composition in Section 4. Experimental results are shown in Section 5, followed by a conclusion.

2 Related Work

Coherence In addition to the early computational work discussed above, local coherence was extensively studied within the modeling framework of Centering Theory (Grosz et al., 1995; Walker et al., 1998; Strube and Hahn, 1999; Poesio et al., 2004), which provides principles to form a coherence metric (Miltsakaki and Kukich, 2000; Hasler, 2004). Centering approaches suffer from a severe dependence on manually annotated input.

A recent popular approach is the entity grid model introduced by Barzilay and Lapata (2008) , in which sentences are represented by a vector of discourse entities along with their grammatical roles (e.g., subject or object). Probabilities of transitions between adjacent sentences are derived from entity features and then concatenated to a document vector representation, which is used as input to machine learning classifiers such as SVM. Many frameworks have extended the entity approach, for example, by pre-grouping entities based on semantic relatedness (Filippova and Strube, 2007) or adding more useful types of features such as coreference (Elsner and Charniak, 2008), named entities (Eisner and Charniak, 2011), and discourse relations (Lin et al., 2011).

Other systems include the global graph model (Guinaudeau and Strube, 2013) which projects entities into a global graph. Louis and Nenkova (2012) introduced an HMM system in which the coherence between adjacent sentences is modeled by a hidden Markov framework captured by the

[2]Our approach is inspired by Collobert et al.'s idea (2011) that a word and its context form a positive training sample while a random word in that same context gives a negative training sample, when training word embeddings in the deep learning framework.

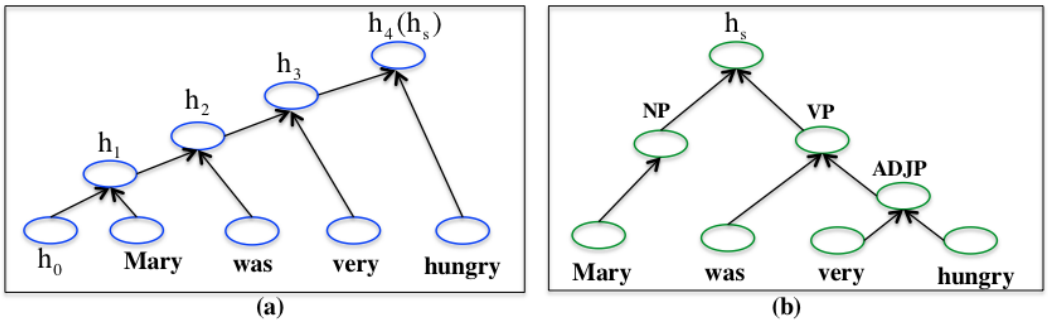

Figure 2: Sentential compositionality obtained from (a) recurrent / (b) recursive neural network. The bottom layer represents word vectors in the sentence. The top layer h_s denotes the resulting sentence vector.

transition rules of different topics.

Recurrent and Recursive Neural Networks In the context of NLP, recurrent neural networks view a sentence as a sequence of tokens and incorporate information from the past (i.e., preceding tokens) (Schuster and Paliwal, 1997; Sutskever et al., 2011) for acquisition of the current output. At each step, the recurrent network takes as input both the output of previous steps and the current token, convolutes the inputs, and forwards the result to the next step. It has been successfully applied to tasks such as language modeling (Mikolov et al., 2010) and spoken language understanding (Mesnil et al., 2013). The advantage of recurrent network is that it does not depend on external deeper structure (e.g., parse tree) and is easy to implement. However, in the recurrent framework, long-distance dependencies are difficult to capture due to the vanishing gradient problem (Bengio et al., 1994); two tokens may be structurally close to each other, even though they are far away in word sequence[3].

Recursive neural networks comprise another class of architecture, one that relies and operates on structured inputs (e.g., parse trees). It computes the representation for each parent based on its children iteratively in a bottom-up fashion. A series of variations have been proposed, each tailored to different task-specific requirements, such as Matrix-Vector RNN (Socher et al., 2012) that represents every word as both a vector and a matrix, or Recursive Neural Tensor Networks (Socher et al., 2013) that allow the model to have greater interactions between the input vectors. Many tasks have benefited from this recursive framework, including parsing (Socher et al., 2011b), sentiment analysis (Socher et al., 2013), and paraphrase detection (Socher et al., 2011a).

[3]For example, a verb and its corresponding direct object can be far away in terms of tokens if many adjectives lies in between, but they are adjacent in the parse tree (Irsoy and Cardie, 2013).

2.1 Distributed Representations

Both recurrent and recursive networks require a vector representation of each input token. Distributed representations for words were first proposed in (Rumelhart et al., 1988) and have been successful for statistical language modeling (Elman, 1990). Various deep learning architectures have been explored to learn these embeddings in an unsupervised manner from a large corpus (Bengio et al., 2006; Collobert and Weston, 2008; Mnih and Hinton, 2007; Mikolov et al., 2013), which might have different generalization capabilities and are able to capture the semantic meanings depending on the specific task at hand. These vector representations can to some extent capture interesting semantic relationships, such as $King - man \approx Queue - woman$ (Mikolov et al., 2010), and recently have been successfully used in various NLP applications, including named entity recognition, tagging, segmentation (Wang et al., 2013), and machine translation (e.g.,(Collobert and Weston, 2008; Zou et al., 2013)).

3 Sentence Model

In this section, we demonstrate the strategy adopted to compute a vector for a sentence given the sequence of its words and their embeddings. We implemented two approaches, Recurrent and Recursive neural networks, following the descriptions in for example (Mikolov et al., 2010; Sutskever et al., 2011; Socher et al., 2013). As

the details of both approaches can be readily found there, we make this section brief and omit the details for brevity.

Let s denote a sentence, comprised of a sequence of words $s = \{w_1, w_2, ..., w_{n_s}\}$, where n_s denotes the number of words within sentence s. Each word w is associated with a specific vector embedding $\mathbf{e_w} = \{e_w^1, e_w^2, ..., e_w^K\}$, where K denotes the dimension of the word embedding. We wish to compute the vector representation for current sentence $h_s = \{h_s^1, h_s^2, ..., h_s^K\}$.

Recurrent Sentence Representation (Recurrent) The recurrent network captures certain general considerations regarding sentential compositionality. As shown in Figure 2 (a), for sentence s, recurrent network successively takes word w_i at step i, combines its vector representation e_w^t with former input h_{i-1} from step $i-1$, calculates the resulting current embedding h_t, and passes it to the next step. The standard recurrent network calculates h_t as follows:

$$h_t = f(V_{Recurrent} \cdot h_{t-1} + W_{Recurrent} \cdot e_w^t + b_{Recurrent}) \quad (1)$$

where $W_{Recurrent}$ and $V_{Recurrent}$ are $K \times K$ matrixes. $b_{Recurrent}$ denotes $K \times 1$ bias vector and $f = tanh$ is a standard element-wise nonlinearity.

Note that calculation for representation at time $t = 1$ is given by:

$$h_1 = f(V_{Recurrent} \cdot h_0 + W_{Recurrent} \cdot e_w^1 + b_{Recurrent}) \quad (2)$$

where h_0 denotes the global sentence starting vector.

Recursive Sentence Representation (Recursive) Recursive sentence representation relies on the structure of parse trees, where each leaf node of the tree corresponds to a word from the original sentence. It computes a representation for each parent node based on its immediate children recursively in a bottom-up fashion until reaching the root of the tree. Concretely, for a given parent p in the tree and its two children c_1 (associated with vector representation h_{c_1}) and c_2 (associated with vector representation h_{c_2}), standard recursive networks calculates h_p for p as follows:

$$h_p = f(W_{Recursive} \cdot [h_{c_1}, h_{c_2}] + b_{Recursive}) \quad (3)$$

where $[h_{c_1}, h_{c_2}]$ denotes the concatenating vector for children vector representation h_{c_1} and h_{c_2}. $W_{Recursive}$ is a $K \times 2K$ matrix and $b_{Recursive}$ is the $1 \times K$ bias vector. $f(\cdot)$ is tanh function.

Recursive neural models compute parent vectors iteratively until the root node's representation is obtained, and use the root embedding to represent the whole sentence, as shown in Figure 2 (b).

4 Coherence Model

The proposed coherence model adopts a window approach (Collobert et al., 2011), in which we train a three-layer neural network based on a sliding windows of L sentences.

4.1 Sentence Convolution

We treat a window of sentences as a clique C and associate each clique with a tag y_C that takes the value 1 if coherent, and 0 otherwise[4]. As shown in Figure 1, cliques taken from original articles are treated as coherent and those with sentences randomly replaced are used as negative examples. .

The sentence convolution algorithm adopted in this paper is defined by a three-layer neural network, i.e., sentence-level input layer, hidden layer, and overall output layer as shown in Figure 3. Formally, each clique C takes as input a $(L \times K) \times 1$ vector h_C by concatenating the embeddings of all its contained sentences, denoted as $h_C = [h_{s_1}, h_{s_2}, ..., h_{s_L}]$. (Note that if we wish to classify the first and last sentences and include their context, we require special beginning and ending sentence vectors, which are defined as $h_{<S>}$ for s_{start} and $h_{</S>}$ for s_{end} respectively.)

Let H denote the number of neurons in the hidden (second) layer. Then each of the hidden layers takes as input h_C and performs the convolution using a non-linear tanh function, parametrized by W_{sen} and b_{sen}. The concatenating output vector for hidden layers, defined as q_C, can therefore be rewritten as:

$$q_C = f(W_{sen} \times h_C + b_{sen}) \quad (4)$$

where W_{sen} is a $H \times (L \times K)$ dimensional matrix and b_{sen} is a $H \times 1$ dimensional bias vector.

[4] instead of a binary classification (correct/incorrect), another commonly used approach is the contrastive approach that minimizes the score function $max(0, 1 - s + s_c)$ (Collobert et al., 2011; Smith and Eisner, 2005). s denotes the score of a true (coherent) window and s_c the score of a corrupt (containing incoherence) one) in an attempt to make the score of true windows larger and corrupt windows smaller. We tried the contrastive one for both recurrent and recursive networks but the binary approach constantly outperformed the contrastive one in this task.

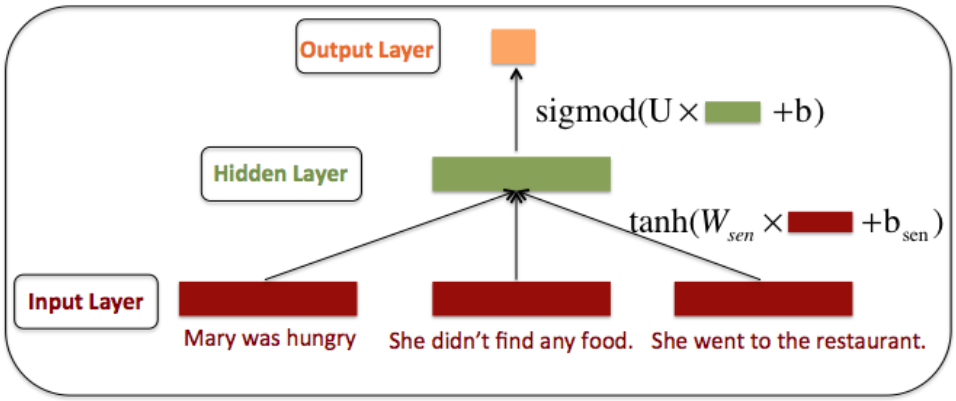

Figure 3: An example of coherence model based on a window of sentences (clique).

The output layer takes as input q_C and generates a scalar using linear function $U^T q_C + b$. A sigmod function is then adopted to project the value to a [0,1] probability space, which can be interpreted as the probability of whether one clique is coherent or not. The execution at the output layer can be summarized as:

$$p(y_C = 1) = \text{sigmod}(U^T q_C + b) \tag{5}$$

where U is an $H \times 1$ vector and b denotes the bias.

4.2 Training

In the proposed framework, suppose we have M training samples, the cost function for recurrent neural network with regularization on the training set is given by:

$$J(\Theta) = \frac{1}{M} \sum_{C \in trainset} \{-y_C \log[p(y_C = 1)] - (1 - y_C) \log[1 - p(y_C = 1)]\} + \frac{Q}{2M} \sum_{\theta \in \Theta} \theta^2 \tag{6}$$

where

$$\Theta = [W_{Recurrent}, W_{sen}, U_{sen}]$$

The regularization part is paralyzed by Q to avoid overfitting. A similar loss function is applied to the recursive network with only minor parameter altering that is excluded for brevity.

To minimize the objective $J(\Theta)$, we use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatches, which is widely applied in deep learning literature (e.g.,(Socher et al., 2011a; Pei et al., 2014)). The learning rate in AdaGrad is adapting differently for different parameters at different steps. Concretely, for parameter updates, let g_τ^i denote the subgradient at time step for parameter θ_i, which is obtained from backpropagation[5], the parameter update at time step t is given by:

$$\theta_\tau = \theta_{\tau-1} - \frac{\alpha}{\sum_{t=0}^{\tau} \sqrt{g_\tau^{i2}}} g_\tau^i \tag{7}$$

where α denotes the learning rate and is set to 0.01 in our approach. Optimal performance is achieved when batch size is set between 20 and 30.

4.3 Initialization

Elements in W_{sen} are initialized by randomly drawing from the uniform distribution $[-\epsilon, \epsilon]$, where $\epsilon = \frac{\sqrt{6}}{\sqrt{H+K \times L}}$ as suggested in (Collobert et al., 2011). $W_{recurrent}$, $V_{recurrent}$, $W_{recursive}$ and h_0 are initialized by randomly sampling from a uniform distribution $U(-0.2, 0.2)$. All bias vectors are initialized with 0. Hidden layer number H is set to 100.

Word embeddings $\{e\}$ are borrowed from Senna (Collobert et al., 2011; Collobert, 2011). The dimension for these embeddings is 50.

5 Experiments

We evaluate the proposed coherence model on two common evaluation approaches adopted in existing work (Barzilay and Lapata, 2008; Louis and Nenkova, 2012; Elsner et al., 2007; Lin et al., 2011): Sentence Ordering and Readability Assessment.

5.1 Sentence Ordering

We follow (Barzilay and Lapata, 2008; Louis and Nenkova, 2012; Elsner et al., 2007; Lin et al.,

[5]For more details on backpropagation through RNNs, see Socher et al. (2010).

2011) that all use pairs of articles, one containing the original document order and the other a random permutation of the sentences from the same document. The pairwise approach is predicated on the assumption that the original article is always more coherent than a random permutation; this assumption has been verified in Lin et al.'s work (2011).

We need to define the coherence score S_d for a given document d, where d is comprised of a series of sentences, $d = \{s_1, s_2, .., s_{N_d}\}$, and N_d denotes the number of sentences within d. Based on our clique definition, document d is comprised of N_d cliques. Taking window size $L = 3$ as example, cliques generated from document d appear as follows:

$$< s_{start}, s_1, s_2 >, < s_1, s_2, s_3 >, ..., \\ < s_{N_d-2}, s_{N_d-1}, s_{N_d} >, < s_{N_d-1}, s_{N_d}, s_{end} >$$

The coherence score for a given document S_d is the probability that all cliques within d are coherent, which is given by:

$$S_d = \prod_{C \in d} p(y_C = 1) \quad (8)$$

For document pair $< d_1, d_2 >$ in our task, we would say document d_1 is more coherent than d_2 if

$$S_{d_1} > S_{d_2} \quad (9)$$

5.1.1 Dataset

We use two corpora that are widely employed for coherence prediction (Barzilay and Lee, 2004; Barzilay and Lapata, 2008; Elsner et al., 2007). One contains reports on airplane accidents from the National Transportation Safety Board and the other contains reports about earthquakes from the Associated Press. These articles are about 10 sentences long and usually exhibit clear sentence structure. For preprocessing, we only lowercase the capital letters to match with tokens in Senna word embeddings. In the recursive network, sentences are parsed using the Stanford Parser[6] and then transformed into binary trees. The accident corpus ends up with a vocabulary size of 4758 and an average of 10.6 sentences per document. The earthquake corpus contains 3287 distinct terms and an average of 11.5 sentences per document.

For each of the two corpora, we have 100 articles for training and 100 (accidents) and 99 (earthquakes) for testing. A maximum of 20 random permutations were generated for each test article to create the pairwise data (total of 1986 test pairs for the accident corpus and 1956 for earthquakes)[7].

Positive cliques are taken from original training documents. For easy training, rather than creating negative examples by replacing centered sentences randomly, the negative dataset contains cliques where centered sentences are replaced only by other sentences within the same document.

5.1.2 Training and Testing

Despite the numerous parameters in the deep learning framework, we tune only two principal ones for each setting: window size L (tried on $\{3, 5, 7\}$) and regularization parameter Q (tried on $\{0.01, 0.1, 0.25, 0.5, 1.0, 1.25, 2.0, 2.5, 5.0\}$). We trained parameters using 10-fold cross-validation on the training data. Concretely, in each setting, 90 documents were used for training and evaluation was done on the remaining articles, following (Louis and Nenkova, 2012). After tuning, the final model was tested on the testing set.

5.1.3 Model Comparison

We report performance of recursive and recurrent networks. We also report results from some popular approaches in the literature, including:

Entity Grid Model : Grid model (Barzilay and Lapata, 2008) obtains the best performance when coreference resolution, expressive syntactic information, and salience-based features are incorporated. Entity grid models represent each sentence as a column of a grid of features and apply machine learning methods (e.g., SVM) to identify the coherent transitions based on entity features (for details of entity models see (Barzilay and Lapata, 2008)). Results are directly taken from Barzilay and Lapata's paper (2008).

HMM : Hidden-Markov approach proposed by Louis and Nenkova (2012) to model the state (cluster) transition probability in the coherent context using syntactic features. Sentences need to be clustered in advance where the number of clusters is tuned as a parameter. We directly take

	Acci	Earthquake	Average
Recursive	0.864	0.976	0.920
Recurrent	0.840	0.951	0.895
Entity Grid	0.904	0.872	0.888
HMM	0.822	0.938	0.880
HMM+Entity	0.842	0.911	0.877
HMM+Content	0.742	0.953	0.848
Graph	0.846	0.635	0.740

Table 1: Comparison of Different Coherence Frameworks. Reported baseline results are among the best performance regarding each approach is reprinted from prior work from (Barzilay and Lapata, 2008; Louis and Nenkova, 2012; Guinaudeau and Strube, 2013).

the results from Louis and Nenkova's paper and report the best results among different combinations of parameter and feature settings[8]. We also report performances of models from Louis and Nenkova's work that combine HMM and entity/content models in a unified framework.

Graph Based Approach : Guinaudeau and Strube (2013) extended the entity grid model to a bipartite graph representing the text, where the entity transition information needed for local coherence computation is embedded in the bipartite graph. The Graph Based Approach outperforms the original entity approach in some of feature settings (Guinaudeau and Strube, 2013).

As can be seen in Table 1, the proposed frameworks (both recurrent and recursive) obtain state-of-art performance and outperform all existing baselines by a large margin. One interpretation is that the abstract sentence vector representations computed by the deep learning framework is more powerful in capturing exactly the relevant the semantic/logical/syntactic features in coherent contexts than features or other representations developed by human feature engineering are.

Another good quality of the deep learning framework is that it can be trained easily and makes unnecessary the effort required of feature engineering. In contrast, almost all existing baselines and other coherence methods require sophisticated feature selection processes and greatly rely on external feature extraction algorithm.

The recurrent network is easier to implement than the recursive network and does not rely on external resources (i.e., parse trees), but the recursive network obtains better performance by building the convolution on parse trees rather than simply piling up terms within the sentence, which is in line with common expectation.

Both recurrent and recursive models obtain better performance on the Earthquake than the Accident dataset. Scrutiny of the corpus reveals that articles reporting earthquakes exhibit a more consistent structure: earthquake outbreak, describing the center and intensity of the earthquake, injuries and rescue operations, etc., while accident articles usually exhibit more diverse scenarios.

5.2 Readability Assessment

Barzilay and Lapata (2008) proposed a readability assessment task for stylistic judgments about the difficulty of reading a document. Their approach combines a coherence system with Schwarm and Ostendorf's (2005) readability features to classify documents into two categories, more readable (coherent) documents and less readable ones. The evaluation accesses the ability to differentiate "easy to read" documents from difficult ones of each model.

5.2.1 Dataset

Barzilay and Lapata's (2008) data corpus is from the $Encyclopedia\ Britannica$ and the $Britannica\ Elementary$, the latter being a new version targeted at children. Both versions contain 107 articles. The $Encyclopedia\ Britannica$ corpus contains an average of 83.1 sentences per document and the $Britannica\ Elementary$ contains 36.6. The encyclopedia lemmas are written by different authors and consequently vary considerably in structure and vocabulary choice. Early researchers assumed that the children version ($Britannica\ Elementary$) is easier to read, hence more coherent than documents in $Encyclopedia\ Britannica$. This is a somewhat questionable assumption that needs further investigation.

5.2.2 Training and Testing

Existing coherence approaches again apply a pairwise ranking strategy and the article associated with the higher score is considered to be the more readable. As the replacement strategy for generating negative example is apparently not well fitted to this task, we adopted the following training framework: we use all sliding windows of sentences from coherent documents (documents from $Britannica\ Elementary$) as positive examples,

[8]The details for information about parameter and feature of best setting can be found in (Louis and Nenkova, 2012).

Approach	Accuracy
Recurrent	0.803
Recursive	0.828
Graph Approach	0.786
Entity	0.509
S&O	0.786
Entity+S&O	0.888

Table 2: Comparison of Different Coherence Frameworks on Readability Assessment. Reported baselines results are are taken from (Barzilay and Lapata, 2008; Guinaudeau and Strube, 2013). S&O: Schwarm and Ostendorf (2005).

and cliques from $Encyclopedia\ Britannica$ as negative examples, and again apply Eq. 6 for training and optimization. During testing, we turn to Equations 8 and 9 for pairwise comparison. We adopted five-fold cross-validation in the same way as in (Barzilay and Lapata, 2008; Guinaudeau and Strube, 2013) for fair comparison. Parameters were tuned within each training set also using five-fold cross-validation. Parameters to tune included window size L and regularization parameter Q.

5.3 Results

We report results of the proposed approaches in the work along with entity model (Barzilay and Lapata, 2008) and graph based approach (Elsner and Charniak, 2008) in Table 2. The tabs shows that deep learning approaches again significantly outperform Entry and Global Approach baselines and are nearly comparable to the combination of entity and S&O features. Again, the recursive network outperforms the recurrent network in this task.

6 Conclusion

In this paper, we apply two neural network approaches to the sentence-ordering (coherence) task, using compositional sentence representations learned by recurrent and recursive composition. The proposed approach obtains state-of-art performance on the standard coherence evaluation tasks.

Acknowledgements

The authors want to thank Richard Socher and Pradeep Dasigi for the clarification of deep learning techniques. We also thank the three anonymous EMNLP reviewers for helpful comments.

Discriminative Reranking of Discourse Parses Using Tree Kernels

Shafiq Joty and **Alessandro Moschitti**

{sjoty,amoschitti}@qf.org.qa

Abstract

In this paper, we present a discriminative approach for reranking discourse trees generated by an existing probabilistic discourse parser. The reranker relies on tree kernels (TKs) to capture the global dependencies between discourse units in a tree. In particular, we design new computational structures of discourse trees, which combined with standard TKs, originate novel discourse TKs. The empirical evaluation shows that our reranker can improve the state-of-the-art sentence-level parsing accuracy from 79.77% to 82.15%, a relative error reduction of 11.8%, which in turn pushes the state-of-the-art document-level accuracy from 55.8% to 57.3%.

1 Introduction

Clauses and sentences in a well-written text are interrelated and exhibit a coherence structure. Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) represents the coherence structure of a text by a labeled tree, called discourse tree (DT) as shown in Figure 1. The leaves correspond to contiguous clause-like units called elementary discourse units (EDUs). Adjacent EDUs and larger discourse units are hierarchically connected by coherence relations (e.g., ELABORATION, CAUSE). Discourse units connected by a relation are further distinguished depending on their relative importance: *nuclei* are the core parts of the relation while *satellites* are the supportive ones.

Conventionally, discourse analysis in RST involves two subtasks: (*i*) *discourse segmentation:* breaking the text into a sequence of EDUs, and (*ii*) *discourse parsing:* linking the discourse units to form a labeled tree. Despite the fact that discourse analysis is central to many NLP applications, the state-of-the-art document-level discourse parser (Joty et al., 2013) has an f-score of only 55.83% using manual discourse segmentation on the RST Discourse Treebank (RST-DT).

Although recent work has proposed rich linguistic features (Feng and Hirst, 2012) and powerful parsing models (Joty et al., 2012), discourse parsing remains a hard task, partly because these approaches do not consider global features and long range structural dependencies between DT constituents. For example, consider the human-annotated DT (Figure 1a) and the DT generated by the discourse parser of Joty et al. (2013) (Figure 1b) for the same text. The parser makes a mistake in finding the right structure: it considers only e_3 as the text to be attributed to e_2, where all the text spans from e_3 to e_6 (linked by CAUSE and ELABORATION) compose the statement to be attributed. Such errors occur because existing systems do not encode long range dependencies between DT constituents such as those between e_3 and e_{4-6}.

Reranking models can make the global structural information available to the system as follows: first, a base parser produces several DT hypotheses; and then a classifier exploits the entire information in each hypothesis, e.g., the complete DT with its dependencies, for selecting the best DT. Designing features capturing such global properties is however not trivial as it requires the selection of important DT fragments. This means selecting subtree patterns from an exponential feature space. An alternative approach is to implicitly generate the whole feature space using tree kernels (TKs) (Collins and Duffy, 2002; Moschitti, 2006).

In this paper, we present reranking models for discourse parsing based on Support Vector Machines (SVMs) and TKs. The latter allows us to represent structured data using the substructure space thus capturing structural dependencies between DT constituents, which is essential for effective discourse parsing. Specifically, we made the following contributions. First, we extend the

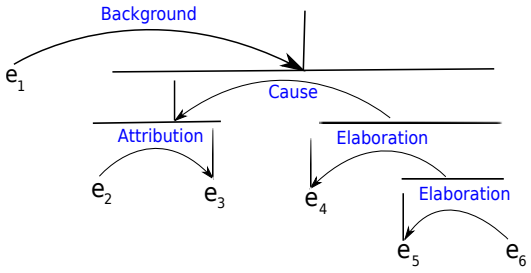
(a) A human-annotated discourse tree.



(b) A discourse tree generated by Joty et al. (2013).

Figure 1: Example of human-annotated and system-generated discourse trees for the text *[what's more,]$_{e_1}$ [he believes]$_{e_2}$ [seasonal swings in the auto industry this year aren't occurring at the same time in the past,]$_{e_3}$ [because of production and pricing differences]$_{e_4}$ [that are curbing the accuracy of seasonal adjustments]$_{e_5}$] [built into the employment data.]$_{e_6}$* Horizontal lines indicate text segments; satellites are connected to their nuclei by curved arrows.

existing discourse parser[1] (Joty et al., 2013) to produce a list of k most probable parses for each input text, with associated probabilities that define the initial ranking.

Second, we define a set of discourse tree kernels (DISCTK) based on the functional composition of standard TKs with structures representing the properties of DTs. DISCTK can be used for any classification task involving discourse trees.

Third, we use DISCTK to define kernels for reranking and use them in SVMs. Our rerankers can exploit the complete DT structure using TKs. They can ascertain if portions of a DT are compatible, incompatible or simply not likely to coexist, since each substructure is an exploitable feature. In other words, problematic DTs are expected to be ranked lower by our reranker.

Finally, we investigate the potential of our approach by computing the oracle f-scores for both document- and sentence-level discourse parsing. However, as demonstrated later in Section 6, for *document-level* parsing, the top k parses often miss the best parse. For example, the oracle f-scores for 5- and 20-best document-level parsing are only 56.91% and 57.65%, respectively. Thus the scope of improvement for the reranker is rather narrow at the document level. On the other hand, the oracle f-score for 5-best *sentence-level* discourse parsing is 88.09%, where the base parser (i.e., 1-best) has an oracle f-score of 79.77%. Therefore, in this paper we address the following two questions: (*i*) how far can a reranker improve the parsing accuracy at the sentence level? and (*ii*) how far can this improvement, if at all, push the (combined) document-level parsing accuracy?

To this end, our comparative experiments on RST-DT show that the sentence-level reranker can improve the f-score of the state-of-the-art from 79.77% to 82.15%, corresponding to a relative error reduction of 11.8%, which in turn pushes the state-of-the-art document-level f-score from 55.8% to 57.3%, an error reduction of 3.4%.

In the rest of the paper, after introducing the TK technology in Section 2, we illustrate our novel structures, and how they lead to the design of novel DISCTKs in Section 3. We present the k-best discourse parser in Section 4. In Section 5, we describe our reranking approach using DISCTKs. We report our experiments in Section 6. We briefly overview the related work in Section 7, and finally, we summarize our contributions in Section 8.

2 Kernels for Structural Representation

Tree kernels (Collins and Duffy, 2002; Shawe-Taylor and Cristianini, 2004; Moschitti, 2006) are a viable alternative for representing arbitrary subtree structures in learning algorithms. Their basic idea is that kernel-based learning algorithms, e.g., SVMs or perceptron, only need the scalar product between the feature vectors representing the data instances to learn and classify; and kernel functions compute such scalar products in an efficient way. In the following subsections, we briefly describe the kernel machines and three types of tree kernels (TKs), which efficiently compute the scalar product in the subtree space, where the vector components are all possible substructures of the corresponding trees.

2.1 Kernel Machines

Kernel Machines (Cortes and Vapnik, 1995), e.g., SVMs, perform binary classification by learning a hyperplane $H(\vec{x}) = \vec{w} \cdot \vec{x} + b = 0$, where

[1] Available from http://alt.qcri.org/tools/

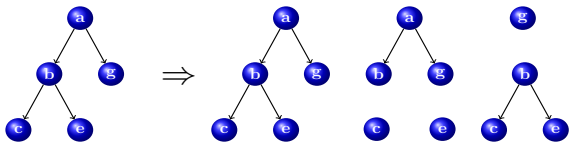


Figure 2: A tree with its STK subtrees; STK$_b$ also includes leaves as features.

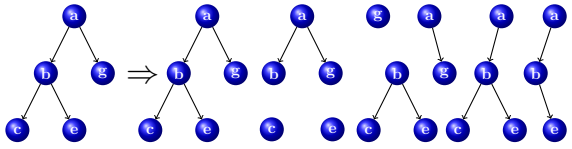

Figure 3: A tree with its PTK fragments.

$\vec{x} \in \mathbb{R}^n$ is the feature vector representation of an object $o \in \mathcal{O}$ to be classified and $\vec{w} \in \mathbb{R}^n$ and $b \in \mathbb{R}$ are parameters learned from the training data. One can train such machines in the dual space by rewriting the model parameter $\vec{w}$ as a linear combination of training examples, i.e., $\vec{w} = \sum_{i=1..l} y_i \alpha_i \vec{x}_i$, where y_i is equal to 1 for positive examples and -1 for negative examples, $\alpha_i \in \mathbb{R}_+$ and $\vec{x}_i \forall i \in \{1, .., l\}$ are the training instances. Then, we can use the data object $o_i \in \mathcal{O}$ directly in the hyperplane equation considering their mapping function $\phi : \mathcal{O} \rightarrow \mathbb{R}^n$, as follows: $H(o) = \sum_{i=1..l} y_i \alpha_i \vec{x}_i \cdot \vec{x} + b = \sum_{i=1..l} y_i \alpha_i \phi(o_i) \cdot \phi(o) + b = \sum_{i=1..l} y_i \alpha_i K(o_i, o) + b$, where the product $K(o_i, o) = \langle \phi(o_i) \cdot \phi(o) \rangle$ is the kernel function (e.g., TK) associated with the mapping ϕ.

2.2 Tree Kernels

Convolution TKs compute the number of common tree fragments between two trees T_1 and T_2 without explicitly considering the whole fragment space. A TK function over T_1 and T_2 is defined as: $TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$, where N_{T_1} and N_{T_2} are the sets of the nodes of T_1 and T_2, respectively, and $\Delta(n_1, n_2)$ is equal to the number of common fragments rooted in the n_1 and n_2 nodes.[2] The computation of Δ function depends on the shape of fragments, conversely, a different Δ determines the richness of the kernel space and thus different tree kernels. In the following, we briefly describe two existing and well-known tree kernels. Please see several tutorials on kernels (Moschitti, 2013; Moschitti, 2012; Moschitti, 2010) for more details.[3]

Syntactic Tree Kernels (STK) produce fragments such that each of their nodes includes all or none of its children. Figure 2 shows a tree T and its three fragments (do not consider the single nodes) in the STK space on the left and right of the arrow, respectively. STK(T,T) counts the number of common fragments, which in this case is the number of subtrees of T, i.e., three. In the figure, we also show three single nodes, c, e, and g, i.e., the leaves of T, which are computed by a variant of the kernel, that we call STK$_b$. The computational complexity of STK is $O(|N_{T_1}||N_{T_2}|)$, but the average running time tends to be linear (i.e. $O(|N_{T_1}| + |N_{T_2}|)$) for syntactic trees (Moschitti, 2006).

Partial Tree Kernel (PTK) generates a richer set of tree fragments. Given a target tree T, PTK can generate any subset of connected nodes of T, whose edges are in T. For example, Figure 3 shows a tree with its nine fragments including all single nodes (i.e., the leaves of T). PTK is more general than STK as its fragments can include any subsequence of children of a target node. The time complexity of PTK is $O(p\rho^2|N_{T_1}||N_{T_2}|)$, where p is the largest subsequence of children that one wants to consider and ρ is the maximal out-degree observed in the two trees. However, the average running time again tends to be linear for syntactic trees (Moschitti, 2006).

3 Discourse Tree Kernels (DISCTK)

Engineering features that can capture the dependencies between DT constituents is a difficult task. In principle, any dependency between words, relations and structures (see Figure 1) can be an important feature for discourse parsing. This may lead to an exponential number of features, which makes the feature engineering process very hard.

The standard TKs described in the previous section serve as a viable option to get useful subtree features automatically. However, the definition of the input to a TK, i.e., the tree representing a training instance, is extremely important as it implicitly affects the subtree space generated by the TK, where the target learning task is carried out. This can be shown as follows. Let $\phi_M()$ be a mapping from linguistic objects o_i, e.g., a discourse parse, to a *meaningful* tree T_i, and let $\phi_{TK}()$ be a mapping into a tree kernel space us-

[2] To get a similarity score between 0 and 1, it is common to apply a normalization in the kernel space, i.e. $\frac{TK(T_1,T_2)}{\sqrt{TK(T_1,T_1) \times TK(T_2,T_2)}}$.

[3] Tutorials notes available at `http://disi.unitn.it/moschitti/`

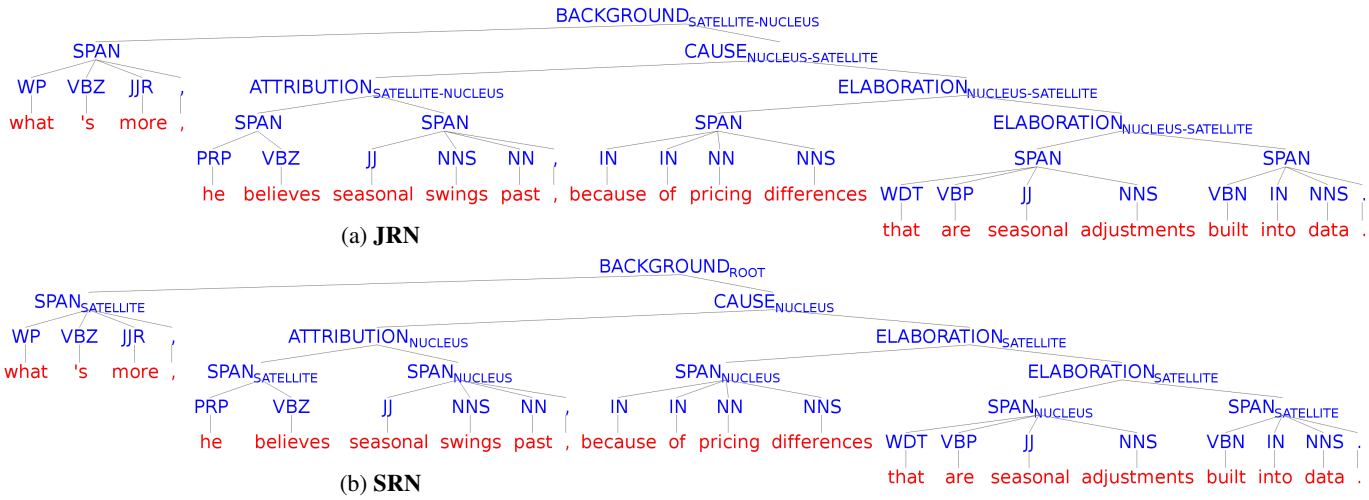

Figure 4: DISCTK trees: (a) Joint Relation-Nucleus (JRN), and (b) Split Relation Nucleus (SRN).

ing one of the TKs described in Section 2.2, i.e., $TK(T_1, T_2) = \phi_{TK}(T_1) \cdot \phi_{TK}(T_2)$. If we apply TK to the objects o_i transformed by $\phi_M()$, we obtain $TK(\phi_M(o_1), \phi_M(o_2)) = \phi_{TK}(\phi_M(o_1)) \cdot \phi_{TK}(\phi_M(o_2)) = \big(\phi_{TK} \circ \phi_M\big)(o_1) \cdot \big(\phi_{TK} \circ \phi_M\big)(o_2) = DiscTK(o_1, o_2)$, which is a new kernel[4] induced by the mapping $\phi_{DiscTK} = \big(\phi_{TK} \circ \phi_M\big)$.

We define two different mappings ϕ_M to transform the discourse parses generated by the base parser into two different tree structures: (*i*) the Joint Relation-Nucleus tree (JRN), and (*ii*) the Split Relation Nucleus tree (SRN).

3.1 Joint Relation-Nucleus Tree (JRN)

As shown in Figure 4a, JRN is a direct mapping of the parser output, where the nuclearity statuses (i.e., satellite or nucleus) of the connecting nodes are attached to the relation labels.[5] For example, the root BACKGROUND$_{Satellite-Nucleus}$ in Figure 4a denotes a *Background* relation between a *satellite* discourse unit on the left and a *nucleus* unit on the right. Text spans (i.e., EDUs) are represented as sequences of Part-of-Speech (POS) tags connected to the associated words, and are grouped under dummy SPAN nodes. We experiment with two lexical variations of the trees: (*i*) *All* includes all the words in the EDU, and (*ii*) *Bigram* includes only the first and last two words in the EDU.

When JRN is used with the STK kernel, an exponential number of fragments are generated. For example, the upper row of Figure 5 shows two smallest (atomic) fragments and one subtree composed of two atomic fragments. Note that much larger structures encoding long range dependencies are also part of the feature space. These fragments can reveal if the discourse units are organized in a compatible way, and help the reranker to detect the kind of errors shown earlier in Figure 1b. However, one problem with JRN representation is that since the relation nodes are composed of three different labels, the generated subtrees tend to be sparse. In the following, we describe SRN that attempts to solve this issue.

3.2 Split Relation Nucleus Tree (SRN)

SRN is not very different from JRN as shown in Figure 4b. The only difference is that instead of attaching the nuclearity statuses to the relation labels, in this representation we assign them to their respective discourse units. When STK kernel is applied to SRN it again produces an exponential number of fragments. For example, the lower row of Figure 5 shows two atomic fragments and one subtree composed of two atomic fragments. Comparing the two examples in Figure 5, it is easy to understand that the space of subtrees extracted from SRN is less sparse than that of JRN.

Note that, as described in Secion 2.2, when the PTK kernel is applied to JRN and SRN trees, it can generate a richer feature space, e.g., features that are paths containing relation labels (e.g., BACKGROUND - CAUSE - ELABORATION or ATTRIBUTION - CAUSE - ELABORATION).

4 Generation of k-best Discourse Parses

In this section we describe the 1-best discourse parser of Joty et al. (2013), and how we extend

[4] People interested in algorithms may like it more designing a complex algorithm to compute $\big(\phi_{TK} \circ \phi_M\big)$. However, the design of ϕ_M is conceptually equivalent and more effective from an engineering viewpoint.

[5] This is a common standard followed by the parsers.

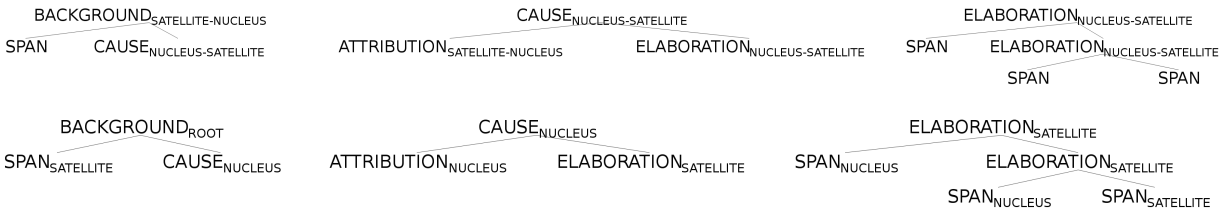

Figure 5: Fragments from JRN in Figure 4a (upper row) and SRN in Figure 4b (lower row).

it to k-best discourse parsing.

Joty et al. (2013) decompose the problem of document-level discourse parsing into two stages as shown in Figure 6. In the first stage, the *intra-sentential* discourse parser produces discourse subtrees for the individual sentences in a document. Then the *multi-sentential* parser combines the sentence-level subtrees and produces a DT for the document. Both parsers have the same two components: a *parsing model* and a *parsing algorithm*. The parsing model explores the search space of possible DTs and assigns a probability to every possible DT. Then the parsing algorithm selects the most probable DT(s). While two separate parsing models are employed for intra- and multi-sentential parsing, the same parsing algorithm is used in both parsing conditions. The two-stage parsing exploits the fact that sentence boundaries correlate very well with discourse boundaries. For example, more than 95% of the sentences in RST-DT have a well-formed discourse subtree in the full document-level discourse tree.

The choice of using two separate models for intra- and multi-sentential parsing is well justified for the following two reasons: (*i*) it has been observed that discourse relations have different distributions in the two parsing scenarios, and (*ii*) the models could independently pick their own informative feature sets. The parsing model used for intra-sentential parsing is a Dynamic Conditional Random Field (DCRF) (Sutton et al., 2007) shown in Figure 7. The observed nodes U_j at the bottom layer represent the discourse units at a certain level of the DT; the binary nodes S_j at the middle layer predict whether two adjacent units U_{j-1} and U_j should be connected or not; and the multi-class nodes R_j at the top layer predict the discourse relation between U_{j-1} and U_j. Notice that the model represents the structure and the label of a DT constituent jointly, and captures the sequential dependencies between the DT constituents. Since the chain-structured DCRF model does not scale up to multi-sentential parsing of long documents,

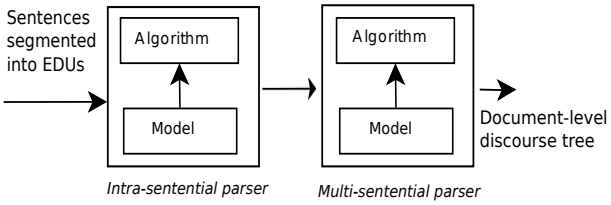

Figure 6: The two-stage document-level discourse parser proposed by Joty et al. (2013).

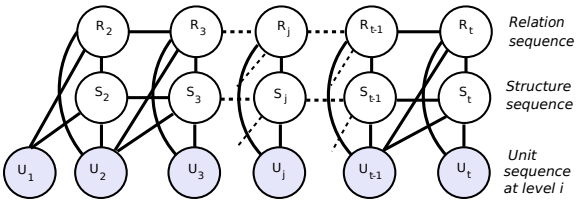

Figure 7: The intra-sentential parsing model.

the multi-sentential parsing model is a CRF which breaks the chain structure of the DCRF model.

The parsing models are applied recursively at different levels of the DT in their respective parsing scenarios (i.e., intra- and multi-sentential), and the probabilities of all possible DT constituents are obtained by computing the posterior marginals over the relation-structure pairs (i.e., $P(R_j, S_j{=}1|U_1, \cdots, U_t, \Theta)$, where Θ are model parameters). These probabilities are then used in a CKY-like probabilistic parsing algorithm to find the globally optimal DT for the given text.

Let U_x^b and U_x^e denote the beginning and end EDU Ids of a discourse unit U_x, and $R[U_i^b, U_m^e, U_j^e]$ refers to a coherence relation R that holds between the discourse unit containing EDUs U_i^b through U_m^e and the unit containing EDUs $U_m^e{+}1$ through U_j^e. Given n discourse units, the parsing algorithm uses the upper-triangular portion of the $n{\times}n$ dynamic programming table A, where cell $A[i,j]$ (for $i < j$) stores:

$$A[i,j] = P(r^*[U_i^b, U_{m^*}^e, U_j^e]), \text{ where}$$

$$(m^*, r^*) = \underset{i \le m < j \ ; \ R}{\operatorname{argmax}} P(R[U_i^b, U_m^e, U_j^e]) \times A[i,m] \times A[m+1,j] \quad (1)$$

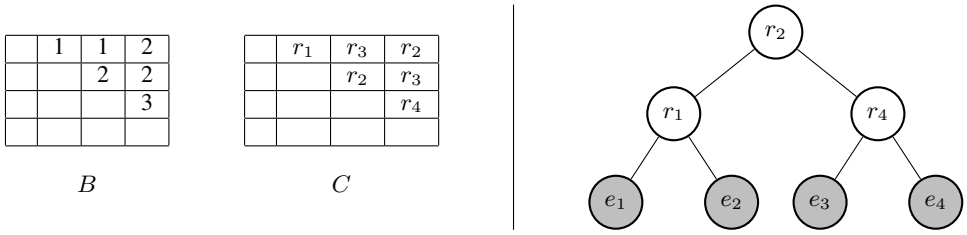

Figure 8: The B and C dynamic programming tables (left), and the corresponding discourse tree (right).

In addition to A, which stores the *probability* of the most probable constituents of a DT, the parsing algorithm also simultaneously maintains two other tables B and C for storing the best structure (i.e., $U^e_{m^*}$) and the relations (i.e., r^*) of the corresponding DT constituents, respectively. For example, given 4 EDUs $e_1 \cdots e_4$, the B and C tables at the left side in Figure 8 together represent the DT shown at the right. More specifically, to generate the DT, we first look at the top-right entries in the two tables, and find $B[1,4] = 2$ and $C[1,4] = r_2$, which specify that the two discourse units $e_{1:2}$ and $e_{3:4}$ should be connected by the relation r_2 (the root in the DT). Then, we see how EDUs e_1 and e_2 should be connected by looking at the entries $B[1,2]$ and $C[1,2]$, and find $B[1,2] = 1$ and $C[1,2] = r_1$, which indicates that these two units should be connected by the relation r_1 (the left pre-terminal). Finally, to see how EDUs e_3 and e_4 should be linked, we look at the entries $B[3,4]$ and $C[3,4]$, which tell us that they should be linked by the relation r_4 (the right pre-terminal).

It is straight-forward to generalize the above algorithm to produce k most probable DTs. When filling up the dynamic programming tables, rather than storing a single best parse for each subtree, we store and keep track of k-best candidates simultaneously. More specifically, each cell in the dynamic programming tables (i.e., A, B and C) should now contain k entries (sorted by their probabilities), and for each such entry there should be a back-pointer that keeps track of the decoding path.

The algorithm works in polynomial time. For n discourse units and M number of relations, the 1-best parsing algorithm has a time complexity of $O(n^3M)$ and a space complexity of $O(n^2)$, where the k-best version has a time and space complexities of $O(n^3Mk^2 \log k)$ and $O(n^2k)$, respectively. There are cleverer ways to reduce the complexity (e.g., see (Huang and Chiang, 2005) for three such ways). However, since the efficiency of the algorithm did not limit us to produce k-best parses for larger k, it was not a priority in this work.

5 Kernels for Reranking Discourse Trees

In Section 3, we described DISCTK, which essentially can be used for any classification task involving discourse trees. For example, given a DT, we can use DISCTK to classify it as correct vs. incorrect. However, such classification is not completely aligned to our purpose, since our goal is to select the best (i.e., the most correct) DT from k candidate DTs; i.e., a ranking task. We adopt a preference reranking technique as described in (Moschitti et al., 2006; Dinarelli et al., 2011).

5.1 Preference Reranker

Preference reranking (PR) uses a classifier $\mathcal{C}$ of pairs of hypotheses $\langle h_i, h_j \rangle$, which decides if h_i (i.e., a candidate DT in our case) is better than h_j. We generate positive and negative examples to train the classifier using the following approach. The pairs $\langle h_1, h_i \rangle$ constitute positive examples, where h_1 has the highest f-score accuracy on the Relation metric (to be described in Section 6) with respect to the gold standard among the candidate hypotheses, and vice versa, $\langle h_i, h_1 \rangle$ are considered as negative examples. At test time, $\mathcal{C}$ classifies all pairs $\langle h_i, h_j \rangle$ generated from the k-best hypotheses. A positive decision is a vote for h_i, and a negative decision is a vote for h_j. Also, the classifier score can be used as a weighted vote. Hypotheses are then ranked according to the number (sum) of the (weighted) votes they get.[6]

We build our reranker using simple SVMs.[7]

[6] As shown by Collins and Duffy (2002), only the classification of k hypotheses (paired with the empty one) is needed in practice, thus the complexity is only $O(k)$.

[7] Structural kernels, e.g., TKs, cannot be used in more advanced algorithms working in structured output spaces, e.g., SVM^{struct}. Indeed, to our knowledge, no one could successfully find a general and exact solution for the $argmax$ equation, typically part of such advanced models, when structural kernels are used. Some approximate solutions for simple kernels, e.g., polynomial or gaussian kernels, are given in (Joachims and Yu, 2009), whereas (Severyn and Moschitti, 2011; Severyn and Moschitti, 2012) provide solutions for using the cutting-plane algorithm (which requires $argmax$ computation) with structural kernels but in binary SVMs.

Since in our problem a pair of hypotheses $\langle h_i, h_j \rangle$ constitutes a data instance, we now need to define the kernel between the pairs. However, notice that DISCTK only works on a single pair.

Considering that our task is to decide whether h_i is better than h_j, it can be convenient to represent the pairs in terms of differences between the vectors of the two hypotheses, i.e., $\phi_K(h_i) - \phi_K(h_j)$, where K (i.e., DISCTK) is defined between two hypotheses (not on two pairs of hypotheses). More specifically, to compute this difference implicitly, we can use the following kernel summation: $PK(\langle h_1, h_2 \rangle, \langle h'_1, h'_2 \rangle) = (\phi_K(h_1) - \phi_K(h_2)) \circ (\phi_K(h'_1) - \phi_K(h'_2)) = K(h_1, h'_1) + K(h_2, h'_2) - K(h_1, h'_2) - K(h_2, h'_1)$.

In general, Preference Kernel (PK) works well because it removes many identical features by taking differences between two huge implicit TK-vectors. In our reranking framework, we also include traditional feature vectors in addition to the trees. Therefore, each hypothesis h is represented as a tuple $\langle T, \vec{v} \rangle$ composed of a tree T and a feature vector $\vec{v}$. We then define a structural kernel (i.e., similarity) between two hypotheses h and h' as follows: $K(h, h') = DiscTK(T, T') + FV(\vec{v}, \vec{v}')$, where DISCTK maps the DTs T and T' to JRN or SRN and then applies STK, STK$_b$ or PTK defined in Sections 2.2 and 3, and FV is a standard kernel, e.g., linear, polynomial, gaussian, etc., over feature vectors (see next section).

5.2 Feature Vectors

We also investigate the impact of traditional (i.e., not subtree) features for reranking discourse parses. Our feature vector comprises two types of features that capture global properties of the DTs.

Basic Features. This set includes eight global features. The first two are the probability and the (inverse) rank of the DT given by the base parser. These two features are expected to help the reranker to perform at least as good as the base parser. The other six features encode the structural properties of the DT, which include depth of the DT, number of nodes connecting two EDUs (i.e., SPANs in Figure 4), number of nodes connecting two relational nodes, number of nodes connecting a relational node and an EDU, number of nodes that connects a relational node as left child and an EDU as right child, and vice versa.

Relation Features. We encode the relations in the DT as bag-of-relations (i.e., frequency count). This will allow us to assess the impact of a flat representation of the DT. Note that more important relational features would be the subtree patterns extracted from the DT. However, they are already generated by TKs in a simpler way. See (Pighin and Moschitti, 2009; Pighin and Moschitti, 2010) for a way to extract the most relevant features from a model learned in the kernel space.

6 Experiments

Our experiments aim to show that reranking of discourse parses is a promising research direction, which can improve the state-of-the-art. To achieve this, we (*i*) compute the oracle accuracy of the k-best parser, (*ii*) test different kernels for reranking discourse parses by applying standard kernels to our new structures, (*iii*) show the reranking performance using the best kernel for different number of hypotheses, and (*iv*) show the relative importance of features coming from different sources.

6.1 Experimental Setup

Data. We use the standard RST-DT corpus (Carlson et al., 2002), which comes with discourse annotations for 385 articles (347 for training and 38 for testing) from the Wall Street Journal. We extracted sentence-level DTs from a document-level DT by finding the subtrees that exactly span over the sentences. This gives 7321 and 951 sentences in the training and test sets, respectively. Following previous work, we use the same 18 coarser relations defined by Carlson and Marcu (2001).

We create the training data for the reranker in a 5-fold cross-validation fashion.[8] Specifically, we split the training set into 5 equal-sized folds, and train the parsing model on 4 folds and apply to the rest to produce k most probable DTs for each text. Then we generate and label the pairs (by comparing with the gold) from the k most probable trees as described in Section 5.1. Finally, we merge the 5 labeled folds to create the full training data.

SVM Reranker. We use SVM-light-TK to train our reranking models,[9] which enables the use of tree kernels (Moschitti, 2006) in SVM-light (Joachims, 1999). We build our new kernels for reranking exploiting the standard built-in TK functions, such as STK, STK$_b$ and PTK. We applied

[8] Note that our earlier experiments with a 2-fold cross validation process yielded only 50% of our current improvement.

[9] http://disi.unitn.it/moschitti/Tree-Kernel.htm

a linear kernel to standard feature vectors as it showed to be the best on our development set.

Metrics. The standard procedure to evaluate discourse parsing performance is to compute Precision, Recall and f-score of the unlabeled and labeled metrics proposed by Marcu (2000b).[10] Specifically, the unlabeled metric *Span* measures how accurate the parser is in finding the right structure (i.e., skeleton) of the DT, while the labeled metrics *Nuclearity* and *Relation* measure the parser's ability to find the right labels (nuclearity and relation) in addition to the right structure. Optimization of the Relation metric is considered to be the hardest and the most desirable goal in discourse parsing since it gives aggregated evaluation on tree structure and relation labels. Therefore, we measure the *oracle* accuracy of the k-best discourse parser based on the f-scores of the *Relation* metric, and our reranking framework aims to optimize the Relation metric.[11] Specifically, the oracle accuracy for k-best parsing is measured as follows: $\text{ORACLE} = \frac{\sum_{i=1}^{N} \max_{j=1}^{k} \text{f-score}_r(g_i, h_i^j)}{N}$, where N is the total number of texts (sentences or documents) evaluated, g_i is the gold DT annotation for text i, h_i^j is the j^{th} parse hypothesis generated by the k-best parser for text i, and $f\text{-}score_r(g_i, h_i^j)$ is the f-score accuracy of hypothesis h_i^j on the Relation metric. In all our experiments we report the f-scores of the Relation metric.

6.2 Oracle Accuracy

Table 1 presents the oracle scores of the k-best intra-sentential parser PAR-S on the standard RST-DT test set. The 1-best result corresponds to the accuracy of the base parser (i.e., 79.77%). The 2-best shows dramatic oracle-rate improvement (i.e., 4.65% absolute), suggesting that the base parser often generates the best tree in its top 2 outputs. 5-best increases the oracle score to 88.09%. Afterwards, the increase in accuracy slows down, achieving, e.g., 90.37% and 92.57% at 10-best and 20-best, respectively.

The results are quite different at the document level as Table 2 shows the oracle scores of the k-best document-level parser PAR-D.[12] The results suggest that the best tree is often missing in the top k parses, and the improvement in oracle-rate is very little as compared to the sentence-level parsing. The 2-best and the 5-best improve over the base accuracy by only 0.7% and 1.0%, respectively. The improvement becomes even lower for larger k. For example, the gain from 20-best to 30-best parsing is only 0.09%. This is not surprising because generally document-level DTs are big with many constituents, and only a very few of them change from k-best to k+1-best parsing. These small changes do not contribute much to the overall f-score accuracy.[13] In summary, the results in Tables 1 and 2 demonstrate that a k-best reranker can potentially improve the parsing accuracy at the sentence level, but may not be a suitable option for improving parsing at the document level. In the following, we report our results for reranking sentence-level discourse parses.

k	1	2	5	10	15	20
PAR-S	79.77	84.42	88.09	90.37	91.74	92.57

Table 1: Oracle scores as a function of k of k-best sentence-level parses on RST-DT test set.

k	1	2	5	10	15	20
PAR-D	55.83	56.52	56.91	57.23	57.54	57.65

Table 2: Oracle scores as a function of k of k-best document-level parses on RST-DT test set.

6.3 Performance of Different DISCTKs

Section 3 has pointed out that different DISCTKs can be obtained by specifying the TK type (e.g., STK, STK$_b$, PTK) and the mapping ϕ_M (i.e., JRN, SRN) in the overall kernel function $\big(\phi_{TK} \circ \phi_M\big)(o_1) \cdot \big(\phi_{TK} \circ \phi_M\big)(o_2)$. Table 3 reports the performance of such model compositions using the 5-best hypotheses on the RST-DT test set. Additionally, it also reports the accuracy for the two versions of JRN and SRN, i.e., Bigram and All. From these results, we can note the following.

Firstly, the kernels generally perform better on Bigram than All lexicalization. This suggests that using all the words from the text spans (i.e., EDUs) produces sparse models.

[10] Precision, Recall and f-score are the same when the discourse parser uses manual discourse segmentation. Since all our experiments in this paper are based on manual discourse segmentation, we only report the f-scores.

[11] It is important to note that optimizing Relation metric may also result in improved Nuclearity scores.

[12] For document-level parsing, Joty et al. (2013) propose two approaches to combine intra- and multi-sentential parsers, namely 1S-1S (1 Sentence-1 Subtree) and Sliding window. In this work we extend 1S-1S to k-best document-level parser PAR-D since it is not only time efficient but it also achieves better results on the Relation metric.

[13] Note that Joty et al. (2012; 2013) report lower f-scores both at the sentence level (i.e., 77.1% as opposed to our 79.77%) and at the document level (i.e., 55.73% as opposed to our 55.83%). We fixed a crucial bug in their (1-best) parsing algorithm, which accounts for the improved performance.

$\phi_{TK} \circ \phi_M$	JRN		SRN	
	Bigram	All	Bigram	All
STK	81.28	80.04	82.15	80.04
STK_b	81.35	80.28	82.18	80.25
PTK	81.63	78.50	81.42	78.25

Table 3: Reranking performance of different discourse tree kernels on different representations.

Secondly, while the tree kernels perform similarly on the JRN representation, STK performs significantly better (p-value < 0.01) than PTK on SRN.[14] This result is interesting as it provides indications of the type of DT fragments useful for improving parsing accuracy. As pointed out in Section 2.2, PTK includes all features generated by STK, and additionally, it includes fragments whose nodes can have any subsets of the children they have in the original DT. Since this does not improve the accuracy, we speculate that complete fragments, e.g., [CAUSE [ATTRIBUTION][ELABORATION]] are more meaningful than the partial ones, e.g., [CAUSE [ATTRIBUTION]] and [CAUSE [ELABORATION]], which may add too much uncertainty on the signature of the relations contained in the DT. We verified this hypothesis by running an experiment with PTK constraining it to only generate fragments whose nodes preserve all or none of their children. The accuracy of such fragments approached the ones of STK, suggesting that relation information should be used as a whole for engineering features.

Finally, STK_b is slightly (but not significantly) better than STK suggesting that the lexical information is already captured by the base parser.

Note that the results in Table 3 confirms many other experiments we carried out on several development sets. For any run: (*i*) STK always performs as well as STK_b, (*ii*) STK is always better than PTK, and (*iii*) SRN is always better than JRN. In what follows, we show the reranking performance based on STK applied to SRN with Bigram.

6.4 Insights on DISCTK-based Reranking

Table 4 reports the performance of our reranker (RR) in comparison with the oracle (OR) accuracy for different values of k, where we also show the corresponding relative error rate reduction (ERR) with respect to the baseline. To assess the generality of our approach, we evaluated our reranker on both the standard test set and the entire training set using 5-fold cross validation.[15]

[14] Statistical significance is verified using paired t-test.

[15] The reranker was trained on 4 folds and tested on the rest

Baseline	Basic feat.	+ Rel. feat.	+ Tree
79.77	79.84	79.81	82.15

Table 5: Comparison of features from different sources for 5-best discourse reranking.

	(Joty et al., 2013)	With Reranker
PAR-D	55.8	**57.3**

Table 6: Document-level parsing results with 5-best sentence-level discourse reranker.

We note that: (*i*) the best result on the standard test set is 82.15% for $k = 4$ and 5, which gives an ERR of 11.76%, and significantly (p-value < 0.01) outperforms the baseline, (*ii*) the improvement is consistent when we move from standard test set to 5-folds, (*iii*) the best result on the 5-folds is 80.86 for $k = 6$, which is significantly (p-value < 0.01) better than the baseline 78.57, and gives an ERR of 11.32%. We also experimented with other values of k in both training and test sets (also increasing k only in the test set), but we could not improve over our best result. This suggests that outperforming the baseline (which in our case is the state of the art) is rather difficult.[16]

In this respect, we also investigated the impact of traditional ranking methods based on feature vectors, and compared it with our TK-based model. Table 5 shows the 5-best reranking accuracy for different feature subsets. The *Basic features* (Section 5.2) alone do not significantly improve over the *Baseline*. The only relevant features are the probability and the rank of each hypothesis, which condense all the information of the local model (TKs models always used them).

Similarly, adding the relations as bag-of-relations in the vector (*Rel. feat.*) does not provide any gain, whereas the relations encoded in the tree fragments (Tree) gives improvement. This shows the importance of using structural dependencies for reranking discourse parses.

Finally, Table 6 shows that if we use our sentence-level reranker in the document-level parser of Joty et al. (2013), the accuracy of the latter increases from 55.8% to 57.3%, which is a significant improvement ($p < 0.01$), and establishes a new state-of-the-art for document-level parsing.

6.5 Error Analysis

We looked at some examples where our reranker failed to identify the best DT. Unsurprisingly, it

[16] The human agreement on sentence-level parsing is 83%.

	Standard test set						5-folds (average)					
	k=1	k=2	k=3	k=4	k=5	k=6	k=1	k=2	k=3	k=4	k=5	k=6
RR	79.77	81.08	81.56	**82.15**	**82.15**	82.11	78.57	79.76	80.28	80.68	80.80	**80.86**
ERR	-	6.48	8.85	**11.76**	**11.76**	11.57	-	5.88	8.45	10.43	11.02	**11.32**
OR	79.77	84.42	86.55	87.68	88.09	88.75	78.57	83.20	85.13	86.49	87.35	88.03

Table 4: Reranking performance (RR) in comparison with oracle (OR) accuracy for different values of k on the standard testset and 5-folds of RST-DT. Second row shows the relative error rate reduction (ERR).

happens many times for small DTs containing only two or three EDUs, especially when the relations are semantically similar. Figure 9 presents such a case, where the reranker fails to rank the DT with *Summary* ahead of the DT with *Elaboration*. Although we understand that the reranker lacks enough structural context to distinguish the two relations in this example, we expected that including the lexical items (e.g., *(CFD)*) in our DT representation could help. However, similar short parenthesized texts are also used to elaborate as in *Senate Majority Leader George Mitchell (D., Maine)*, where the text *(D., Maine)* (i.e., Democrat from state Maine) elaborates its preceding text. This confuses our reranker. We also found error examples where the reranker failed to distinguish between *Background* and *Elaboration*, and between *Cause* and *Elaboration*. This suggests that we need rich semantic representation of the text to improve our reranker further.

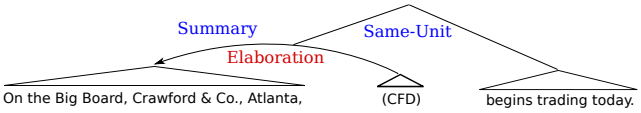

Figure 9: An error made by our reranker.

7 Related Work

Early work on discourse parsing applied hand-coded rules based on discourse cues and surface patterns (Marcu, 2000a). Supervised learning was first attempted by Marcu (2000b) to build a shift-reduce discourse parser. This work was then considerably improved by Soricut and Marcu (2003). They presented probabilistic generative models for *sentence-level* discourse parsing based on lexico-syntactic patterns. Sporleder and Lapata (2005) investigated the necessity of syntax in discourse analysis. More recently, Hernault et al. (2010) presented the HILDA discourse parser that iteratively employs two SVM classifiers in pipeline to build a DT in a greedy way. Feng and Hirst (2012) improved the HILDA parser by incorporating rich linguistic features, which include lexical semantics and discourse production rules.

Joty et al. (2013) achieved the best prior results by (*i*) jointly modeling the structure and the label of a DT constituent, (*ii*) performing optimal rather than greedy decoding, and (*iii*) discriminating between intra- and multi-sentential discourse parsing. However, their model does not consider long range dependencies between DT constituents, which are encoded by our kernels. Regarding the latter, our work is surely inspired by (Collins and Duffy, 2002), which uses TK for syntactic parsing reranking or in general discriminative reranking, e.g., (Collins and Koo, 2005; Charniak and Johnson, 2005; Dinarelli et al., 2011). However, such excellent studies do not regard discourse parsing, and in absolute they achieved lower improvements than our methods.

8 Conclusions and Future Work

In this paper, we have presented a discriminative approach for reranking discourse trees generated by an existing discourse parser. Our reranker uses tree kernels in SVM preference ranking framework to effectively capture the long range structural dependencies between the constituents of a discourse tree. We have shown the reranking performance for sentence-level discourse parsing using the standard tree kernels (i.e., STK and PTK) on two different representations (i.e., JRN and SRN) of the discourse tree, and compare it with the traditional feature vector-based approach. Our results show that: (*i*) the reranker improves only when it considers subtree features computed by the tree kernels, (*ii*) SRN is a better representation than JRN, (*iii*) STK performs better than PTK for reranking discourse trees, and (*iv*) our best result outperforms the state-of-the-art significantly.

In the future, we would like to apply our reranker to the document-level parses. However, this will require a better hypotheses generator.

Abstract

Text-level discourse parsing remains a challenge: most approaches employ features that fail to capture the intentional, semantic, and syntactic aspects that govern discourse coherence. In this paper, we propose a recursive model for discourse parsing that jointly models distributed representations for clauses, sentences, and entire discourses. The learned representations can to some extent learn the semantic and intentional import of words and larger discourse units automatically,. The proposed framework obtains comparable performance regarding standard discoursing parsing evaluations when compared against current state-of-art systems.

1 Introduction

In a coherent text, units (clauses, sentences, and larger multi-clause groupings) are tightly connected semantically, syntactically, and logically. Mann and Thompson (1988) define a text to be coherent when it is possible to describe clearly the role that each discourse unit (at any level of grouping) plays with respect to the whole. In a coherent text, no unit is completely isolated. Discourse parsing tries to identify how the units are connected with each other and thereby uncover the hierarchical structure of the text, from which multiple NLP tasks can benefit, including text summarization (Louis et al., 2010), sentence compression (Sporleder and Lapata, 2005) or question-answering (Verberne et al., 2007).

Despite recent progress in automatic discourse segmentation and sentence-level parsing (e.g., (Fisher and Roark, 2007; Joty et al., 2012; Soricut and Marcu, 2003), document-level discourse parsing remains a significant challenge. Recent attempts (e.g., (Hernault et al., 2010b; Feng and Hirst, 2012; Joty et al., 2013)) are still considerably inferior when compared to human gold-standard discourse analysis. The challenge stems from the fact that compared with sentence-level dependency parsing, the set of relations between discourse units is less straightforward to define. Because there are no clause-level 'parts of discourse' analogous to word-level parts of speech, there is no discourse-level grammar analogous to sentence-level grammar. To understand how discourse units are connected, one has to understand the communicative function of each unit, and the role it plays within the context that encapsulates it, taken recursively all the way up for the entire text. Manually developed features relating to words and other syntax-related cues, used in most of the recent prevailing approaches (e.g., (Feng and Hirst, 2012; Hernault et al., 2010b)), are insufficient for capturing such nested intentionality.

Recently, deep learning architectures have been applied to various natural language processing tasks (for details see Section 2) and have shown the advantages to capture the relevant semantic and syntactic aspects of units in context. As word distributions are composed to form the meanings of clauses, the goal is to extend distributed clause-level representations to the single- and multi-sentence (discourse) levels, and produce the hierarchical structure of entire texts.

Inspired by this idea, we introduce in this paper a deep learning approach for discourse parsing. The proposed parsing algorithm relies on a recursive neural network to decide (1) whether two discourse units are connected and if so (2) by what relation they are connected. Concretely, the parsing algorithm takes as input a document of any length, and first obtains the distributed representation for each of its sentences using recursive convolution based on the sentence parse tree. It then proceeds bottom-up, applying a binary classifier to determine the probability of two adjacent

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2061–2069,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

discourse units being merged to form a new subtree followed by a multi-class classifier to select the appropriate discourse relation label, and calculates the distributed representation for the subtree so formed, gradually unifying subtrees until a single overall tree spans the entire sentence. The compositional distributed representation enables the parser to make accurate parsing decisions and capture relations between different sentences and units. The binary and multi-class classifiers, along with parameters involved in convolution, are jointly trained from a collection of gold-standard discourse structures.

The rest of this paper is organized as follows. We present related work in Section 2 and describe the RST Discourse Treebank in Section 3. The sentence convolution approach is illustrated in Section 4 and the discourse parser model in Section 5. We report experimental results in Section 6 and conclude in Section 7.

2 Related Work

2.1 Discourse Analysis and Parsing

The basis of discourse structure lies in the recognition that discourse units (minimally, clauses) are related to one another in principled ways, and that the juxtaposition of two units creates a joint meaning larger than either unit's meaning alone. In a coherent text this juxtaposition is never random, but serves the speaker's communicative goals.

Considerable work on linguistic and computational discourse processing in the 1970s and 80s led to the development of several proposals for relations that combine units; for a compilation see (Hovy and Maier, 1997). Of these the most influential is Rhetorical Structure Theory RST (Mann and Thompson, 1988) that defines about 25 relations, each containing semantic constraints on its component parts plus a description of the overall functional/semantic effect produced as a unit when the parts have been appropriately connected in the text. For example, the SOLUTIONHOOD relation connects one unit describing a problem situation with another describing its solution, using phrases such as "the answer is"; in successful communication the reader will understand that a problem is described and its solution is given.

Since there is no syntactic definition of a problem or solution (they can each be stated in a single clause, a paragraph, or an entire text), one has to characterize discourse units by their communicative (rhetorical) function. The functions are reflected in text as signals of the author's intentions, and take various forms (including expressions such as "therefore", "for example", "the answer is", and so on; patterns of tense or pronoun usage; syntactic forms; etc.). The signals govern discourse blocks ranging from a clause to an entire text , each one associated with some discourse relation.

In order to build a text's hierarchical structure, a discourse parser needs to recognize these signals and use them to appropriately compose the relationship and nesting. Early approaches (Marcu, 2000a; LeThanh et al., 2004) rely mainly on overt discourse markers (or cue words) and use hand-coded rules to build text structure trees, bottom-up from clauses to sentences to paragraphs.... Since a hierarchical discourse tree structure is analogous to a constituency based syntactic tree, modern research explored syntactic parsing techniques (e.g., CKY) for discourse parsing based on multiple text-level or sentence-level features (Soricut and Marcu, 2003; Reitter, 2003; Baldridge and Lascarides, 2005; Subba and Di Eugenio, 2009; Lin et al., 2009; Luong et al., 2014).

A recent prevailing idea for discourse parsing is to train two classifiers, namely a binary structure classifier for determining whether two adjacent text units should be merged to form a new subtree, followed by a multi-class relation classifier for determining which discourse relation label should be assigned to the new subtree. The idea is proposed by Hernault and his colleagues (Duverle and Prendinger, 2009; Hernault et al., 2010a) and followed by other work using more sophisticated features (Feng and Hirst, 2012; Hernault et al., 2010b). Current state-of-art performance for relation identification is achieved by the recent representation learning approach proposed by (Ji and Eisenstein, 2014). The proposed framework presented in this paper is similar to (Ji and Eisenstein, 2014) for transforming the discourse units to the abstract representations.

2.2 Recursive Deep Learning

Recursive neural networks constitute one type of deep learning frameworks which was first proposed in (Goller and Kuchler, 1996). The recursive framework relies and operates on structured inputs (e.g., a parse tree) and computes the representation for each parent based on its children

iteratively in a bottom-up fashion. A series of variations of RNN has been proposed to tailor different task-specific requirements, including Matrix-Vector RNN (Socher et al., 2012) that represents every word as both a vector and a matrix, or Recursive Neural Tensor Network (Socher et al., 2013) that allows the model to have greater interactions between the input vectors. Many tasks have benefited from the recursive framework, including parsing (Socher et al., 2011b), sentiment analysis (Socher et al., 2013), textual entailment (Bowman, 2013), segmentation (Wang and Mansur, 2013; Houfeng et al., 2013), and paraphrase detection (Socher et al., 2011a).

3 The RST Discourse Treebank

There are today two primary alternative discourse treebanks suitable for training data: the Rhetorical Structure Theory Discourse Treebank RST-DT (Carlson et al., 2003) and the Penn Discourse Treebank (Prasad et al., 2008). In this paper, we select the former. In RST (Mann and Thompson, 1988), a coherent context or a document is represented as a hierarchical tree structure, the leaves of which are clause-sized units called Elementary Discourse Units (EDUs). Adjacent nodes (siblings in the tree) are linked with discourse relations that are either binary (hypotactic) or multi-child (paratactic). One child of each hypotactic relation is always more salient (called the NUCLEUS); its sibling (the SATELLITE) is less salient compared and may be omitted in summarization. Multi-nuclear relations (e.g., CONJUNCTION) exhibit no distinction of salience between the units.

The RST Discourse Treebank contains 385 annotated documents (347 for training and 38 for testing) from the Wall Street Journal. A total of 110 fine-grained relations defined in (Marcu, 2000b) are used for tagging relations in RST-DT. They are subtypes of 18 original high-level RST categories. For fair comparison with existing systems, we use in this work the 18 coarse-grained relation classes, which with nuclearity attached form a set of 41 distinct relations. Non-binary relations are converted into a cascade of right-branching binary relations.

Conventionally, discourse parsing in RST-DT involves the following sub-tasks: (1) EDU segmentation to segment the raw text into EDUs, (2) tree-building. Since the segmentation task is essentially clause delimitation and hence relatively easy (with state-of-art accuracy at most 95%), we focus on the latter problem. We assume that the gold-standard EDU segmentations are already given, as assumed in other past work (Feng and Hirst, 2012).

4 EDU Model

In this section, we describe how we compute the distributed representation for a given sentence based on its parse tree structure and contained words. Our implementation is based on (Socher et al., 2013). As the details can easily be found there, we omit them for brevity.

Let s denote any given sentence, comprised of a sequence of tokens $s = \{w_1, w_2, ..., w_{n_s}\}$, where n_s denotes the number of tokens in s. Each token w is associated with a specific vector embedding $\mathbf{e_w} = \{e_w^1, e_w^2, ..., e_w^K\}$, where K denotes the dimension of the word embedding. We wish to compute the vector representation h_s for current sentence, where $h_s = \{h_s^1, h_s^2, ..., h_s^K\}$.

Parse trees are obtained using the Stanford Parser[1], and each clause is treated as an EDU. For a given parent p in the tree and its two children c_1 (associated with vector representation h_{c_1}) and c_2 (associated with vector representation h_{c_2}), standard recursive networks calculate the vector for parent p as follows:

$$h_p = f(W \cdot [h_{c_1}, h_{c_2}] + b) \quad (1)$$

where $[h_{c_1}, h_{c_2}]$ denotes the concatenating vector for children representations h_{c_1} and h_{c_2}; W is a $K \times 2K$ matrix and b is the $1 \times K$ bias vector; and $f(\cdot)$ is the function $tanh$. Recursive neural models compute parent vectors iteratively until the root node's representation is obtained, and use the root embedding to represent the whole sentence.

5 Discourse Parsing

Since recent work (Feng and Hirst, 2012; Hernault et al., 2010b) has demonstrated the advantage of combining the binary structure classifier (determining whether two adjacent text units should be merged to form a new subtree) with the multi-class classifier (determining which discourse relation label to assign to the new subtree) over the older single multi-class classifier with the additional label NO-REL, our approach follows the modern

[1] http://nlp.stanford.edu/software/lex-parser.shtml

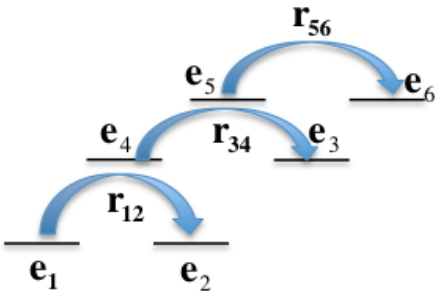

Figure 1: RST Discourse Tree Structure.

strategy but trains binary and multi-class classifiers jointly based on the discourse structure tree.

Figure 2 illustrates the structure of a discourse parse tree. Each node e in the tree is associated with a distributed vector h_e. e_1, e_2, e_3 and e_6 constitute the leaves of trees, the distributed vector representations of which are assumed to be already obtained from convolution in Section 4. Let N_r denote the number of relations and we have $N_r = 41$.

5.1 Binary (Structure) Classification

In this subsection, we train a binary (structure) classifier, which aims to decide whether two EDUs or spans should be merged during discourse tree reconstruction.

Let $t_{\text{binary}}(e_i, e_j)$ be the binary valued variable indicating whether e_i and e_j are related, or in other words, whether a certain type of discourse relations holds between e_i and e_j. According to Figure 2, the following pairs constitute the training data for binary classification:

$$t_{\text{binary}}(e_1, e_2) = 1, \;\; t_{\text{binary}}(e_3, e_4) = 1,$$
$$t_{\text{binary}}(e_2, e_3) = 0, \;\; t_{\text{binary}}(e_3, e_6) = 0,$$
$$t_{\text{binary}}(e_5, e_6) = 1$$

To train the binary classifier, we adopt a three-layer neural network structure, i.e., input layer, hidden layer, and output layer. Let $H = [h_{e_i}, h_{e_j}]$ denote the concatenating vector for two spans e_i and e_j. We first project the concatenating vector H to the hidden layer with N_{binary} hidden neurons. The hidden layer convolutes the input with non-linear tanh function as follows:

$$L^{\text{binary}}_{(e_i,e_j)} = f(G_{\text{binary}} * [h_{e_i}, h_{e_j}] + b_{\text{binary}})$$

where G_{binary} is an $N_{\text{binary}} * 2K$ convolution matrix and b_{binary} denotes the bias vector.

The output layer takes as input $L^{\text{binary}}_{(e_i,e_j)}$ and generates a scalar using the linear function $U_{binary} \cdot L^{\text{binary}}_{(e_i,e_j)} + b$. A $sigmod$ function is then adopted to project the value to a [0,1] probability space. The execution at the output layer can be summarized as:

$$p[t_{\text{binary}}(e_i, e_j) = 1] = g(U_{binary} \cdot L^{\text{binary}}_{(e_i,e_j)} + b^*_{\text{binary}}) \quad (2)$$

where U_{binary} is an $N_{\text{binary}} \times 1$ vector and b^*_{binary} denotes the bias. $g(\cdot)$ is the sigmod function.

5.2 Multi-class Relation Classification

If $t_{binary}(e_i, e_j)$ is determined to be 1, we next use variable $r(e_i, e_j)$ to denote the index of relation that holds between e_i and e_j. A multi-class classifier is train based on a three-layer neural network, in the similar way as binary classification in Section 5.1. Concretely, a matrix G_{Multi} and bias vector b_{Multi} are first adopted to convolute the concatenating node vectors to the hidden layer vector $L^{\text{multi}}_{(e_i,e_j)}$:

$$L^{\text{multi}}_{(e_i,e_j)} = f(G_{\text{multi}} * [h_{e_i}, h_{e_j}] + b_{\text{multi}}) \quad (3)$$

We then compute the posterior probability over labels given the hidden layer vector L using the softmax and obtain the N_r dimensional probability vector $P_{(e_1,e_2)}$ for each EDU pair as follows:

$$S_{(e_i,e_j)} = U_{\text{multi}} \cdot L^{\text{multi}}_{(e_i,e_j)} \quad (4)$$

$$P_{(e_1,e_2)}(i) = \frac{\exp(S_{(e_1,e_2)}(i))}{\sum_k \exp(S_{(e_1,e_2)})(k)} \quad (5)$$

where U_{multi} is the $N_r \times 2K$ matrix. The i^{th} element in $P_{(e_1,e_2)}$ denotes the probability that i^th relation holds between e_i and e_j. To note, binary and multi-class classifiers are trained independently.

5.3 Distributed Vector for Spans

What is missing in the previous two subsections are the distributed vectors for non-leaf nodes (i.e., e_4 and e_5 in Figure 1), which serve as structure and relation classification. Again, we turn to recursive deep learning network to obtain the distributed vector for each node in the tree in a bottom-up fashion.

Similar as for sentence parse-tree level compositionally, we extend a standard recursive neural network by associating each type of relations r with one specific $K \times 2K$ convolution matrix W_r.

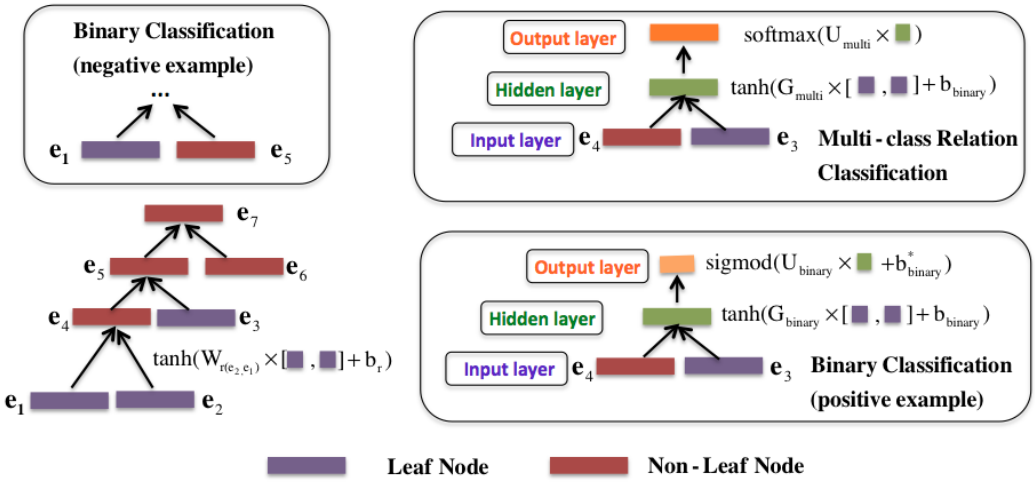

Figure 2: System Overview.

The representation for each node within the tree is calculated based on the representations for its children in a bottom-up fashion. Concretely, for a parent node p, given the distributed representation h_{e_i} for left child, h_{e_j} for right child, and the relation $r(e_1, e_2)$, its distributed vector h_p is calculated as follows:

$$h_p = f(W_{r(e_1,e_2)} \cdot [h_{e_i}, h_{e_j}] + b_{r(e_1,e_2)}) \quad (6)$$

where $b_{r(e_1,e_2)}$ is the bias vector and $f(\cdot)$ is the non-linear tanh function.

To note, our approach does not make any distinction between within-sentence text spans and cross-sentence text spans, different from (Feng and Hirst, 2012; Joty et al., 2013)

5.4 Cost Function

The parameters to optimize include sentence-level convolution parameters $[W, b]$, discourse-level convolution parameters $[\{W_r\}, \{b_r\}]$, binary classification parameters $[G_{\text{binary}}, b_{\text{binary}}, U_{\text{binary}}, b^*_{\text{binary}}]$, and multi-class parameters $[G_{\text{multi}}, b_{\text{multi}}, U_{\text{multi}}]$.

Suppose we have M_1 binary training samples and M_2 multi-class training examples (M_2 equals the number of positive examples in M_1, which is also the non-leaf nodes within the training discourse trees). The cost function for our framework with regularization on the training set is given by:

$$J(\Theta_{\text{binary}}) = \sum_{(e_i,e_j)\in\{\text{binary}\}} J_{\text{binary}}(e_i, e_j) + Q_{\text{binary}} \cdot \sum_{\theta\in\Theta_{\text{binary}}} \theta^2 \quad (7)$$

$$J(\Theta_{\text{multi}}) = \sum_{(e_i,e_j)\in\{\text{multi}\}} J_{\text{multi}}(e_i, e_j) + Q_{\text{multi}} \cdot \sum_{\theta\in\Theta_{\text{multi}}} \theta^2 \quad (8)$$

where

$$\begin{aligned} J_{\text{binary}}(e_i, e_j) &= -t(e_i, e_j) \log p(t(e_i, e_j) = 1) \\ &\quad - (1 - t(e_i, e_j)) \log[1 - p(t(e_i, e_j) = 1)] \\ J_{\text{multi}}(e_i, e_j) &= -\log[p(r(e_i, e_j) = r)] \end{aligned} \quad (9)$$

5.5 Backward Propagation

The derivative for parameters involved is computed through backward propagation. Here we illustrate how we compute the derivative of $J_{\text{multi}}(e_i, e_j)$ with respect to different parameters.

For each pair of nodes $(e_i, e_j) \in$ multi, we associate it with a N_r dimensional binary vector $R(e_i, e_j)$, which denotes the ground truth vector with a 1 at the correct label $r(e_i, e_j)$ and all other entries 0. Integrating softmax error vector, for any parameter θ, the derivative of $J_{\text{multi}}(e_i, e_j)$ with respect to θ is given by:

$$\frac{\partial J_{\text{multi}}(e_i, e_j)}{\partial \theta} = [P_{(e_i,e_j)} - R_{(e_i,e_j)}] \otimes \frac{\partial S_{(e_i,e_j)}}{\partial \theta} \quad (10)$$

where $\otimes$ denotes the Hadamard product between the two vectors. Each training pair recursively backpropagates its error to some node in the discourse tree through $[\{W_r\}, \{b_r\}]$, and then to nodes in sentence parse tree through $[W, b]$, and the derivatives can be obtained according to standard backpropagation (Goller and Kuchler, 1996; Socher et al., 2010).

5.6 Additional Features

When determining the structure/multi relation between individual EDUs, additional features are also considered, the usefulness of which has been illustrated in a bunch of existing work (Feng and Hirst, 2012; Hernault et al., 2010b; Joty et al., 2012). We consider the following simple text-level features:

- Tokens at the beginning and end of the EDUs.
- POS at the beginning and end of the EDUs.
- Whether two EDUs are in the same sentence.

5.7 Optimization

We use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatches, which is widely applied in deep learning literature (e.g.,(Socher et al., 2011a; Pei et al., 2014)). The learning rate in AdaGrad is adapted differently for different parameters at different steps. Concretely, let g_τ^i denote the subgradient at time step t for parameter θ_i obtained from backpropagation, the parameter update at time step t is given by:

$$\theta_\tau = \theta_{\tau-1} - \frac{\alpha}{\sum_{t=0}^{\tau}\sqrt{g_\tau^{i2}}} g_\tau^i \tag{11}$$

where α denotes the learning rate and is set to 0.01 in our approach.

Elements in $\{W_r\}$, W, G_{binary}, G_{multi}, U_{binary}, U_{multi} are initialized by randomly drawing from the uniform distribution $[-\epsilon, \epsilon]$, where ϵ is calculated as suggested in (Collobert et al., 2011). All bias vectors are initialized with 0. Word embeddings $\{e\}$ are borrowed from Senna (Collobert et al., 2011; Collobert, 2011).

5.8 Inference

For inference, the goal is to find the most probable discourse tree given the EDUs within the document. Existing inference approach basically include the approach adopted in (Feng and Hirst, 2012; Hernault et al., 2010b) that merges the most likely spans at each step and SPADE (Fisher and Roark, 2007) that first finds the tree structure that is globally optimal, then assigns the most probable relations to the internal nodes.

In this paper, we implement a probabilistic CKY-like bottom-up algorithm for computing the most likely parse tree using dynamic programming as are adopted in (Joty et al., 2012; Joty et al., 2013; Jurafsky and Martin, 2000) for the search of global optimum. For a document with n EDUs, as different relations are characterized with different compositions (thus leading to different vectors), we use a $N_r \times n \times n$ dynamic programming table Pr, the cell $Pr[r, i, j]$ of which represents the span contained EDUs from i to j and stores the probability that relation r holds between the two spans within i to j. $Pr[r, i, j]$ is computed as follows:

$$\begin{aligned} Pr[r, i, j] =& \max_{r_1, r_2, k} Pr[r_1, i, k] \cdot Pr[r_2, k, j] \\ & \times P(t_{\text{binary}}(e_{[i,k]}, e_{[k,j]}) = 1) \\ & \times P(r(e_{[i,k]}, e_{[k,j]}) = 1) \end{aligned} \tag{12}$$

At each merging step, a distributed vector for the merged point is calculated according to Eq. 13 for different relations. The CKY-like algorithms finds the global optimal. To note, the worst-case running time of our inference algorithm is O($N_r^2 n^3$), where n denotes the number of sentences within the document, which is much slower than the greedy search. In this work, for simplification, we simplify the framework by maintaining the top 10 options at each step.

6 Experiments

A measure of the performance of the system is realized by comparing the structure and labeling of the RS-tree produced by our algorithm to gold-standard annotations.

Standard evaluation of discourse parsing output computes the ratio of the number of identical tree constituents shared in the generated RS-trees and the gold-standard trees against the total number of constituents in the generated discourse trees[2], which is further divided to three matrices: **Span** (on the blank tree structure), **nuclearity** (on the tree structure with nuclearity indication), and **relation** (on the tree structure with rhetorical relation indication but no nuclearity indication).

The **nuclearity** and **relation** decisions are made based on the multi-class output labels from the deep learning framework. As we do not consider nuclearity when classifying different discourse relations, the two labels *attribute[N][S]* and *attribute[S][N]* made by multi-class classifier will be treated as the same relation label ATTRIBUTE.

[2]Conventionally, evaluation matrices involve precision, recall and F-score in terms of the comparison between tree structures. But these are the same when manual segmentation is used (Marcu, 2000b).

Approach	Span	Nuclearity	Relation
HILDA	75.3	60.0	46.8
Joty et al.	82.5	68.4	55.7
Feng and Hirst	**85.7**	71.0	58.2
Ji and Eisenstein	82.1	**71.1**	**61.6**
Unified (with feature)	82.0	70.0	57.1
Ours (no feature)	82.4	69.2	56.8
Ours (with feature)	84.0	70.8	58.6
human	88.7	77.7	65.7

Table 1: Performances for different approaches. Performances for baselines are reprinted from (Joty et al., 2013; Feng and Hirst, 2014; Ji and Eisenstein, 2014).

Also, we do not train a separate classifier for NUCLEUS and SATELLITE identification. The nuclearity decision is made based on the relation type produced by the multi-class classifier.

6.1 Parameter Tuning

The regularization parameter Q constitutes the only parameter to tune in our framework. We tune it on the 347 training documents. Concretely, we employ a five-fold cross validation on the RST dataset and tune Q on 5 different values: 0.01, 0.1, 0.5, 1.5, 2.5. The final model was tested on the testing set after parameter tuning.

6.2 Baselines

We compare our model against the following currently prevailing discourse parsing baselines:

HILDA A discourse parser based on support vector machine classification introduced by Hernault et al. (Hernault et al., 2010b). HILDA uses the binary and multi-class classifier to reconstruct the tree structure in a greedy way, where the most likely nodes are merged at each step. The results for HILDA are obtained by running the system with default settings on the same inputs we provided to our system.

Joty et al The discourse parser introduced by Joty et al. (Joty et al., 2013). It relies on CRF and combines intra-sentential and multi-sentential parsers in two different ways. Joty et al. adopt the global optimal inference as in our work. We reported the performance from their paper (Joty et al., 2013).

Feng and Hirst The linear-time discourse parser introduced in (Feng and Hirst, 2014) which relies on two linear-chain CRFs to obtain a sequence of discourse constituents.

Ji and Eisenstein The shift-reduce discourse parser introduced in (Ji and Eisenstein, 2014) which parses document by relying on the distributed representations obtained from deep learning framework.

Additionally, we implemented a simplified version of our model called **unified** where we use a unified convolutional function with unified parameters $[W_{sen}, b_{sen}]$ for span vector computation. Concretely, for a parent node p, given the distributed representation h_{e_i} for left child, h_{e_j} for right child, and the relation $r(e_1, e_2)$, rather than taking the inter relation between two children, its distributed vector h_p is calculated:

$$h_p = f(W_{sen} \cdot [h_{e_i}, h_{e_j}] + b_{sen}) \qquad (13)$$

6.3 Performance

Performances for different models approaches reported in Table 1. And as we can observe, although the proposed framework obtains comparable result compared with existing state-of-state performances regarding all evaluating parameters for discourse parsing. Specifically, as for the three measures, no system achieves top performance on all three, though some systems outperform all others for one of the measures. The proposed system achieves high overall performance on all three, although it does not achieve top score on any measure. The system gets a little bit performance boost by considering text-level features illustrated in Section 5.6. The simplified version of the original model underperforms against the original approach due to lack of expressive power in convolution. Performance plummets when different relations are uniformly treated, which illustrates the importance of taking into consideration different types of relations in the span convolution procedure.

7 Conclusion

In this paper, we describe an RST-style text-level discourse parser based on a neural network model. The incorporation of sentence-level distributed vectors for discourse analysis obtains comparable performance compared with current state-of-art discourse parsing system.

Our future work will focus on extending discourse-level distributed presentations to related

tasks, such as implicit discourse relation identification or dialogue analysis. Further, once the tree structure for a document can be determined, the vector for the entire document can be obtained in bottom-up fashion, as in this paper. One can now investigate whether the discourse parse tree is useful for acquiring a single document-level vector representation, which would benefit multiple tasks, such as document classification or macro-sentiment analysis.

Acknowledgements

The authors want to thank Vanessa Wei Feng and Shafiq Joty for helpful discussions regarding RST dataset. We also want to thank Richard Socher, Zhengyan He and Pradeep Dasigi for the clarification of deep learning techniques.

Recall Error Analysis for Coreference Resolution

Sebastian Martschat and **Michael Strube**
Heidelberg Institute for Theoretical Studies gGmbH
Schloss-Wolfsbrunnenweg 35, 69118 Heidelberg, Germany
(sebastian.martschat|michael.strube)@h-its.org

Abstract

We present a novel method for coreference resolution error analysis which we apply to perform a recall error analysis of four state-of-the-art English coreference resolution systems. Our analysis highlights differences between the systems and identifies that the majority of recall errors for nouns and names are shared by all systems. We characterize this set of common challenging errors in terms of a broad range of lexical and semantic properties.

1 Introduction

Coreference resolution is the task of determining which mentions in a text refer to the same entity. State-of-the-art approaches include both learning-based (Fernandes et al., 2012; Björkelund and Farkas, 2012; Durrett and Klein, 2013) and deterministic models (Lee et al., 2013; Martschat, 2013). These approaches achieve state-of-the-art performance mainly relying on morphosyntactic and lexical factors. However, consider the following example.

> In order to improving the added value of oil products, the second phase project of **the Qinghai Petroleum Bureau's Ge'ermu oil refinery** has been put into production. This will further improve **the factory's** oil products structure.

Due to the lack of any string overlap, most state-of-the-art systems will miss the link between *the factory* and *the Qinghai Petroleum Bureau's Ge'ermu oil refinery*. The information that *factory* is a hypernym of *refinery*, however, may be useful to resolve such links.

The aim of this paper is to quantify and characterize such recall errors made by state-of-the-art coreference resolution systems. By doing so, we provide a solid foundation for work on employing knowledge sources for improving recall for coreference resolution (Ponzetto and Strube, 2006; Rahman and Ng, 2011; Ratinov and Roth, 2012; Bansal and Klein, 2012, inter alia). In particular, we make the following contributions:

We present a novel framework for coreference resolution error analysis. This yields a formal foundation for previous work on link-based error analysis (Uryupina, 2008; Martschat, 2013) and complements work on transformation-based error analysis (Kummerfeld and Klein, 2013).

We apply the method proposed in this paper to perform a recall error analysis of four state-of-the-art systems, encompassing deterministic and learning-based approaches. In particular, we identify and characterize a set of challenging errors common to all systems, and discuss strengths and weaknesses of each system regarding specific error types. We also present a brief precision error analysis.

A toolkit which implements the framework proposed in this paper is available for download.[1]

2 A Link-Based Analysis Framework

In this section we discuss challenges in coreference resolution error analysis and devise an error analysis framework to overcome these challenges.

2.1 Motivation

Suppose a document contains the entity BARACK OBAMA, which is referenced by four mentions in the following order: *Obama*, *he*, *the president* and *his*. A typical output of a current system not equipped with world knowledge will consist of two entities: {*Obama*, *he*} and {*the president*, *his*}

Obviously, the system made a recall error. But, due to the complex nature of the coreference resolution task, it is not clear how to represent the re-

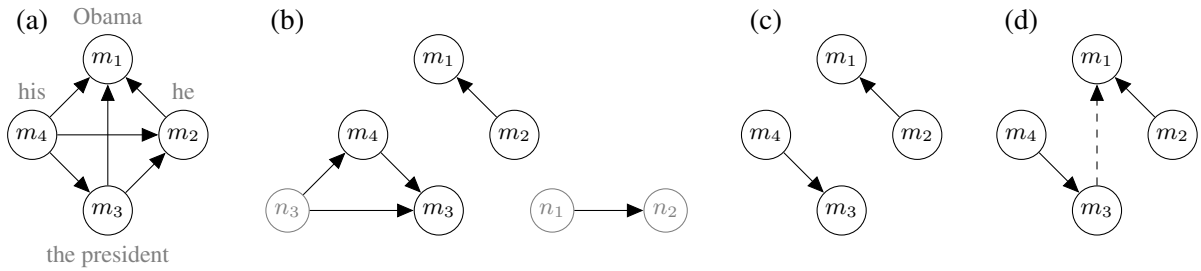

Figure 1: (a) a reference entity r, represented as a complete one-directional graph, (b) a set S of three system entities, (c) the partition r_S, (d) a spanning tree for r.

call error: is it missing the link between *the president* and *Obama*? Can the error be attributed to deficiencies in pronoun resolution?

Linguistically motivated error representations would facilitate both understanding of current challenges and make system development faster and easier. The aim of this section is to devise such representations.

2.2 Formalizing Coreference Resolution

To start with, we give a formal description of the coreference resolution task following the terminology used for the ACE (Mitchell et al., 2004) and OntoNotes (Weischedel et al., 2013) projects. A *mention* is a linguistic realization of a reference to an entity. Two mentions *corefer* if they refer to the same entity. Hence, coreference is reflexive, symmetric and transitive, and therefore an *equivalence relation*. The task of coreference resolution is to predict equivalence classes of mentions in a document according to the coreference relation.

In order to extract errors, we need to compare the *reference equivalence classes*, given by the annotation, with the *system equivalence classes* obtained from system output. The key question now is how we represent these equivalence classes of mentions. Adapting common terminology, we also refer to the equivalence classes as entities.

2.3 Representing Entities

The most straightforward entity representation ignores any structure and models an entity as a set of mentions. This representation was utilized for error analysis by Kummerfeld and Klein (2013), who extract errors by transforming reference into system entities. In this set-based representation, we can only extract whether two mentions corefer at all. More fine-grained information, for example about antecedent information, is not accessible.

We therefore propose to employ a *structured* entity representation, which explicitly models links established by the coreference relation between mentions. This leads to a link-based error representation which formalizes the methods presented in Uryupina (2008) and Martschat (2013).

We employ for representation a *complete one-directional graph*. That is, we represent an entity e over mentions $\{m_1, \ldots, m_n\}$ as a graph $e = (N, A)$, where $N = \{m_1, \ldots, m_n\}$ and $A = \{(m_k, m_j) \mid k > j\}$. The indices respect the mention ordering. Mentions earlier in the text have a lower index. An example graph for an entity over four mentions $m_1, \ldots, m_4$ (such as the BARACK OBAMA entity) is depicted in Figure 1a. In this graph, we express all coreference relations between all pairs of mentions.[2]

Using this representation, we can represent a set of entities as a set of graphs. In particular, given a document we consider the set of *reference entities* R given by the annotation, and the set of *system entities* S, given by the system output. In order to extract errors, we compare the graphs in R with the graphs in S.

In the following, we discuss how to compute recall errors for a reference entity $r \in R$ with respect to the system entities S. For computing precision errors, we just switch the roles of R and S.

2.4 Comparing Reference and System Entities

As we represent entities as sets of links between mentions, errors can be quantified as differences in the links. For example, if an edge (representing a link) from some reference entity $r \in R$ is missing

[2]We could also use an undirected instead of a one-directional graph, but using a one-directional graph conveniently models sequential information, which simplifies notation and the algorithms we will present.

in all system entities in S, this is a recall error.

In order to formalize this, we employ the notion of a *partition* of an entity. Let $r \in R$ be some reference entity, and let S be a set of system entities. The partition of r by S, written r_S, is obtained by taking all edges in r that also appear in S. r_S consists of all connected components of r (we will refer to these as *subentities*) that are also in S. All edges in r that are not in r_S are candidates for recall errors, as these were not in any entity in S.

Figure 1b shows a set S of three system entities: two consist of two mentions, one of three mentions. In our running example, this corresponds to the system output {*Obama*, *he*} and {*the president*, *his*} plus some spurious mentions, which are colored gray. The graph r_S for our example is shown in Figure 1c. The two edges correspond to the correctly recognized links (*he*, *Obama*) and (*his*, *the president*). All edges in r (Figure 1a) missing from this graph are candidates for errors.

2.5 Spanning Trees

However, taking all edges in r missing in r_S as errors leads to unintuitive results. In the BARACK OBAMA example, this would lead to four errors being extracted: (*the president*, *Obama*), (*his*, *Obama*), (*the president*, *he*) and (*his*, *he*). But, in order to correctly predict the BARACK OBAMA entity, a coreference resolution system only needs to predict three correct links, i.e. it has to provide a *spanning tree* of the entity's graph representation.

Therefore, to extract errors, we compute a spanning tree T_r of r, and take all edges in T_r that do not appear in r_S as errors. Figure 1d shows an example spanning tree for the running example entity r. The dashed edge, which corresponds to the link (*the president*, *Obama*), does not appear in r_S and is therefore extracted as an error.

The strategies for computing a spanning tree may differ for recall and precision errors. Hence, our extraction algorithm is parametrized by two procedures $\texttt{ST}_{\text{rec}}(e, P)$ and $\texttt{ST}_{\text{prec}}(e, P)$ which, given an entity e and a set of entities P, output a spanning tree T_e of e. The whole algorithm for error extraction is summarized in Algorithm 1.

Algorithm 1 Error Extraction from a Corpus

Input: A corpus $\mathcal{C}$, algorithms $\texttt{ST}_{\text{rec}}$, $\texttt{ST}_{\text{prec}}$ for computing spanning trees.

function ERRORS($\mathcal{C}$, $\texttt{ST}_{\text{rec}}$, $\texttt{ST}_{\text{prec}}$)

`recall_errors` $= [\,]$

`precision_errors` $= [\,]$

for $d \in \mathcal{C}$ **do**

Let R_d be the reference entities and S_d be the system entities of document d.

for $r \in R_d$ **do**

Add all edges in $\texttt{ST}_{\text{rec}}(r, S_d)$ not in r_{S_d} to `recall_errors`.

for $s \in S_d$ **do**

Add all edges in $\texttt{ST}_{\text{prec}}(s, R_d)$ not in s_{R_d} to `precision_errors`.

Output: `recall_errors`, `precision_errors`

3 Spanning Tree Algorithms

In the last section we presented a framework for link-based error analysis, which extracts errors by comparing entity spanning trees to entity partitions. Therefore we can accommodate different notions of errors by varying the algorithm for computing spanning trees. We now present some spanning tree algorithms for extracting recall and precision errors.

3.1 Recall Errors

We first observe that for error extraction, the structure of the spanning trees of the subentities appearing in r_S does not play a role. Edges present in r_S are not candidates for errors, since they appear in both the reference entity r and the system output S. Therefore, it does not matter which edges from the subentities are in the spanning tree.

Hence, to build the spanning tree, we first choose arbitrary spanning trees for the subentities in the partition. We choose the remaining edges according to the spanning tree algorithm.

Having settled on this, we only have to decide which edges to choose that connect the trees representing the subentities. There are many possible choices for this. For example, the graph in Figure 1c has four candidate edges which connect the trees for the subentities.

We can reduce the number of candidate edges by only considering the first mention (with respect to textual order) in a subentity as the source of an edge to be added. This makes sense since all other mentions in that subentity were correctly resolved to be coreferent with some preceding mention. We still have to decide on the target of the edge. In Figure 1c, we have two choices for edges: (m_3, m_1) and (m_3, m_2). We now present two methods for choosing edges.

Choosing Edges by Distance. The most straight-forward way to decide on an edge is to take the edge with smallest mention distance between source and target. This is the approach taken by Martschat (2013).

Choosing Edges by Accessibility. However, the distance-based approach may lead to unintuitive results. Let us consider again the BARACK OBAMA example from Figure 1. When choosing edges by distance, we would extract the error (*the president*, *he*). However, such links with a non-pronominal anaphor and a pronominal antecedent are difficult to process and considered unreliable (Ng and Cardie, 2002; Bengtson and Roth, 2008). On the other hand, the missed link (*the president*, *Obama*) constitutes a well-defined hyponymy relation which can be found in knowledge bases and is easily interpretable by humans.

Uryupina (Uryupina, 2007; Uryupina, 2008) presents a recall error analysis where she takes the "intuitively easiest" missing link to analyze (Uryupina, 2007, p. 196). How can we formalize such an intuition? We will employ a notion grounded in accessibility theory (Ariel, 1988). Names and nouns refer to less accessible entities than pronouns do. For such anaphors, we prefer descriptive (name/nominal) antecedents. Inspired by Ariel's degrees of accessibility, we choose a target for a given anaphor m_i as follows:

- If m_i is a pronoun, choose the closest preceding mention.
- If m_i is not a pronoun, choose the closest preceding proper name. If no such mention exists, choose the closest preceding common noun. If no such mention exists, choose the closest preceding mention.

Applied to the example from Figure 1, this algorithm extracts the error (*the president*, *Obama*).[3]

3.2 Precision Errors

Virtually all approaches to coreference resolution obtain entities by outputting pairs of anaphor and antecedent, subject to the constraint that one anaphor has at most one antecedent.

We use this information to build spanning trees for system entities: these spanning trees consist of exactly the edges which correspond to anaphor/antecedent pairs in the system output.

[3] A similar procedure was used by Ng and Cardie (2002) to extract meaningful antecedents when training a coreference resolution system.

4 Data and Systems

We now discuss data and coreference resolution systems which we will employ for our analysis.

4.1 Data

We analyze the errors of the systems on the English development data of the CoNLL'12 shared task on multilingual coreference resolution (Pradhan et al., 2012). This corpus contains 343 documents, spanning seven genres: bible texts, broadcast conversation, broadcast news, magazine texts, news wire, telephone conversations and web logs.

4.2 Systems

State-of-the-art approaches to coreference resolution encompass various paradigms, ranging from deterministic pairwise systems to learning-based structured prediction models. Hence, we want to conduct our analysis on a representative sample of the state of the art, which should be publicly available. Therefore, we decided on two deterministic and two learning-based systems:

- **StanfordSieve**[4] (Lee et al., 2013) was the winning system of the CoNLL'11 shared task. It employs a multi-sieve approach by making more confident decisions first.
- **Multigraph**[5] (Martschat, 2013) is a deterministic pairwise system which is based on Martschat et al. (2012), the second-ranking system in the English track of the CoNLL'12 shared task. It uses a subset of features as hard constraints and chooses an antecedent for a mention by summing up the remaining boolean features.
- **IMSCoref**[6] (Björkelund and Farkas, 2012) ranked second overall in the CoNLL'12 shared task (third for English). It stacks multiple decoders and relies on a combination of standard pairwise and lexicalized features.
- **BerkeleyCoref**[7] (Durrett and Klein, 2013) is a state-of-the-art system that uses mainly lexicalized features and a latent antecedent ranking architecture. It outperforms StanfordSieve and IMSCoref on the CoNLL'11 data.

[4] Part of Stanford CoreNLP, available at `http://nlp.stanford.edu/software/corenlp.shtml`. We use version 3.4.

[5] `http://smartschat.de/software`

[6] `http://www.ims.uni-stuttgart.de/forschung/ressourcen/werkzeuge/IMSCoref.en.html` . We use the *CoNLL 2012 system*.

[7] `http://nlp.cs.berkeley.edu/berkeleycoref.shtml`

System	MUC	B^3	$CEAF_e$	Average
Fernandes et al.	69.46	57.83	54.43	60.57
Martschat	66.22	55.47	51.90	57.86
StanfordSieve	64.96	54.49	51.24	56.90
Multigraph	69.13	58.61	56.06	61.28
IMSCoref	67.15	55.19	50.94	57.76
BerkeleyCoref	70.27	59.29	56.11	61.89

Table 1: Comparison of the systems with Fernandes et al. (2012) and with Martschat (2013) on CoNLL'12 English development data.

For Multigraph, we modified the system described in Martschat (2013) slightly to allow for the incorporation of distance (similar to Cai and Strube (2010)). Inspired by Lappin and Leass (1994), we add salience weights for subjects and objects to the model to improve third-person pronoun resolution. We also extended the feature set by a substring feature. Furthermore, motivated by Chen and Ng (2012), we added a lexicalized feature for non-pronominal mentions that were coreferent in at least 50% of the cases in the training data.

StanfordSieve was run with its standard CoNLL shared task settings. The learning-based systems were trained on the CoNLL'12 training data. We trained IMSCoref with its standard settings, and trained BerkeleyCoref with the *final* feature set from Durrett and Klein (2013) for twenty iterations. We evaluate the systems on English CoNLL'12 development data and compare it with the winning system of the CoNLL'12 shared task (Fernandes et al., 2012) and with Martschat (2013) in Table 1, using the reference implementation v7 of the CoNLL scorer (Pradhan et al., 2014).

BerkeleyCoref performs best according to all metrics, followed by Multigraph. StanfordSieve is the worst performing system: the gap to BerkeleyCoref is five points in average score.

4.3 Discussion

Although we analyze recent systems on a recently published coreference data set, we believe that the results of our analysis will have implications for coreference in general. The data set is the largest and most genre-diverse coreference corpus so far. The systems we investigate represent major directions in coreference resolution model research, and make use of large and diverse feature sets proposed in the literature (Ng, 2010).

5 A Comparative Analysis

The coreference resolution systems presented in the previous section are a representative sample of the state of the art. Therefore, by analyzing the errors they make, we can learn about remaining challenges in coreference resolution and analyze the qualitative differences between the systems. The results of such an analysis will deepen our understanding of coreference resolution and will suggest promising directions for further research.

5.1 Experimental Settings

Previous studies identified the presence of recall errors as a main bottleneck for improving performance (Raghunathan et al., 2010; Durrett and Klein, 2013; Kummerfeld and Klein, 2013). This is also evidenced by the CoNLL shared tasks on coreference resolution (Pradhan et al., 2011; Pradhan et al., 2012), where most competitive systems had higher precision than recall. This indicates that an analysis of recall errors helps to understand and improve the state of the art. Hence, we focus on analyzing recall errors, and complement this by a brief analysis of precision errors.

We analyze errors of the four systems presented in the previous section on the CoNLL'12 English development data. To extract recall errors we employ the spanning tree algorithm which **chooses edges by accessibility**. We obtain precision errors from the pairwise output of the systems.

5.2 A Recall Error Analysis of StanfordSieve

Since StanfordSieve is currently the most-widely used coreference resolution system, it serves as a good starting point for our analysis. Remember that we represent each error as a pair of anaphor and antecedent. For an initial analysis, we categorize each error by mention type, distinguishing between proper name, common noun, pronoun, demonstrative pronoun and verb.[8]

StanfordSieve makes 5245 recall errors. To put this number into context, we compare it with the maximum number of recall errors a system can make. This count is obtained by extracting recall errors from the output of a system that puts each mention in its own entity, which yields 14609 errors. In Table 2 we present a detailed analysis. For each pair of mention type of anaphor and an-

[8]We obtain the type from the part-of-speech tag of the mention's head. Furthermore, we treat every mention whose head has a NER label in the data as a proper name.

	Name	Noun	Pron.	Dem.	Verb
Name					
Errors	1006	181	43	0	0
Maximum	3578	206	56	2	0
Noun					
Errors	517	1127	46	14	91
Maximum	742	2063	51	14	91
Pron.					
Errors	483	761	543	45	53
Maximum	1166	1535	4596	92	53
Dem.					
Errors	23	86	41	31	117
Maximum	27	93	43	46	117
Verb					
Errors	1	20	2	4	10
Maximum	1	20	2	4	11

Table 2: Number of StanfordSieve's recall errors according to mention type, compared to the maximum possible number of errors. Rows are anaphors, columns antecedents.

tecedent, the table displays the number of recall errors and of maximum errors possible.

StanfordSieve gets almost none of the links involving verbal or demonstrative mentions correct. This is due to the system not attempting to handle event coreference, and performing very poorly for demonstratives. On the other hand, recall for pronoun resolution is quite good, at least when considering non-verbal antecedents. While StanfordSieve makes 1885 recall errors when the anaphor is a pronoun, it successfully resolves most of such links present in the corpus. Finally, let us consider the links involving only proper names and common nouns. In total, these amount to 6589 links in the corpus (around 45% of all links). StanfordSieve misses 2831 of these links. Pairs of proper names seem to be easier to resolve than pairs of common nouns. Links between a common noun and a proper name are less frequent, but much more difficult: most of the links are missing.

5.3 Analysis of the Other Systems

In the previous section we identified various characteristics of the errors made by StanfordSieve: only (comparatively) few errors are made for pronoun resolution and name coreference, while other types of nominal anaphora and coreference of demonstrative/verbal mentions pose a challenge for the system. Do the other systems in our study also have these characteristics? In order to answer this question, we repeated the analysis for the three other systems described in Section 4. We summarize the results in Table 3. We only report numbers for pronoun resolution and name/noun coreference, as all systems do not resolve verbal mentions and perform poorly for demonstratives.

		Proportion	
System	**Total**	**Anaphor Pron.**	**Name/Noun**
StanfordSieve	5245	36%	54%
Multigraph	4630	32%	56%
IMSCoref	5220	32%	58%
BerkeleyCoref	4635	32%	56%

Table 3: Recall error numbers for all systems.

StanfordSieve makes the most recall errors, closely followed by IMSCoref. Multigraph and BerkeleyCoref make around 600 errors less. While the total number of errors differs between the systems, the distributions are similar. In particular, around 55% of recall errors made involve only proper names and common nouns. The number is a bit higher for IMSCoref. We conclude that, despite variations in performance, both deterministic and learning-based state-of-the-art systems have similar weaknesses regarding recall.

The results displayed in Table 3 suggest various opportunities for future research. In this paper, we will focus on analyzing name/noun recall errors, as these constitute a large fraction of all recall errors. Future work should address the pronoun resolution errors and a characterization of the verbal/demonstrative errors.

5.4 Analysis of the Name/Noun Recall Errors

We now turn towards a fine-grained analysis of the name/noun recall errors.

Table 4 displays the number of such recall errors made by each system, according to the mention types of anaphor and antecedent. We are interested in errors common to all systems, and in qualitative differences of errors between the systems.

5.4.1 Common Errors

Let us first analyze the errors common to all systems. Our analysis is driven by the question how these can be characterized, and which knowledge is missing to resolve such links. We discuss the errors depending on the mention types of anaphor and antecedent. The lower part of Table 4 displays the number of common errors for each category.

Description	Number of Recall Errors (Anaphor-Antecedent)			
	Name-Name	Noun-Name	Name-Noun	Noun-Noun
StanfordSieve	1006	517	181	1127
Multigraph	753	501	189	1152
IMSCoref	1082	500	188	1264
BerkeleyCoref	910	456	171	1072
Common errors	475	371	147	835
Correct boundaries idenfified	257	273	108	563
excl. IMSCoref	156	222	97	475

Table 4: Name/Noun recall errors for all systems.

Common		All	
Type	%	Type	%
ORG	25%	PERSON	26%
PERSON	19%	GPE	26%
GPE	16%	ORG	20%
DATE	14%	NONE	14%
NONE	9%	DATE	6%

Table 5: Distribution of top five named entity types of common name-name recall errors and all possible name-name recall errors.

Furthermore, in order to assess the impact of mention detection, the table shows the number of common errors where boundaries for both mentions were identified correctly by some system. We can see that boundary identification is a difficult problem, especially for proper name pairs: for 48% of such errors, no system found the correct boundaries of both mentions participating in the error. The number of errors where correct boundaries could be found drops significantly after excluding IMSCoref. This is due to the mention extraction strategy of IMSCoref: the other systems in our study discard the shorter mention when two mentions have the same head, IMSCoref keeps both mentions. Hence, the system is able to correctly identify some mentions even in the presence of parsing or preprocessing errors. However, as a result, IMSCoref has to process many spurious mentions, which makes learning more difficult.

We conclude that mention detection still constitutes a challenge. We now proceed to a detailed analysis of errors common to all systems. In passing we will discuss difficulties in mention detection with regard to specific error types.

Errors between Pairs of Proper Names. The systems share 475 recall errors between pairs of proper names. In Table 5, we compare the distribution of gold named entity types of these errors with the distribution of gold named entity types of all possible errors (obtained via a singleton system). We see that especially difficult classes of links are pairs with type ORG or DATE.

Let us now consider lexical features of the errors.[9] In 154 errors, the strings match completely, but the correct resolution was mostly prevented by annotation inconsistencies (e.g. *China* instead of *China's*) or propagated parsing and NER errors, which lead to deficiencies in mention extraction.

For 217 errors, at least one token appears in both mention strings, as in *the "Cole"* and *the "USS Cole"*. This shows the insufficiency of the features which hint to alias relations, may it be heuristics or learned lexical similarities (for 109 of the 217 errors, both mention boundaries were identified correctly by at least one system). Disambiguation with respect to knowledge bases could provide a principled way to identify name variations.

We classified the remaining 104 errors manually, see Table 6. For a couple of categories such as identifying acronyms, spelling variations and aliases, disambiguation could also help. Many errors happen for date mentions, which suggests the use of temporal tagging features.

Errors for Noun-Name Pairs. We now investigate the errors where the anaphor is a common noun and the antecedent is a proper name. 371 errors are common to all systems. The high fraction of common errors shows that this is an especially challenging category. We again start by investigating how the distribution of the named entity type

[9] When computing these, we ignored case and ignored all tokens with part-of-speech tag DT or POS.

Description	Occ.	Example
Acronyms	20	*National Ice Hockey League* and *NHL*
Alias	24	*Florida* and *the Sunshine State*
Annotation	2	Annotation errors (pronoun as name)
Context	2	*Paula Coccoz* and *juror number ten*
Date	29	*1989* and *last year's*
Metonymy	12	*South Afria* and *Pretoria*
Roles	8	*Al Gore* and *the Vice President*
Spelling	7	*Hsiachuotzu* and *Hsiachuotsu*

Table 6: Classification of common name-name recall errors without common tokens.

Common		All	
Type	%	Type	%
ORG	28%	ORG	27%
PERSON	22%	GPE	22%
GPE	19%	PERSON	18%
NONE	7%	NONE	11%
DATE	5%	DATE	5%

Table 7: Distribution of top five named entity types of common noun-name recall errors and all possible noun-name recall errors.

of the antecedent differs when we compare common errors to all possible errors. The results are shown in Table 7. Links with a proper name antecedent of type PERSON are especially difficult. They constitute 22% of the common errors, but only 18% of all possible errors.

Most mentions are in a hyponymy relation, like *the prime minister* and *Mr. Papandreou*. This confirms that harnessing such relations could improve coreference resolution (Rahman and Ng, 2011; Uryupina et al., 2011). For 65 of the errors (18%) there is lexical overlap: the head of the anaphor is contained in the proper name antecedent, as in *the entire park* and *the Ocean Park*.

When categorizing all common errors according to the head of the anaphor, we observe 204 different heads. 142 heads appear only once, but the top ten heads make up 88 of the 371 errors. The most frequent heads are *company* (15), *group* (12), *government*, *country* and *nation* (each 9). This suggests that even with few reliable hyponymy relations recall could be significantly improved.

We observe similar trends when the anaphor is a proper name and the antecedent is a noun.

	Reference System			
System	Stanford	MG	IMS	Berkeley
Stanford	-	51	47	61
MG	17	-	42	60
IMS	26	54	-	54
Berkeley	12	42	25	-

Table 8: Comparison of noun-name recall errors. Entries are errors made by the system in the row, while the participating mentions are coreferent according to the the system in the column.

Errors between Pairs of Common Nouns. 835 errors between pairs of common nouns are shared by all systems. For 174 of these, the anaphor is an indefinite noun phase, which makes resolution a lot harder, since most coreference resolution systems classify these as non-anaphoric and therefore do not attempt resolution.

For further analysis, we split all 835 errors in two categories, distinguishing whether the head matches between the mentions or not. In 341 cases the heads match. For many of these cases, parsing errors propagate and prevent the systems from recognizing the correct mention boundaries.

In order to get a better understanding of the errors for nouns with different heads, we randomly extracted 50 of the 494 pairs and investigated the relation that holds between the heads. In 23 cases, the heads were related via hyponymy. In 10 cases they were synonyms. The remaining 17 cases involve many different phenomena, for example meronymy. This confirms findings from previous research (Vieira and Poesio, 2000).

Hence, looking up lexical relations, especially hyponymy, might be helpful to solve these cases.

5.4.2 Differences between the Systems

In order to analyze differences between the systems, we compare the recall errors they make. The information how recall errors differ between systems will enable us to understand individual strengths and weaknesses.

Exemplarily, we will have a look at the differences in the errors when the anaphor is a common noun and the antecedent is a proper name. By system design and by the total error numbers (Table 4) we expect the learning-based systems to have a slight advantage over the deterministic systems.

In Table 8 we compare noun-name recall errors made by each system. Entries are errors made by

	Number and Proportion of Precision Errors (Anaphor-Antecedent)

Common errors	158		1		2		167	

Table 9: Name/Noun precision errors for all systems. The percentages are the proportion of precision errors with respect to all decision of the system in that category.

the system in the row, while the participating mentions are coreferent according to the the system in the column. The numbers confirm our hypothesis, but also show that the deterministic systems are able to recover a few links missed by the learning-based systems.

For example, BerkeleyCoref recovers 60 links that could not be found by Multigraph, including 34 links without any common token, such as *the airline* and *Pan Am*. Multigraph recovers only 42 links not found by BerkeleyCoref, 21 without any common token. Qualitatively, StanfordSieve and Multigraph are able to resolve a few links thanks to their engineered substring match, such as *the judge* and *Dallas District Judge Jack Hampton*.

We also conducted similar investigations for common noun and proper name pairs. For common nouns, the trends are similar: the learning-based systems have an advantage over the deterministic systems. However, only few relations between nouns with different heads are learned – compared to StanfordSieve, BerkeleyCoref recovers only 11 such pairs, such as *the man* and *an expert in the law*. Recall of the deterministic systems is further hampered by their strict checks for modifier agreement, which they employ to keep precision high. Both systems miss for example the link from the anaphor *the Milosevic regime* to *the regime*, since the nominal modifier of the anaphor does not appear in the antecedent.

For proper names, Multigraph employs sophisticated alias heuristics which help to resolve matches such as *Marshall Ye Ting's* and *his grandfather Ye Ting*. This explains the corresponding low number in Table 4. The lexicalized features of Multigraph, IMSCoref and BerkeleyCoref help to learn aliases when there is no string match, especially for the bible part of the corpus (resolving links such as *Jesus* and *the Son of Man*).

5.5 Precision Errors

In the above analysis we identified common name/noun recall errors and discussed strengths and weaknesses of each system. Let us complement this analysis by a brief discussion of corresponding precision errors.

Table 9 gives an overview. It displays the number of precision errors for each category, and the proportion of these errors compared to all decisions in that category. We can see some general trends from this table: first, more decisions lead to a higher proportion of errors. This shows the difficulty of balancing recall and precision. Second, proper name coreference seems much easier than common noun coreference. Coreference involving different mention types is a lot harder – the systems only attempt few decisions, most of them are wrong. This confirms findings from our recall error analysis. Third, the fraction of common errors is very low, which indicates that precisions errors stem from various sources, which are handled differently by each system.

6 Related Work

We now discuss related work in coreference resolution error analysis and in the related field of coreference resolution evaluation metrics.

Error Analysis. While many papers on coreference resolution briefly discuss errors made and resolved by the system under consideration, only few concentrate on error analysis. Uryupina (2008) presents a manual error analysis on the small MUC-7 test set; Martschat (2013) performs an automatic coarse-grained error classification on CoNLL data. By extending and formalizing the approach of Martschat (2013), we are able to perform a large-scale investigation of recall errors made by state-of-the-art systems.

Kummerfeld and Klein (2013) devise a method to extract errors from transformations of reference to system entities. They apply this method to a variety of systems and aggregate errors over these systems. By aggregating, they are not able to analyze differences. They furthermore focus on describing many different error classes, instead of closely investigating particular phenomena.

Evaluation Metrics. We extract recall and precision errors. How does our error analysis framework relate to coreference resolution evaluation metrics, which *quantify* recall and precision errors? We first observe a fundamental difference: evaluation metrics deal with *scoring* coreference chains, they provide no means of extracting recall or precision errors. Therefore our analysis complements insights obtained via evaluation metrics.

We follow Chen and Ng (2013) and distinguish between *linguistically agnostic metrics*, which do not employ linguistic information during scoring, and *linguistically informed metrics*, which employ linguistic information similar as we do when computing spanning trees.

We limit the discussion of linguistically agnostic metrics to the three most popular evaluation metrics whose average constitutes the official score in the CoNLL shared tasks on coreference resolution: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998) and $CEAF_e$ (Luo, 2005).[10]

Our framework bears most similarities to the MUC metric, as both are based on the same link-based entity representation. In particular, when we divide the number of errors extracted from an entity by the size of a spanning tree for that entity, we obtain a score linearly related[11] to the MUC score for that entity (recall for reference entities, precision for system entities). B^3 and $CEAF_e$ are not founded on a link-based structure. B^3 computes recall by computing the relative overlap of reference and system entity for each reference mention, and then normalizes by the number of mentions. $CEAF_e$ computes an optimal entity alignment with respect to the relative overlap, and then normalizes by the number of entities. As the metrics are not link-based, they do not provide means to extract link-based errors. We leave determining whether the framework of these metrics exhibits a useful notion of errors to future work.

[10]These are linguistically agnostic since they do not differ between different mention or entity types when evaluating.

[11]via the transformation $x \mapsto 1 - x$

Recent work considered devising evaluation metrics which take linguistic information into account. Chen and Ng (2013) inject linguistic knowledge into existing evaluation metrics by weighting links in an entity representation graph. Tuggener (2014) devises scoring algorithms tailored for particular applications by redefining the notion of a correct link. While both of these works focus on scoring, they weight or explicitly define links in the reference and system entities, thereby they in principle allow error extraction. However, the authors do not attempt this and it is not clear whether the errors extracted that way are useful for analysis and system development.

7 Conclusions

We presented a novel link-based framework for coreference resolution error analysis, which extends and complements previous work. We applied the framework to analyze recall errors of four state-of-the-art systems on a large English benchmark dataset. Concentrating on errors involving only proper names and common nouns, we identified a core set of challenging errors common to all systems in our study.

We characterized the common errors among a broad range of properties. In particular, our analysis highlights and quantifies the usefulness of world knowledge. Furthermore, by comparing the recall errors made by each system, we identified individual strengths and weaknesses. A brief precision error analysis highlighted the hardness of resolving noun-name and noun-noun links.

The presented method and findings help to identify challenges in coreference resolution and to investigate ways to overcome these challenges.

Abstract

Bridging resolution plays an important role in establishing (local) entity coherence. This paper proposes a rule-based approach for the challenging task of unrestricted bridging resolution, where bridging anaphors are not limited to definite NPs and semantic relations between anaphors and their antecedents are not restricted to meronymic relations. The system consists of eight rules which target different relations based on linguistic insights. Our rule-based system significantly outperforms a reimplementation of a previous rule-based system (Vieira and Poesio, 2000). Furthermore, it performs better than a learning-based approach which has access to the same knowledge resources as the rule-based system. Additionally, incorporating the rules and more features into the learning-based system yields a minor improvement over the rule-based system.

1 Introduction

Bridging resolution recovers the various non-identity relations between anaphora and antecedents. It plays an important role in establishing entity coherence in a text. In Example 1, the links between the bridging anaphors (**The five astronauts** and **touchdown**) and the antecedent (*The space shuttle Atlantis*) establish (local) entity coherence.[1]

(1) *The space shuttle Atlantis* landed at a desert air strip at Edwards Air Force Base, Calif., ending a five-day mission that dispatched the Jupiter-bound Galileo space probe. **The five astronauts** returned to Earth about three hours early because high winds had been predicted at the landing site. Fog shrouded the base before **touchdown**.

Bridging or *associative anaphora* has been widely discussed in the linguistic literature (Clark, 1975; Prince, 1981; Gundel et al., 1993; Löbner, 1998). Poesio and Vieira (1998) and Bunescu (2003) include cases where antecedent and anaphor are coreferent but do not share the same head noun (*different-head coreference*). We follow our previous work (Hou et al., 2013b) and restrict *bridging* to non-coreferential cases. We also exclude *comparative anaphora* (Modjeska et al., 2003).

Bridging resolution includes two subtasks: (1) recognizing bridging anaphors and (2) finding the correct antecedent among candidates. In recent empirical work, these two subtasks have been tackled separately: (Markert et al., 2012; Cahill and Riester, 2012; Rahman and Ng, 2012; Hou et al., 2013a) handle bridging recognition as part of information status (IS) classification, while (Poesio et al., 1997; Poesio et al., 2004; Markert et al., 2003; Lassalle and Denis, 2011; Hou et al., 2013b) concentrate on antecedent selection only, assuming that bridging recognition has already been performed. One exception is Vieira and Poesio (2000). They propose a rule-based system for processing definite NPs. However, they include *different-head coreference* into *bridging*. They report results for the whole anaphora resolution but do not report results for bridging resolution only. Another exception is Rösiger and Teufel (2014). They apply a coreference resolution system with several additional semantic features to find bridging links in scientific text where bridging anaphors are limited to definite NPs. They report preliminary results using the CoNLL scorer. However, we think the coreference resolution system and the evaluation metric for coreference resolution are

[1]Examples are from OntoNotes (Weischedel et al., 2011). Bridging anaphora are typed in boldface; antecedents in italics.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2082–2093,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

not suitable for bridging resolution since bridging is not a set problem.

Another vein of research for bridging resolution focuses on formal semantics. Asher and Lascarides (1998) and Cimiano (2006) model bridging by integrating discourse structure and semantics from a formal semantics viewpoint. However, the implementation of such a theoretical framework is beyond the current capabilities of NLP since it depends heavily on commonsense entailment.

In this paper, we propose a rule-based system for unrestricted bridging resolution. The system consists of eight rules which we carefully design based on linguistic intuitions, i.e., how the nature of bridging is reflected by various lexical, syntactic and semantic features. We evaluate our rule-based system on a corpus where bridging is reliably annotated. We find that our rule-based system significantly outperforms a reimplementation of a previous rule-based system (Vieira and Poesio, 2000). We further notice that our rule-based system performs better than a learning-based approach which has access to the same knowledge resources as the rule-based system. Surprisingly, incorporating the rules and more features into the learning-based approach only yields a minor improvement over the rule-based system. We observe that diverse bridging relations and relatively small-scale data for each type of relations make generalization difficult for the learning-based approach. This work is – to the best of our knowledge – the first system recognizing bridging anaphora and finding links to antecedents for unrestricted phenomenon where bridging anaphors are not limited to definite NPs and semantic relations between anaphors and their antecedents are not restricted to meronymic relations.

2 Data

All the data used throughout the paper come from the ISNotes corpus[2] released by Hou et al. (2013b). This corpus contains around 11,000 NPs annotated for information status including 663 bridging NPs and their antecedents in 50 texts taken from the WSJ portion of the OntoNotes corpus (Weischedel et al., 2011). ISNotes is reliably annotated for bridging: for bridging anaphor recognition, κ is over 60 for all three possible annotator pairings (κ is over 70 for two expert annotators); for selecting bridging antecedents, agreement is around 80% for all annotator pairings.

It is notable that bridging anaphors in ISNotes are not limited to definite NPs as in previous work (Poesio et al., 1997; Poesio et al., 2004; Lassalle and Denis, 2011). Table 1 shows the bridging anaphora distribution with regard to determiners in ISNotes: only around 38% of bridging anaphors are definite NPs (NPs modified by *the*); 15.4% of bridging anaphors are modified by determiners such as *a*, *an* or *one* which normally indicate indefinite NPs. Most bridging anaphors (43%) are not modified by any determiners, such as **touchdown** in Example 1. A small fraction of bridging anaphors (1.2%) are modified by other determiners, such as demonstratives.

Bridging Anaphors	663
Non-determiner	44.9%
Definite	38.5%
Indefinite	15.4%
Other-determiner	1.2%

Table 1: Bridging anaphora distribution w.r.t. determiners in ISNotes.

The semantic relations between anaphor and antecedent in the corpus are extremely diverse: only 14% of anaphors have a part-of/attribute-of relation with the antecedent (see Example 2) and only 7% of anaphors stand in a set relationship to the antecedent (see Example 3). 79% of anaphors have "other" relations with their antecedents (without further distinction), including encyclopedic relations such as *The space shuttle Atlantis*-**The five astronauts** (see Example 1) as well as context-specific relations such as *The space shuttle Atlantis*-**touchdown** (Example 1).

(2) At age eight, Josephine Baker was sent by her mother to *a white women's house* to do chores in exchange for meals and a place to sleep – a place in **the basement** with coal.

(3) This creates *several problems*. **One** is that there are not enough police to satisfy small businesses.

In ISNotes, bridging anaphora with distant antecedents are common when the antecedent is the global focus of a document. 29% of the anaphors in the corpus have antecedents that are three or more sentences away.

[2] http://www.h-its.org/english/research/nlp/download/isnotes.php

Bridging resolution is an extremely challenging task in ISNotes. In contrast with surface clues for coreference resolution, there are no clear surface clues for bridging resolution. In Example 4, the bridging anaphor **low-interest disaster loans** associates to the antecedent *the Carolinas and Caribbean*, whereas in Example 5 the NP loans is a generic use. In Example 6, the bridging anaphor **The opening show** associates to the antecedent *Mancuso FBI*, whereas the NP the show is coreferent with its antecedent *Mancuso FBI*.

(4) The $2.85 billion measure comes on top of $1.1 billion appropriated after Hugo stuck *the Carolinas and Caribbean* last month, and these totals don't reflect the additional benefit of **low-interest disaster loans**.

(5) Many states already have Enterprise Zones and legislation that combines tax incentives, loans, and grants to encourage investment in depressed areas.

(6) Over the first few weeks, *Mancuso FBI* has sprung straight from the headlines. **The opening show** featured a secretary of defense designate accused of womanizing (a la John Tower).
...
Most of all though, the show is redeemed by the character of Mancuso.

Our previous work on bridging resolution on this corpus only focuses on its subtasks. In Hou et al. (2013a) we model bridging anaphora recognition as a subtask of learning fine-grained information status. We report an F-measure of 0.42 for bridging anaphora recognition. In Hou et al. (2013b) we propose a joint inference framework for antecedent selection by exploring Markov logic networks. We report an accuracy of 0.41 for antecedent selection given gold bridging anaphora. In this paper, we aim to solve these two substasks together, i.e., recognizing bridging anaphora and finding links to antecedents.

3 Method

In this section, we describe our rule-based system for unrestricted bridging resolution. We choose ten documents randomly from the corpus as the development set. Then we carefully design rules for finding "bridging links" among all NPs in a document based on the generalizations of bridging in the linguistic literature as well as our inspections of bridging annotations in the development set. The system consists of two components: bridging link prediction and post processing.

3.1 Bridging Link Prediction

The bridging link prediction component consists of eight rules. Löbner (1985; 1998) interprets bridging anaphora as a particular kind of functional concept, which in a given situation assign a necessarily unique correlate to a (implicit) possessor argument. He distinguishes between relational nouns (e.g. parts terms, kinship terms, role terms) and sortal nouns and points out that relational nouns are more frequently used as bridging anaphora than sortal nouns. Rule1 to Rule4 in our system aim to resolve such relational nouns. We design Rule5 and Rule6 to capture set bridging. Finally, Rule7 and Rule8 are motivated by previous work on implicit semantic role labeling (Laparra and Rigau, 2013) which focuses on few predicates.

For all NPs in a document, each rule r is applied separately to predict a set of potential bridging links. Every rule has its own constraints on bridging anaphora and antecedents respectively. Bridging anaphors are diverse with regard to syntactic form and function: they can be modified by definite or indefinite determiners (Table 1), furthermore they can take the subject (e.g. Example 3 and Example 6) or other positions (e.g. Example 2 and Example 4) in sentences. The only frequent syntactic property shared is that bridging anaphors most often have a simple internal structure concerning modification. Therefore we first create an initial list of potential bridging anaphora A which excludes NPs which have a complex syntactic structure. An NP is added to A if it does not contain any other NPs and do not have modifications strongly indicating comparative NPs (such as *other symptoms*)[3]. Since head match is a strong indicator of coreference anaphora for definite NPs (Vieira and Poesio, 2000; Soon et al., 2001), we further exclude definite NPs from A if they have the same head as a previous NP. Then a set of potential bridging anaphors A_r is chosen from A based on r's constraints on bridging anaphora. Finally, for each potential bridging anaphor $ana \in$

[3] A small list of 10 markers such as *such, another* ... and the presence of adjectives or adverbs in the comparative form are used to predict comparative NPs.

A_r, a single best antecedent $ante$ from a list of candidate NPs (C_{ana}) is chosen if the rule's constraint on antecedents is applied successfully.

Every rule has its own scope to form the antecedent candidate set C_{ana}. Instead of using a static sentence window to construct the list of antecedent candidates like most previous work for resolving bridging anaphora (Poesio et al., 1997; Markert et al., 2003; Poesio et al., 2004; Lassalle and Denis, 2011), we use the development set to estimate the proper scope for each rule. The scope is influenced by the following factors: (1) the nature of the target bridging link (e.g., set bridging is a local coherence phenomenon where the antecedent often occurs in the same or up to two sentences prior to the anaphor); and (2) the strength of the rule's constraint to select the correct antecedent (e.g., in Rule8, the ability to select the correct antecedent decreases with increasing the scope to contain more antecedent candidates). In the following, we describe the motivation for each rule and their constraints in detail.

Rule1: building part NPs. To capture typical part-of bridging (see Example 2), we extract a list of 45 nouns which specify building parts (e.g. *room* or *roof*) from the General Inquirer lexicon (Stone et al., 1966). A common noun phrase from A is added to A_{r1} if: (1) its head appears in the building part list; and (2) it does not contain any nominal pre-modifications. Then for each potential bridging anaphor $ana \in A_{r1}$, the NP with the strongest semantic connectivity to the potential anaphor ana among all NPs preceding ana from the same sentence as well as from the previous two sentences is predicted to be the antecedent.

The semantic connectivity of an NP to a potential anaphor is measured via the hit counts of the preposition pattern query (*anaphor preposition NP*) in big corpora[4]. An initial effort to extract partOf relations using WordNet yields low recall on the development set. Therefore we use semantic connectivity expressed by prepositional patterns (e.g. *the basement of the house*) to capture underlying semantic relations. Such syntactic patterns are also explored in Poesio et al. (2004) to resolve meronymy bridging.

[4]We use Gigaword (Parker et al., 2011) with automatic POS tag and NP chunk information.

Rule2: relative person NPs. This rule is used to capture the bridging relation between a relative (e.g. *The husband*) and its antecedent (e.g. *She*). A list of 110 such relative nouns is extracted from WordNet. However, some relative nouns are frequently used generically instead of being bridging, such as *children*. To exclude such cases, we compute the argument taking ratio α for an NP using NomBank (Meyers et al., 2004). For each NP, α is calculated via its head frequency in the NomBank annotation divided by the head's total frequency in the WSJ corpus in which the NomBank annotation is conducted. The value of α reflects how likely an NP is to take arguments. For instance, the value of α is 0.90 for *husband* but 0.31 for *children*. To predict bridging anaphora more accurately, a conservative constraint is used. An NP from A is added to A_{r2} if: (1) its head appears in the relative person list; (2) its argument taking ratio α is bigger than 0.5; and (3) it does not contain any nominal or adjective pre-modifications. Then for each potential bridging anaphor $ana \in A_{r2}$, the closest non-relative person NP among all NPs preceding ana from the same sentence as well as from the previous two sentences is chosen as its antecedent.

Rule3: GPE job title NPs. In news articles, it is common that a globally salient geo-political entity (hence GPE, e.g. *Japan* or *U.S.*) is introduced in the beginning, then later a related job title NP (e.g. *officials* or *the prime minister*) is used directly without referring to this GPE explicitly. To resolve such bridging cases accurately, we compile a list of twelve job titles which are related to GPEs (e.g. *mayor* or *official*). An NP from A is added to A_{r3} if its head appears in this list and does not have a country pre-modification (e.g. *the Egyptian president*). Then for each potential bridging anaphor $ana \in A_{r3}$, the most salient GPE NP among all NPs preceding ana is predicted as its antecedent. We use the NP's frequency in the whole document to measure its salience throughout the paper. In case of a tie, the closest one is chosen to be the predicted antecedent.

Rule4: role NPs. Compared to Rule3, Rule4 is designed to resolve more general role NPs to their implicit possessor arguments. We extract a list containing around 100 nouns which specify professional roles from WordNet (e.g. *chairman*, *president* or *professor*). An NP from A is added to

A_{r4} if its head appears in this list. Then for each potential bridging anaphor $ana \in A_{r4}$, the most salient proper name NP which stands for an organization among all NPs preceding ana from the same sentence as well as from the previous four sentences is chosen as its antecedent (if such an NP exists). Recency is again used to break ties.

Rule5: percentage NPs. In set bridging as shown in Example 7, the anaphor (**Seventeen percent**) is indicated by a percentage expression from A, which is often in the subject position. The antecedent (*the firms*) is predicted to be the closest NP which modifies another percentage NP via the preposition "of" among all NPs occurring in the same or up to two sentences prior to the potential anaphor.

(7) 22% of *the firms* said employees or owners had been robbed on their way to or from work. **Seventeen percent** reported their customers being robbed.

Rule6: other set member NPs. In set bridging, apart from percentage expressions, numbers or indefinite pronouns are also good indicators for bridging anaphora. For such cases, the anaphor is predicted if it is: (1) a number expression (e.g. **One** in Example 3) or an indefinite pronoun(e.g. **some**, as shown in Example 8) from A; and (2) a subject NP. The antecedent is predicted to be the closest NP among all plural, subject NPs preceding the potential anaphor from the same sentence as well as from the previous two sentences (e.g. *Reds and yellows* in Example 8). If such an NP does not exist, the closest NP among all plural, object NPs preceding the potential anaphor from the same sentence as well as from the previous two sentences is chosen to be the predicted antecedent (e.g. *several problems* in Example 3).

(8) *Reds and yellows* went about their business with a kind of measured grimness. **Some** frantically dumped belongings into pillowcases.

Rule7: argument-taking NPs I. Laparra and Rigau (2013) found that different instances of the same predicate in a document likely maintain the same argument fillers. Here we follow this assumption but apply it to nouns and their nominal modifiers only: different instances of the same noun predicate likely maintain the same argument fillers indicated by nominal modifiers. First, a common noun phrase from A is added to A_{r7} if: (1) its argument taking ratio α is bigger than 0.5; (2) it does not contain any nominal or adjective pre-modifications; and (3) it is not modified by indefinite determiners[5] which usually introduce new discourse referents (Hawkins, 1978). Then for each potential bridging anaphor $ana \in A_{r7}$, we choose the antecedent by performing the following steps:

1. We take ana's head lemma form ana_h and collect all its syntactic modifications in the document. We consider nominal premodification, possessive modification as well as prepositional post-modification. All realizations of these modifications which precede ana form the antecedent candidates set C_{ana}.

2. We choose the most recent NP from C_{ana} as the predicted antecedent for the potential bridging anaphor ana.

In Example 9, we first predict the two occurrences of **residents** as bridging anaphors. Since in the text, other occurrences of the lemma "resident" are modified by "Marina" (supported by Marina residents) and "buildings" (supported by some residents of badly damaged buildings), we collect all NPs whose syntactic head is "Marina" or "buildings" in C_{ana} (i.e. *Marina*, *badly damaged buildings* and *buildings with substantial damage*). Then among all NPs in C_{ana}, the most recent NP is chosen to be the antecedent (i.e. *buildings with substantial damage*).

(9) She finds the response of Marina residents to the devastation of their homes "incredible".
...
Out on the streets, some residents of badly damaged buildings were allowed a 15 minute scavenger hunt through their possessions.
...
After being inspected, *buildings with substantial damage* were color - coded.
Green allowed **residents** to re-enter; red allowed **residents** one last entry to gather everything they could within 15 minutes.

Rule8: argument-taking NPs II. Prince (1992) found that discourse-old entities are more likely

[5]We compile a list of 17 such determiners, such as *a*, *an* or *one*.

to be represented by NPs in subject position. Although she could not draw a similar conclusion when collapsing *Inferrable* (= *bridging*) with *Discourse-old Nonpronominal*, we find that in the development set, an argument-taking NP in the subject position is a good indicator for bridging anaphora (e.g. **participants** in Example 10). A common noun phrase from A is collected in A_{r8} if: (1) its argument taking ratio α is bigger than 0.5; (2) it does not contain any nominal or adjective pre-modifications; and (3) it is in the subject position. Semantic connectivity again is used as the criteria to choose the antecedent: for each potential bridging anaphor $ana \in A_{r8}$, the NP with the strongest semantic connectivity to ana among all NPs preceding ana from the same sentence as well as from the previous two sentences is predicted to be the antecedent.

(10) Initial steps were taken at *Poland's first international environmental conference, which I attended last month*. ... While Polish data have been freely available since 1980, it was no accident that **participants** urged the free flow of information.

3.2 Post-processing

In the bridging link prediction component, each rule is applied separately. To resolve the conflicts between different rules (e.g., two rules predict different antecedents for the same potential anaphor), a post processing step is applied. We first order the rules according to their precision for predicting bridging pairs (i.e., recognizing bridging anaphors and finding links to antecedents) in the development set. When a conflict happens, the rule with the highest order has the priority to decide the antecedent. Table 2 summarizes the rules described in Section 3.1, the numbers in square brackets in the first column indicate the order of the rules. Table 3 shows the precisions of bridging anaphora recognition and bridging pairs prediction for each rule in the development set. Firing rate is the proportion of bridging links predicted by rule r among all predicted links.

4 Experiments and Results

4.1 Experimental Setup

We conduct all experiments on the ISNotes corpus. We use the OntoNotes named entity and syntactic annotations to extract features. Ten documents containing 113 bridging anaphors from the ISNotes corpus are set as the development set to estimate parameters for the rule-based system. The remaining 40 documents are used as the test set. In order to compare the results of different systems directly, we evaluate all systems on the test set.

4.2 Evaluation Metric

In ISNotes, bridging is annotated mostly between an NP (anaphor) and an entity (antecedent)[6], so that a bridging anaphor could have multiple links to different instantiations of the same entity (entity information is based on the Ontonotes coreference annotation). For bridging resolution, we use an evaluation metric based on bridging anaphors instead of all links between bridging anaphors and their antecedent instantiations. A link predicted by the system is counted as correct if it recognizes the bridging anaphor correctly and links the anaphor to any instantiation of the right antecedent entity preceding the anaphor.

In the evaluation metric, recall is calculated via the number of the correct links predicted by the system (one unique link per each predicted anaphor) divided by the total number of the gold bridging anaphors, precision is calculated via the number of the correct links predicted by the system divided by the total links predicted by the system.

4.3 A Learning-based Approach

To compare our rule-based system (hence *ruleSystem*, described in Section 3) with other approaches, we implement a learning-based system for unrestricted bridging resolution. We adapt the pairwise model which is widely used in coreference resolution (Soon et al., 2001). Similar to the rule-based system, we first create an initial list of possible bridging anaphora A_{ml} with one more constraint. The purpose is to exclude as many obvious non-bridging anaphoric NPs from the list as possible. An NP is added to A_{ml} if: (1) it does not contain any other NPs; (2) it is not modified by pre-modifications which strongly indicate comparative NPs; and (3) it is not a pronoun or a proper name. Then for each NP $a \in A_{ml}$, a list of antecedent candidates C_a is created by including all NPs preceding a from the same sentence

[6]There are a few cases where bridging is annotated between an NP and a non-NP antecedent (e.g. *verbs* or *clauses*).

rule	anaphor	antecedent	antecedent candidates scope
rule1 [2]	building part NPs	the NP with the strongest semantic connectivity to the potential anaphor	two
rule2 [5]	relative person NPs	the closest person NP which is not a relative NP	two
rule3 [6]	GPE job title NPs	the most salient GPE NP	all
rule4 [7]	role NPs	the most salient organization NP	four
rule5 [1]	percentage NPs	the closest NP which modifies another percentage NP via the preposition "of"	two
rule6 [3]	other set member NPs	the closest subject, plural NP; otherwise the closest object, plural NP	two
rule7 [4]	argument-taking NPs I	the closest NP whose head is an unfilled role of the potential anaphor (such a role is predicted via syntactic modifications of NPs which have the same head as the potential anaphor)	all
rule8 [8]	argument-taking NPs II	the NP with the strongest semantic connectivity to the potential anaphor	two

Table 2: Rules for unrestricted bridging resolution. Antecedent candidates scope are verified in the development set: "all" represents all NPs preceding the potential anaphor from the whole document, "four" NPs occurring in the same or up to four sentences prior to the potential anaphor, "two" NPs occurring in the same or up to two sentences prior to the potential anaphor.

rule	anaphora	anaphora recognition precision	bridging pairs prediction precision	firing rate
rule1 [2]	building part NPs	75.0%	50.0%	6.1%
rule2 [5]	relative person NPs	69.2%	46.2%	6.1%
rule3 [6]	GPE job title NPs	52.6%	44.7%	19.4%
rule4 [7]	role NPs	61.7%	32.1%	28.6%
rule5 [1]	percentage NPs	100.0%	100.0%	2.6%
rule6 [3]	other set member NPs	66.7%	46.7%	7.8%
rule7 [4]	argument-taking NPs I	53.8%	46.4%	6.1%
rule8 [8]	argument-taking NPs II	64.5%	25.0%	25.5%

Table 3: Precision of bridging anaphora recognition and bridging pairs prediction for each rule in the development set. The numbers in square brackets in the first column indicate the order of the rules.

as well as from the previous two sentences[7]. We create a pairwise instance (a, c) for every $c \in C_a$. We also add extra pairwise instances from the prediction of *ruleSystem* to the learning-based system. In the decoding stage, the *best first* strategy (Ng and Cardie, 2002) is used to predict the bridging links. Specifically, for each $a \in A_{ml}$, we predict the bridging link to be the most confident pair (a, c_{ante}) among all instances with the positive prediction. We use SVM^{light} to conduct the experiments[8]. All experiments are conducted via 10-fold cross-validation on the whole corpus[9].

mlSystem_ruleFeats We provide *mlSystem_ruleFeats* with the same knowledge resources as the rule-based system. All rules from the rule-based system are incorporated into *mlSystem_ruleFeats* as the features.

mlSystem_ruleFeats + atomFeats We augment *mlSystem_ruleFeats* with more features from our previous work (Markert et al., 2012; Hou et al., 2013a; Hou et al., 2013b) on bridging anaphora recognition and antecedent selection. Some of these features overlap with the atomic features used in the rule-based system.

Table 4 shows all the features we use for recognizing bridging anaphora. "$*$" indicates the resources are used in the rule-based system. We apply them to the first element a of a pairwise instance (a, c). Markert et al. (2012) and Hou et

[7]In ISNotes, 71% of NP antecedents occur in the same or up to two sentences prior to the anaphor. Initial experiments show that increasing the window size more than two sentences decreases the performance.

[8]To deal with data imbalance, the SVM^{light} parameter is set according to the ratio between positive and negative instances in the training set.

[9]To compare the learning-based approach to the rule-based system described in Section 3 directly, we report the results of learning-based approaches on the same test set as the rule-based system.

Table 6: Additional atomic features from the rule-based system.

$f14$ and $f16$).

Table 5 shows all features we use for selecting antecedents for bridging anaphora. "$*$" indicates the resources that are used in the rule-based system. These features are from Hou et al. (2013b)'s local pairwise model. They try to model: (1) the semantic relations between bridging anaphors and their antecedents ($f1$ to $f4$); (2) the salience of an antecedent from different perspectives ($f5$ to $f8$); and (3) the syntactic and lexical constraints between anaphor and antecedent ($f9$ to $f12$).

Apart from the features shown in Table 4 and Table 5, we further enrich *mlSystem_ruleFeats+atomFeats* with additional atomic features used in the rule-based system (Table 6).

mlSystem_atomFeats Based on *mlSystem_ruleFeats+atomFeats*, the rule features from the rule-based system are removed.

4.4 Baseline

We also reimplement the rule-based system from Vieira and Poesio (2000) as a baseline. The original algorithm focuses on processing definite NPs. It classifies four categories for the definite NPs: *discourse new*, *direct anaphora* (same-head coreferent anaphora), *lenient bridging* and *Unknown*. This algorithm also finds antecedents for NPs which belong to *direct anaphora* or *lenient bridging*.

Since Vieira and Poesio (2000) include *different-head coreference* into their *lenient bridging* category, we further divide their *lenient bridging* category into two subcategories: *different-head coreference* and *bridging*. Figure 1 shows the details of the division after failing to classify an NP as *discourse new* or *direct anaphora*. For more details about the whole system, see Vieira and Poesio (2000). We then apply this slightly revised algorithm to process all NPs in the initial list of potential bridging anaphora A from *ruleSystem* (described in Section 3.1).

4.5 Results and Discussion

Table 7 shows the results on the same test set of different approaches for unrestricted bridging resolution. The results reveal the difficulty of the task, when evaluating on a realistic scenario without constraints on types of bridging anaphora and bridging relations.

Both our rule-based system and all learning-based approaches significantly outperform the baseline at $p < 0.01$ (randomization test). The low recall in *baseline* is predictable, since it only considers meronymy bridging and compound noun anaphors whose head is prenominally modified by the antecedent head. (e.g. *the state–***state gasoline taxes**). Under the same features, the learning-based approach (*mlSystem_ruleFeats*) performs slightly worse than the rule-based system (*ruleSystem*) with regard to the F-score.

	R	P	F
baseline	2.9	13.3	4.8
ruleSystem	11.9	42.9	**18.6**
mlSystem_ruleFeats	12.1	35.0	18.0
mlSystem_ruleFeats+atomFeats	16.7	21.2	**18.7**
mlSystem_atomFeats	20.5	10.1	13.5

Table 7: Experimental results for the baseline, the rule-based system and the learning-based systems.

Surprisingly, incorporating rich features into the learning-based approach (*mlSystem_ruleFeats+atomFeats*) does not yield much improvement over the rule-based system (with an

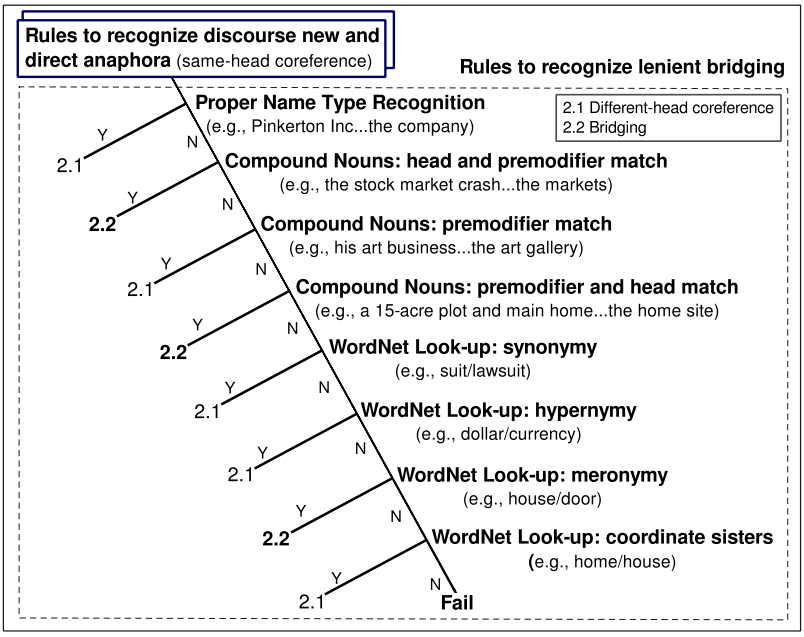

Figure 1: Vieria & Poesio's (2000) original algorithm for processing definite NPs. We further divide their lenient bridging category into two subcategories: *2.1 Different-head coreference* and *2.2 Bridging*.

F-score of 18.7 in *mlSystem_ruleFeats+atomFeats* compared to 18.6 in *ruleSystem*). We suppose that the learning-based system generalizes poorly with only atomic features in Table 4, Table 5 and Table 6. Results on *mlSystem_atomFeats* support our assumption: the F-score drops considerably after removing the rule features. Although ISNotes is a reasonably sized corpus for bridging compared to previous work, diverse bridging relations, especially lots of context specific relations such as *pachinko*-**devotees** or *palms*-**the thieves**, lead to relatively small-scale training data for each type of relation. Therefore it is difficult for the learning-based approach to learn effective rules to predict bridging links.

However, all learning-based systems tend to have higher recall but lower precision compared to the rule-based system. This suggests that the learning-based systems are "greedy" to predict bridging links. A close look at these links in *mlSystem_atomFeats* indicates that the learning-based system predicts more correct bridging anaphors but fails to find the correct antecedents. In fact, lots of those "half" correct links sound reasonable without the specific context, such as *the story-readers* (gold bridging link: *this novel*-**readers**) or *the executive director's office-the desks* (gold bridging link: *the fund's building*-**the desks**).

5 Conclusions

We proposed a rule-based approach for unrestricted bridging resolution where bridging anaphora are not limited to definite NPs and the relations between anaphor and antecedent are not restricted to meronymic relations. We designed eight rules to resolve bridging based on linguistic intuition. Our rule-based system performs better than a learning-based approach which has access to the same knowledge resources as the rule-based system. Particularly, the learning-based system enriched with more features does not yield much improvement over the rule-based system. We speculate that the learning-based system could benefit from more training data. Furthermore, better methods to model the semantics of the specific context need to be explored in the future.

This work is – to our knowledge – the first bridging resolution system that handles the unrestricted phenomenon in a realistic setting.

Abstract

Unlike traditional over-the-phone spoken dialog systems (SDSs), modern dialog systems tend to have visual rendering on the device screen as an additional modality to communicate the system's response to the user. Visual display of the system's response not only changes human behavior when interacting with devices, but also creates new research areas in SDSs. On-screen item identification and resolution in utterances is one critical problem to achieve a natural and accurate human-machine communication. We pose the problem as a classification task to correctly identify intended on-screen item(s) from user utterances. Using syntactic, semantic as well as context features from the display screen, our model can resolve different types of referring expressions with up to 90% accuracy. In the experiments we also show that the proposed model is robust to domain and screen layout changes.

1 Introduction

Todays natural user interfaces (NUI) for applications running on smart devices, e.g, phones (SIRI, Cortana, GoogleNow), consoles (Amazon FireTV, XBOX), tablet, etc., can handle not only simple spoken commands, but also natural conversational utterances. Unlike traditional over-the-phone spoken dialog systems (SDSs), user hears and sees the system's response displayed on the screen as an additional modality. Having visual access to the system's response and results changes human behavior when interacting with the machine, creating new and challenging problems in SDS.

[System]: How can i help you today ?
[User]: *Find non-fiction books by Chomsky.*
[System]: (Fetches the following books from database)

[User]: ***"show details for the oldest production"*** or
"details for the syntax book" or
"open the last one" or
"i want to see the one on linguistics" or
"bring me Jurafsky's text book"

Table 1: A sample multi-turn dialog. A list of second turn utterances referring to the last book (in bold) and a new search query (highlighted) are shown.

Consider a sample dialog in Table 1 between a user and a NUI in the books domain. After the system displays results on the screen, the user may choose one or more of the on-screen items with natural language utterances as shown in Table 1. Note that, there are multiple ways of referring to the same item, (e.g. the last book)[1]. To achieve a natural and accurate human to machine conversation, it is crucial to accurately identify and resolve referring expressions in utterances. As important as interpreting referring expressions (REs) is for modern NUI designs, relatively few studies have investigated withing the SDSs. Those that do focus on the impact of the input from multimodal interfaces such as gesture for understanding (Bolt, 1980; Heck et al., 2013; Johnston et al., 2002), touch for ASR error correction (Huggins-Daines and Rudnicky, 2008), or cues from the screen (Balchandran et al., 2008; Anastasiou et al., 2012). Most of these systems are engineered for a specific

[1] An item could be anything from a list, e.g. restaurants, games, contact list, organized in different lay-outs on the screen.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2094–2104,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

task, making it harder to generalize for different domains or SDSs. In this paper, we investigate a rather generic contextual model for resolving natural language REs for on-screen item selection to improve conversational understanding.

Our model, which we call FIS (Flexible Item Selection), is able to (1) detect if the user is referring to any item(s) on the screen, and (2) resolve REs to identify which items are referred to and score each item. FIS is a learning based system that uses information from pair of user utterance and candidate items on the screen to model association between them. We cast the task as a classification problem to determine whether there is a relation between the utterance and the item, representing each instance in the training dataset as relational features.

In a typical SDS, the spoken language understanding (SLU) engine maps user utterances into meaning representation by identifying user's intent and token level semantic slots via a semantic parser (Mori et al., 2008). The dialog manager uses the SLU components to decide on the correct system action. For on-screen item selection SLU alone may not be sufficient. To correctly associate the user's utterance with any of the on-screen items one would need to resolve the relational information between the utterance and the items. For instance, consider the dialog in Table 1. SLU engine can provide signals to the dialog model about the selected item, e.g., that "*linguistics*" is a book-genre or content, but may not be enough to indicate which book the user is referring. FIS module provides additional information for the dialog manager by augmenting SLU components.

In §3, we provide details about our data as well as data collection and annotation steps. In §4, we present various syntactic and semantic features to resolve different REs in utterances. In the experiments (§6), we evaluate the individual impact of each feature on the FIS model. We analyze the performance of the FIS model per each type of REs. Finally, we empirically investigate the robustness of the FIS model to domain and display screen changes. When tested on a domain that is unseen to the training data or on a device that has a different NUI design, the performance only slightly degrades proving its robustness to domain and design changes.

2 Related Work

Although the problems of modern NUIs on smart devices are fairly new, RE resolution in natural language has been studied by many in NLP community.

Multimodal systems provide a natural and effective way for users to interact with computers through multiple modalities such as speech, gesture, and gaze. Since the first appearance of the Put-That-There system (Bolt, 1980), a number of multimodal systems have been built, among which there are systems that combine speech, pointing (Neal, 1991), and gaze (Koons et al., 1993), systems that engage users in an intelligent conversation (Gustafson et al., 2000). Earlier studies have shown that multimodal interfaces enable users to interact with computers naturally and effectively (Schober and Clark, 1989; Oviatt et al., 1997). Considered as part of the situated interactive frameworks, many work focus on the problem of predicting how the user has resolved REs that is generated by the system, e.g., (Clark and Wilkes-Gibbs, ; Dale and Viethen, 2009; Gieselmann, 2004; Janarthanam and Lemon, 2010; Golland et al., 2010). In this work, focusing on smart devices, we investigate how the system resolves the REs in user utterances to take the next correct action.

In (Pfleger and J.Alexandersson, 2006) a reference resolution model is presented for a question-answering system on a mobile, multi-modal interface. Their system has several features to parse the posed question and keep history of the dialog to resolve co-reference issues. Their question-answering model uses gesture as features to resolve queries such as "*what's the name of that [pointing gesture] player*?", but they do not resolve locational referrals such as "*the middle one*" or "*the second harry potter movie*". Others such as (Funakoshi et al., 2012) resolve anaphoric ("*it*") or exophoric ("*this one*") types of expressions in user utterances to identify geometric objects. In this paper, we study several types of REs to build a natural and flexible interaction for the user.

(Heck et al., 2013) present an intent prediction model enriched with gesture detector to help disambiguate between different user intents related to the interface. In (Misu et al., 2014) a situated in-car dialog model is presented to answer drivers' spoken queries about their surroundings (no display screen). They integrate multi-modal inputs of

speech, geo-location and gaze. We investigate a variety of REs for visual interfaces, and analyze automatic resolution in a classification task introducing a wide range of syntactic, semantic and contextual features. We look at how REs change with screen layout comparing different devices. To the best of our knowledge, our work is first to analyze REs from these aspects.

3 Data

Crowdsourcing services, such as Amazon Mechanical Turk or CrowdFlower, have been extensively used for a variety of NLP tasks (Callison-Burch and Dredze, 2010). Here we explain how we collected the raw utterances from CrowdFlower platform (crowdflower.com).

For each HITApp (Human Intelligence Task Application), we provide judges with a written explanation about our Media App, a SDS built on a device with a large screen which displays items in a grid style layout, and what this particular system would do, namely search for books, music, tv and movies media result [2] Media App returns results based on the user query using an already implemented speech recognition, SLU and dialog engines. For each HIT, the users are shown a different screenshot showing the Media App's search results after a first-turn query is issued (e.g., "*find non-fiction books by Chomsky*" in Table 1). Users are asked to provide five different second turn text utterances for each screenshot. We launch several hitapps each with a different prompt to cover different REs.

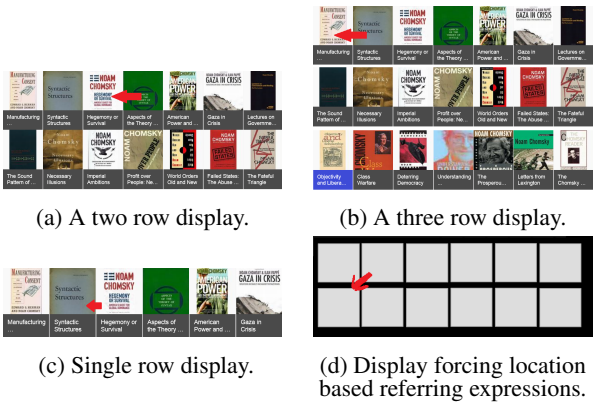
3.1 HITApp Types and Data Collection

A grid of media items is shown to the user with a red arrow pointing to the media result we want them to refer to (see Fig. 1). They can ask to play (an album or an audio book), select, or ask details about the particular media item. Each item in each grid layout becomes a different HIT or screenshot.

3.1.1 Item Layout and Screen Type Variation

The applications we consider have the following row×column layouts: 1×6, 2×6 and 3×6, as shown in Fig. 1 (columns vary depending on the returned item size). By varying the layout, we expect the referent of the last and the bottom layer items to change depending on how many rows, or

[2]Please e-mail the first author to inquire about the datasets.



(a) A two row display.

(b) A three row display.

(c) Single row display.

(d) Display forcing location based referring expressions.

Figure 1: Sketches of different HITApp Screens. The red arrows point to the media we want the annotators to refer.

columns exist in the grid. In addition, phrases like "*middle*", or *"center"* would not appear in the data when there are only one or two rows. Also, we expect that the distribution of types of utterances to vary. For example, in a grid of 1×6, "*the second one*" makes sense, but not so much on a 2×6 grid. We expect similar change based on the number of columns.

We use two kinds of screenshots to collect utterances with variations in REs. The first type of screenshots are aimed to bias the users to refer to items '*directly*' using (full/partial) titles or '*indirectly*' using other descriptors, or meta information such as year the movie is taken, or the author of the book. To collect utterances that indirectly referred to items, we need to show screen shots displaying system results with common titles, eventually forcing the user to use other descriptors for disambiguation. For example, given the first turn query "*find harry potter movies*", the system returns all the *Harry Potter* series, all of which contain the words *Harry Potter* in the title. The user can either refer in their utterance with the series number, the subtitle (e.g. *The prisoners of Azkaban*) or the location of the movie in the grid or by date, e.g., "*the new one*",

Because some media items have long titles, or contain foreign names that are not easy to pronounce, users may chose to refer these items by their location on the display, such as "*top right*", "*first album*", "*the movie on the bottom left*", etc. The second type of screen shots contains a template for each layout with no actual media item (Fig. 1(d)) which simply forces user to use locational references.

3.1.2 Interface Design Variation

In order to test our model's robustness to a different screen display on a new device, we employ an additional collection running another application named *places*, designed for hand-held devices. The places application can assist users in finding local businesses (restaurants, hotels, schools, etc.). and by nature of the device size can display fewer media items and arranges them in a list (one column). The number of items on the screen at any given time depends on the size of the hand-held device screen. The user can scroll down to see the rest of the results. Our collection displays the items in a 3, 4, and 5-rows per 1 column layout as shown in Fig. 2. We use the same variations in prompts as in §3.1. To generate the HitApp screens, we search for nearby places, in the top search engines (Google, Bing) and collect the results to the first turn natural language search queries (e.g.,"*find me sushi restaurants near me*").

Figure 2: A HitApp screen of places app. Items returned by the system regarding the first-turn utterance *"burger places near me?"*

3.2 Data Annotation

We collect text utterances using our media and places application. Using a similar HitApp we labeled each utterance with a domain, intent and segments in utterance with slot tags (see Table 2). The annotation agreement, Kappa measure (Cohen, 1960) is around 85%. Since we are building a relational model between utterances and each item on the screen, we ask the annotators to label each utterance-item as '0' or '1' indicating if the utterance is referring to that item or not. '1' means the item is the intended one. '0' indicates the item is not intended one or the utterance is not referring to any item on the screen, e.g., new search query. We also ask the annotators to label each utterance whether they contain locational (spatial) references.

Domain	Intents (I) & Slots
movie	I: find-movie/director/actor,buy-ticket Slots: name, mpaa-rating (*g-rated*), date,
books	I: find-book, buy-book, Slots: name, genre(*thriller*), author, publisher,
music	I: find-album, find-song, Slots: song-name, genre, album-type,...
tv	I: find-tvseries/play/add-to-queue.. Slots: name, type(*cartoon*), show-time....
places	I: find-place, select-item(*first one*).. Slots: place-type, rating, nearby(*closest*)....

Table 2: A sample of intents and semantic slot tags of utterance segments per domain. Examples for some slots values are presented in parenthesis as *italicized*.

3.3 Types of Observed Referring Expressions

We observe four main categories of REs in the utterances that are collected by varying the prompts and HITApp screens in crowd-sourcing:

Explicit Referential : Explicit mentions of whole or portions of the title of the item on the screen, and no other descriptors, e.g.,"*show me the details of star wars six*" (referring to the item with title "Star wars: Episode VI - Return of the Jedi").

Implicit Referential : The user refers to the item using distinguishing features other than the title, such as the release or publishing date, writers, actors, image content (describing the item image), genre, etc. "*how about the one with Kevin Spacey*".

Explicit Locational : The user refers to the item using the grid design, e.g., "*i want to purchase the e-book on the bottom right corner*".

Implicit Locational : Locational references in relation to other items on the screen, e.g., "*the second of Dan Brown's book*" (showing two of the Dan Brown's book on the same row).

4 Feature Extraction for FIS Model

Here, provide descriptions of each set of features of FIS model used to resolve each expression.

4.1 Similarity Features (SIM)

Similarity features represent the lexical overlap between the utterance and the item's title (that is displayed on the user's screen) and are mainly aimed to resolve *explicit REs*. We represent each utterance u_i and item-title t_k as sequence of words:

$$u_i=\{w_i(1),\ldots,w_i(n_i)\}$$
$$t_k=\{w_k(1),\ldots,w_k(m_k)\}$$

item bigrams	<bos> call five guys and fries <eos>
<bos> five	
five guys	●—●
guys burgers	
burgers and	
and fries	●—●
fries <eos>	●—●

Table 3: Bigram overlap between the item "*five guys burgers and fries*" and utterance"*five guys and fries*".

where $w_i(j)$ and $w_k(j)$ are the *j*th word in the sequence. Since inflectional morphology may make a word appear in an utterance in a different form than what occurs in the official title, we use both the word form as it appears in the utterance and in the item title. For example, *burger* and *burgers*, or *woman* and *women* are considered as four distinct words and all included in the bag-of-words. Using this representation we calculate four different similarity measures:

Jaccard Similarity: A common feature that can represent the ratio of the intersection to the union of unigrams. Consider, for instance, u_i="*call five guys and fries*" and the item t_k="*five guys burgers and fries*" in Fig 2. The Jaccard similarity *S*(*i*,*k*) is:

$$S(i,k)=1-\left(\, c(r_i \cap r_k)/c(r_i \cup r_k)\,\right)$$

where the r_i and r_k are unigrams of u_i and t_k respectively. $c(r_i \cap r_k)$ is the number of common words of u_i and t_k, $c(r_i \cup r_k)$ is the total unigram vocabulary size between them. In this case, the *S*(*i*,*k*)=0.66.

Orthographic Distance: Orthographic distance represent similarity of two text and can be as simple as an edit distance (Levenshtein distance) between their graphemes. The Levenshtein distance (Levenshtein, 1965) counts the insertion, deletion and substitution operations that are required to transform an utterance u_i into item's title t_k.

Word Order: This feature represents how similar are the order of words in two text. Sentences containing the same words but in different orders may result in different meanings. We extend Jaccard similarity by defining bigram word vectors r_i and r_k and look for overlapping bigrams as in Table 3. Among 6 bigrams between them, only 2 are overapping, hence the word-order similarity is *S*(*i*,*k*)=0.33.

Word Vector: This feature is the cosine similarity between the utterance u_i and the item-title t_k that measures the cosine of the angle between them. Here, we use the unigram word counts to represent the word vectors and the word vector similarity is defined as: $S(i,k)=(r_i \cdot r_k)/\|r_i\| \cdot \|r_k\|$.

4.2 Knowledge Graph Features

This binary feature is used to represent overlap between utterance and the meta information about the item and is mainly aimed to resolve *implicit REs*.

First, we obtain the meta information about the on-screen items using Freebase (Bollacker et al., 2008), the knowledge graph that contains knowledge about classes (books, movies, ...) and their attributes (title, publisher, year-released, ...). Knowledge is often represented as the attributes of the instances, along with values for those properties. Once we obtain the attribute values of the item from Freebase, we check if any attribute overlaps with part of the utterance. For instance, given an utterance "*how about the one with Kevin Spacey*", and the item-title "*House of Cards*", the knowledge graph attributes include **year**(*2013*), **cast**(*Kevin Spacey*), **director**(*James Foley*),... We turn the freebase feature 'on' since the actor attribute of that item is contained in the utterance. We also consider partial matches, e.g., last name of the actor attribute.

This feature is also used to resolve implicit REs, with item descriptions, such as "*the messenger boy with bicycle*" referring to the media item *Ride Like Hell*, a movie about a bike messenger. The synopsis feature in Freebase fires the freebase meta feature as the synopsis includes the following passage: "*... in which real messenger boys are used as stunts...* ".

4.3 Semantic Location Labeler (SLL) Feature

This feature set captures spatial cues in utterances and is mainly aimed to resolve *explicit locational* REs. Our goal is to capture the location indicating tokens in utterances and then resolve the referred location on the screen by using an indicator feature. We implement the SLL (Semantic Location Labeler), a sequence labeling model to tag locational cues in utterances using Conditional Random Fields (CRF) (Lafferty et al., 2001).

We sampled a set of locational utterances from each domain to be used as training set. We asked the annotators to label tokens with four different semantic tags that indicate a location.

The semantic tags include row and column indicator tags, referring to the position or pivotal reference. For instance, in "*second from the top*", "*second*" is the `column-position`, and "*top*" is the `row-pivot`, indicating the pivotal reference of the row in a multi-row grid display. Also in "*third from the last*", the "*third*" is the `column-position`, and the "*last*" is the `column-pivot`, the pivotal reference of the column in a multi-column grid display. The fourth tag, `row-position`, is used when the specific row is explicitly referred, such as in "*the Harry Potter movie in the first row*".

To train our CRF-based SLL model we use three types of features: the current word, window words e.g., previous-word, next-word, etc., using five-window around the current word, and syntactic features from the part-of-speech (POS) tagger using the Stanford's parser (Klein and Manning, 2003).

Row Indicator Feature: This feature sets the relationship between the n-gram in an utterance indicated by the `row-position` or `row-pivot` tag and the item's row number on the screen. For instance, given SSL output `row-pivot('top')` and item's location *row*=1, the value of the feature is set to '1'. If no row tag is found by SLL, this feature is set to '0'. We use regular expressions to parse the numerical indicators, e.g., '*top*'='1'.

Column Indicator Feature: Similarly, this feature indicates if a phrase in utterance indicated by the `column-position` or `column-pivot` tag matches the item's column number on the screen. If SLL model tags `column-pivot('on the left')`, then using the item's column number(=1), the value of this feature is set to '1'.

4.4 SLU Features

The SLU (Spoken Language Understanding) features are used to resolve *implicit* and *explicit REs*.

For our dialog system, we build one SLU model per each domain to extract two sets of semantic attributes from utterances: user's intent and semantic slots based on a predefined semantic schema (see examples in Table 2). We use the best intent hypothesis as a categorical feature in our FIS model. Although FIS is not an intent detection model, the intent from SLU is an effective semantic feature in resolving REs. Consider second turn utterance such as "*weather in seattle*", which is a '*find*' intent that is a new search or not related to any item on the screen. We map SLU intents such as *find-book* or *find-place*, to more specific ones, so that the intent feature would have values such as *find*, *filter*, *check-time*, not specific to a domain or device. The intent feature helps us to identify if user's utterance is related to any item on the screen. We also use the best slot hypothesis from the SLU slot model and search if there is full overlap of any recognized slot value with either the item-title or the item meta-information from freebase. In addition, we include the longest slot value n-gram match as an additional feature. We add a binary feature per domain, indicating whether there is a slot value match. Because we are using generic intents as categorical features instead of specific intents, and a slot value match feature instead of domain specific slot types as features, our models are rather domain independent.

5 GBDT Classifier

Among various classifier learning algorithms, we choose the GBDT (gradient boosted decision tree) (Friedman, 2001; Hastie et al., 2009), also known as MART (Multiple Additive Regression Trees). GBDT[3] is an efficient algorithm which learns an ensemble of trees. We find the main advantage of the decision tree classifier as opposed to other non-linear classifiers such as SVM (support vector machines) (Vapnik, 1995) or NN (neural networks) (Bishop, 1995) is the interpretability. Decision trees are "white boxes" in the sense that per-feature gain can be expressed by the magnitude of their weights, while SVM or NN's are generally black boxes, i.e. we cannot read the acquired knowledge in a comprehensible way. Additionally, decision trees can easily accept categorical and continuous valued features. We also present the results of the SVM models.

6 Experiments

We investigate several aspects of the SISI model including its robustness in resolving REs for domain or device variability. We start with the details of the data and model parameters.

We collect around 16K utterances in the media domains (movies, music, tv, and books) and around 10K utterances in places (businesses and

[3]Treenet: http://www.salford-systems.com/products/treenet is the implementation of the GBDT which is used in this paper.

locations) domain. We also construct additional negative instances from utterance-item pairs using first turn non-selection queries, which mainly indicate a new search or starting over. In total we compile around 250K utterance-item pairs for media domains and 150K utterance-item pairs for the places domain.[4] We randomly split each collection into 60%-20%-20% parts to construct the train/dev/test datasets. We use the dev set to tune the regularization parameter for the GBDT and SVM using LIBSVM (Chang and Lin, 2011) with linear kernel.

We use the training dataset to build the SLU intent and slot models for each domain. For the intent model, we use the GBDT classifier with n-gram and lexicon features. The lexicon entries are obtained from Freebase and are used as indicator variables, e.g., whether the utterance contains an instance which exists in the lexicon. Similarly, we train a semantic slot tagging model using CRF method. We use n-gram features with up to five-gram window, and lexicon features similar to the intent models. Table 4 shows the accuracy and F-score values of SLU models on the test data. The slot and intent performance is consistent accroess domains. The books domain has only two intents and hence we observe much better intent performance compared to other domains.

[4]In the final version of the paper, we will provide annotated data sets on a web page, which is reserved due to blind review.

6.1 Impact of Individual FIS Features

In our first experiment, we investigate the impact of individual feature sets on FIS model's performance. We train a set of FIS models on the entire media dataset to investigate the per-feature gain on the test dataset for each domain. We also train another set of FIS models with the same feature sets, this time on the places dataset and present the results on the places test set. Table 5 shows the results. We measure the performance starting with individual feature sets, and then incrementally add each feature set. Note that the SLU feature set includes the categorical intent, binary slot-value match and the longest slot value n-gram match with the item's title or meta information. The SLL feature set includes two features indicating the row and column (see §4.3).

As expected, larger gains in accuracy are observed when features that resolve different REs are used. Resolving locational cues in utterances with SLL features considerably impacts the performance when used together with similarity (SIM) features. We see a positive impact on performance as we add the knowledge graph features, which are used to resolve implicit REs. Using only the predicted SLU features in feature generation without golden values degrades the performance. Although the results are not statistically significant, the GBDT outperforms the SVM for almost all models, except for a few models, where the results are similar. However, the models which

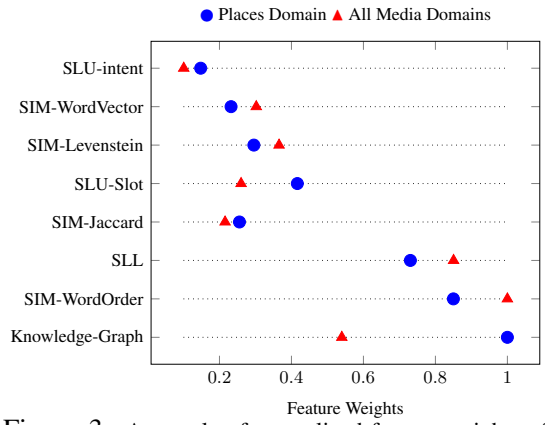

Figure 3: A sample of normalized feature weights of the GBDT FIS models across domains.

combine different features as apposed to individual feature set (the above the line models versusu below the horizantil line models) are statistically significant (based on the student t-test p¡0.01).

Next, we illustrate the significance of individual features across domains as well as devices. Fig. 3 compares the normalized feature weights of media and places domains. Across domains there are similar features with similar weight values such as SLU-intent, some similarity features (SIM-) and even spatial cue features (SLL). It is not surprising to observe that the places domain knowledge-graph meta feature weights are noticeably larger than all media model features. We think that this is due to the way the REs are used when the device changes (places app is on a phone with a smaller screen display). Especially, places application users refer items related to restaurants, libraries, etc., not so much by their names, but more so with implicit REs by using: the location (referring to the address: "*call the one on 31 street*") or cuisine ("*Chinese*"), or the star-rating ("*with the most stars*"), etc.

6.2 Resolution Across REs

We go on to analyze the performance of different RE types. A particularly interesting set of errors we found from the previous experiments are those that involve implicit referrals. Table 6 shows the distribution of different REs in the collected datasets.

Some noticeable instances with false positives for implicit locational REs include ambiguous cases or item referrals with one of its facets that require further resolution including comparison to other items, e.g., "*the nearest one*". Table 7 shows further examples. As might be expected, the locational cues are less common compared to other

Utterance Type	%	Acc.	%	Acc.
All utterances	100%	93.7%	100%	86.3%
Direct/Indirect RE	81%	93.9%	73%	86.9%
Locational RE	19%	92.5%	28%	85.2%
Explicit RE	60%	94.3%	45%	88.4%
Implicit RE	21%	83.4%	28%	72.2%
Explicit Locational RE	15%	75.2%	24%	86.2%
Implicit Locational RE	3%	56.6%	2%	56.7%

Table 6: Distribution of referring expressions (**RE**) in the media (large screen like tv) and places (handheld device like phone) corpus and the FIS accuracies per RE type.

Utterance	Displayed on screen
"*the most rated restaurant*"	★★★'s next to each item
"*first thomas crown affair*"	original release (vs. remake)
"*second one over*"	(incomplete row/col. information)

Table 7: Display screen as user utters.

expressions. We also confirm that the handheld (places domain) users implicitly refer to the items more commonly compared to media app, and use the contextual information about the items such as their location, address, star-rating, etc. The models are considerably better at resolving explicit referrals (both non-spatial and spatial) compared to implicit ones. However, for locational referrals, the difference between the accuracy of implicit and explicit REs is significant (75.2% vs. 56.6% in media and 86.2% vs. 56.7% in places). Although not very common, we observe negative expressions, e.g., "*the one with no reviews*", which are harder for the FIS to resolve. They require quantifying over every other item on the screen, namely the context features, which we leave as a future work.

6.3 New Domains and Device Independence

In the series of experiments below, we empirically investigate the FIS model's robustness to when a new domain or device is introduced.

Robustness to New Domains: So far we trained media domain FIS models on utterances from all domains. To investigate how FIS models would behave when tested on a new domain, we train additional models by leaving out utterances from one domain and test on the left out domain. We used GBDT with all the feature sets. To set up an upper bound, we also train models on each individual domain and test on the same domain.

Table 8 shows the performance of the FIS mod-

	Models tested on:			
Model trained on:	**Movies**	**TV**	**Music**	**Books**
All domains	96.2%	95.2%	90.3%	94.6%
All other domains	94.6%	92.4%	89.7%	%
Only *this domain	96.4%	96.8%	93.4%	%

Table 8: Accuracy of FIS models tested on domains that are: seen at training time (all domains), unseen at training time (all other domains) and trained on individual domains.

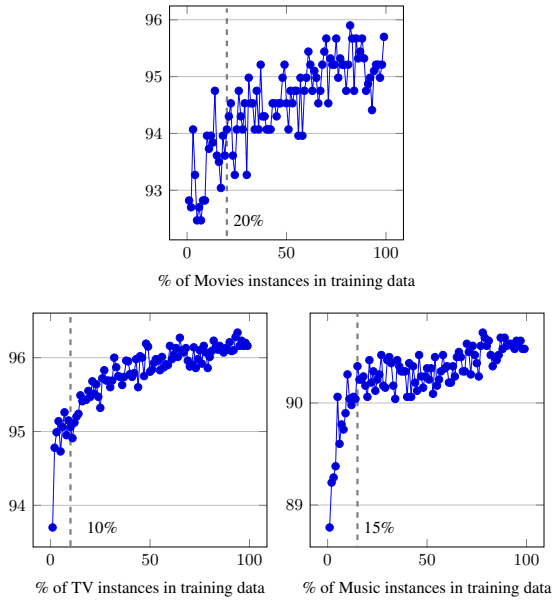

Figure 4: The accuracy (y-axis) versus the percentage (%) of in-domain utterances used in the training dataset. The dashed vertical line indicates an optimum threshold for the amount of in-domain data to be added to the training data.

els in accuracy on each media test domain. The first row shows the results when all domains are used at training time (same as in Table 5). The second row represents models where one domain is unseen at training time. We notice that the accuracy, although degraded for movies and tv domains, is in general not significantly effected by the domain variations. We setup another experiment, where we incrementally add utterances from the domain that we are testing the model on. For instance, we incrementally add random samples from movies training utterances on the dataset that does not contain movies utterances and test on all movies test data. The charts in Fig. 4 show the % improvement in accuracy as in-domain data is incrementally added to the training dataset. The results are interesting in that, using as low as 10-20% in-domain data is sufficient to build a flexible item selection model given enough utterances from other domains with varying REs.

Robustness to a New Device: The difference between the vocabulary and language usage observed in the data collected from the two devices

Media
"*only the new movies*" ; "*second one on the left*"
"*show me the thriller song*"; "*by Lewis Milestone*"
"*the first harry potter book*"
Places
"*directions to Les Schwab tire center*"
"*the closest one*" ;"*show me a map of ...*"
"*get hours of Peking restaurant*"; "*call Mike's burgers*"

Table 9: Sample of utterances collected from media and places applications illustrating the differences in language usage.

Trained on	Tested on Media	Tested on Places
Media	93.7 %	85.9%
Places	85.9%	86.3%
Media+Places	92.7%	85.8%

Table 10: Accuracy of FIS models tested on two separate devices (large screen media, and small screen places) that are unseen at test time.

is mainly due to changes in: (*i*) the screen design (places on phone has one column format wheres the media app has multi-column layout); (*ii*) the domain of the data. Table 9 shows some examples. Here, we add a little bit of complexity, and train one FIS model using the training data collected on one device and test the model on a different one, which is unseen at training time. Table 10 shows the comparisons for media and phone interfaces. The results are interesting. The performance of the places domain on phone does not get affected when the models are trained on the media data and tested on the phone device (86.3% down to 85.9% which is statistically insignificant). But when the data is trained on the places and tested on the media, we see a rather larger degradation on the performance (93.7% down to 85.9%). This is due to the fact that the media display screens are much complicated compared to phone resulting in a larger vocabulary with more variation in REs compared to places domain.

6.4 Conclusion

We presented a framework for identifying and recognizing referring expressions in user utterances of human-machine conversations in natural user interfaces. We use several on-screen cues to interpret whether the user is referring to on-screen items, and if so, which item is being referred to. We investigate the effect of different set of features on the FIS models performance. We also show that our model is domain and device independent which is very beneficial when new do-

mains are added to the application to cover more scenarios or when FIS is implemented on new devices. As a future work, we would like to adapt our model for different languages and include other features from multi modality including gesture or geo-location.

Abstract

In this paper, we propose a Connective-driven Dependency Tree (CDT) scheme to represent the discourse rhetorical structure in Chinese language, with elementary discourse units as leaf nodes and connectives as non-leaf nodes, largely motivated by the Penn Discourse Treebank and the Rhetorical Structure Theory. In particular, connectives are employed to directly represent the hierarchy of the tree structure and the rhetorical relation of a discourse, while the nuclei of discourse units are globally determined with reference to the dependency theory. Guided by the CDT scheme, we manually annotate a Chinese Discourse Treebank (CDTB) of 500 documents. Preliminary evaluation justifies the appropriateness of the CDT scheme to Chinese discourse analysis and the usefulness of our manually annotated CDTB corpus.

1 Introduction

It is well-known that interpretation of a text requires understanding of its rhetorical relation hierarchy since discourse units rarely exist in isolation. Such discourse structure is fundamental to many text-based applications, such as summarization (Marcu, 2000) and question-answering (Verberne et al., 2007). Due to the wide and potential use of discourse structure, constructing discourse resources has been attracting more and more attention in recent years. In comparison with English, there are much fewer discourse resources for Chinese which largely restricts the researches in Chinese discourse analysis.

The general notion of discourse structure mainly consists of discourse unit, connective, structure, relation and nuclearity. However, previous studies on discourse failed to fully express these kinds of information. For example, the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) represents a discourse as a tree with phrases or clauses as elementary discourse units (EDUs). However, RST ignores the importance of connectives to a great extent. Figure 1 gives an example tree structure with four EDUs (e1-e4). In comparison, Penn Discourse Treebank (PDTB) (Prasad et al., 2008) adopts the predicate-argument view of discourse relation, with discourse connective as predicate and two text spans as its arguments. Example (1) shows an explicit reason relation signaled by the discourse connective "particularly if" and an implicit result relation represented by the inserted discourse connective "so", with Arg1 in italics and Arg2 in bold. However, as a connective and its arguments are determined in a local contextual window, it is normally difficult to deduce a complete discourse structure from such a connective-argument scheme. In this sense, the PDTB at best only provides a partial solution to the discourse structure.

[Catching up with commercial competitors in retail banking and financial services,] e1 [they argue,] e2 [will be difficult,] e3 [particularly if market conditions turn sour.]e4

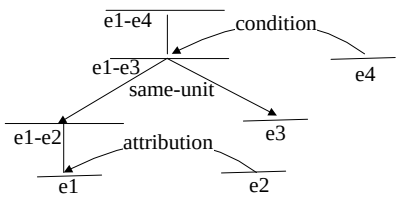

Figure 1: An example of discourse structure in RST

Example (1): An example of the connective-argument scheme in PDTB

A)[Catching up with commercial competitors in retail banking and financial services will be difficult]$_{Arg1}$, they argue, will be difficult, particularly **if** **[market**

conditions turn sour] $_{Arg2}$. (Contingency.Condition. Hypothetical) (0616)

B) So much of the stuff poured into its Austin, Texas, offices *[that its mail rooms there simply stopped delivering it.]*$_{Arg1}$ (Implicit = so)**[Now, thousands of mailers, catalogs and sales pitches go straight into the trash.]**$_{Arg2}$ (Contingency.Cause. Result) (0989)

Obviously, both RST and PDTB have their own advantages and disadvantages in representing different characteristics of the discourse structure. In this paper, we attempt to propose a new scheme to Chinese discourse structure, adopt advantages of the tree structure from RST and connective from PDTB. Meanwhile, the special characteristics of Chinese discourse structure are well addressed.

First, it is difficult to define EDU in Chinese due to the frequent occurrence of the ellipsis of subjects, objects and predicates, and the lack of functional marks for EDU. Second, the connectives in Chinese omit much more frequently than those in English with about 82.0% vs. 54.5% in Zhou and Xue (2012). In Example (2), there are even no explicit connectives. Third, previous studies have shown the difference in classifying Chinese discourse relations from English (Xing, 2001; Huang and Liao, 2011). This suggests that the discourse relations defined for English (both RST and PDTB) are not readily suitable for Chinese. Finally, the nucleus of a Chinese discourse relation is normally not directly related to a particular relation type but should be dynamically determined from the global meaning of a discourse.

Example (2): An example of discourse with 4 EDUs

[据悉， 东莞 海关 共 接受
According to reports,Dongguan Customs total accept
企业 合同 备案 八千四百多份，]e1 [比 试点
company contract record 8400 plus class, than pilot
前 略 有 上升，]e2 [企业 反应 良好，]e3
before a slight increase, company responses well,
[普遍 表示 接受。]e4
generally acknowledge acceptance.

"[According to reports, Dongguan District Customs accepted more than 8400 records of company contracts,] e1 [a slight increase from before the pilot.]e2 [Companies responded well,]e3 [generally acknowledging acceptance.]e4"

In this paper, we present a Connective-driven Dependency Tree (CDT) discourse representation scheme, which takes advantage of both RST and PDTB, with elementary discourse units (limited to clauses) as leaf nodes and connectives as non-leaf nodes. Especially, we define EDU from three aspects, and employ the connective' level and semantic to indicate the rhetorical structure and the discourse relation. Besides, the nuclearity of discourse units in a discourse relation is decided on the overall discourse meaning. On the basis, we adopt the CDT scheme to annotate a certain scale corpus, called Chinese Discourse Treebank (CDTB) thereafter in this paper. Evaluation shows the appropriateness of the CDT scheme to Chinese discourse analysis.

The rest of this paper is organized as follows. Section 2 overviews related work. In Section 3, we present the CDT discourse representation scheme. In Section 4, we describe the annotation of the CDTB corpus. Section 5 compares CDTB with other major discourse corpora. Section 6 gives the experimental results on EDU recognition, the crucial step for discourse parsing. Finally, conclusion is given in section 7.

2 Related Work

In the past decade, several discourse corpora for English have emerged, with the Rhetorical Structure Theory Discourse Treebank (RST-DT) (Carlson et al., 2003) and the Penn Discourse Treebank (PDTB) (Prasad et al., 2008) most prevalent.

In the RST framework, a text is represented as a discourse tree, with non-overlapping text spans (either phrases or clauses) as leaves, and adjacent nodes are related through particular rhetorical relations to form a discourse sub-tree, which is then related to other adjacent nodes in the tree structure. According to RST, there are two types of discourse relations, mononuclear and multinuclear. Figure 1 shows an example of discourse tree representation, following the notational convention of RST. Among the four EDUs (e1-e4), e1 and e2 are connected by a mononuclear relation "attribution", where e1 is the nucleus, the span (e1-e2) and the EDU e3 are further connected by a multi-nuclear relation "same-unit", where they are equally salient. Annotated according to the RST framework, the RST-DT consists of 385 documents from the Wall Street Journal (WSJ). Besides, the original 24 discourse relations defined by Mann and Thompson (1988) are further divided into a set of 18 relation classes with 78 finer grained rhetorical relations in RST-DT.

As the largest discourse corpus so far, the Penn Discourse Treebank (PDTB) contains over one million words from WSJ. With EDUs limited to clauses, the PDTB adopts the predicate-

argument view of discourse relations, with connective as predicate and two text spans as its arguments. Example (1) shows two annotation tokens for the connective "particularly if" and "so". The current version of PDTB 2.0 annotates 40600 tokens, including 18459 explicit relations of 100 distinct types (e.g. "particularly if" and "if" are the same type) and 16224 implicit discourse relations of 102 distinct token types. Besides, PDTB provides a three level hierarchy of relation tags with the first level consisting of four major relation classes (Temporal, Contingency, Comparison, and Expansion), which are further divided into 16 types and 23 subtypes.

In comparison, there are few researches on Chinese discourse annotation (Xue, 2005a; Chen, 2006; Yue, 2008; Huang and Chen, 2011; Zhou and Xue, 2012), with no exception employing existing RST or PDTB frameworks. For example, Zhou and Xue (2012) use the PDTB annotation guidelines to annotate Chinese discourse with 98 files from Chinese Treebank (Xue et al., 2005b) of Xinhua newswire. In particular, they adopt a lexically grounded approach and make some adaptation based on the linguistic and statistical characteristics of Chinese text, with Arg1 and Arg2 defined semantically and the senses of discourse relations annotated besides connectives and their lexical alternatives. The agreement on relation types reaches 95.1% and the agreement on implicit relations with exact span match reaches 76.9%.

Instead, Chen (2006) and Yue (2008) use RST to annotate Chinese discourse. Chen (2006) selects comma as the segmentation signal of EDUs (in Example (2), "据悉(According to reports)" will be segmented as an EDU), and finds that RST fails to deal with some special features of Chinese. Yue (2008) manually annotates a set of 97 texts according to RST and shows the cross-lingual transferability of RST to Chinese. However, it also shows that EDUs in Chinese are much different from those in English, and many relation types in Chinese have no correspondence to English, and vice versa.

3 Connective-driven Dependency Tree

An appropriate representation scheme is fundamental to linguistic resource construction. With reference to various theories and representation scheme on the tree structure and nuclearity of RST, the connective, relation and discourse structure of Chinese complex sentence (Xing, 2001), the sentence-group theory (Cao, 1984), the connective treatment of PDTB, the conjunction dependent analysis (Feng and Ji, 2011) and the center theory of dependency grammar (Hays, 1964), we propose a new discourse representation scheme for Chinese, called Connective-driven Dependency Tree (CDT), with EDUs as leaf nodes and connectives as non-leaf nodes, to accommodate the special characteristics of the Chinese language in discourse structure.

For instance, Example (3) consists of 2 sentences, which is part of a paragraph from "chtb_0001", and its corresponding CDT representation is shown in Figure 2. Here, the number of "|" in Example (3) stands for the level of EDUs in CDT and the numbers marked in Figure 2 (such as 1, 2 etc.) distinguish EDUs. While an arrow points to the main EDU or main discourse unit (called nucleus), the combination of different EDUs can be considered as EDUs in a higher level and the new discourse units can thus be combined into higher-level units from bottom to up. In this way, the discourse structure can be expressed as a tree structure via bottom-up combination of EDUs.

Obviously, such discourse structure is constructed by two kinds of basic units, EDUs (leaf nodes) and connectives (non-leaf nodes). On the one hand, connectives can represent the discourse structure by its hierarchical level in the tree. The discourse structure is independent on the connective level essentially, rather than the reverse. On the other hand, connectives themselves can represent the discourse relation. This is why we call the scheme "Connective-driven". As for the abstract discourse relation, we can construct a set of discourse relations, mapping a connective to discourse relation, according to the users' specific requirements.

"1 Pudong's development and opening up is a century-spanning undertaking for vigorously promoting Shanghai and constructing a modern economic, trade, and financial center. ‖ 2 **Because of this,** new situations and new questions that have not been encountered before are emerging in great numbers. | 3 In response to this, Pudong is not simply adopting an approach of "work for a short time and then draw up laws and regulations only after experience has been accumulated."‖ 4 **Instead,** Pudong is taking advantage of the lessons from experience of developed countries and special regions such as Shenzhen, ||||5 by hiring appropriate domestic and foreign specialists and scholars, ||||6 actively and promptly formulating and issuing regulatory documents. ||| 7 So these economic activities are incorporated into the sphere of influence of the legal system as soon as they appear."

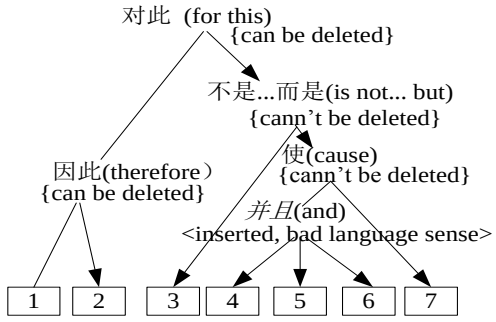

Figure 2: CDT representation of Example (3)

3.1 Elementary Discourse Unit

As the leaf nodes of CDT, EDUs are limited to clauses. In principle, EDUs play a crucial role to discourse analysis. Since from bottom-up discourse combination, EDUs are the start of discourse analysis, while from top-down discourse segmentation, they are the end of discourse analysis. Unfortunately, since there lacks obvious distinction between Chinese sentence structure and phrase structure, it is rather difficult to define Chinese EDU (clause). Till now, there is still no widely accepted definition in the Chinese linguistics community (Wang, 2010). Inspired by Li et al. (2013a), we give the definition of Chinese EDU from three perspectives. First, from the syntactic structure perspective, an EDU should contain at least one predicate and express at least one proposition. Second, from the functional perspective, an EDU should be related to other EDUs with some propositional function, i.e. not act as a grammatical element of other EDUs. Finally, from the morphological perspective, an EDU should be segmented by some punctuation, e.g. comma, semicolon and period. We use punctuation because there usually has a pause between clauses (EDUs), which can be shown in written commas, semicolons etc (Huang and Liao, 2011). Normally, it is easy to handle complex sentences and special sentence patterns (e.g. serial predicate sentences). For Example (4), A) is a single sentence with serial predicate; B) is complex sentence with two EDUs (clauses):

Example (4): EDU examples

A) He opened the door and went out. (single sentence, serial predicate, one EDU)
B) 1 He opened the door,| 2 **and** went out. (complex sentence, two EDUs)

Take as example, there exist 7 EDUs in Example (3), each marked with a number in front. According to our definition, the fragment "干一段时间，…法规条例"("work for a short time…has been accumulated") in EDU 3 is not segmented as a EDU since: 1) it acts as a grammatical element of other EDUs and has no direct relationship with other EDUs on propositional function; 2) it is marked by a pair of quotation marks and does not end with any punctuation. In contrast, the fragment "而是借鉴发达…法制轨道"("but learn developed…legality track.") is segment as 4 EDUs since it meets the three criteria in our EDU definition.

3.2 Connective

As non-leaf nodes in the CDT representation, connectives connect EDUs or discourse units. Thus, the main criterion of determining whether an expression is a connective is to check whether the two fragments it connects are EDUs (or discourse units). In our scheme, the list of explicit discourse connectives is judged by a data driven approach, i.e. with any discourse-like word or phrase marked as connective in the annotation practice, e.g. "因此(therefore)", "对此(to this)", "不是...而是...(is not...but....)", "使(so that), "正因为(just because)" in Example (3), "先...然后(first...then) ", "同时也(and at the same time)" in Example (5).

Example (5): Connective examples from CTB

A) 1<如果；只要>建筑公司进区，| 2 有关部门**先**送上这些法规性文件，‖ 3 **然后**有专门队伍进行监督检查。(chtb_0001)
1<If ; As long as>The construction company enters the region, |2 **first** the appropriate bureau delivers these regulatory documents,‖ 3 **Then** there is a specialized contingent that carries out a supervisory inspection.
B) 1 加工贸易…, 2 **同时 也** 是粤港澳台经贸合作的重要内容。(chtb_0031)

1 The processing trade …, | 2 **and at the same time** is important content in the economic and trade cooperation between Guangdong, Hong Kong, Macao and Taiwan.

It is worthy of mention that from the part-of-speech perspective, connectives are not necessarily conjunctions. For example, in Example (3) and (5), adverbs "先...然后(first…then)", verb phrases "不是…而是(is not…but)", and preposition phrases "对此(to this)" are determined as connectives. From the morphological perspective, a connective may contain more than one word, even discontinuous. As a common occurring phenomenon in Chinese discourse, there exist many paired Chinese connectives, e.g. "不是…而是 (is not…but)" in Figure 2. Even in some paired connectives, such as "因为…所以(because…so)", a word in a paired connective can appear independently as a connective. Please note that this may not be applied to other cases, e.g. "不是…而是 (is not…but)" as appeared in Example (3). Moreover, in many cases whether an expression is a connective or not depends on its meaning, e.g., "为 (in order to)" is a connective, while "为 (for)" is not. For the positional distribution, a connective may appear anywhere, i.e. in the beginning, middle, or the end of the first or second EDU. Example (3) and (5) show some of cases in different positions. The above characteristics pose special challenges on connective determination in Chinese language.

According to the appearance of a connective or not, a discourse relation can be either explicit or implicit. Previous studies have shown the difficulty of implicit relation recognition in English due to the omission of connectives (Pitler et al., 2009; Lin et al., 2009). This becomes even worse in Chinese since compared with the implicit ratio of 54.5% in English connectives, this ratio rises up to about 82% in Chinese (Zhou and Xue, 2012). It is worth noting that the majority of discourse relations in Chinese are implicit, so the insertion of a connective in an implicit position can significantly ease the understanding of the discourse. That is, a connective driven representation scheme is still applicable to a discourse with implicit connectives. To help determine implicit relations, two special strategies are proposed.

First, for each explicit connective, a decision is made whether or not it can be deleted without changing the rhetorical relation of a discourse. It should be emphasized that this constraint is largely semantic. The motivation behind the removal of explicit connectives is to enlarge implicit instances and help recognize implicit relations. As shown in Figure 2, we use the paired mark "()" to indicate that a connective can be deleted, e.g. connectives "(对此 to this)", "(因此 therefore)", "(正因此 just because)", and the paired mark "{}" to indicate that a connective cannot be deleted, e.g. connectives "{使 so that}", "{不是…而是 is not…but}".

Second, since a connective can be inserted to represent an implicit relation, our scheme tries to insert a connective which can be easily interpreted from the semantic perspective with little ambiguity into the most appropriate place. Most of the connective insertions for implicit relations occur between adjacent discourse spans. It is worth noting that not all implicit connectives are subjective to the language sense. To mark this difference, we cluster implicit connectives into two categories according to their language senses, either "good language intuition" or "bad language intuition". In our scheme, we use the paired mark "<>"to indicate inserted implicit connectives, e.g. connectives"<例如 e.g.>", "<却 but>" with "good language sense", connective "<并且 and>" with "bad language sense", as shown in Figure 2.

In some cases, it is possible that there exist several insertion options for an implicit connective due to the ambiguity in a discourse. For example, in Example (5A), connectives "如果 (if)" and "只要 (as long as)" are inserted into the first level to show the two discourse relation options. As far as this happens, connectives are inserted and ordered according to annotators' first intuition.

3.3 Discourse Structure

In Figure 2, the paragraph is organized as a tree structure, in which EDUs appear in the leaf nodes and the connectives appear in the non-leaf ones. The adoption of tree structure conforms to traditional Chinese discourse theories and practice. For example, a native Chinese speaker tends to determine the overall level boundary first and then the analysis goes on step by step to the individual clauses, when understanding a complex sentence. This process naturally forms a tree structure. Besides, tree structure is easier to formalize, compared with graph.

More specifically, the hierarchical structure of connectives indicates the hierarchical structure of discourse units. Apparently, discourse struc-

ture analysis can be viewed as hierarchical analysis of connectives, with hierarchical connective structure reflecting hierarchical combination of discourse units. Essentially, the discourse hierarchy indicates the correlation degrees of semantic relations in the discourse, the deeper tree level of two discourse units, the higher correlation degree of their semantic relation. Therefore, a discourse relation is the ultimate factor for the choice of hierarchical discourse structure. For a reference, please take Sentence 2 in Figure 2 as an example.

3.4 Discourse Relation

For discourse relation representation, a general approach is to assign an abstract relation type to a discourse relation directly, such as cause, conjunction, condition, purpose, etc, as done in RST-DT and PDTB. In our CDT scheme, we avoid to directly assign an abstract relation type to a discourse relation. Instead, we use the connective itself to express the discourse relation, as shown in Figure 2. In this way, the difficulty of pre-defining a set of acknowledged discourse relations and selecting an exact discourse relation can be avoided during the corpus annotation process. Since a Chinese discourse relation is largely controlled by connective (Xing, 2001), the key to determine a relation is to identify a suitable connective. Normally, most of relation annotations can easily map from connectives to abstract semantic classes of relations, if necessary, with the help of the discourse context. The majority of discourse relations in Chinese are implicit, but it makes sense to insist on a connective driven representation. With connective as a bridge, at least it makes discourse representation easier.

For the abstraction of discourse relations, we leave it in a later separate stage. Of course, there are cases where a connective may represent more than one discourse relation. For example, connective "而" can denotes the continuous relation "而 (especially)" and the transitional relation "而 (however)". Compared with annotating discourse relation directly, annotator's intuition is more accurate for specific connective. We don't object to label discourse relation, referring to the general work and Chinese analysis practice, give a set of relations (Figure 3), regarding it as connective's semantics, and then annotate the connective with it. In this way, we can obtain a general relation set and resolve the connective's polysemy problem. We believe that the connective itself is the foundation of discourse relation, and the relation set can be adjusted dynamically according to the application requirements.

Figure 3 shows a three-level set of discourse relations example. In the first level, this set contains four relations of causality, coordination, transition and explanation, which are further clustered into 17 sub-relations in the second level. For example, relation causality contains 6 sub-relations, i.e. cause-result, inference, hypothetical, purpose, condition and background. In the third level, the connectives are under each sub-relation. For example, cause-result relation can be represented by "because", 'therefore' etc. The numbers shown in the parentheses illustrate the distributions of different relations in our corpus. For example, there are 1335 causality relations in the first level, including 686 cause-result relations, 38 inference relations, 70 hypothetical relations, 335 purpose relations, 72 condition relations and 134 background relations.

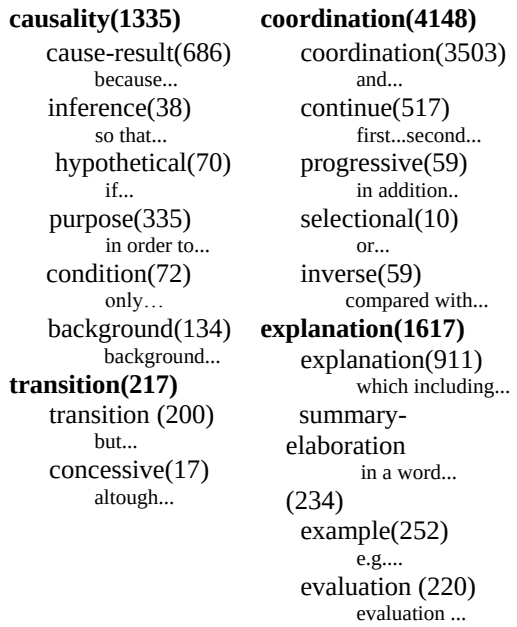

Figure 3: A three-level set of discourse relations

3.5 Nucleus and Satellite

Once discourse units are determined, adjacent spans are linked together via connectives to build a hierarchical structure. As stated above, discourse relations may be either mononuclear or multi-nuclear. A mononuclear relation holds between a nucleus and a satellite unit. Normally, the nucleus usually reflects the intention focus of the discourse and is thus more salient in the discourse structure, while the satellite usually represents supportive information for the nucleus. In comparison, a multi-nuclear relation usually

holds two or more discourse units of equal weight in the discourse structure.

For nucleus determination, we adopt the dependency grammar, and select the unit which can stand for the relationship with other discourse units in a discourse. As shown in Figure 2, on the first level, discourse relation "对此 (to this)" has the latter unit "浦东…法制轨道 (Pudong…as soon as they appear.)" as nucleus and the former unit "浦东…新问题 (Pudong …new problem)" as satellite, since the latter unit agrees with the main purpose of the discourse, which emphasizes some methods for the progress of Pudong. Moreover, since the combination of 4, 5 and 6 has the cause relation with 7, we choose 7 as nucleus because it can stand for the combination of 4, 5, 6 and 7, and has the selection relationship with 3.

4 Chinese Discourse Treebank

Given above the CDT scheme, we choose 500 Xinhua newswire documents from the Chinese Treebank (Xue et al., 2005b) in our Chinese Discourse Treebank (CDTB) annotation. In particular, we annotate one discourse tree for each paragraph.

In this section, we address the key issues with the CDTB annotation, such as annotator training, tagging strategies, corpus quality, along with the statistics of the CDTB corpus.

4.1 Annotator Training

The annotator team consists of a Ph.D. in Chinese linguistics as the supervisor (senior annotator) and four undergraduate students in Chinese linguistics as annotators (two pairs). The annotation is done in four phases. In the first phase, the annotators spend 3 months on learning the principles of CDT and the use of our developed discourse annotation tool. In the second phase, the annotators spend 2 months on independently annotating the same 50 documents (about 260 paraphrases), and another 2 months on cross-checking to resolve the difference and to revise the guidelines. In the third phase, the annotators spend 9 months on annotating the remaining 450 documents. In the final phase, the supervisor spends 3 months carefully proofread all 500 documents.

4.2 Tagging Strategies

In the CDTB annotation, we employ a top-down strategy. That is, we determine the overall level first and then the analysis goes on step by step to the individual EDUs. This strategy is adopted in our annotation tool. The advantages of the top-down strategy are three folds. First, such a strategy can easily grasp the whole discourse structure. This conforms to the global nature of discourse analysis. Second, due to the lack of clear difference between Chinese sentence and phrase structure, such a strategy can largely avoid the error propagation in Chinese EDU segmentation. Since in such a top-down strategy, EDU segmentation becomes an end question, and even if an EDU segmentation error happens, its impact is localized, i.e. with little impact on the whole discourse structure. Our annotation practice shows that such strategy is effective. Third, such a strategy accords with the cognitive of Chinese characteristics, and conforms to the mental process of Chinese discourse understanding (Huang and Liao, 2011). However, we do not exclude the bottom-up strategy. In some cases, on the cognitive psychological process, annotator is combine top-down and bottom-up strategies.

Take Example (3) as an example, an annotator first finds the first level, with the period at the end of sentence 1, and chooses discourse relation (either explicit or implicit), connective, and connective related information (e.g. whether can be added, deleted, and the language sense, etc.), nuclearity etc. Then, the annotator turns to sentence 1 and marks the second comma as level 2 with necessary information annotated, and goes on to sentence 2, recursively, until all EDUs are marked. In this way, a discourse tree with the CDT representation is constructed.

4.3 Quality Assurance

A number of steps are taken to ensure the quality of CDTB. These involve two tasks: checking the validity of the trees and tracking inter-annotator consistency.

4.3.1 Tree validation

We first manually check if a tree has a single root node and compare the tree with the document to check for missing sentence or fragments from the end of text. Then we check the attached information such as connectives, relations and nuclearity in the tree. We also check the tree with a tree traversal program to find the errors undetected by the manual validation process. Finally, all of the trees work successfully.

4.3.2 Consistency

To ensure the quality of CDTB, we adopt the inter-annotator consistency using Agreement and kappa on 60 documents (chtb0041-chtb

0100). Table 1 illustrates the inter-annotator consistency in details.

As shown in Table 1, we measure the agreement of EDU segmentation by determining whether punctuation (all period, comma etc. are considered) is treated as an EDU boundary. It shows that the agreement reaches 91.7% with Cohen's kappa value (Cohen, 1960) 0.91. This justifies the appropriateness of our EDU definition. Explicit or Implicit agreement 94.7% is calculate by the same EDU boundary (intersection) of two annotators. For the same explicit relation, the connective identification agreement is 82.3%, because this is strict measure when two annotators choose the same connective word. If we relax the measure to contain the same word, the agreement can reach 98%. For example, one annotate "也…并(also…and)", and the other annotate "并(and)" is wrong with our strict measure.

	Agreement	Kappa
EDU segmentation	91.7	0.91
Explicit or Implicit	94.7	0.81
Explicit connective identification	82.3	--
Implicit connective insertion	74.6	--
Mononuclear or Multinuclear	80.8	--
Nuclearity	82.4	--
Structure	77.4	--

Table 1: Inter-annotator consistency

It is not surprising that the agreement on implicit connective insertion with the same position and the same connective only reaches 74.6% since for some discourse relations, there may existing several connective alternatives. For example, both "so" and "therefore" can express the same causation relation. If we relax the constraint to the compatible connective, the agreement on implicit connective insertion can reach up to 84.5%.

Finally, it shows that the agreement on overall discourse structure (with the same connectives as non-leaf nodes, the same EDUs as leaf nodes) reaches 77.4%. This justifies the appropriateness of our CDT scheme, given the inherent ambiguity in Chinese discourse structure.

4.4 Corpus Statistics

Currently, the CDTB corpus consists of 500 newswire articles from Chinese Treebank, which are further divided into 2342 paragraphs with a CDT representation for one paragraph.

- For EDUs, CDTB contains 10650 EDUs with an average of 4.5 EDUs per tree. On average, there are 2 EDUs per sentence and 22 Chinese characters per EDU.
- For discourse relations, CDTB contains 7310 relations, of which 1812 are explicit relations (24.8%) and 5498 are implicit relations (75.2%). This indicates that implicit relations occur much more frequently in Chinese than in English, e.g. 75.2% in CDTB (Chinese) vs. ~50% in PDTB (English).
- With the deepest level of 9, most (98.5%) of discourse relations occur in level 1 (2342), level 2(2372), level 3(1532), level 4(712), and level 5(242). It also shows that 3557 (48.7%) relations are mononuclear relations with 2110 nucleus ahead, while the remaining 3754 relations are multi-nuclear. The numbers shown in the parentheses of Figure 3 illustrate the distributions of different relations. In comparison with the top 2 most frequently occurring relations in PDTB (English), i.e. the coordination and explanation relations, there exist 3503 (47.9%) and 911 instances respectively, with regard to the abstract relation set as shown in Figure 3.
- CDTB contains 282 connectives, among which 274 (140 can be deleted) appears as explicit connectives and 44 can be inserted in place of implicit connectives. Table 2 lists the top 10 frequent explicit connectives and implicit connectives.

Explicit connectives		Implicit connectives	
connectives	frequency	connectives	frequency
并(and)	208	因此(so)	368
其中(among them)	154	并(and)	354
也(also)	131	并且(and)	259
而(however)	70	例如(e.g)	140
但(but)	69	来(in order to)	68
还(also)	68	以(in order to)	61
使(so that)	56	然后(then)	55
以(in order to)	52	其中(among them)	48
为(in order to)	49	而(while)	47
同时(meanwhile)	46	因为(because)	32

Table 2: The most frequent connectives in CDTB

5 Comparison with other Discourse Banks

Table 3 compares the difference of CDTB with RST-DT and PDTB from various perspectives, such as EDU, connective, relation, structure and nuclearity.

	RST-DB	PDTB	CDTB
EDU	Clear defined; start of combination; one relation has two or more EDUs	Predicate-argument view; one relation has two arguments	Clear defined from three aspects; end of top-down segmentation; one relation has two or more EDUs
Connective	--	Mark explicit connectives and insert implicit connectives	Mark whether an connective can be deleted without changing the rhetorical relation; insert implicit connective with good intuition and bad intuition differentiated
Relation	Abstract set of relation types; annotate the relation types	Abstract set of relation types; annotate connective and relation type	Represent relation by connective; annotate connective and it's attribute; mapping of connective to the set of discourse relations in a later stage
Structure	Complete tree	Partial tree, deduced by connective and it's argument	Complete tree; top-down segmentation; structure can be represented by the connective hierarchy
Nuclearity	Determined by certain rhetorical relation	--	Determined by the global meaning of a discourse

Table 3: The comparison of RST-DT, PDTB and CDTB

6 Preliminary Experimentation

In order to evaluate the computability of CDTB, we give the experimental results on EDU recognition, which is crucial in discourse parsing. After excluding sentence end punctuations (such as period, question mark, and exclamatory mark), which are certainly EDU boundaries, there remains 7625 punctuations as EDU boundaries (positive instances) and 4876 punctuations as non-EDU boundaries (negative instances). With various features as adopted in Xue and Yang (2011) and Li et al. (2013b), Table 4 shows the performance of EDU recognition on the CDTB corpus with 10-fold cross validation.

Classifier	Gold standard parse			Automatic parse		
	Accuracy	F1(+)	F1(-)	Accuracy	F1(+)	F1(-)
MaxEnt	**90.6**	**91.1**	**90.5**	**89.0**	**90.3**	**87.2**
C45	90.2	90.5	90.1	88.7	90.0	87.7
NiveBayes	90.2	89.9	88.9	88.0	89.0	86.9

Table 4: Performance of EDUs recognition

As shown in Table 4, MaxEnt performs best, with accuracy up to 90.6% on gold standard parse tree, close to human agreement of 91.7%, and with accuracy up to 89% on automatic parse tree. This suggests the appropriateness of our definition of clause as EDU. Table 4 also gives the performance on both positive and negative instances. It shows better F1-measure on recognizing positive instances than negative instances.

7 Conclusions

In this paper, we propose a Connective-driven Dependency Tree (CDT) structure as a representation scheme for Chinese discourse structure. CDT takes advantage of both RST and PDTB, and well adapts to the special characteristics of Chinese discourse. In particular, we describe CDT in detail from various perspectives, such as EDU, connective, structure, relation and nuclearity. Given the CDT scheme, we annotate 500 documents in a top-down segmentation process to keep consistent with Chinese native's cognitive habit. Evaluation of the CDTB corpus on EDU recognition justifies the appropriateness of the CDT scheme to Chinese discourse structure and the usefulness of our CDTB corpus.

In the future work, we will focus on enlarging the scale of the corpus annotation and developing a complete Chinese discourse parser.

Prune-and-Score: Learning for Greedy Coreference Resolution

Abstract

We propose a novel search-based approach for greedy coreference resolution, where the mentions are processed in order and added to previous coreference clusters. Our method is distinguished by the use of two functions to make each coreference decision: a *pruning* function that prunes bad coreference decisions from further consideration, and a *scoring* function that then selects the best among the remaining decisions. Our framework reduces learning of these functions to rank learning, which helps leverage powerful off-the-shelf rank-learners. We show that our *Prune-and-Score* approach is superior to using a single scoring function to make both decisions and outperforms several state-of-the-art approaches on multiple benchmark corpora including OntoNotes.

1 Introduction

Coreference resolution is the task of clustering a set of mentions in the text such that all mentions in the same cluster refer to the same entity. It is one of the first stages in deep language understanding and has a big potential impact on the rest of the stages. Several of the state-of-the-art approaches learn a scoring function defined over mention pair, cluster-mention or cluster-cluster pair to guide the coreference decision-making process (Daumé III, 2006; Bengtson and Roth, 2008; Rahman and Ng, 2011b; Stoyanov and Eisner, 2012; Chang et al., 2013; Durrett et al., 2013; Durrett and Klein, 2013). One common and persistent problem with these approaches is that the scoring function has to make all the coreference decisions, which leads to a highly non-realizable learning problem.

Inspired by the recent success of the $\mathcal{HC}$-Search Framework (Doppa et al., 2014a) for studying a variety of structured prediction problems (Lam et al., 2013; Doppa et al., 2014c), we study a novel approach for search-based coreference resolution called *Prune-and-Score*. $\mathcal{HC}$-Search is a divide-and-conquer solution that learns multiple components with pre-defined roles, and each of them contribute towards the overall goal by making the role of the other components easier. The $\mathcal{HC}$-Search framework operates in the space of complete outputs, and relies on the loss function which is only defined on the complete outputs to drive its learning. Unfortunately, this method does not work for incremental coreference resolution since the search space for coreference resolution consists of partial outputs, i.e., a set of mentions only some of which have been clustered so far.

We develop an alternative framework to $\mathcal{HC}$-Search that allows us to effectively learn from partial output spaces and apply it to greedy coreference resolution. The key idea of our work is to address the problem of non-realizability of the scoring function by learning two different functions: 1) a *pruning function* to prune most of the bad decisions, and 2) a *scoring function* to pick the best decision among those that are remaining. Our Prune-and-Score approach is a particular instantiation of the general idea of learning nearly-sound constraints for pruning, and leveraging the learned constraints to learn improved heuristic functions for guiding the search. The pruning constraints can take different forms (e.g., classifiers, decision-list, or ranking functions) depending on the search architecture. Therefore, other coreference resolution systems (Chang et al., 2013; Durrett and Klein, 2013; Björkelund and Kuhn, 2014) can also benefit from this idea. While our basic idea of two-level selection might appear similar to the coarse-to-fine inference architectures (Felzenszwalb and McAllester, 2007; Weiss and Taskar, 2010), the details differ significantly. Importantly, our pruning and scoring functions operate sequentially at

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2115–2126,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

each greedy search step, whereas in the cascades approach, the second level function makes its prediction only when the first level decision-making is done.

Summary of Contributions. The main contributions of our work are as follows. First, we motivate and introduce the *Prune-and-Score* approach to search-based coreference resolution. Second, we identify a decomposition of the overall loss of the Prune-and-Score approach into the pruning loss and the scoring loss, and reduce the problem of learning these two functions to rank learning, which allows us to leverage powerful and efficient off-the-shelf rank learners. Third, we evaluate our approach on OntoNotes, ACE, and MUC data, and show that it compares favorably to several state-of-the-art approaches as well as a greedy search-based approach that uses a single scoring function.

The remainder of the paper proceeds as follows. In Section 2, we dicuss the related work. We introduce our problem setup in Section 3 and then describe our *Prune-and-Score* approach in Section 4. We explain our approaches for learning the pruning and scoring functions in Section 5. Section 6 presents our experimental results followed by the conclusions in Section 7.

2 Related Work

The work on learning-based coreference resolution can be broadly classified into three types. First, the *pair-wise classifier* approaches learn a classifier on mention pairs (edges) (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008), and perform some form of approximate decoding or post-processing using the pair-wise scores to make predictions. However, the pair-wise classifier approach suffers from several drawbacks including class imbalance (fewer positive edges compared to negative edges) and not being able to leverage the global structure (instead making independent local decisions).

Second, the *global* approaches such as Structured SVMs and Conditional Random Fields (CRFs) learn a cost function to score a potential clustering output for a given input set of mentions (Mccallum and Wellner, 2003; Finley and Joachims, 2005; Culotta et al., 2007; Yu and Joachims, 2009; Haghighi and Klein, 2010; Wick et al., 2011; Wick et al., 2012; Fernandes et al., 2012). These methods address some of the problems with pair-wise classifiers, however, they suffer from the intractability of "Argmin" inference (finding the least cost clustering output among exponential possibilities) that is encountered during both training and testing. As a result, they resort to approximate inference algorithms (e.g., MCMC, loopy belief propagation), which can suffer from local optima.

Third, the *incremental* approaches construct the clustering output incrementally by processing the mentions in some order (Daumé III, 2006; Denis and Baldridge, 2008; Rahman and Ng, 2011b; Stoyanov and Eisner, 2012; Chang et al., 2013; Durrett et al., 2013; Durrett and Klein, 2013). These methods learn a scoring function to guide the decision-making process and differ in the form of the scoring function (e.g., mention pair, cluster-mention or cluster-cluster pair) and how it is being learned. They have shown great success and are very efficient. Indeed, several of the approaches that have achieved state-of-the-art results on OntoNotes fall under this category (Chang et al., 2013; Durrett et al., 2013; Durrett and Klein, 2013; Björkelund and Kuhn, 2014). However, their efficiency requirement leads to a highly non-realizable learning problem. Our Prune-and-Score approach is complementary to these methods, as we show that having a pruning function (or a set of learned pruning rules) makes the learning problem easier and can improve over the performance of scoring-only approaches. Also, the models in (Chang et al., 2013; Durrett et al., 2013) try to leverage cluster-level information implicitly (via a latent antecedents) from mention-pair features, whereas our model explicitly leverages the cluster level information.

Coreference resolution systems can benefit by incorporating the world knowledge including rules, constraints, and additional information from external knowledge bases (Lee et al., 2013; Rahman and Ng, 2011a; Ratinov and Roth, 2012; Chang et al., 2013; Zheng et al., 2013; Hajishirzi et al., 2013). Our work is orthogonal to this line of work, but domain constraints and rules can be incorporated into our model as done in (Chang et al., 2013).

3 Problem Setup

Coreference resolution is a structured prediction problem where the set of mentions $m_1, m_2, \cdots, m_D$ extracted from a document cor-

reponds to a structured input x and the structured output y corresponds to a partition of the mentions into a set of clusters $C_1, C_2, \cdots, C_k$. Each mention m_i belongs to exactly one of the clusters C_j. We are provided with a training set of input-output pairs drawn from an unknown distribution $\mathcal{D}$, and the goal is to return a function/predictor from inputs to outputs. The learned predictor is evaluated against a non-negative *loss function* $L : \mathcal{X} \times \mathcal{Y} \times \mathcal{Y} \mapsto \Re^+$, $L(x, y', y)$ is the loss associated with predicting incorrect output y' for input x when the true output is y (e.g., B-Cubed Score).

In this work, we formulate the coreference resolution problem in a search-based framework. There are three key elements in this framework: 1) the *Search space* $\mathcal{S}_p$ whose states correspond to partial clustering outputs; 2) the *Action pruning function* $\mathcal{F}_{prune}$ that is used to prune irrelevant actions at each state; and 3) the *Action scoring function* $\mathcal{F}_{score}$ that is used to construct a complete clustering output by selecting actions from those that are left after pruning. $\mathcal{S}_p$ is a 3-tuple $\langle I, A, T \rangle$, where I is the initial state function, A gives the set of possible actions in a given state, and T is a predicate which is true for terminal states. In our case, $s_0 = I(x)$ corresponds to a state where every mention is unresolved, and $A(s_i)$ consists of actions to place the next mention m_{i+1} in each cluster in s_i or a NEW action which creates a new cluster for it. Terminal nodes correspond to states with all mentions resolved.

We focus on greedy search. The decision process for constructing an output corresponds to selecting a sequence of actions leading from the initial state to a terminal state using both $\mathcal{F}_{prune}$ and $\mathcal{F}_{score}$, which are parameterized functions over state-action pairs ($F_{prune}(\phi_1(s, a)) \in \Re$ and $F_{score}(\phi_2(s, a)) \in \Re$), where ϕ_1 and ϕ_2 stand for feature functions. We want to learn the parameters of both $\mathcal{F}_{prune}$ and $\mathcal{F}_{score}$ such that the predicted outputs on unseen inputs have low expected loss.

4 Greedy Prune-and-Score Approach

Our greedy *Prune-and-Score* approach for coreference resolution is parameterized by a pruning function $\mathcal{F}_{prune} : \mathcal{S} \times \mathcal{A} \mapsto \Re$, a scoring function $\mathcal{F}_{score} : \mathcal{S} \times \mathcal{A} \mapsto \Re$, and a pruning parameter $b \in [1, A_{max}]$, where A_{max} is the maximum number of actions at any state $s \in \mathcal{S}$. Given a set of input mentions $m_1, m_2, \cdots, m_D$ extracted from a document (input x), and a pruning parameter b, our Prune-and-Score approach makes predictions as follows. The search starts at the initial state $s_0 = I(x)$ (see Algorithm 1). At each non-terminal state s, the pruning function $\mathcal{F}_{prune}$ retains only the top b actions (A') from $A(s)$ (Step 3), and the scoring function $\mathcal{F}_{score}$ picks the best scoring action $a_p \in A'$ (Step 4) to reach the next state. When a terminal state is reached its contents are returned as the prediction. Figure 1 illustrates the decision-making process of our Prune-and-Score approach for an example state.

Algorithm 1 Greedy Prune-and-Score Resolver

Input: x = set of mentions $m_1, m_2, \cdots, m_D$ from a document D, $\langle I, A, T \rangle$ = Search space definition, $\mathcal{F}_{prune}$ = learned pruning function, b = pruning parameter, $\mathcal{F}_{score}$ = learned scoring function

1: $s \leftarrow I(x)$ *// initial state*
2: **while not** $T(s)$ **do**
3: $A' \leftarrow$ Top b actions from $A(s)$ according to $\mathcal{F}_{prune}$ *// prune*
4: $a_p \leftarrow \arg\max_{a \in A'} \mathcal{F}_{score}(s, a)$ *// score*
5: $s \leftarrow$ Apply a_p on s
6: **end while**
7: **return** coreference output corresponding to s

We now formalize the learning objective of our Prune-and-Score approach. Let $\hat{y}$ be the predicted coreference output for a coreference input-output pair (x, y^*). The expected loss of the greedy Prune-and-Score approach $\mathcal{E}(\mathcal{F}_{prune}, \mathcal{F}_{score})$ for a given pruning function $\mathcal{F}_{prune}$ and scoring function $\mathcal{F}_{score}$ can be defined as follows.

$$\mathcal{E}(\mathcal{F}_{prune}, \mathcal{F}_{score}) = \mathbb{E}_{(x,y^*)\sim\mathcal{D}}\ L\left(x, \hat{y}, y^*\right)$$

Our goal is to learn an optimal pair of pruning and scoring functions $\left(\mathcal{F}^o_{prune}, \mathcal{F}^o_{score}\right)$ that minimizes the expected loss of the Prune-and-Score approach. The behavior of our Prune-and-Score approach depends on the pruning parameter b, which dictates the workload of pruning and scoring functions. For small values of b (aggressive pruning), pruning function learning may be harder, but scoring function learning will be easier. Similarly, for large values of b (conservative pruning), scoring function learning becomes hard, but pruning function learning is easy. Therefore, we would expect beneficial behavior if pruning function can aggressively prune (small values of b) with little loss in accuracy. It is interesting to note that our Prune-and-Score approach degenerates to existing incremental approaches that use only the scoring function for search (Daumé III, 2006; Rahman and

(a) Text with input set of mentions

Ramallah (West Bank $_2$)$_1$ 10-15 (AFP$_3$) - Eyewitnesses$_4$ reported that Palestinians$_5$ demonstrated today Sunday in the West Bank$_6$ against the Sharm el-Sheikh$_7$ summit to be held in Egypt$_8$ tomorrow Monday. (b) Illustration of Prune-and-Score approach

State: $s = \{C_1, C_2, C_3, C_4, C_5, C_6\}$ Actions: $A(s) = \{a_1, a_2, a_3, a_4, a_5, a_6, a_7\}$

Pruning step: a_2 (2.5) a_1 (2.2) a_7 (1.9) a_5 (1.5) a_6 (1.4) a_3 (0.7) a_4 (0.4) ← $\mathcal{F}_{prune}$ values

$b = 3$

$A'(s) = \{a_2, a_1, a_7\}$

Scoring step: a_1 (4.5) a_2 (3.1) a_7 (2.6) ← $\mathcal{F}_{score}$ values

Decision: a_1 is the best action for state s

Figure 1: Illustration of Prune-and-Score approach. (a) Text with input set of mentions. Mentions are highlighted and numbered. (b) Illustration of decision-making process for mention m_{11}. The partial clustering output corresponding to the current state s consists of six clusters denoted by $C_1, C_2, \cdots, C_6$. Highlighted circles correspond to the clusters. Edges from mention m_{11} to each of the six clusters and to itself stand for the set of possible actions $A(s)$ in state s, and are denoted by $a_1, a_2, \cdots, a_7$. The pruning function $\mathcal{F}_{prune}$ scores all the actions in $A(s)$ and only keeps the top 3 actions $A' = \{a_2, a_1, a_7\}$ as specified by the pruning parameter b. The scoring function picks the best scoring action $a_1 \in A'$ as the final decision, and mention m_{11} is merged with cluster C_1.

Ng, 2011b) when $b = \infty$. Additionally, for $b = 1$, our pruning function coincides with the scoring function.

Analysis of Representational Power. The following proposition formalizes the intuition that two functions are strictly better than one in expressive power. See Appendix for the proof.

Proposition 1. *Let $\mathcal{F}_{prune}$ and $\mathcal{F}_{score}$ be functions from the same function space. Then for all learning problems,* $\min_{\mathcal{F}_{score}} \mathcal{E}(\mathcal{F}_{score}, \mathcal{F}_{score}) \geq \min_{(\mathcal{F}_{prune}, \mathcal{F}_{score})} \mathcal{E}(\mathcal{F}_{prune}, \mathcal{F}_{score})$. *Moreover there exist learning problems for which* $\min_{\mathcal{F}_{score}} \mathcal{E}(\mathcal{F}_{score}, \mathcal{F}_{score})$ *can be arbitrarily worse than* $\min_{(\mathcal{F}_{prune}, \mathcal{F}_{score})} \mathcal{E}(\mathcal{F}_{prune}, \mathcal{F}_{score})$.

5 Learning Algorithms

In general, learning the optimal $\left(\mathcal{F}^o_{prune}, \mathcal{F}^o_{score}\right)$ pair can be intractable due to their potential interdependence. Specifically, when learning $\mathcal{F}_{prune}$ in the worst case there can be ambiguity about which of the non-optimal actions to retain, and for only some of those an effective $\mathcal{F}_{score}$ can be found. However, we observe a loss decomposition in terms of the individual losses due to $\mathcal{F}_{prune}$ and $\mathcal{F}_{score}$, and develop a stage-wise learning approach that first learns $\mathcal{F}_{prune}$ and then learns a corresponding $\mathcal{F}_{score}$.

5.1 Loss Decomposition

The overall loss of the *Prune-and-Score* approach $\mathcal{E}\left(\mathcal{F}_{prune}, \mathcal{F}_{score}\right)$ can be decomposed into *pruning loss* ϵ_{prune}, the loss due to $\mathcal{F}_{prune}$ not being able to retain the *optimal* terminal state in the search space; and *scoring loss* $\epsilon_{score|\mathcal{F}_{prune}}$, the additional loss due to $\mathcal{F}_{score}$ not guiding the greedy search to the best terminal state after pruning using $\mathcal{F}_{prune}$. Below, we will define these losses more formally.

Pruning Loss is defined as the expected loss of the *Prune-and-Score* approach when we perform greedy search with $\mathcal{F}_{prune}$ and $\mathcal{F}^*_{score}$, the optimal scoring function. A scoring function is said to be *optimal* if at every state s in the search space

$\mathcal{S}_p$, and for any set of remaining actions $A(s)$, it can score each action $a \in A(s)$ such that greedy search can reach the best terminal state (as evaluated by task loss function L) that is reachable from s through $A(s)$. Unfortunately, computing the optimal scoring function is highly intractable for the non-decomposable loss functions that are employed in coreference resolution (e.g., B-Cubed F1). The main difficulty is that the decision at any one state has interdependencies with future decisions (see Section 5.5 in (Daumé III, 2006) for more details). So we need to resort to some form of *approximate* optimal scoring function that exhibits the intended behavior. This is very similar to the dynamic oracle concept developed for dependency parsing (Goldberg and Nivre, 2013).

Let y^*_{prune} be the coreference output corresponding to the terminal state reached from input x by *Prune-and-Score* approach when performing search using $\mathcal{F}_{prune}$ and $\mathcal{F}^*_{score}$. Then the pruning loss can be expressed as follows.

$$\epsilon_{prune} = \mathbb{E}_{(x,y^*)\sim\mathcal{D}}\, L\left(x, y^*_{prune}, y^*\right)$$

Scoring Loss is defined as the additional loss due to $\mathcal{F}_{score}$ not guiding the greedy search to the best terminal state reachable via the pruning function $\mathcal{F}_{score}$ (i.e., y^*_{prune}). Let $\hat{y}$ be the coreference output corresponding to the terminal state reached by *Prune-and-Score* approach by performing search with $\mathcal{F}_{prune}$ and $\mathcal{F}_{score}$ for an input x. Then the scoring loss can be expressed as follows:

$$\epsilon_{score|\mathcal{F}_{prune}} = \mathbb{E}_{(x,y^*)\sim\mathcal{D}}\, L\left(x, \hat{y}, y^*\right) - L\left(x, y^*_{prune}, y^*\right)$$

The overall loss decomposition of our *Prune-and-Score* approach can be expressed as follows.

$$\mathcal{E}\left(\mathcal{F}_{prune}, \mathcal{F}_{score}\right) = \underbrace{\mathbb{E}_{(x,y^*)\sim\mathcal{D}}\, L\left(x, y^*_{prune}, y^*\right)}_{\epsilon_{\mathbf{prune}}} + \underbrace{\mathbb{E}_{(x,y^*)\sim\mathcal{D}}\, L\left(x, \hat{y}, y^*\right) - L\left(x, y^*_{prune}, y^*\right)}_{\epsilon_{\mathbf{score}|\mathcal{F}_{\mathbf{prune}}}}$$

5.2 Stage-wise Learning

The loss decomposition motivates a learning approach that targets minimizing the errors of pruning and scoring functions independently. In particular, we optimize the overall loss of the *Prune-and-Score* approach in a stage-wise manner. We first train a pruning function $\hat{\mathcal{F}}_{prune}$ to optimize the pruning loss component ϵ_{prune} and then train a scoring function $\hat{\mathcal{F}}_{score}$ to optimize the scoring loss $\epsilon_{score|\hat{\mathcal{F}}_{prune}}$ conditioned on $\hat{\mathcal{F}}_{prune}$.

$$\hat{\mathcal{F}}_{prune} \approx \arg\min_{\mathcal{F}_{prune}\in\mathbf{F_p}} \quad \epsilon_{prune}$$
$$\hat{\mathcal{F}}_{score} \approx \arg\min_{\mathcal{F}_{score}\in\mathbf{F_s}} \quad \epsilon_{score|\hat{\mathcal{F}}_{prune}}$$

Note that this approach is myopic in the sense that $\hat{\mathcal{F}}_{prune}$ is learned without considering the implications for learning $\hat{\mathcal{F}}_{score}$. Below, we first describe our approach for pruning function learning, and then explain our scoring function learning algorithm.

5.3 Pruning Function Learning

In our greedy *Prune-and-Score* approach, the role of the pruning function $\mathcal{F}_{prune}$ is to prune away irrelevant actions (as specified by the pruning parameter b) at each search step. More specifically, we want $\mathcal{F}_{prune}$ to score actions $A(s)$ at each state s such that the optimal action $a^* \in A(s)$ is ranked within the top b actions to minimize ϵ_{prune}. For this, we assume that for any training input-output pair (x, y^*) there exists a unique action sequence, or *solution path* (initial state to terminal state), for producing y^* from x. More formally, let $(s^*_0, a^*_0), (s^*_1, a^*_1), \cdots, (s^*_D, \varnothing)$ correspond to the sequence of state-action pairs along this solution path, where s^*_0 is the initial state and s^*_D is the terminal state. The goal is to learn the parameters of $\mathcal{F}_{prune}$ such that at each state s^*_i, $a^*_i \in A(s^*_i)$ is ranked among the top b actions.

While we can employ an *online-LaSO* style approach (III and Marcu, 2005; Xu et al., 2009) to learn the parameters of the pruning function, it is quite inefficient, as it must regenerate the same search trajectory again and again until it learns to make the right decision. Additionally, this approach limits applicability of the off-the-shelf learners to learn the parameters of $\mathcal{F}_{prune}$. To overcome these drawbacks, we apply offline training.

Reduction to Rank Learning. We reduce the pruning function learning to a rank learning problem. This allows us to leverage powerful and efficient off-the-shelf rank-learners (Liu, 2009). The reduction is as follows. At each state s^*_i on the solution path of a training example (x, y^*), we create an example by labeling optimal action $a^*_i \in A(s^*_i)$ as the only relevant action, and then try to learn

a ranking function that can rank actions such that the relevant action a_i^* is in the top b actions, where b is the input pruning paramter. In other words, we have a rank learning problem, where the learner's goal is to optimize the *Precision at Top-b*. The training approach creates such an example for each state s in the solution path. The set of aggregate imitation examples collected over all the training data is then given to a rank learner (e.g., LambdaMART (Burges, 2010)) to learn the parameters of $\mathcal{F}_{prune}$ by optimizing the *Precision at Top-b* loss. See appendix for the pseudocode.

If we can learn a function $\mathcal{F}_{prune}$ that is consistent with these imitation examples, then the learned pruning function is guaranteed to keep the solution path within the pruned space for all the training examples. We can also employ more advanced imitation learning algorithms including DAgger (Ross et al., 2011) and SEARN (Hal Daumé III et al., 2009) if we are provided with an (approximate) optimal scoring function $\mathcal{F}^*_{score}$ that can pick optimal actions at states that are not in the solution path (i.e., *off-trajectory* states).

5.4 Scoring Function Learning

Given a learned pruning function $\mathcal{F}_{prune}$, we want to learn a scoring function that can pick the best action from the b actions that remain after pruning at each state. We formulate this problem in the framework of *imitation learning* (Khardon, 1999). More formally, let $(\hat{s}_0, a_0^*), (\hat{s}_1, a_1^*), \cdots, (\hat{s}_D^*, \varnothing)$ correspond to the sequence of state-action pairs along the greedy trajectory obtained by running the Prune-and-Score approach with $\mathcal{F}_{prune}$ and $\mathcal{F}^*_{score}$, the optimal scoring function, on a training example (x, y^*), where $\hat{s}_D^*$ is the best terminal state in the pruned space. The goal of our imitation training approach is to learn the parameters of $\mathcal{F}_{score}$ such that at each state $\hat{s}_i$, $a_i^* \in A'$ is ranked higher than all other actions in A', where $A' \subseteq A(\hat{s}_i)$ is the set of b actions that remain after pruning.

It is important to note that the distribution of states in the pruned space due to $\mathcal{F}_{prune}$ on the testing data may be somewhat different from those on training data. Therefore, we train our scoring function via cross-validation by training the scoring function on heldout data that was not used to train the pruning function. This methodology is commonly employed in Re-Ranking and Stacking approaches (Collins, 2000; Cohen and de Carvalho, 2005).

Our scoring function learning procedure uses cross validation and consists of the following four steps. First, we divide the training data $\mathcal{D}$ into k folds. Second, we learn k different pruners, where each pruning function $\mathcal{F}^i_{prune}$ is learned using the data from all the folds excluding the i^{th} fold. Third, we generate ranking examples for scoring function learning as described above using each pruning function $\mathcal{F}^i_{prune}$ on the data it was not trained on. Finally, we give the aggregate set of ranking examples $\mathcal{R}$ to a rank learner (e.g., SVM-Rank or LambdaMART) to learn the scoring function $\mathcal{F}_{score}$. See appendix for the pseudocode.

Approximate Optimal Scoring Function. If the learned pruning function is not consistent with the training data, we will encounter states $\hat{s}_i$ that are not on the target path, and we will need some supervision for learning in those cases. As discussed before in Section 5.1, computing an optimal scoring function $\mathcal{F}^*_{score}$ is intractable for combinatorial loss functions that are used for coreference resolution. So we employ an approximate function from existing work that is amenable to evaluate partial outputs (Daumé III, 2006). It is a variant of the ACE scoring function that removes the bipartite matching step from the ACE metric. Moreover this score is computed only on the partial coreference output corresponding to the "after state" s' resulting from taking action a in state s, i.e., $\mathcal{F}^*_{score}(s, a) = \mathcal{F}^*_{score}(s')$. To further simplify the computation, we give uniform weight to the three types of costs: 1) Credit for correct linking, 2) Penalty for incorrect linking, and 3) Penalty for missing links. Intuitively, this is similar to the correct-link count computed only on a subgraph. We direct the reader to (Daumé III, 2006) for more details (see Section 5.5).

6 Experiments and Results

In this section, we evaluate our greedy Prune-and-Score approach on three benchmark corpora – OntoNotes 5.0 (Pradhan et al., 2012), ACE 2004 (NIST, 2004), and MUC6 (MUC6, 1995) – and compare it against the state-of-the-art approaches for coreference resolution. For OntoNotes data, we report the results on both gold mentions and predicted mentions. We also report the results on gold mentions for ACE 2004 and MUC6 data.

6.1 Experimental Setup

Datasets. For OntoNotes corpus, we employ the official split for training, validation, and testing. There are 2802 documents in the training set; 343 documents in the validation set; and 345 documents in the testing set. The ACE 2004 corpus contains 443 documents. We follow the (Culotta et al., 2007; Bengtson and Roth, 2008) split in our experiments by employing 268 documents for training, 68 documents for validation, and 107 documents (ACE2004-CULOTTA-TEST) for testing. We also evaluate our system on the 128 newswire documents in ACE 2004 corpus for a fair comparison with the state-of-the-art. The MUC6 corpus containts 255 documents. We employ the official test set of 30 documents (MUC6-TEST) for testing purposes. From the remaining 225 documents, which includes 195 official training documents and 30 dry-run test documents, we randomly pick 30 documents for validation, and use the remaining ones for training.

Evaluation Metrics. We compute three most popular performance metrics for coreference resolution: MUC (Vilain et al., 1995), B-Cubed (Bagga and Baldwin, 1998), and Entity-based CEAF (CEAF$_{\phi 4}$) (Luo, 2005). As it is commonly done in CoNLL shared tasks (Pradhan et al., 2012), we employ the average F1 score (CoNLL F1) of these three metrics for comparison purposes. We evaluate all the results using the updated version[1] (7.0) of the coreference scorer.

Features. We built[2] our coreference resolver based on the Easy-first coreference system (Stoyanov and Eisner, 2012), which is derived from the Reconcile system (Stoyanov et al., 2010). We essentially employ the same features as in the Easy-first system. However, we provide some high-level details that are necessary for subsequent discussion. Recall that our features $\phi(s, a)$ for both pruning and scoring functions are defined over state-action pairs, where each state s consists of a set of clusters and an action a corresponds to merging an unprocessed mention m with a cluster C in state s or create one for itself. Therefore, $\phi(s, a)$ defines features over cluster-mention pairs (C, m). Our feature vector consists of three parts: a) mention pair features; b) entity pair features; and c) a single indicator feature to represent NEW action (i.e., mention m starts its own cluster). For mention pair features, we average the pair-wise features over all links between m and every mention m_c in cluster C (often referred to as *average-link*). Note that, we cannot employ the *best-link* feature representation because we perform offline training and do not have weights for scoring the links. For entity pair features, we treat mention m as a singleton entity and compute features by pairing it with the entity represented by cluster C (exactly as in the Easy-first system). The indicator feature will be 1 for the NEW action and 0 for all other actions.We have a total of 140 features: 90 mention pair features; 49 entity pair features; and one NEW indicator feature. We believe that our approach can benefit from employing features of the mention for the NEW action (Rahman and Ng, 2011b; Durrett and Klein, 2013). However, we were constrained by the Reconcile system and could not leverage these features for the NEW action.

Base Rank-Learner. Our pruning and scoring function learning algorithms need a base rank-learner. We employ LambdaMART (Burges, 2010), a state-of-the art rank learner from the RankLib[3] library. LambdaMART is a variant of boosted regression trees. We use a learning rate of 0.1, specify the maximum number of boosting iterations (or trees) as 1000 noting that its actual value is automatically decided based on the validation set, and tune the number of leaves per tree based on the validation data. Once we fix the hyper-parameters of LambdaMART, we train the final model on all of the training data. LambdaMART uses an internal train/validation split of the input ranking examples to decide when to stop the boosting iterations. We fixed this ratio to 0.8 noting that the performance is not sensitive to this parameter. For scoring function learning, we used 5 folds for the cross-validation training.

Pruning Parameter b. The hyper-parameter b controls the amount of pruning in our Prune-and-Score approach. We perform experiments with different values of b and pick the best value based on the performance on the validation set.

Singleton Mention Filter for OntoNotes Corpus. We employ the Illinois-Coref system (Chang et al., 2012) to extract system mentions for our OntoNotes experiments, and observe that the num-

[1] http://code.google.com/p/reference-coreference-scorers/

[2] See http://research.engr.oregonstate.edu/dral/ for our software.

[3] http://sourceforge.net/p/lemur/wiki/RankLib/

ber of predicted mentions is thrice the number of gold mentions. Since the training data provides the clustering supervision for only gold mentions, it is not clear how to train with the system mentions that are not part of gold mentions. A common way of dealing with this problem is to treat all the extra system mentions as singleton clusters (Durrett and Klein, 2013; Chang et al., 2013). However, this solution most likely will not work with our current feature representation (i.e., NEW action is represented as a single indicator feature). Recall that to predict these extra system mentions as singleton clusters with our incremental clustering approach, the learned model should first predict a NEW action while processing these mentions to form a temporary singleton cluster, and then refrain from merging any of the subsequent mentions with that cluster so that it becomes a singleton cluster in the final clustering output. However, in OntoNotes corpus, the training data does not include singleton clusters for the gold mentions. Therefore, only the large number (57%) of system mentions that are not part of gold mentions will constitute the set of singleton clusters. This leads to a highly imbalanced learning problem because our model needs to learn (the weight of the single indicator feature) to predict NEW as the best action for a large set of mentions, which will bias our model to predict large number of NEW actions during testing. As a result, we will generate many singleton clusters, which will hurt the recall of the mention detection after post-processing. Therefore, we aim to learn a singleton mention filter that will be used as a pre-processor before training and testing to overcome this problem. We would like to point out that our filter is complementary to other solutions (e.g., employing features that can discriminate a given mention to be anaphoric or not in place of our single indicator feature, or using a customized loss to weight our ranking examples for cost-sensitive training)(Durrett and Klein, 2013).

Filter Learning. The singleton mention filter is a classifier that will label a given mention as "singleton" or not. We represent each mention m in a document by averaging the mention-pair features $\phi(m, m')$ of the k-most similar mentions (obtained by ranking all other mentions m' in the document with a learned ranking function R given m) and then learn a decision-tree classifier by optimizing the F1 loss. We learn the mention-ranking function R by optimizing the recall of positive pairs for a given k, and employ LambdaMART as our base ranker. The hyper-parameters are tuned based on the performance on the validation set.

6.2 Results

We first describe the results of the learned singleton mention filter, and then the performance of our Prune-and-Score approach with and without the filter. Next, we compare the results of our approach with several state-of-the-art approaches for coreference resolution.

Singleton Mention Filter Results. Table 1 shows the performance of the learned singleton mention filter with $k = 2$ noting that the results are robust for all values of $k \geq 2$. As we can see, the learned filter improves the precision of the mention detection with only small loss in the recall of gold mentions.

	Mention Detection Accuracy		
	P	R	F1
Before-filtering	43.18% (16664/38596)	86.99% (16664/19156)	57.71%
After-filtering	79.02% (15516/19640)	80.98% (15516/19156)	79.97%

Table 1: Performance of the singleton mention filter on the OntoNotes 5.0 development set. The numerators of the fractions in the brackets show the exact numbers of mentions that are matched with the gold mentions.

Prune-and-Score Results. Table 2 shows the performance of Prune-and-Score approach with and without the singleton mention filter. We can see that the results with filter are much better than the corresponding results without the filter. These results show that our approach can benefit from having a good singleton mention filter.

Filter settings	MUC	B^3	$CEAF_{\phi 4}$	CoNLL
OntoNotes 5.0 Dev Set w. Predict Ment.				
O.S. (w.o. Filter)	66.73	53.40	44.23	54.79
P&S (w.o. Filter)	65.93	52.96	50.24	56.38
P&S (w. Filter)	**71.18**	**58.87**	**57.88**	**62.64**

Table 2: Performance of Prune-and-Score approach with and without the singleton mention filter, and Only-Score approach without the filter.

Table 3 shows the performance of different configurations of our Prune-and-Score approach. As we can see, Prune-and-Score gives better results than the configuration where we employ only the scoring function ($b = \infty$) for small values of b.

Table 4: Comparison of Prune-and-Score with state-of-the-art approaches. Metric values reflect version 7 of CoNLL scorer.

The performance is clearly better than the degenerate case ($b = \infty$) over a wide range of b values, suggesting that it is not necessary to carefully tune the parameter b.

Pruning param. b	MUC	B^3	$CEAF_{\phi4}$	CoNLL
OntoNotes 5.0 Dev Set w. Predict Ment.				
2	69.12	56.80	56.30	60.74
3	70.50	57.89	57.24	61.88
4	71.00	58.65	57.41	62.35
5	**71.18**	**58.87**	**57.88**	**62.64**
6	70.93	58.66	57.85	62.48
8	70.12	58.13	57.37	61.87
10	70.24	58.34	56.27	61.61
20	67.97	57.73	56.63	60.78
∞	67.03	56.31	55.56	59.63

Table 3: Performance of Prune-and-Score approach with different values of the pruning parameter b. For $b = \infty$, Prune-and-Score becomes an Only-Scoring algorithm.

Comparison to State-of-the-Art. Table 4 shows the results of our **Prune-and-Score** approach compared with the following state-of-the-art coreference resolution approaches: **HOTCoref** system (Björkelund and Kuhn, 2014); **Berkeley** system with the FINAL feature set (Durrett and Klein, 2013); **CPL^3M** system (Chang et al., 2013); **Stanford** system (Lee et al., 2013); **Easy-first** system (Stoyanov and Eisner, 2012); and **Fernandes et al., 2012** (Fernandes et al., 2012). **Only Scoring** is the special case of our Prune-and-Score approach where we employ only the scoring function. This corresponds to existing incremental approaches (Daumé III, 2006; Rahman and Ng, 2011b). We report the best published results for CPL^3M system, Easy-first, and Fernandes et al., 2012. We ran the publicly available software to generate the results for Berkeley and Stanford systems with the updated CoNLL scorer. We include the results of Prune-and-Score for best b on the development set with singleton mention filter for the comparison. In Table 4, '-' indicates that we could not find published results for those cases. We see

that results of the Prune-and-Score approach are comparable to or better than the state-of-the-art including Only-Scoring.

7 Conclusions and Future Work

We introduced the Prune-and-Score approach for greedy coreference resolution whose main idea is to learn a pruning function along with a scoring function to effectively guide the search. We showed that our approach improves over the methods that only learn a scoring function, and gives comparable or better results than several state-of-the-art coreference resolution systems.

Our Prune-and-Score approach is a particular instantiation of the general idea of learning nearly-sound constraints for pruning, and leveraging the learned constraints to learn improved heuristic functions for guiding the search (See (Chen et al., 2014) for another instantiation of this idea for multi-object tracking in videos). Therefore, other coreference resolution systems (Chang et al., 2013; Durrett and Klein, 2013; Björkelund and Kuhn, 2014) can also benefit from this idea. One way to further improve the peformance of our approach is to perform a search in the Limited Discrepancy Search (LDS) space (Doppa et al., 2014b) using the learned functions.

Future work should apply this general idea to other natural language processing tasks including dependency parsing (Nivre et al., 2007) and information extraction (Li et al., 2013). We would expect more beneficial behavior with the pruning constraints for problems with large action sets (e.g., labeled dependency parsing). It would be interesting and useful to generalize this approach to search spaces where there are multiple target paths from the initial state to the terminal state, e.g., as in the Easy-first framework.

Acknowledgments

Authors would like to thank Veselin Stoyanov (JHU) for answering several questions related to the Easy-first and Reconcile systems; Van Dang (UMass, Amherst) for technical discussions related to the RankLib library; Kai-Wei Chang (UIUC) for the help related to the Illinois-Coref mention extractor; and Greg Durrett (UC Berkeley) for his help with the Berkeley system. Abstract

A typical discussion thread in an online forum spans multiple pages involving participation from multiple users and thus, may contain multiple view-points and solutions. A user interested in the topic of discussion or having a problem similar to being discussed in the thread may not want to read all the previous posts but only a few selected posts that provide her a concise summary of the ongoing discussion. This paper describes an extractive summarization technique that uses textual features and dialog act information of individual messages to select a subset of posts. Proposed approach is evaluated using two real life forum datasets.

1 Introduction

In recent times, online discussion boards (or *forums*) have become quite popular as they provide an easily accessible platform to users in different parts of the world to come together, share information and discuss issues of common interest. The archives of web forums contain millions of discussion threads and act as a valuable repository of human generated information that can be utilized for various applications. Oftentimes, the discussions in a thread span multiple pages involving participation from multiple users and thus, may contain multiple view-points and solutions. In such a case, the end-user may prefer a concise summary of the ongoing discussion to save time. Further, such a summary helps the user to understand the background of the whole discussion as well as provides an overview of different view-points in a time efficient manner. In addition to generic forums on the web, automatic forum summarization methods can prove to be useful for various domain specific applications, such as helping students and supporting tutors in virtual learning environments (Carbonaro, 2010).

A typical discussion thread in a web forum consists of a number of individual *posts* or messages posted by different participating users. Often, the thread initiator posts a question to which other users reply, leading to an active discussion. As an example, consider the discussion thread shown in Figure 1 where the thread starter describes his problem about the missing headphone switch in his Linux installation. In the third post in the thread, some other user asks about some clarifying details and in the next post the topic starter provides the requested details that makes the problem clearer. On receiving additional details about the problem, some other user provides a possible solution to the problem (fifth post). The topic starter tries the suggested solution and reports his experience in the next post (sixth post). Thus, we see that each individual post in a discussion thread serves a different purpose in the discussion and we posit that *identifying the purpose of each such post is essential for creating effective summaries of the discussions.* Intuitively, the most important messages in a discussion are the ones that describe the problem being discussed and the solutions being proposed to solve the problem.

The *role* of an individual message in a discussion is typically specified in terms of *dialog acts*. There have been efforts to automatically assign dialog acts to messages in online forum discussions (Jeong et al., 2009; Joty et al., 2011; Bhatia et al., 2012) and also using dialog acts for linguistic analysis of forum data, such as in subjectivity analysis of forum threads (Biyani et al., 2012; Biyani et al., 2014). In this paper, we describe our initial efforts towards addressing the problem of *automatically creating summaries of such online discussion threads*. We frame forum summarization as a classification problem and identify messages that should be included in a summary of the

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2127–2131,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

discussion. In addition to textual features, we employ dialog act labels of individual messages for summarization and show that incorporating dialog acts leads to substantial improvements in summarization performance.

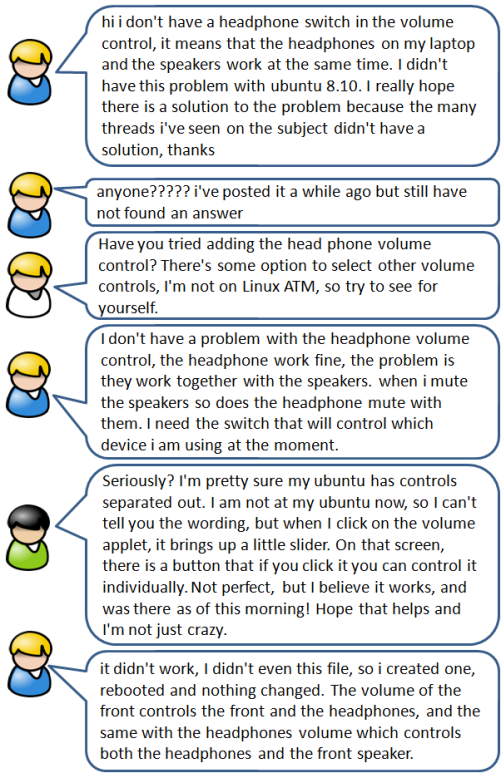

Figure 1: An example thread illustrating different role played by each post in the discussion. Different users are indicated by different colors.

2 Definition of Dialog Acts Used

We use the same set of dialog acts as defined by Bhatia et al. (2012). Note that based on the application context and requirements new dialog acts can be defined and added.

1. Question: The poster asks a question which initiates discussion in the thread. This is usually the first post in the thread but not always. Often, the topic initiator or some other user may ask other related questions in the thread.

2. Repeat Question: Some user repeats a previously asked question (e.g. *Me too having the same problem.*).

3. Clarification: The poster asks clarifying questions in order to gather more details about the problem or question being asked. For example, *Could you provide more details about the issue you are facing*.

4. Further Details: The poster provides more details about the problem as asked by other fellow posters.

5. Solution: The poster suggests a solution to the problem being discussed in the thread.

6. Positive Feedback: Somebody tries the suggested solution and provides a positive feedback if the solution worked.

7. Negative Feedback: Somebody tries the suggested solution and provides a negative feedback if the solution did not work.

8. Junk: There is no useful information in the post. For example, someone justs posts a smiley or some comments that is not useful to topic being discussed. For example, *"bump", "sigh"*, etc., or messages posted by forum moderators such as *this thread is being closed for discussion.*

3 Proposed Approach for Thread Summarization

In general, text summarization techniques can be classified into two categories, namely extractive Summarization, and Abstractive Summarization (Hahn and Mani, 2000). Extractive summarization involves extracting salient units of text (e.g., sentences) from the document and then concatenating them to form a shorter version of the document. Abstractive summarization, on the other hand, involves generating new sentences by utilizing the information extracted from the document corpus (Carenini and Cheung, 2008), and often involves advanced natural language processing tools such as parsers, lexicons and grammars, and domain-specific knowledge bases (Hahn and Mani, 2000). Owing to their simplicity and good performance, extractive summarization techniques are often the preferred tools of choice for various summarization tasks (Liu and Liu, 2009) and we also adopt an extractive approach for discussion summarization in this work.

3.1 Summarization Unit – Individual Sentence vs Individual Message

Before we can perform extractive summarization on discussion threads, we need to define an appropriate text unit that will be used to construct the desired summaries. For typical summarization tasks, a sentence is usually treated as a unit of text and summaries are constructed by extracting most relevant sentences from a document. However, a typical discussion thread is different from

a generic document in that the text of a discussion thread is created by multiple authors (users participating in the thread). Further, the text of a discussion can be divided into individual user messages, each message serving a specific role in the whole discussion. In that sense, summarizing a discussion thread is similar to the task of multi-document summarization where content of multiple documents that are topically related is summarized simultaneously to construct an inclusive, coherent summary. However, we also note that an individual user message in a discussion is much smaller than a stand-alone document (compare $3 \sim 4$ sentences in a message to a few dozen sentences in a document). Thus, the sentences in a message are much more coherent and contextually related to each other than in a stand-alone document. Hence, selecting just a few sentences from a message may lead to loss of context and make the resulting summaries hard to comprehend. Therefore, in this work, we choose each individual message as a text unit and thus, the thread summaries are created by extracting most relevant posts from a discussion.

3.2 Framing Thread Summarization as Post Classification

We consider the problem of extracting relevant posts from a discussion thread as a binary classification problem where the task is to classify a given post as either belonging to the summary or not. We perform classification in a supervised fashion by employing following features.

1. Similarity with Title (TitleSim): This feature is computed as the cosine similarity score between the post and the title of the thread.

2. Length of Post (Length): The number of unique words in the post.

3. Post Position (Position): The normalized position of the post in the discussion thread. It is defined as follows:

$$\frac{\text{Position of the post in the thread}}{\text{Total \# of posts in the thread}} \quad (1)$$

4. Centroid Similarity (Centroid): This feature is obtained by computing the cosine similarity score between the post document vector and the vector obtained as the centroid of all the post vectors of the thread. Similarity with centroid measures the *relatedness* of each post with the underlying discussion topic. A post with a higher similarity score with the thread centroid vector indicates that the post better represents the basic ideas of the thread.

5. Inter Post Similarity: This feature is computed by taking the mean of the post's cosine similarity scores with all the other posts in the thread.

6. Dialog Act Label (Class): This is a set of binary features indicating the dialog act class label of the post. We have one binary feature corresponding to each dialog act.

4 Experimental Evaluation

4.1 Data Description

We used the dataset used by Bhatia et al. (2012) that consists of randomly sampled 100 threads from two different online discussion forums – `ubuntuforums.org` and `tripadvisor.com`. There are a total of 556 posts in the 100 threads from Ubuntu dataset and 916 posts in 100 threads from NYC dataset. The associated dialog act labels of individual messages in each of the threads are also available.

Next, for creating data for the summarization task, two independent human evaluators (H1 and H2) were recruited to create summaries of the discussion threads in the two datasets. For each thread, the evaluators were asked to read the whole discussion and write a summary of the discussion in their own words. The annotators were requested to keep the length of summaries roughly between 10% and 25% of the original text length. Thus for each thread, we obtain two human written summaries.

These hand-written summaries were then used to identify most relevant posts in a discussion thread in a manner similar to one used by Rambow et al. (2004). We compute cosine similarity scores for each post in the thread with the corresponding thread summary and the top k ranked posts are then selected to be part of the summary of the thread. The number k is determined by the compression factor used for creating summaries. We choose a compression factor of 20%. The top k ranked posts, thus constitute the gold summary of each thread. Note that we obtain two gold summaries for each thread – one corresponding to each evaluator. This summarization data can be downloaded for research purposes from `http://sumitbhatia.net/source/datasets.html`.

Evaluator	Method	Ubuntu		NYC	
		Precision	F-1	Precision	F-1
H1	Baseline	0.39	0.53	0.32	0.46
	Without Dialog Acts	0.578	0.536	0.739	0.607
	With Dialog Acts	0.620	0.608	0.760	0.655
	Gain	+7.27%	+13.43%	+2.84%	+7.91%
H2	Baseline	0.38	0.52	0.31	0.45
	Without Dialog Acts	0.739	0.607	0.588	0.561
	With Dialog Acts	0.760	0.655	0.652	0.588
	Gain	+14.94%	+20.53%	+10.88%	+4.81%

Table 1: Results of post classification for summarization task. H1 and H2 correspond to the two human evaluators. Percentage improvements obtained by addition of post class label information is also reported.

4.2 Baseline

As a baseline method, we use a rule based classifier that classifies all the *Question* and *Solution* posts in a thread as belonging to the summary and discards the remaining posts.

4.3 Results and Discussions

We used Naive Bayes classifier as implemented in the Weka machine learning toolkit (Hall et al., 2009) for classification experiments. We trained the classifier on 75% of the data and used the remaining 25% for testing. Table 1 reports the classification results using *(i)* the baseline method,*(ii)* features 1–5 only, and *(iii)* using all the features (dialog act labels, in addition to the five features). For both the datasets, we observe that incorporating dialog act information along with textual features results in performance gain across all reported metrics. The strong performance improvements achieved for the two datasets corroborate the proposed hypothesis that knowing the role of each individual message in an online discussion can help create better summaries of discussion threads. Further, we observe that the precision values are very low for the baseline algorithm (from 0.31 to 0.39) with moderate F-1 values (0.45 to 0.53), indicating a higher recall. This means that even though many of the posts in the gold summaries belong to question and solution categories, not all the posts belonging to these two categories are useful for summarization. Using textual features and dialog act labels in a supervised machine learning framework captures the distinguishing characteristics of *in-summary* and *out of summary* posts and thus, yields a much better classification performance.

5 Related Work

Among various applications of text summarization, work on E-Mail thread summarization (Rambow et al., 2004; Cohen et al., 2004) can be considered as closely related to the problem discussed in this paper. An E-Mail thread is similar to a forum discussion thread in that it involves back and forth communication with the participants, however, the problem of discussion thread summarization is very different (and difficult) due to a relatively larger number of participants, highly informal and noisy language, and frequent topic drifts in discussions. Zhou and Hovy (2005) identify clusters in internet relay chats (irc) and then employ lexical and structural features to summarize each cluster. Ren et al. (2011) have proposed a forum summarization algorithm that models the reply structures in a discussion thread.

6 Conclusions and Future Work

We proposed that dialog act labels of individual messages in an online forums can be helpful in summarizing discussion threads. We framed discussion thread summarization as a binary classification problem and tested our hypothesis on two different datasets. We found that for both the datasets, incorporating dialog act information as features improves classification performance as measured in terms of precision and F-1 measure. As future work, we plan to explore various other forum specific features such as user reputation and quality of content to improve summarization performance.
