Preface by the General Chair

Welcome to the 2014 Conference on Empirical Methods in Natural Language Processing.

The EMNLP conference series is annually organized by SIGDAT, the Association for Computational Linguistics' special interest group on linguistic data and corpus-based approaches to NLP. This year the conference is being held from October 25, 2014 (Sat.) to October 29, 2014 (Wed.) in Doha, Qatar.

In the past five years, the EMNLP conference attendance has been continuously growing, reaching just over 500 paying attendees in 2013, and it is nowadays considered as one of the leading conferences in Computational Linguistics and Natural Language Processing.

Given the growing trend, we believed it was the right time to lead EMNLP into an organization structure typical of large and important conferences. Therefore, we proposed several novelties: first of all, a large organization committee consisting of twenty (plus twenty-six area chairs) well-known members of the ACL community, who carried out several tasks required by the new achieved scale.

Secondly, as this is the first conference edition spanning five days, in addition to six workshops, we also selected and included for the first time an excellent selection of eight tutorials. We defined a registration policy that allows the participants to attend any of the tutorials and workshops (held on October 25th and 29th) by just paying a low flat rate on top of the registration fee for the main conference. We believe this can greatly increase the spread of advanced technology and promote a unified view of the techniques and foundations of our research field.

Thirdly, as a standalone conference, EMNLP required the definition of new administrative procedures and policies, regarding sponsorship booklets, double submission, scholarship assignment, and the joint EACL-ACL-EMNLP call for workshop proposals.

Next, EMNLP is finding new ways to foster the dissemination of research work by facing the increasing number of papers to be presented at the conference. Our new approach consisted in presenting posters in nine sessions each proposing a small numbers of papers: this way poster presentations can receive the space and consideration that they deserve. Then, we are adding a surprise in terms of paper presentation and dissemination, which will be unveiled only few days before the start of the conference.

Finally, this is the first time that an ACL conference is largely supported by a government research foundation. The Qatar National Research Foundation (QNRF) has included EMNLP 2014 as one of its local funding events. This enabled EMNLP and SIGDAT to perform unprecedented student scholarship support: more than 30 students were sponsored (partially or entirely) for participating in the conference. The obtained funds also allowed for offering a social dinner free of charge to all the attendees and still closing the conference budget in active, thus creating additional resources that SIGDAT can use to support the upcoming conferences.

The novelties above as well as the traditional activities that the EMNLP conference series proposes to its members could not have been organized without the work of our large committee. In this respect, I would like to thank our PC co-chairs Walter Daelemans and Bo Pang, who greatly used their large experience with program committees of our community for selecting an excellent program.

Special thanks go to our publication chair Yuval Marton, who did a terrific job in organizing and preparing the proceedings. As a side effect of his proactive action, workshop organizers and future publication chairs using the SoftConf START/ACLPUB systems can now streamline the inclusion of workshops and conference schedules in the proceedings, without heavy manual customization.

We are very grateful to Enrique Alfonseca and Eric Gaussier for selecting interesting and successful

workshops and to Lucia Specia and Xavier Carreras, who, for the first time, carried out the new task of selecting tutorials for an EMNLP conference. The workshops and tutorials nicely filled the additional two days of EMNLP, making our conference even more valuable.

Many thanks are due to Katrin Erk and Sebastian Padó, who were challenged by the new activity (for EMNLP) of defining policy for the selection and assignment of participation scholarships to the most deserving students. The uncertainty over the final amount of funds and their diverse nature made this task particularly difficult. Nevertheless, they were able to find appropriate and successful solutions.

As any large conference, we could count on the help of publicity co-chairs to advertise the old and new EMNLP features. We give our gratitude to Mona Diab and Irina Matveeva for their professional work.

Fund hunting is a very important activity for conferences, in this respect, I would like to thank our sponsorship co-chairs, Jochen Leidner, Veselin Stoyanov and Min Zhang, for helping us to look for sponsors in three different continents.

Regarding the SIGDAT side, a special thank is devoted to Noah Smith, who promptly answered any question I came out with. I am also grateful to the other SIGDAT officers (past and new): Eugene Charniak, Mark Johnson, Philipp Koehn, Mark Steedman, who were always there to give suggestions and solutions to critical issues that inevitably arise in any large event.

Many thanks also to Tim Baldwin, Anna Korhonen, Graeme Hirst and David Yarowsky who provided much useful information from past conferences. Last but not least, I would like to thank Priscilla Rasmussen for her help and advice, and her undoubtful qualities of soothsayer regarding the estimation of conference numbers.

Coming back to the sponsor topic, we are enormously thankful to QNRF, for accepting our proposal to fund EMNLP: this has made it possible to sponsor an unprecedented number of students and offer a banquet free of charge to all participants (we needed to create a new level of sponsorship for them, namely, Diamond). We are very grateful to The Qatar Computing Research Institute, which in addition to providing the very valuable Platinum sponsorship, also provided the required man power for organizing the event.

In particular, EMNLP could not be organized in Qatar without the work of Kareem Darwish, the local organization chair. We are also very grateful to Kemal Oflazer, local co-chair and Francisco Guzman Herrera, local sponsorship chair, whose work was determinant to obtain the QNRF sponsorship. We are deeply in debt with the other local organizers, Lluís Màrquez, who also edited the conference booklet, Preslav Nakov, Fabrizio Sebastiani and Stephan Vogel for their help with the daily big and little issues.

Special thanks go to The Carnegie Mellon University in Qatar for helping us with the proposal preparation and management of the QNRF funds and also for supporting us with a Gold sponsorship. Additionally, many thanks go to our silver sponsors, Facebook and Yandex and our bronze sponsor iHorizons, who show the increasing interest of industry in the technology of our community for the design of real-world and high-societal impact applications. In this respect, we sincerely thank Google Inc. and IBM Watson, New York, for supporting the student participation with their scholarships.

Finally, and foremost, thanks to all the authors and conference attendees who are the main actors of this event, bringing the real value to it and determining its success. My personal thanks also go to the entire SIGDAT committee, for choosing me as the chair of this fantastic conference, held in a fascinating venue.

Alessandro Moschitti

General Chair of EMNLP 2014

Preface by the Program Committee Co-Chairs

We welcome you to the 2014 Conference on Empirical Methods in Natural Language Processing.

As in the previous EMNLP, we invited both long and short papers with a single submission deadline. Short papers encourage the submission of smaller and more preliminary contributions.

We received 790 submissions (after initial withdrawals of unfinished submissions and removal of duplicates), of which 28 were rejected before review for not adhering to the instructions in the call for papers regarding paper length or anonymity. The remaining 510 long and 252 short papers were allocated to one of the fourteen areas. The most popular areas this year were Machine Translation, Semantics, and Syntax (Tagging, Chunking, and Parsing).

Reviewing for a conference this size involves an army of dedicated professionals volunteering to donate their valuable and scarce time to make sure that the highest possible reviewing standards are reached. We are very grateful to our 26 area chairs and a programme committee of more than 500 for their efforts. We accepted 155 long and 70 short papers, representing a global acceptance rate of just under 30%. Nine papers accepted by the ACL journal TACL were added to the program.

Based on the reviews and on nominations by the area chairs, 5 long papers were shortlisted for the best paper award. The best paper will be presented in a plenary best paper award ceremony. We would like to thank Mark Johnson and Claire Cardie for their willingness to serve in the best paper award committee that was set up and for providing excellent advice and motivation for their choice.

We are grateful to the authors for selecting EMNLP as the venue for their work. Congratulations to the authors of accepted submissions. To the authors of rejected submissions we would like to offer as consolation the fact that because of the competitive nature of the conference and the inevitable time and space limitations, many worthwhile papers could not be included in the program. We hope the feedback of the reviewers will be considered worthwhile by them and lead to successful future submissions.

We are very grateful to our invited speakers Thorsten Joachims and Salim Roukos. Thorsten Joachims is professor at the Computer Science and Information Science departments at Cornell University and shows how integrating microeconomic models of human behavior into the learning process leads to new interaction models and learning algorithms, in turn leading to better performing systems. Salim Roukos is senior manager of multilingual NLP and CTO of Translation Technologies at IBM T.J. Watson research Center and addresses IBM's approach to cognitive computing for building systems and solutions that enable and support richer human-machine interactions, and remaining opportunities in this area for novel statistical models for natural language processing. We thank them for their inspiring talks and presence at the conference.

We would also like to thank our general chair Alessandro Moschitti for his leadership, advice, encouragement, and support, Kareem Darwish and his colleagues for impeccable cooperation from local organization, and Yuval Marton for doing an excellent job assembling these proceedings.

It was an honour to serve as Programme Chairs of EMNLP 2014, and we hope that you will enjoy the conference and be able to think back later and remember a scientifically stimulating conference and a pleasant time in Doha, Qatar.

Bo Pang and Walter Daelemans

EMNLP 2014 Program Chairs

Organizers:

General Conference Chair

Alessandro Moschitti, Qatar Computing Research Institute

Program Committee Co-Chairs

Walter Daelemans, University of Antwerp
Bo Pang, Google

Workshops Co-Chairs

Enrique Alfonseca, Google Research at Zurich
Eric Gaussier, Université Joseph Fourier (Grenoble I)

Tutorial Co-Chairs

Lucia Specia, University of Sheffield
Xavier Carreras, Universitat Politècnica de Catalunya

Publication Chair

Yuval Marton, Microsoft Corporation

Publicity Co-Chairs

Mona Diab, George Washington University
Irina Matveeva, NexLP

Sponsorship Co-Chairs

Jochen Leidner, Thomson Reuters
Veselin Stoyanov, Facebook
Min Zhang, Soochow University

Student Scholarship Co-Chairs

Katrin Erk, University of Texas at Austin
Sebastian Padó, University of Stuttgart

Reviewing Coordinators

Mark Dredze, Johns Hopkins University
Jiang Guo (Student Volunteer), Harbin Institute of Technology

Area Chairs

Phonology, Morphology, and Segmentation
Tomaž Erjavec, Jožef Stefan Institute

Tagging, Chunking, Syntax and Parsing
Gosse Bouma, University of Groningen
Yuji Matsumoto, Nara Institute of Science and Technology

Discourse, Dialogue, and Pragmatics
Jennifer Chu-Carroll, IBM Watson Research Center
Olga Uryupina, University of Trento

Semantics
Rada Mihalcea, University of Michigan
Sameer Pradhan, Harvard Medical School

Summarization and Generation
Anja Belz, University of Brighton
Dilek Hakkani-Tür, Microsoft Research

NLP-related Machine Learning: theory, methods and algorithms
Ivan Titov, University of Amsterdam
Jerry Zhu, University of Wisconsin-Madison

Machine Translation
Chris Callison-Burch, University of Pennsylvania
Dan Gildea, University of Rochester

Information Retrieval, Text Categorization, and Question Answering
Sien Moens, Katholieke Universiteit Leuven
Hinrich Schütze, Ludwig Maximilian University of Munich

Information Extraction
Doug Downey, Northwestern University
Marius Pasca, Google

Text Mining and Natural Language Processing Applications
Massimiliano Ciaramita, Google
Hwee Tou Ng, National University of Singapore

Sentiment Analysis and Opinion Mining
Yejin Choi, Stony Brook University
Minlie Huang, Tsinghua University

NLP for the Web and Social Media
Irwin King, The Chinese University of Hong Kong
Qiaozhu Mei, University of Michigan

Spoken Language Processing
Pascale Fung, Hong Kong University of Science and Technology
Hugo Van hamme, Katholieke Universiteit Leuven

Computational Psycholinguistics
Sharon Goldwater, University of Edinburgh

Local Organization

Local Arrangements Co-Chairs
Kareem Darwish, Qatar Computing Research Institute
Kemal Oflazer, Carnegie Mellon University – Qatar

Local Sponsorship Chair
Francisco Guzmán, Qatar Computing Research Institute

Conference Handbook Editor
Lluís Màrquez, Qatar Computing Research Institute

Local Organizing Committee
Preslav Nakov, Qatar Computing Research Institute
Fabrizio Sebastiani, Qatar Computing Research Institute

Local QCRI Administration
Kimberly Mathern, Qatar Computing Research Institute
Lawrence Tingson, Qatar Computing Research Institute
Jacqueline Caparas, Qatar Computing Research Institute

Program Committee:

Omri Abend, The University of Edinburgh; Amjad Abu-Jbara, University of Michigan; Eneko Agirre, University of the Basque Country; Cem Akkaya, University of Pittsburgh; Iñaki Alegria, University of the Basque Country (UPV/EHU); Nikolaos Aletras, University of Sheffield; Enrique

Alfonseca, Google; James Allan, University of Massachusetts Amherst; Alexander Allauzen, Université Paris-Sud / LIMSI-CNRS; Waleed Ammar, CMU; David Andrzejewski, Sumo Logic; Gabor Angeli, Stanford University; Stephen Anthony, The University of New South Wales; Jordi Atserias Batalla, Yahoo! Research; Giuseppe Attardi, Università di Pisa; Michael Auli, Microsoft Research; Wilker Aziz, University of Sheffield;

Alexandra Balahur, Joint Research Centre, European Commission; Timothy Baldwin, The University of Melbourne; Borja Balle, UPC; David Bamman, Carnegie Mellon University; Carmen Banea, University of Michigan; Roberto Basili, University of Roma, Tor Vergata; Daniel Beck, University of Sheffield; Kedar Bellare, Facebook; Emily M. Bender, University of Washington; Michael Bendersky, Google; Fabrício Benevenuto, Federal University of Minas Gerais (UFMG); Jonathan Berant, Stanford University; Taylor Berg-Kirkpatrick, UC Berkeley; Nicola Bertoldi, FBK; Steven Bethard, University of Alabama at Birmingham; Chandra Bhagavatula, Northwestern University; Pushpak Bhattacharyya, CSE Department, IIT Bombay; Klinton Bicknell, Northwestern University; Chris Biemann, TU Darmstadt; Alexandra Birch, University of Edinburgh; Arianna Bisazza, University of Amsterdam; Yonatan Bisk, University of Illinois at Urbana-Champaign; Anders Björkelund, IMS, Stuttgart; Graeme Blackwood, IBM Research; Eduardo Blanco, Lymba Corporation; Roi Blanco, Yahoo! Labs; Phil Blunsom, University of Oxford; Bernd Bohnet, University Birmingham; Kalina Bontcheva, University of Sheffield; Houda Bouamor, Carnegie Mellon University; Jordan Boyd-Graber, University of Maryland; Pavel Braslavski, Kontur labs / Ural federal university; Chris Brew, Nuance Communications; Chris Brockett, Microsoft Research; Eric Brown, IBM Research; Paul Buitelaar, INSIGHT, National University of Ireland, Galway; Donna Byron, IBM Watson Solutions;

Aoife Cahill, Educational Testing Service; Erik Cambria, Nanyang Technological University; Marie Candito, Univ Paris Diderot - INRIA - Alpage; Hailong Cao, HIT; Sandra Carberry, University of Delaware; Marine Carpuat, National Research Council; Xavier Carreras, Universitat Politecnica de Catalunya; Francisco Casacuberta, Universitat Politècnica de València; Taylor Cassidy, IBM TJ Watson Research Center; Carlos Castillo, Qatar Computing Research Institute; Asli Celikyilmaz, Microsoft; Daniel Cer, Google; Özlem Çetinoğlu, IMS, University of Stuttgart; Jonathan Chang, Facebook; Berlin Chen, National Taiwan Normal University; Boxing Chen, NRC; Chen Chen, University of Texas at Dallas; Hsin-Hsi Chen, National Taiwan University; John Chen, AT&T Labs-Research; Lin Chen, University of Illinois at Chicago; Colin Cherry, NRC; Jackie Chi Kit Cheung, University of Toronto; David Chiang, USC/ISI; Jinho D. Choi, Emory University; Christos Christodoulopoulos, University of Illinois at Urbana Champaign; Grzegorz Chrupała, Tilburg University; Stephen Clark, University of Cambridge; Shay B. Cohen, University of Edinburgh; Trevor Cohn, University of Melbourne; Gao Cong, Nanyang Technological University; Paul Cook, The University of Melbourne; Bonaventura Coppola, IBM Research;

Additional Reviewers:

Aditya Joshi, Alexander Beloborodov, Ali Elkahky, Alvin Grissom II, Antoine Rozenknop, Burcu Can, Caitlin Richter, Chen Li, Christian Gaida, Dave Carter, Dongwoo Kim, Fandong Meng, Feifei Zhai, Frank Ferraro, Georgeta Bordea, Hadi Amiri, Hector Martinez Alonso, Heng Yu, Henning Wachsmuth, Hugo Escalante, Jacob Andreas, Jan Rygl, Janis Dalins, Jeff Mitchell, Jeffrey Flanigan, Jenna Kanerva, Ji Liu, Ji Ma, JinYeong Bak, Jiri Materna, Jiwei Li, John Wieting, Juhani Luotolahti, Jun Xie, Kai Hakala, Kai Liu, Kepa Sarasola, Kristian Woodsend, Li Dong, Li Wang, Likun Qiu, Loic Barrault, Mark Cusick, Martin Riedl, Michael Voelske, Miikka Silfverberg, Mikael Kågebäck, Milos Jakubicek, Mitchell Koch, Mohamed Yahya, Mohit Iyyer, Muhammad Ibrahim, Muhua Zhu, Nadi Tomeh, Ni Lao, Patrick Lange, Pushpendre Rastogi, Qing Dou, Roy Schwartz, Scott Martin, Shumin Wu, Colorado, Steffen Remus, Suwisa Kaewphan, Tim Rocktaeschel, Tongfei Chen, Travis Wolfe, Veronica Perez-Rosas, Vojtech Kovar, Wei He, Wenbin Jiang, Xutao Li, Zhanyi Liu, Zhaohui Wu, and Zhen Hai.

Invited Speakers:

Salim Roukos, IBM T. J. Watson Research Center

Thorsten Joachims, Cornell University

Table of Contents

Conference Program

Sunday, October 26, 2014

08:00–17:00 ***Registration***

08:00–09:00 ***Refreshments***

Plenary Session

08:40–09:00 *Opening Remarks, QNRF Presentation, Conference Logistics, Paper Selection Process and Statistics*
Alessandro Moschitti, Rekha Pilla, Kareem M. Darwish, and Walter Daelemans

09:00–10:00 Invited Talk: *IBM Cognitive Computing - An NLP Renaissance!*
Salim Roukos

10:00–10:30 ***Coffee Break***

Session 1a: Neural Net Mixer I

10:30–10:55 *Modeling Interestingness with Deep Neural Networks*
Jianfeng Gao, Patrick Pantel, Michael Gamon, Xiaodong He and Li Deng

10:55–11:20 *Translation Modeling with Bidirectional Recurrent Neural Networks*
Martin Sundermeyer, Tamer Alkhouli, Joern Wuebker and Hermann Ney

11:20–11:45 *A Neural Network Approach to Selectional Preference Acquisition*
Tim Van de Cruys

11:45–12:10 *Learning Image Embeddings using Convolutional Neural Networks for Improved Multi-Modal Semantics*
Douwe Kiela and Léon Bottou

Sunday, October 26, 2014 (continued)

Session 1b: Discourse, Dialogue and Pragmatics

10:30–10:55 *Identifying Argumentative Discourse Structures in Persuasive Essays*
Christian Stab and Iryna Gurevych

10:55–11:20 *Policy Learning for Domain Selection in an Extensible Multi-domain Spoken Dialogue System*
Zhuoran Wang, Hongliang Chen, Guanchun Wang, Hao Tian, Hua Wu and Haifeng Wang

11:20–11:45 *A Constituent-Based Approach to Argument Labeling with Joint Inference in Discourse Parsing*
Fang Kong, Hwee Tou Ng and Guodong Zhou

11:45–12:10 *Strongly Incremental Repair Detection*
Julian Hough and Matthew Purver

Session 1c: Segmentation / Spoken Language

10:30–10:55 *Semi-Supervised Chinese Word Segmentation Using Partial-Label Learning With Conditional Random Fields*
Fan Yang and Paul Vozila

10:55–11:20 *Accurate Word Segmentation and POS Tagging for Japanese Microblogs: Corpus Annotation and Joint Modeling with Lexical Normalization*
Nobuhiro Kaji and Masaru Kitsuregawa

11:20–11:45 *Revisiting Embedding Features for Simple Semi-supervised Learning*
Jiang Guo, Wanxiang Che, Haifeng Wang and Ting Liu

11:45–12:10 *Combining Punctuation and Disfluency Prediction: An Empirical Study*
Xuancong Wang, Khe Chai Sim and Hwee Tou Ng

Session 1p: Machine Translation

10:30–12:10 *Poster Session*
Multiple presenters

Submodularity for Data Selection in Machine Translation
Katrin Kirchhoff and Jeff Bilmes

Improve Statistical Machine Translation with Context-Sensitive Bilingual Semantic Embedding Model
Haiyang Wu, Daxiang Dong, Xiaoguang Hu, Dianhai Yu, Wei He, Hua Wu, Haifeng Wang and Ting Liu

Transformation from Discontinuous to Continuous Word Alignment Improves Translation Quality
Zhongjun He, Hua Wu, Haifeng Wang and Ting Liu

Unsupervised Word Alignment Using Frequency Constraint in Posterior Regularized EM
Hidetaka Kamigaito, Taro Watanabe, Hiroya Takamura and Manabu Okumura

Asymmetric Features Of Human Generated Translation
Sauleh Eetemadi and Kristina Toutanova

Syntax-Augmented Machine Translation using Syntax-Label Clustering
Hideya MINO, Taro WATANABE and Eiichiro SUMITA

Testing for Significance of Increased Correlation with Human Judgment
Yvette Graham and Timothy Baldwin

Syntactic SMT Using a Discriminative Text Generation Model
Yue Zhang, Kai Song, Linfeng Song, Jingbo Zhu and Qun Liu

Learning Hierarchical Translation Spans
jingyi zhang, Masao Utiyama, Eiichiro Sumita and Hai Zhao

Neural Network Based Bilingual Language Model Growing for Statistical Machine Translation
Rui Wang, Hai Zhao, Bao-Liang Lu, Masao Utiyama and Eiichiro Sumita

Better Statistical Machine Translation through Linguistic Treatment of Phrasal Verbs
Kostadin Cholakov and Valia Kordoni

Fitting Sentence Level Translation Evaluation with Many Dense Features
Miloš Stanojević and Khalil Sima'an

A Human Judgement Corpus and a Metric for Arabic MT Evaluation
Houda Bouamor, Hanan Alshikhabobakr, Behrang Mohit and Kemal Oflazer

Learning to Differentiate Better from Worse Translations
Francisco Guzmán, Shafiq Joty, Lluís Màrquez, Alessandro Moschitti, Preslav Nakov and Massimo Nicosia

Two Improvements to Left-to-Right Decoding for Hierarchical Phrase-based Machine Translation
Maryam Siahbani and Anoop Sarkar

Reordering Model for Forest-to-String Machine Translation
Martin Cmejrek

12:10–13:30 ***Lunch Break***

Session 2a: Computational Psycholinguistics

13:30–13:55 *Aligning context-based statistical models of language with brain activity during reading*
Leila Wehbe, Ashish Vaswani, Kevin Knight and Tom Mitchell

13:55–14:20 *A Cognitive Model of Semantic Network Learning*
Aida Nematzadeh, Afsaneh Fazly and Suzanne Stevenson

14:20–14:45 *The Benefits of a Model of Annotation*
Rebecca J. Passonneau and Bob Carpenter

14:45–15:10 *Learning Abstract Concept Embeddings from Multi-Modal Data: Since You Probably Can't See What I Mean*
Felix Hill and Anna Korhonen

Session 2b: Tagging, Chunking, Parsing and Syntax

13:30–13:55 *Go Climb a Dependency Tree and Correct the Grammatical Errors*
Longkai Zhang and Houfeng WANG

13:55–14:20 *An Unsupervised Model for Instance Level Subcategorization Acquisition*
Simon Baker, Roi Reichart and Anna Korhonen

14:20–14:45 *Parsing low-resource languages using Gibbs sampling for PCFGs with latent annotations*
Liang Sun, Jason Mielens and Jason Baldridge

14:45–15:10 *Incremental Semantic Role Labeling with Tree Adjoining Grammar*
Ioannis Konstas, Frank Keller, Vera Demberg and Mirella Lapata

Session 2c: NLP for the Web and Social Media

13:30–13:55 *A Graph-based Approach for Contextual Text Normalization*
Cagil Sonmez and Arzucan Ozgur

13:55–14:20 *Entity Linking on Microblogs with Spatial and Temporal Signals*
Yuan Fang and Ming-Wei Chang

14:20–14:45 *ReNoun: Fact Extraction for Nominal Attributes*
Mohamed Yahya, Steven Whang, Rahul Gupta and Alon Halevy

14:45–15:10 *Hierarchical Discriminative Classification for Text-Based Geolocation*
Benjamin Wing and Jason Baldridge

Session 2p: Semantics

13:30–15:10 *Poster Session*
Multiple presenters

Probabilistic Models of Cross-Lingual Semantic Similarity in Context Based on Latent Cross-Lingual Concepts Induced from Comparable Data
Ivan Vulić and Marie-Francine Moens

Multi-Predicate Semantic Role Labeling
Haitong Yang and Chengqing Zong

Werdy: Recognition and Disambiguation of Verbs and Verb Phrases with Syntactic and Semantic Pruning
Luciano Del Corro, Rainer Gemulla and Gerhard Weikum

Multi-Resolution Language Grounding with Weak Supervision
R. Koncel-Kedziorski, Hannaneh Hajishirzi and Ali Farhadi

Incorporating Vector Space Similarity in Random Walk Inference over Knowledge Bases
Matt Gardner, Partha Talukdar, Jayant Krishnamurthy and Tom Mitchell

Composition of Word Representations Improves Semantic Role Labelling
Michael Roth and Kristian Woodsend

Automatic Domain Assignment for Word Sense Alignment
Tommaso Caselli and Carlo Strapparava

Nothing like Good Old Frequency: Studying Context Filters for Distributional Thesauri
Muntsa Padró, Marco Idiart, Aline Villavicencio and Carlos Ramisch

Aligning English Strings with Abstract Meaning Representation Graphs
Nima Pourdamghani, Yang Gao, Ulf Hermjakob and Kevin Knight

A Shortest-path Method for Arc-factored Semantic Role Labeling
Xavier Lluís, Xavier Carreras and Lluís Màrquez

Semantic Kernels for Semantic Parsing
Iman Saleh, Alessandro Moschitti, Preslav Nakov, Lluís Màrquez and Shafiq Joty

Multi-Modal Models for Concrete and Abstract Concept Meaning
Felix Hill, Roi Reichart, Anna Korhonen

An I-vector Based Approach to Compact Multi-Granularity Topic Spaces Representation of Textual Documents
Mohamed Morchid, Mohamed Bouallegue, Richard Dufour, Georges Linares, Driss Matrouf and Renato de Mori

15:10–15:40 ***Coffee Break***

Session 3a: Sentiment Analysis and Opinion Mining

15:40–16:05 *Explaining the Stars: Weighted Multiple-Instance Learning for Aspect-Based Sentiment Analysis*
Nikolaos Pappas and Andrei Popescu-Belis

16:05–16:30 *Sentiment Analysis on the People's Daily*
Jiwei Li and Eduard Hovy

16:30–16:55 *A Joint Segmentation and Classification Framework for Sentiment Analysis*
Duyu Tang, Furu Wei, Bing Qin, Li Dong, Ting Liu and Ming Zhou

16:55–17:20 *Positive Unlabeled Learning for Deceptive Reviews Detection*
yafeng ren, donghong ji and hongbin zhang

Session 3b: Semantics

15:40–16:05 *Resolving Shell Nouns*
Varada Kolhatkar and Graeme Hirst

16:05–16:30 *A Comparison of Selectional Preference Models for Automatic Verb Classification*
Will Roberts and Markus Egg

16:30–16:55 *Learning to Solve Arithmetic Word Problems with Verb Categorization*
Mohammad Javad Hosseini, Hannaneh Hajishirzi, Oren Etzioni and Nate Kushman

16:55–17:20 *NaturalLI: Natural Logic Inference for Common Sense Reasoning*
Gabor Angeli and Christopher D. Manning

Sunday, October 26, 2014 (continued)

Session 3c: Machine Translation

15:40–16:05 *Modeling Term Translation for Document-informed Machine Translation*
Fandong Meng, Deyi Xiong, Wenbin Jiang and Qun Liu

16:05–16:30 *Beyond Parallel Data: Joint Word Alignment and Decipherment Improves Machine Translation*
Qing Dou, Ashish Vaswani and Kevin Knight

16:30–16:55 *Latent Domain Phrase-based Models for Adaptation*
Cuong Hoang and Khalil Sima'an

16:55–17:20 *Translation Rules with Right-Hand Side Lattices*
Fabien Cromieres and Sadao Kurohashi

Session 3p: Information Retrieval, Summarization and Question Answering

15:40–17:20 *Poster Session*
Multiple presenters

Learning to Translate: A Query-Specific Combination Approach for Cross-Lingual Information Retrieval
Ferhan Ture and Elizabeth Boschee

Semantic-Based Multilingual Document Clustering via Tensor Modeling
Salvatore Romeo, Andrea Tagarelli and Dino Ienco

Lexical Substitution for the Medical Domain
Martin Riedl, Michael Glass and Alfio Gliozzo

Question Answering with Subgraph Embeddings
Antoine Bordes, Sumit Chopra and Jason Weston

Correcting Keyboard Layout Errors and Homoglyphs in Queries
Derek Barnes, Mahesh Joshi and Hassan Sawaf

Non-linear Mapping for Improved Identification of 1300+ Languages
Ralf Brown

A Neural Network for Factoid Question Answering over Paragraphs
Mohit Iyyer, Jordan Boyd-Graber, Leonardo Claudino, Richard Socher and Hal Daumé III

Joint Relational Embeddings for Knowledge-based Question Answering
Min-Chul Yang, Nan Duan, Ming Zhou and Hae-Chang Rim

Adding High-Precision Links to Wikipedia
Thanapon Noraset, Chandra Bhagavatula and Doug Downey

Crosslingual and Multilingual Construction of Syntax-Based Vector Space Models
Jason Utt and Sebastian Padó

Finding Good Enough: A Task-Based Evaluation of Query Biased Summarization for Cross-Language Information Retrieval
Jennifer Williams, Sharon Tam and Wade Shen

Chinese Poetry Generation with Recurrent Neural Networks
Xingxing Zhang and Mirella Lapata

Fear the REAPER: A System for Automatic Multi-Document Summarization with Reinforcement Learning
Cody Rioux, Sadid A. Hasan and Yllias Chali

Improving Multi-documents Summarization by Sentence Compression based on Expanded Constituent Parse Trees
Chen Li, Yang Liu, Fei Liu, Lin Zhao and Fuliang Weng

Analyzing Stemming Approaches for Turkish Multi-Document Summarization
Muhammed Yavuz Nuzumlalı and Arzucan Özgür

Monday, October 27, 2014

08:00–17:00 ***Registration***

08:00–09:00 ***Refreshments***

Plenary Session

09:00–10:00 Invited Talk: *Learning from Rational Behavior*
Thorsten Joachims

10:00–10:30 ***Coffee Break***

Session 4a: Neural Net Mixer II

10:30–10:55 *Evaluating Neural Word Representations in Tensor-Based Compositional Settings*
Dmitrijs Milajevs, Dimitri Kartsaklis, Mehrnoosh Sadrzadeh and Matthew Purver

10:55–11:20 *Opinion Mining with Deep Recurrent Neural Networks*
Ozan Irsoy and Claire Cardie

11:20–11:45 *The Inside-Outside Recursive Neural Network model for Dependency Parsing*
Phong Le and Willem Zuidema

11:45–12:10 *A Fast and Accurate Dependency Parser using Neural Networks*
Danqi Chen and Christopher Manning

Session 4b: Discourse, Dialogue and Pragmatics / Summarization and Generation

10:30–10:55 *Why are You Taking this Stance? Identifying and Classifying Reasons in Ideological Debates*
Kazi Saidul Hasan and Vincent Ng

10:55–11:20 *Chinese Zero Pronoun Resolution: An Unsupervised Probabilistic Model Rivaling Supervised Resolvers*
Chen Chen and Vincent Ng

11:20–11:45 *Unsupervised Sentence Enhancement for Automatic Summarization*
Jackie Chi Kit Cheung and Gerald Penn

11:45–12:10 *ReferItGame: Referring to Objects in Photographs of Natural Scenes*
Sahar Kazemzadeh, Vicente Ordonez, Mark Matten and Tamara Berg

Session 4c: Information Extraction

10:30–10:55 *Unsupervised Template Mining for Semantic Category Understanding*
Lei Shi, Shuming Shi, Chin-Yew Lin, Yi-Dong Shen and Yong Rui

10:55–11:20 *Taxonomy Construction Using Syntactic Contextual Evidence*
Tuan Luu Anh, Jung-jae Kim and See Kiong Ng

11:20–11:45 *Analysing recall loss in named entity slot filling*
Glen Pink, Joel Nothman and James R. Curran

11:45–12:10 *Relieving the Computational Bottleneck: Joint Inference for Event Extraction with High-Dimensional Features*
Deepak Venugopal, Chen Chen, Vibhav Gogate and Vincent Ng

Session 4p: Segmentation, Tagging and Parsing

10:30–12:10 *Poster Session*
Multiple presenters

Syllable weight encodes mostly the same information for English word segmentation as dictionary stress
John K Pate and Mark Johnson

A Joint Model for Unsupervised Chinese Word Segmentation
Miaohong Chen, Baobao Chang and Wenzhe Pei

Domain Adaptation for CRF-based Chinese Word Segmentation using Free Annotations
Yijia Liu, Yue Zhang, Wanxiang Che, Ting Liu and Fan Wu

Balanced Korean Word Spacing with Structural SVM
Changki Lee, Edward Choi and Hyunki Kim

Morphological Segmentation for Keyword Spotting
Karthik Narasimhan, Damianos Karakos, Richard Schwartz, Stavros Tsakalidis and Regina Barzilay

What Can We Get From 1000 Tokens? A Case Study of Multilingual POS Tagging For Resource-Poor Languages
Long Duong, Trevor Cohn, Karin Verspoor, Steven Bird and Paul Cook

An Experimental Comparison of Active Learning Strategies for Partially Labeled Sequences
Diego Marcheggiani and Thierry Artières

Language Modeling with Functional Head Constraint for Code Switching Speech Recognition
Ying LI and Pascale Fung

A Polynomial-Time Dynamic Oracle for Non-Projective Dependency Parsing
Carlos Gómez-Rodríguez, Francesco Sartorio and Giorgio Satta

Ambiguity Resolution for Vt-N Structures in Chinese
Yu-Ming Hsieh, Jason S. Chang and Keh-Jiann Chen

Neural Networks Leverage Corpus-wide Information for Part-of-speech Tagging
Yuta Tsuboi

System Combination for Grammatical Error Correction
Raymond Hendy Susanto, Peter Phandi and Hwee Tou Ng

Dependency parsing with latent refinements of part-of-speech tags
Thomas Mueller, Richárd Farkas, Alex Judea, Helmut Schmid and hinrich schuetze

Importance weighting and unsupervised domain adaptation of POS taggers: a negative result
Barbara Plank, Anders Johannsen and Anders Søgaard

POS Tagging of English-Hindi Code-Mixed Social Media Content
Yogarshi Vyas, Spandana Gella, Jatin Sharma, Kalika Bali and Monojit Choudhury

Data Driven Grammatical Error Detection in Transcripts of Children's Speech
Eric Morley, Anna Eva Hallin and Brian Roark

12:10–13:30 ***Lunch Break***

12:50–13:30 ***SIGDAT Business Meeting***

Session 5a: Tagging, Chunking, Parsing and Syntax

13:30–13:55 *Improved CCG Parsing with Semi-supervised Supertagging*
Mike Lewis and Mark Steedman

13:55–14:20 *A* CCG Parsing with a Supertag-factored Model*
Mike Lewis and Mark Steedman

14:20–14:45 *A Dependency Parser for Tweets*
Lingpeng Kong, Nathan Schneider, Swabha Swayamdipta, Archna Bhatia, Chris Dyer and Noah A. Smith

14:45–15:10 *Greed is Good if Randomized: New Inference for Dependency Parsing*
Yuan Zhang, Tao Lei, Regina Barzilay and Tommi Jaakkola

Session 5b: Semantics

13:30–13:55 *A Unified Model for Word Sense Representation and Disambiguation*
Xinxiong Chen, Zhiyuan Liu and Maosong Sun

13:55–14:20 *Reducing Dimensions of Tensors in Type-Driven Distributional Semantics*
Tamara Polajnar, Luana Fagarasan and Stephen Clark

14:20–14:45 *An Etymological Approach to Cross-Language Orthographic Similarity. Application on Romanian*
Alina Maria Ciobanu and Liviu P. Dinu

14:45–15:10 *Efficient Non-parametric Estimation of Multiple Embeddings per Word in Vector Space*
Arvind Neelakantan, Jeevan Shankar, Alexandre Passos and Andrew McCallum

Session 5c: Information Retrieval and Question Answering

13:30–13:55 *Tailor knowledge graph for query understanding: linking intent topics by propagation*
Shi Zhao and Yan Zhang

13:55–14:20 *Queries as a Source of Lexicalized Commonsense Knowledge*
Marius Pasca

14:20–14:45 *Question Answering over Linked Data Using First-order Logic*
Shizhu He, Kang Liu, Yuanzhe Zhang, Liheng Xu and Jun Zhao

14:45–15:10 *Knowledge Graph and Corpus Driven Segmentation and Answer Inference for Telegraphic Entity-seeking Queries*
Mandar Joshi, Uma Sawant and Soumen Chakrabarti

Session 5p: NLP for the Web, Social Media and Sentiment Analysis

13:30–15:10 *Poster Session*
Multiple presenters

A Regularized Competition Model for Question Difficulty Estimation in Community Question Answering Services
Quan Wang, Jing Liu, Bin Wang and Li Guo

Vote Prediction on Comments in Social Polls
Isaac Persing and Vincent Ng

Exploiting Social Relations and Sentiment for Stock Prediction
Jianfeng Si, Arjun Mukherjee, Bing Liu, Sinno Jialin Pan, Qing Li and Huayi Li

Developing Age and Gender Predictive Lexica over Social Media
Maarten Sap, Gregory Park, Johannes Eichstaedt, Margaret Kern, David Stillwell, Michal Kosinski, Lyle Ungar and Hansen Andrew Schwartz

Dependency Parsing for Weibo: An Efficient Probabilistic Logic Programming Approach
William Yang Wang, Lingpeng Kong, Kathryn Mazaitis and William W Cohen

Exploiting Community Emotion for Microblog Event Detection
Gaoyan Ou, Wei Chen, Tengjiao Wang, Zhongyu Wei, Binyang LI, Dongqing Yang and Kam-Fai Wong

Detecting Disagreement in Conversations using Pseudo-Monologic Rhetorical Structure
Kelsey Allen, Giuseppe Carenini and Raymond Ng

+/-EffectWordNet: Sense-level Lexicon Acquisition for Opinion Inference
Yoonjung Choi and Janyce Wiebe

A Sentiment-aligned Topic Model for Product Aspect Rating Prediction
Hao Wang and Martin Ester

Learning Emotion Indicators from Tweets: Hashtags, Hashtag Patterns, and Phrases
Ashequl Qadir and Ellen Riloff

Fine-Grained Contextual Predictions for Hard Sentiment Words
Sebastian Ebert and Hinrich Schütze

An Iterative Link-based Method for Parallel Web Page Mining
Le Liu, Yu Hong, Jun Lu, Jun Lang, Heng Ji and Jianmin Yao

Exploiting Social Network Structure for Person-to-Person Sentiment Analysis
Robert West, Hristo Paskov, Jure Leskovec, Christopher Potts

15:10–15:40 ***Coffee Break***

Session 6a: Machine Translation

15:40–16:05 *Human Effort and Machine Learnability in Computer Aided Translation*
Spence Green, Sida I. Wang, Jason Chuang, Jeffrey Heer, Sebastian Schuster and Christopher D. Manning

16:05–16:30 *Exact Decoding for Phrase-Based Statistical Machine Translation*
Wilker Aziz, Marc Dymetman and Lucia Specia

16:30–16:55 *Large-scale Expected BLEU Training of Phrase-based Reordering Models*
Michael Auli, Michel Galley and Jianfeng Gao

16:55–17:20 *Confidence-based Rewriting of Machine Translation Output*
Benjamin Marie and Aurélien Max

Session 6b: Semantic Parsing

15:40–16:05 *Learning Compact Lexicons for CCG Semantic Parsing*
Yoav Artzi, Dipanjan Das and Slav Petrov

16:05–16:30 *Morpho-syntactic Lexical Generalization for CCG Semantic Parsing*
Adrienne Wang, Tom Kwiatkowski and Luke Zettlemoyer

16:30–16:55 *Semantic Parsing Using Content and Context: A Case Study from Requirements Elicitation*
Reut Tsarfaty, Ilia Pogrebezky, Guy Weiss, Yaarit Natan, Smadar Szekely and David Harel

16:55–17:20 *Semantic Parsing with Relaxed Hybrid Trees*
Wei Lu

Monday, October 27, 2014 (continued)

Session 6c: NLP-Related Machine Learning

15:40–16:05 *Low-dimensional Embeddings for Interpretable Anchor-based Topic Inference*
David Mimno and Moontae Lee

16:05–16:30 *Weakly-Supervised Learning with Cost-Augmented Contrastive Estimation*
Kevin Gimpel and Mohit Bansal

16:30–16:55 *Don't Until the Final Verb Wait: Reinforcement Learning for Simultaneous Machine Translation*
Alvin Grissom II, He He, Jordan Boyd-Graber, John Morgan and Hal Daumé III

16:55–17:20 *PCFG Induction for Unsupervised Parsing and Language Modelling*
James Scicluna and Colin de la Higuera

Session 6p: Computational Psycholinguistics, Text Mining and NLP Applications

15:40–17:20 *Poster Session*
Multiple presenters

Can characters reveal your native language? A language-independent approach to native language identification
Radu Tudor Ionescu, Marius Popescu and Aoife Cahill

Formalizing Word Sampling for Vocabulary Prediction as Graph-based Active Learning
Yo Ehara, Yusuke Miyao, Hidekazu Oiwa, Issei Sato and Hiroshi Nakagawa

Language Transfer Hypotheses with Linear SVM Weights
Shervin Malmasi and Mark Dras

Predicting Dialect Variation in Immigrant Contexts Using Light Verb Constructions
A. Seza Dogruoz and Preslav Nakov

Device-Dependent Readability for Improved Text Understanding
A-Yeong Kim, Hyun-Je Song, Seong-Bae Park and Sang-Jo Lee

Predicting Chinese Abbreviations with Minimum Semantic Unit and Global Constraints
Longkai Zhang, li li, Houfeng WANG and Xu Sun

Tuesday, October 28, 2014

08:00–17:00 ***Registration***

08:00–09:00 ***Refreshments***

Plenary Session

09:00–09:05 *Best Paper Award*
Bo Pang and Walter Daelemans

09:05–09:30 *Language Modeling with Power Low Rank Ensembles*
Ankur P. Parikh, Avneesh Saluja, Chris Dyer and Eric Xing

09:30–09:55 *Modeling Biological Processes for Reading Comprehension*
Jonathan Berant, Vivek Srikumar, Pei-Chun Chen, Abby Vander Linden, Brittany Harding, Brad Huang and Christopher D. Manning

10:00–10:30 ***Coffee Break***

Session 7a: Semantics

10:30–10:55 *Sensicon: An Automatically Constructed Sensorial Lexicon*
Serra Sinem Tekiroglu, Gözde Özbal and Carlo Strapparava

10:55–11:20 *Word Semantic Representations using Bayesian Probabilistic Tensor Factorization*
Jingwei Zhang, Jeremy Salwen, Michael Glass and Alfio Gliozzo

11:20–11:45 *Glove: Global Vectors for Word Representation*
Jeffrey Pennington, Richard Socher and Christopher Manning

11:45–12:10 *Jointly Learning Word Representations and Composition Functions Using Predicate-Argument Structures*
Kazuma Hashimoto, Pontus Stenetorp, Makoto Miwa and Yoshimasa Tsuruoka

Session 7b: Information Extraction

10:30–10:55 *Combining Distant and Partial Supervision for Relation Extraction*
Gabor Angeli, Julie Tibshirani, Jean Wu and Christopher D. Manning

10:55–11:20 *Typed Tensor Decomposition of Knowledge Bases for Relation Extraction*
Kai-Wei Chang, Wen-tau Yih, Bishan Yang and Christopher Meek

11:20–11:45 *A convex relaxation for weakly supervised relation extraction*
Edouard Grave

11:45–12:10 *Knowledge Graph and Text Jointly Embedding*
Zhen Wang, Jianwen Zhang, Jianlin Feng and Zheng Chen

Session 7c: Sentiment Analysis and NLP Applications

10:30–10:55 *Abstractive Summarization of Product Reviews Using Discourse Structure*
Shima Gerani, Yashar Mehdad, Giuseppe Carenini, Raymond T. Ng and Bita Nejat

10:55–11:20 *Clustering Aspect-related Phrases by Leveraging Sentiment Distribution Consistency*
Li Zhao, Minlie Huang, Haiqiang Chen, Junjun Cheng and Xiaoyan Zhu

11:20–11:45 *Automatic Generation of Related Work Sections in Scientific Papers: An Optimization Approach*
Yue Hu and Xiaojun Wan

11:45–12:10 *Fast and Accurate Misspelling Correction in Large Corpora*
Octavian Popescu and Ngoc Phuoc An Vo

Session 7p: Machine Translation and Machine Learning

10:30–12:10 *Poster Session*
Multiple presenters

Assessing the Impact of Translation Errors on Machine Translation Quality with Mixed-effects Models
Marcello Federico, Matteo Negri, Luisa Bentivogli and Marco Turchi

Refining Word Segmentation Using a Manually Aligned Corpus for Statistical Machine Translation
Xiaolin Wang, Masao Utiyama, Andrew Finch and Eiichiro Sumita

Improving Pivot-Based Statistical Machine Translation by Pivoting the Co-occurrence Count of Phrase Pairs
Xiaoning Zhu, Zhongjun He, Hua Wu, Conghui Zhu, Haifeng Wang and Tiejun Zhao

Word Translation Prediction for Morphologically Rich Languages with Bilingual Neural Networks
Ke M. Tran, Arianna Bisazza and Christof Monz

Dependency-Based Bilingual Language Models for Reordering in Statistical Machine Translation
Ekaterina Garmash and Christof Monz

Combining String and Context Similarity for Bilingual Term Alignment from Comparable Corpora
Georgios Kontonatsios, Ioannis Korkontzelos, Jun'ichi Tsujii and Sophia Ananiadou

Random Manhattan Integer Indexing: Incremental L1 Normed Vector Space Construction
Behrang Q. Zadeh and Siegfried Handschuh

Learning Phrase Representations using RNN Encoder–Decoder for Statistical Machine Translation
Kyunghyun Cho, Bart van Merrienboer, Caglar Gulcehre, Dzmitry Bahdanau, Fethi Bougares, Holger Schwenk and Yoshua Bengio

Type-based MCMC for Sampling Tree Fragments from Forests
Xiaochang Peng and Daniel Gildea

Convolutional Neural Networks for Sentence Classification
Yoon Kim

Sometimes Average is Best: The Importance of Averaging for Prediction using MCMC Inference in Topic Modeling
Viet-An Nguyen, Jordan Boyd-Graber and Philip Resnik

Large-scale Reordering Model for Statistical Machine Translation using Dual Multinomial Logistic Regression
Abdullah Alrajeh and Mahesan Niranjan

Dynamic Language Models for Streaming Text
Dani Yogatama, Chong Wang, Bryan Routledge, Noah A. Smith, Eric P. Xing

Improved Decipherment of Homophonic Ciphers
Malte Nuhn, Julian Schamper and Hermann Ney

Cipher Type Detection
Malte Nuhn and Kevin Knight

12:10–13:30 ***Lunch Break***

Session 8sa: Segmentation and Tagging / Spoken Language / Semantics

13:30–13:50 *Joint Learning of Chinese Words, Terms and Keywords*
Ziqiang Cao, Sujian Li and Heng Ji

13:50–14:10 *Cross-Lingual Part-of-Speech Tagging through Ambiguous Learning*
Guillaume Wisniewski, Nicolas Pécheux, Souhir Gahbiche-Braham and François Yvon

14:10–14:30 *Comparing Representations of Semantic Roles for String-To-Tree Decoding*
Marzieh Bazrafshan and Daniel Gildea

14:30–14:50 *Detecting Non-compositional MWE Components using Wiktionary*
Bahar Salehi, Paul Cook and Timothy Baldwin

14:50–15:10 *(Empty slot)*
(No presentation)

Session 8sb: Sentiment Analysis / Social / Computational Psycholinguistics / Text Classification

13:30–13:50 *Joint Emotion Analysis via Multi-task Gaussian Processes*
Daniel Beck, Trevor Cohn and Lucia Specia

13:50–14:10 *Detecting Latent Ideology in Expert Text: Evidence From Academic Papers in Economics*
Zubin Jelveh, Bruce Kogut and Suresh Naidu

14:10–14:30 *A Model of Individual Differences in Gaze Control During Reading*
Niels Landwehr, Sebastian Arzt, Tobias Scheffer and Reinhold Kliegl

14:30–14:50 *Muli-label Text Categorization with Hidden Components*
li li, Longkai Zhang and Houfeng WANG

14:50–15:10 *#TagSpace: Semantic Embeddings from Hashtags*
Jason Weston, Sumit Chopra and Keith Adams

Session 8sc: Summarization / Machine Translation / Information Extraction

13:30–13:50 *Joint Decoding of Tree Transduction Models for Sentence Compression*
Jin-ge Yao, Xiaojun Wan and Jianguo Xiao

13:50–14:10 *Dependency-based Discourse Parser for Single-Document Summarization*
Yasuhisa Yoshida, Jun Suzuki, Tsutomu Hirao and Masaaki Nagata

14:10–14:30 *Improving Word Alignment using Word Similarity*
Theerawat Songyot and David Chiang

14:30–14:50 *Constructing Information Networks Using One Single Model*
Qi Li, Heng Ji, Yu HONG and Sujian Li

14:50–15:10 *Event Role Extraction using Domain-Relevant Word Representations*
Emanuela Boros, Romaric Besançon, Olivier Ferret and Brigitte Grau

Session 8p: Information Extraction

13:30–15:10 *Poster Session*
Multiple presenters

Modeling Joint Entity and Relation Extraction with Table Representation
Makoto Miwa and Yutaka Sasaki

ZORE: A Syntax-based System for Chinese Open Relation Extraction
Likun Qiu and Yue Zhang

Coarse-grained Candidate Generation and Fine-grained Re-ranking for Chinese Abbreviation Prediction
Longkai Zhang, Houfeng WANG and Xu Sun

Type-Aware Distantly Supervised Relation Extraction with Linked Arguments
Mitchell Koch, John Gilmer, Stephen Soderland and Daniel S. Weld

Automatic Inference of the Tense of Chinese Events Using Implicit Linguistic Information
Yuchen Zhang and Nianwen Xue

Joint Inference for Knowledge Base Population
Liwei Chen, Yansong Feng, Jinghui Mo, Songfang Huang and Dongyan Zhao

Combining Visual and Textual Features for Information Extraction from Online Flyers
Emilia Apostolova and Noriko Tomuro

CTPs: Contextual Temporal Profiles for Time Scoping Facts using State Change Detection
Derry Tanti Wijaya, Ndapandula Nakashole and Tom M. Mitchell

Noisy Or-based model for Relation Extraction using Distant Supervision
Ajay Nagesh, Gholamreza Haffari and Ganesh Ramakrishnan

15:10–15:40 ***Coffee Break***

Tuesday, October 28, 2014 (continued)

Session 9a: Machine Learning and Machine Translation

15:40–16:05 *Search-Aware Tuning for Machine Translation*
Lemao Liu and Liang Huang

IBM Cognitive Computing - An NLP Renaissance!

Salim Roukos
Senior Manager of Multi-Lingual NLP and CTO for Translation Technologies
IBM T. J. Watson Research Center
roukos@us.ibm.com

Abstract

Electronically available multi-modal data (primarily text and meta-data) is unprecedented in terms of its volume, variety, velocity, (and veracity). The increased interest and investment in cognitive computing for building systems and solutions that enable and support richer human-machine interactions presents a unique opportunity for novel statistical models for natural language processing.

In this talk, I will describe a journey at IBM during the past three decades in developing novel statistical models for NLP covering statistical parsing, machine translation, and question-answering systems. Along with a discussion of some of the recent successes, I will discuss some difficult challenges that need to be addressed to achieve more effective cognitive systems and applications.

About the Speaker

Salim Roukos is Senior Manager of Multi-Lingual NLP and CTO for Translation Technologies at IBM T. J. Watson Research Center. Dr. Roukos received his B.E. from the American University of Beirut, in 1976, his M.Sc. and Ph.D. from the University of Florida, in 1978 and 1980, respectively. He joined Bolt Beranek and Newman from 1980 through 1989, where he was a Senior Scientist in charge of projects in speech compression, time scale modification, speaker identification, word spotting, and spoken language understanding. He was an Adjunct Professor at Boston University in 1988 before joining IBM in 1989. Dr. Roukos has served as Chair of the IEEE Digital Signal Processing Committee in 1988.

Salim Roukos currently leads a group at IBM T.J. Watson research Center that focuses on various problems using machine learning techniques for natural language processing. The group pioneered many of the statistical methods for NLP from statistical parsing, to natural language understanding, to statistical machine translation and machine translation evaluation metrics (BLEU metric). Roukos has over a 150 publications in the speech and language areas and over two dozen patents. Roukos was the lead of the group which introduced the first commercial statistical language understanding system for conversational telephony systems (IBM ViaVoice Telephony) in 2000 and the first statistical machine translation product for Arabic-English translation in 2003. He has recently lead the effort to create IBM's offering of IBM Real-Time Translation Services (RTTS) a platform for enabling real-time translation applications such as multilingual chat and on-demand document translation.

Abstract

This paper presents a deep semantic similarity model (DSSM), a special type of deep neural networks designed for text analysis, for recommending *target* documents to be of interest to a user based on a *source* document that she is reading. We observe, identify, and detect naturally occurring signals of *interestingness* in click transitions on the Web between source and target documents, which we collect from commercial Web browser logs. The DSSM is trained on millions of Web transitions, and maps source-target document pairs to feature vectors in a latent space in such a way that the distance between source documents and their corresponding interesting targets in that space is minimized. The effectiveness of the DSSM is demonstrated using two *interestingness* tasks: automatic highlighting and contextual entity search. The results on large-scale, real-world datasets show that the semantics of documents are important for modeling interestingness and that the DSSM leads to significant quality improvement on both tasks, outperforming not only the classic document models that do not use semantics but also state-of-the-art topic models.

1 Introduction

Tasks of predicting what interests a user based on the document she is reading are fundamental to many online recommendation systems. A recent survey is due to Ricci et al. (2011). In this paper, we exploit the use of a deep semantic model for two such *interestingness* tasks in which document semantics play a crucial role: automatic highlighting and contextual entity search.

Automatic Highlighting. In this task we want a recommendation system to automatically discover the entities (e.g., a person, location, organization etc.) that interest a user when reading a document and to highlight the corresponding text spans, referred to as *keywords* afterwards. We show in this study that document semantics are among the most important factors that influence what is perceived as interesting to the user. For example, we observe in Web browsing logs that when a user reads an article about a movie, she is more likely to browse to an article about an actor or character than to another movie or the director.

Contextual entity search. After identifying the keywords that represent the entities of interest to the user, we also want the system to recommend new, interesting documents by searching the Web for supplementary information about these entities. The task is challenging because the same keywords often refer to different entities, and interesting supplementary information to the highlighted entity is highly sensitive to the semantic context. For example, "Paul Simon" can refer to many people, such as the singer and the senator. Consider an article about the music of Paul Simon and another about his life. Related content about his upcoming concert tour is much more interesting in the first context, while an article about his family is more interesting in the second.

At the heart of these two tasks is the notion of interestingness. In this paper, we model and make use of this notion of interestingness with a deep semantic similarity model (DSSM). The model, extending from the deep neural networks shown recently to be highly effective for speech recognition (Hinton et al., 2012; Deng et al., 2013) and computer vision (Krizhevsky et al., 2012; Markoff, 2014), is *semantic* because it maps documents to feature vectors in a latent semantic space, also known as semantic representations. The model is *deep* because it employs a neural network with several hidden layers including a special convolutional-pooling structure to identify keywords and extract hidden semantic features at different levels of abstractions, layer by layer. The semantic representation is computed through a deep neural network after its training by back-propagation with respect to an objective tailored

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 2–13,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

to the respective interestingness tasks. We obtain naturally occurring "interest" signals by observing Web browser transitions, from a source document to a target document, in Web usage logs of a commercial browser. Our training data is sampled from these transitions.

The use of the DSSM to model interestingness is motivated by the recent success of applying related deep neural networks to computer vision (Krizhevshy et al. 2012; Markoff, 2014), speech recognition (Hinton et al. 2012), text processing (Collobert et al. 2011), and Web search (Huang et al. 2013). Among them, (Huang et al. 2013) is most relevant to our work. They also use a deep neural network to map documents to feature vectors in a latent semantic space. However, their model is designed to represent the *relevance* between queries and documents, which differs from the notion of interestingness between documents studied in this paper. It is often the case that a user is interested in a document because it provides supplementary information about the entities or concepts she encounters when reading another document although the overall contents of the second documents is not highly relevant. For example, a user may be interested in knowing more about the history of University of Washington after reading the news about President Obama's visit to Seattle. To better model interestingness, we extend the model of Huang et al. (2013) in two significant aspects. First, while Huang et al. treat a document as a bag of words for semantic mapping, the DSSM treats a document as a sequence of words and tries to discover prominent keywords. These keywords represent the entities or concepts that might interest users, via the convolutional and max-pooling layers which are related to the deep models used for computer vision (Krizhevsky et al., 2013) and speech recognition (Deng et al., 2013a) but are not used in Huang et al.'s model. The DSSM then forms the high-level semantic representation of the whole document based on these keywords. Second, instead of directly computing the document relevance score using cosine similarity in the learned semantic space, as in Huang et al. (2013), we feed the features derived from the semantic representations of documents to a ranker which is trained in a supervised manner. As a result, a document that is not highly relevant to another document a user is reading (i.e., the distance between their derived feature vectors is big) may still have a high score of interestingness because the former provides useful information about an entity mentioned in the latter. Such information and entity are encoded, respectively, by (some subsets of) the semantic features in their corresponding documents. In Sections 4 and 5, we empirically demonstrate that the aforementioned two extensions lead to significant quality improvements for the two interestingness tasks presented in this paper.

Before giving a formal description of the DSSM in Section 3, we formally define the *interestingness* function, and then introduce our data set of naturally occurring interest signals.

2 The Notion of Interestingness

Let D be the set of all documents. Following Gamon et al. (2013), we formally define the *interestingness* modeling task as learning the mapping function:

$$\sigma: D \times D \rightarrow \mathbb{R}^{+}$$

where the function $\sigma(s,t)$ is the quantified degree of interest that the user has in the target document $t \in D$ after or while reading the source document $s \in D$.

Our notion of a document is meant in its most general form as a string of raw unstructured text. That is, the interestingness function should not rely on any document structure such as title tags, hyperlinks, etc., or Web interaction data. In our tasks, documents can be formed either from the plain text of a webpage or as a text span in that plain text, as will be discussed in Sections 4 and 5.

2.1 Data

We can observe many naturally occurring manifestations of interestingness on the Web. For example, on Twitter, users follow shared links embedded in tweets. Arguably the most frequent signal, however, occurs in Web browsing events where users click from one webpage to another via hyperlinks. When a user clicks on a hyperlink, it is reasonable to assume that she is interested in learning more about the anchor, modulo cases of erroneous clicks. Aggregate clicks can therefore serve as a proxy for interestingness. That is, for a given source document, target documents that attract the most clicks are more interesting than documents that attract fewer clicks[1].

[1] We stress here that, although the click signal is available to form a dataset and a gold standard ranker (to be described in Section 4), our task is to model interestingness between unstructured documents, i.e., without access to any document structure or Web interaction data. Thus, in our experiments,

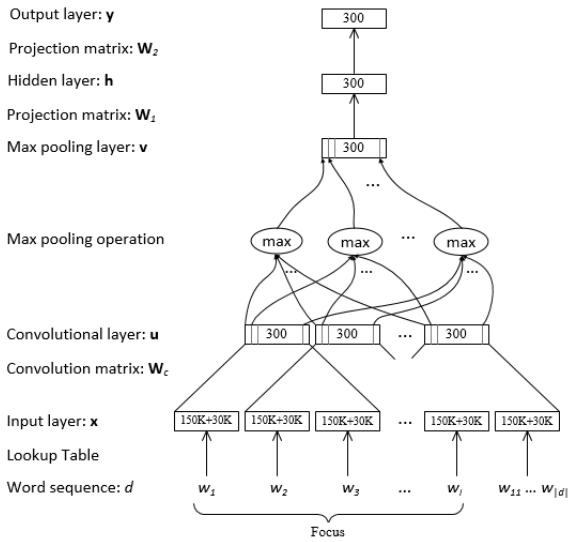

Figure 1: Illustration of the network architecture and information flow of the DSSM

We collect a large dataset of user browsing events from a commercial Web browser. Specifically, we sample 18 million occurrences of a user click from one Wikipedia page to another during a one year period. We restrict our browsing events to Wikipedia since its pages tend to contain many anchors (79 on average, where on average 42 have a unique target URL). Thus, they attract enough traffic for us to obtain robust browsing transition data[2]. We group together all transitions originating from the same page and randomly hold out 20% of the transitions for our evaluation data (**EVAL**), 20% for training the DSSM described in Section 3.2 (**TRAIN_1**), and the remaining 60% for training our task specific rankers described in Section 3.3 (**TRAIN_2**). In our experiments, we used different settings for the two interestingness tasks. Thus, we postpone the detailed description of these datasets and other task-specific datasets to Sections 4 and 5.

3 A Deep Semantic Similarity Model (DSSM)

This section presents the architecture of the DSSM, describes the parameter estimation, and the way the DSSM is used in our tasks.

3.1 Network Architecture

The heart of the DSSM is a deep neural network with convolutional structure, as shown in Figure 1. In what follows, we use lower-case bold letters, such as $\mathbf{x}$, to denote column vectors, $x(i)$ to denote the i^{th} element of $\mathbf{x}$, and upper-case letters, such as $\mathbf{W}$, to denote matrices.

Input Layer x. It takes two steps to convert a document d, which is a sequence of words, into a vector representation $\mathbf{x}$ for the input layer of the network: (1) convert each word in d to a word vector, and (2) build $\mathbf{x}$ by concatenating these word vectors. To convert a word w into a word vector, we first represent w by a one-hot vector using a vocabulary that contains N high frequent words ($N = 150$K in this study). Then, following Huang et al. (2013), we map w to a separate tri-letter vector. Consider the word "#dog#", where # is a word boundary symbol. The nonzero elements in its tri-letter vector are "#do", "dog", and "og#". We then form the word vector of w by concatenating its one-hot vector and its tri-letter vector. It is worth noting that the tri-letter vector complements the one-hot vector representation in two aspects. First, different OOV (out of vocabulary) words can be represented by tri-letter vectors with few collisions. Second, spelling variations of the same word can be mapped to the points that are close to each other in the tri-letter space. Although the number of unique English words on the Web is extremely large, the total number of distinct tri-letters in English is limited (restricted to the most frequent 30K in this study). As a result, incorporating tri-letter vectors substantially improves the representation power of word vectors while keeping their size small.

To form our input layer $\mathbf{x}$ using word vectors, we first identify a text span with a high degree of relevance, called *focus*, in d using task-specific heuristics (see Sections 4 and 5 respectively). Second, we form $\mathbf{x}$ by concatenating each word vector in the focus and a vector that is the summation of all other word vectors, as shown in Figure 1. Since the length of the focus is much smaller than that of its document, $\mathbf{x}$ is able to capture the contextual information (for the words in the focus)

we remove all structural information (e.g., hyperlinks and XML tags) in our documents, except that in the highlighting experiments (Section 4) we use anchor texts to simulate the candidate keywords to be highlighted. We then convert each Web document into plain text, which is white-space tokenized and lowercased. Numbers are retained and no stemming is performed.

[2] We utilize the May 3, 2013 English Wikipedia dump consisting of roughly 4.1 million articles from http://dumps.wikimedia.org.

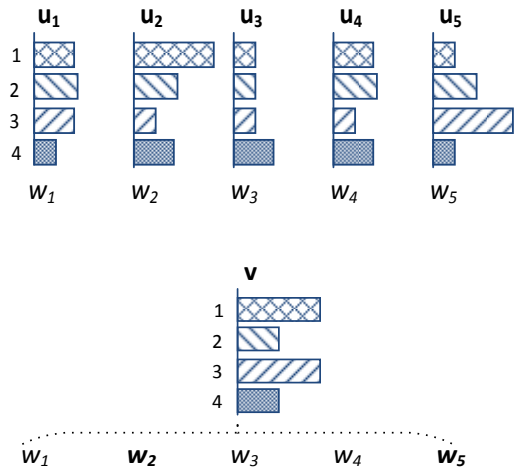

Figure 2: Toy example of (upper) a 5-word document and its local feature vectors extracted using a convolutional layer, and (bottom) the global feature vector of the document generated after max-pooling.

useful to the corresponding tasks, with a manageable vector size.

Convolutional Layer u. A convolutional layer extracts local features around each word w_i in a word sequence of length I as follows. We first generate a contextual vector $\mathbf{c}_i$ by concatenating the word vectors of w_i and its surrounding words defined by a window (the window size is set to 3 in this paper). Then, we generate for each word a local feature vector $\mathbf{u}_i$ using a tanh activation function and a linear projection matrix $\mathbf{W}_c$, which is the same across all windows i in the word sequence, as:

$$\mathbf{u}_i = \tanh\left(\mathbf{W}_c^{\mathrm{T}}\mathbf{c}_i\right), \text{where } i = 1 \dots I \quad (1)$$

Max-pooling Layer v. The size of the output $\mathbf{u}$ depends on the number of words in the word sequence. Local feature vectors have to be combined to obtain a global feature vector, with a fixed size independent of the document length, in order to apply subsequent standard affine layers. We design $\mathbf{v}$ by adopting the max operation over each "time" i of the sequence of vectors computed by (1), which forces the network to retain only the most useful, partially invariant local features produced by the convolutional layer:

$$v(j) = \max_{i=1,\dots,I}\{\mathrm{u}_i(j)\} \quad (2)$$

where the max operation is performed for each dimension of $\mathbf{u}$ across $i = 1, \dots, I$ respectively.

That convolutional and max-pooling layers are able to discover prominent keywords of a document can be demonstrated using the procedure in Figure 2 using a toy example. First, the convolutional layer of (1) generates for each word in a 5-word document a 4-dimensional local feature vector, which represents a distribution of four *topics*. For example, the most prominent topic of w_2 within its three word context window is the first topic, denoted by $u_2(1)$, and the most prominent topic of w_5 is $u_5(3)$. Second, we use max-pooling of (2) to form a global feature vector, which represents the topic distribution of the whole document. We see that $v(1)$ and $v(3)$ are two prominent topics. Then, for each prominent topic, we trace back to the local feature vector that survives max-pooling:

$$v(1) = \max_{i=1,\dots,5}\{u_i(1)\} = u_2(1)$$

$$v(3) = \max_{i=1,\dots,5}\{u_i(3)\} = u_5(3).$$

Finally, we label the corresponding words of these local feature vectors, w_2 and w_5, as keywords of the document.

Figure 3 presents a sample of document snippets and their keywords detected by the DSSM according to the procedure elaborated in Figure 2. It is interesting to see that many names are identified as keywords although the DSSM is not designed explicitly for named entity recognition.

Fully-Connected Layers h and y. The fixed sized global feature vector $\mathbf{v}$ of (2) is then fed to several standard affine network layers, which are stacked and interleaved with nonlinear activation functions, to extract highly non-linear features $\mathbf{y}$ at the output layer. In our model, shown in Figure 1, we have:

$$\mathbf{h} = \tanh(\mathbf{W}_1^{\mathrm{T}}\mathbf{v}) \quad (3)$$

$$\mathbf{y} = \tanh(\mathbf{W}_2^{\mathrm{T}}\mathbf{h}) \quad (4)$$

where $\mathbf{W}_1$ and $\mathbf{W}_2$ are learned linear projection matrices.

3.2 Training the DSSM

To optimize the parameters of the DSSM of Figure 1, i.e., $\boldsymbol{\theta} = \{\mathbf{W}_c, \mathbf{W}_1, \mathbf{W}_2\}$, we use a pair-wise rank loss as objective (Yih et al. 2011). Consider a source document s and two candidate target documents t_1 and t_2, where t_1 is more interesting than t_2 to a user when reading s. We construct two pairs of documents (s, t_1) and (s, t_2), where the former is preferred and should have a higher

Figure 3: A sample of document snippets and the keywords (in **bold**) detected by the DSSM.

interestingness score. Let Δ be the difference of their interestingness scores: $\Delta = \sigma(s, t_1) - \sigma(s, t_2)$, where σ is the interestingness score, computed as the cosine similarity:

$$\sigma(s,t) \equiv \text{sim}_{\boldsymbol{\theta}}(s,t) = \frac{\mathbf{y}_s^{\mathrm{T}}\mathbf{y}_t}{\|\mathbf{y}_s\|\|\mathbf{y}_t\|} \qquad (5)$$

where $\mathbf{y}_s$ and $\mathbf{y}_t$ are the feature vectors of s and t, respectively, which are generated using the DSSM, parameterized by $\boldsymbol{\theta}$. Intuitively, we want to learn $\boldsymbol{\theta}$ to maximize Δ. That is, the DSSM is learned to represent documents as points in a hidden interestingness space, where the similarity between a document and its interesting documents is maximized.

We use the following logistic loss over Δ, which can be shown to upper bound the pairwise accuracy:

$$\mathcal{L}(\Delta; \boldsymbol{\theta}) = \log(1 + \exp(-\gamma\Delta)) \qquad (6)$$

The loss function in (6) has a shape similar to the hinge loss used in SVMs. Because of the use of the cosine similarity function, we add a scaling factor γ that magnifies Δ from [-2, 2] to a larger range. Empirically, the value of γ makes no difference as long as it is large enough. In the experiments, we set $\gamma = 10$. Because the loss function is differentiable, optimizing the model parameters can be done using gradient-based methods. Due to space limitations, we omit the derivation of the gradient of the loss function, for which readers are referred to related derivations (e.g., Collobert et al. 2011; Huang et al. 2013; Shen et al. 2014).

In our experiments we trained DSSMs using mini-batch Stochastic Gradient Descent. Each mini-batch consists of 256 source-target document pairs. For each source document s, we randomly select from that batch four target documents which are not paired with s as negative training samples[3]. The DSSM trainer is implemented using a GPU-accelerated linear algebra library, which is developed on CUDA 5.5. Given the training set (**TRAIN_1** in Section 2), it takes approximately 30 hours to train a DSSM as shown in Figure 1, on a Xeon E5-2670 2.60GHz machine with one Tesla K20 GPU card.

In principle, the loss function of (6) can be further regularized (e.g. by adding a term of $L2$ norm) to deal with overfitting. However, we did not find a clear empirical advantage over the simpler early stop approach in a pilot study, hence we adopted the latter in the experiments in this paper. Our approach adjusts the learning rate η during the course of model training. Starting with $\eta = 1.0$, after each epoch (a pass over the entire training data), the learning rate is adjusted as $\eta = 0.5 \times \eta$ if the loss on validation data (held-out from **TRAIN_1**) is not reduced. The training stops if either η is smaller than a preset threshold (0.0001) or the loss on training data can no longer be reduced significantly. In our experiments, the DSSM training typically converges within 20 epochs.

3.3 Using the DSSM

We experiment with two ways of using the DSSM for the two interestingness tasks. First, we use the DSSM as a feature generator. The output layer of the DSSM can be seen as a set of semantic features, which can be incorporated in a boosted tree

[3] In our experiments, we observed better results by sampling more negative training examples (e.g., up to 100) although this makes the training much slower. An alternative approach is to approximate the partition function using Noise Contrastive Estimation (Gutmann and Hyvarinen 2010). We leave it to future work.

Table 1: Highlighting task performance (NDCG @ K) of interest models over HEAD, TORSO and TAIL test sets. Bold indicates statistical significance over all non-shaded results using *t*-test ($p = 0.05$).

based ranker (Friedman 1999) trained discriminatively on the task-specific data. Given a source-target document pair (s, t), the DSSM generates 600 features (300 from the output layers $\mathbf{y}_s$ and $\mathbf{y}_t$ for each s and t, respectively).

Second, we use the DSSM as a direct implementation of the interestingness function σ. Recall from Section 3.2 that in model training, we measure the interestingness score for a document pair using the cosine similarity between their corresponding feature vectors ($\mathbf{y}_s$ and $\mathbf{y}_t$). Similarly at runtime, we define $\sigma = \text{sim}_{\boldsymbol{\theta}}(s, t)$ as (5).

4 Experiments on Highlighting

Recall from Section 1 that in this task, a system must select k most interesting keywords in a document that a user is reading. To evaluate our models using the click transition data described in Section 2, we simulate the task as follows. We use the set of anchors in a source document s to simulate the set of candidate keywords that may be of interest to the user while reading s, and treat the text of a document that is linked by an anchor in s as a target document t. As shown in Figure 1, to apply DSSM to a specific task, we need to define the focus in source and target documents. In this task, the *focus* in *s* is defined as the anchor text, and the *focus* in *t* is defined as the first 10 tokens in *t*.

We evaluate the performance of a highlighting system against a gold standard interestingness function σ' which scores the interestingness of an anchor as the number of user clicks on t from the anchor in s in our data. We consider the ideal selection to then consist of the k most interesting anchors according to σ'. A natural metric for this task is Normalized Discounted Cumulative Gain (NDCG) (Jarvelin and Kekalainen 2000).

We evaluate our models on the **EVAL** dataset described in Section 2. We utilize the transition distributions in **EVAL** to create three other test sets, following the stratified sampling methodology commonly employed in the IR community, for the frequently, less frequently, and rarely viewed source pages, referred to as **HEAD**, **TORSO**, and **TAIL**, respectively. We obtain these sets by first sorting the unique source documents according to their frequency of occurrence in **EVAL**. We then partition the set so that **HEAD** corresponds to all transitions from the source pages at the top of the list that account for 20% of the transitions in **EVAL**; **TAIL** corresponds to the transitions at the bottom also accounting for 20% of the transitions in **EVAL**; and **TORSO** corresponds to the remaining transitions.

4.1 Main Results

Table 1 summarizes the results of various models over the three test sets using NDCG at truncation levels 1, 5, and 10.

Rows 1 to 3 are simple heuristic baselines. **RAND** selects k random anchors, **1stK** selects the first k anchors and **LastK** the last k anchors.

The other models in Table 1 are boosted tree based rankers trained on **TRAIN_2** described in Section 2. They vary only in their features. The ranker in Row 4 uses Non-Semantic Features (**NSF**) only. These features are derived from the

source document *s* and from user session information in the browser log. The document features include: position of the anchor in the document, frequency of the anchor, and anchor density in the paragraph.

The rankers in Rows 5 to 12 use the NSF and the semantic features computed from source and target documents of a browsing transition. We compare semantic features derived from three different sources. The first feature source comes from our DSSMs (**DSSM** and **DSSM_BOW**) using the output layers as feature generators as described in Section 3.3. **DSSM** is the model described in Section 3 and **DSSM_BOW** is the model proposed by Huang et al. (2013) where documents are view as bag of words (BOW) and the convolutional and max-pooling layers are not used. The two other sources of semantic features are used as a point of comparison to the DSSM. One is a generative semantic model (Joint Transition Topic model, or **JTT**) (Gamon et al. 2013). **JTT** is an LDA-style model (Blei et al. 2003) that is trained jointly on source and target documents linked by browsing transitions. **JTT** generates a total of 150 features from its latent variables, 50 each for the source topic model, the target topic model and the transition model. The other semantic model of contrast is a manually defined one, which we use to assess the effectiveness of automatically learned models against human modelers. To this effect, we use the page categories that editors assign in Wikipedia as semantic features (**WCAT**). These features number in the multiple thousands. Using features such as **WCAT** is not a viable solution in general since Wikipedia categories are not available for all documents. As such, we use it solely as a point of comparison against **DSSM** and **JTT**.

We also distinguish between two types of learned rankers: those which draw their features only from the *source* (**src only**) document and those that draw their features from both the *source* and *target* (**src+tar**) documents. Although our task setting allows access to the content of both source and target documents, there are practical scenarios where a system should predict what interests the user without looking at the target document because the extra step of identifying a suitable target document for each candidate concept or entity of interest is computationally expensive.

4.2 Analysis of Results

As shown in Table 1, **NSF+DSSM**, which incorporates our DSSM, is the overall best performing system across test sets. The task is hard as evidenced by the weak baseline scores. One reason is the large average number of candidates per page. On **HEAD**, we found an average of 170 anchors (of which 95 point to a unique target URL). For **TORSO** and **TAIL**, we found the average number of anchors to be 94 (52 unique targets) and 41 (19 unique targets), respectively.

Clearly, the semantics of the documents form important signals for this task: **WCAT**, **JTT**, **DSSM_BOW**, and **DSSM** all significantly boost the performance over NSF alone. There are two interesting comparisons to consider: (a) manual semantics vs. learned semantics; and (b) deep semantic models vs. generative topic models. On (a), we observe somewhat surprisingly that the learned DSSM produces features that outperform the thousands of features coming from manually (editor) assigned Wikipedia category features (**WCAT**), in all but the TAIL where the two perform statistically the same. In contrast, features from the generative model (**JTT**) perform worse than **WCAT** across the board except on **TAIL** where **JTT** and **WCAT** are statistically tied. On (b), we observe that DSSM outperforms a state-of-the-art generative model (**JTT**) on **HEAD** and **TORSO**. On **TAIL**, they are statistically indistinguishable.

We turn now to inspecting the scenario where features are only drawn from the source document (Rows 1-8 in Table 1). Again we observe that semantic features significantly boost the performance against **NSF** alone, however they significantly deteriorate when compared to using features from both source and target documents. In this scenario, the manual semantics from **WCAT** outperform all other models, but with a diminishing effect as we move from **HEAD** through **TORSO** to **TAIL**. **DSSM** is the best performing learned semantic model.

Finally, we present the results to justify the two modifications we made to extend the model of Huang et al. (2013) to the DSSM, as described in Section 1. First, we see in Table 1 that **DSSM_BOW**, which has the same network structure of Huang et al.'s model, is much weaker than **DSSM**, demonstrating the benefits of using convolutional and max-pooling layers to extract semantic features for the highlighting task. Second, we conduct several experiments by using the cosine scores between the output layers of **DSSM** for s and t as features (following the procedure in Section 3.3 for using the DSSM as a direct implementation of σ). We found that adding the cosine

#	Models	@1	@3	AUC
1	**BM25 (entity)**	0.133	0.195	0.583
2	**BM25**	0.142	0.227	0.675
3	**WTM**	0.191	0.287	0.678
4	**BLTM**	0.214	0.306	0.704
5	**DSSM**	0.259*	0.356*	0.711*
6	**DSSM_BOW**	0.223	0.322	0.699
7	**Baseline ranker**	0.283	0.360	0.723
8	**7 + DSSM(1)**	0.301#	0.385#	0.758#
9	**7 + DSSM(600)**	0.327##	0.402##	0.782##

Table 2: Contextual entity search task performance (NDCG @ K and AUC). * indicates statistical significance over all non-shaded single model results (Rows 1 to 6) using *t*-test ($p < 0.05$). # indicates statistical significance over results in Row 7. ## indicates statistical significance over results in Rows 7 and 8.

features to **NSF+DSSM** does not lead to any improvement. We also combined **NSF** with solely the cosine features from **DSSM** (i.e., without the other semantic features drawn from its output layers). But we still found no improvement over using **NSF** alone. Thus, we conclude that for this task it is much more effective to feed the features derived from **DSSM** to a supervised ranker than directly computing the interestingness score using cosine similarity in the learned semantic space, as in Huang et al. (2013).

5 Experiments on Entity Search

We construct the evaluation data set for this second task by randomly sampling a set of documents from a traffic-weighted set of Web documents. In a second step, we identify the entity names in each document using an in-house named entity recognizer. We issue each entity name as a query to a commercial search engine, and retain up to the top-100 retrieved documents as candidate *target* documents. We form for each entity a *source* document which consists of the entity text and its surrounding text defined by a 200-word window. We define the *focus* (as in Figure 1) in s as the entity text, and the *focus* in t as the first 10 tokens in t.

The final evaluation data set contains 10,000 source documents. On average, each source document is associated with 87 target documents. Finally, the source-target document pairs are labeled in terms of interestingness by paid annotators. The label is on a 5-level scale, 0 to 4, with 4 meaning the target document is the most interesting to the source document and 0 meaning the target is of no interest.

We test our models on two scenarios. The first is a ranking scenario where k interesting documents are displayed to the user. Here, we select the top-k ranked documents according to their interestingness scores. We measure the performance via NDCG at truncation levels 1 and 3. The second scenario is to display to the user all interesting results. In this scenario, we select all target documents with an interestingness score exceeding a predefined threshold. We evaluate this scenario using ROC analysis and, specifically, the area under the curve (AUC).

5.1 Main Results

The main results are summarized in Table 2. Rows 1 to 6 are **single model** results, where each model is used as a direct implementation of the interestingness function σ. Rows 7 to 9 are **ranker** results, where σ is defined as a boosted tree based ranker that incorporates different sets of features extracted from source and target documents, including the features derived from single models. As in the highlighting experiments, all the machine-learned single models, including the DSSM, are trained on **TRAIN_1**, and all the rankers are trained on **TRAIN_2**.

5.2 Analysis of Results

BM25 (Rows 1 and 2 in Table 2) is the classic document model (Robertson and Zaragoza 2009). It uses the bag-of-words document representation and the BM25 term weighting function. In our setting, we define the interestingness score of a document pair as the dot product of their BM25-weighted term vectors. To verify the importance of using contextual information, we compare two different ways of forming the term vector of a source document. The first only uses the entity text (Row 1). The second (Row 2) uses both the entity text and and its surrounding text in a 200-word window (i.e., the entire *source* document). Results show that the model using contextual information is significantly better. Therefore, all the other models in this section use both the entity texts and their surrounding text.

WTM (Row 3) is our implementation of the word translation model for IR (Berger and Lafferty 1999; Gao et al. 2010). **WTM** defines the interestingness score as:

$$\sigma(s,t) = \prod_{w_t \in t} \sum_{w_s \in s} P(w_t|w_s) P(w_s|s),$$

where $P(w_s|s)$ is the unigram probability of word w_s in s, and $P(w_t|w_s)$ is the probability of *translating* w_s into w_t, trained on source-target document pairs using EM (Brown et al. 1993). The translation-based approach allows any pair of non-identical but semantically related words to have a nonzero matching score. As a result, it significantly outperforms **BM25**.

BTLM (Row 4) follows the best performing bilingual topic model described in Gao et al. (2011), which is an extension of PLSA (Hofmann 1999). The model is trained on source-target document pairs using the EM algorithm with a constraint enforcing a source document s and its target document t to not only share the same prior topic distribution, but to also have similar fractions of words assigned to each topic. **BLTM** defines the interestingness score between s and t as:

$$\sigma(s,t) = \prod_{w_t \in t} \sum_z P(w_t|\phi_z) P(z|\theta^s).$$

The model assumes the following story of generating t from s. First, for each topic z a word distribution ϕ_z is selected from a Dirichlet prior with concentration parameter β. Second, given s, a topic distribution θ^s is drawn from a Dirichlet prior with parameter α. Finally, t is generated word by word. Each word w_t is generated by first selecting a topic z according to θ^s, and then drawing a word from ϕ_z. We see that **BLTM** models interestingness by taking into account the semantic topic distribution of the entire documents. Our results in Table 2 show that **BLTM** outperforms **WTM** by a significant margin in both NDCG and AUC.

DSSM (Row 5) outperforms all the competing single models, including the state-of-the-art topic model **BLTM**. Now, we inspect the difference between **DSSM** and **BLTM** in detail. Although both models strive to generate the semantic representation of a document, they use different modeling approaches. **BLTM** by nature is a generative model. The semantic representation in **BLTM** is a distribution of hidden semantic topics. Such a distribution is learned using Maximum Likelihood Estimation in an unsupervised manner, i.e., maximizing the log-likelihood of the source-target document pairs in the training data. On the other hand, **DSSM** represents documents as points in a hidden semantic space using a supervised learning method, i.e., paired documents are closer in that latent space than unpaired ones. We believe that the superior performance of **DSSM** is largely due to the fact that the model parameters are discriminatively trained using an objective that is tailored to the interestingness task.

In addition to the difference in training methods, **DSSM** and **BLTM** also use different model structures. **BLTM** treats a document as a bag of words (thus losing some important contextual information such as word order and inter-word dependencies), and generates semantic representations of documents using linear projection. **DSSM**, on the other hand, treats text as a sequence of words and better captures local and global context, and generates highly non-linear semantic features via a deep neural network. To further verify our analysis, we inspect the results of a variant of **DSSM**, denoted as **DSSM_BOW** (Row 6), where the convolution and max-pooling layers are removed. This model treats a document as a bag of words, just like **BLTM**. These results demonstrate that the effectiveness of **DSSM** can also be attributed to the convolutional architecture in the neural network, in addition to being deep and being discriminative.

We turn now to discussing the ranker results in Rows 7 to 9. The baseline ranker (Row 7) uses 158 features, including many counts and single model scores, such as **BM25** and **WMT**. **DSSM** (Row 5) alone is quite effective, being close in performance to the baseline ranker with non-DSSM features. Integrating the DSSM score computed in (5) as one single feature into the ranker (Row 8) leads to a significant improvement over the baseline. The best performing combination (Row 9) is obtained by incorporating the DSSM feature vectors of source and target documents (i.e., 600 features in total) in the ranker.

We thus conclude that on both tasks, automatic highlighting and contextual entity search, features drawn from the output layers of our deep semantic model result in significant gains after being added to a set of non-semantic features, and in comparison to other types of semantic models used in the past.

6 Related Work

In addition to the notion of relevance as described in Section 1, related to interestingness is also the notion of *salience* (also called *aboutness*) (Gamon et al. 2013; 2014; Parajpe 2009; Yih et al. 2006). Salience is the centrality of a term to the content of a document. Although salience and interestingness interact, the two are not the same. For example, in a news article about President Obama's visit to Seattle, Obama is salient, yet the average user would probably not be interested in learning more about Obama while reading that article.

There are many systems that identify popular content in the Web or recommend content (e.g., Bandari et al. 2012; Lerman and Hogg 2010; Szabo and Huberman 2010), which is closely related to the highlighting task. In contrast to these approaches, we strive to predict what term a user is likely to be interested in when reading content, which may or may not be the same as the most popular content that is related to the current document. It has empirically been demonstrated in Gamon et al. (2013) that popularity is in fact a rather poor predictor for interestingness. The task of contextual entity search, which is formulated as an information retrieval problem in this paper, is also related to research on entity resolution (Stefanidis et al. 2013).

Latent Semantic Analysis (Deerwester et al. 1990) is arguably the earliest semantic model designed for IR. Generative topic models widely used for IR include PLSA (Hofmann 1990) and LDA (Blei et al. 2003). Recently, these models have been extended to handle cross-lingual cases, where there are pairs of corresponding documents in different languages (e.g., Dumais et al. 1997; Gao et al. 2011; Platt et al. 2010; Yih et al. 2011).

By exploiting deep architectures, deep learning techniques are able to automatically discover from training data the hidden structures and the associated features at different levels of abstraction useful for a variety of tasks (e.g., Collobert et al. 2011; Hinton et al. 2012; Socher et al. 2012; Krizhevsky et al., 2012; Gao et al. 2014). Hinton and Salakhutdinov (2010) propose the most original approach based on an unsupervised version of the deep neural network to discover the hierarchical semantic structure embedded in queries and documents. Huang et al. (2013) significantly extends the approach so that the deep neural network can be trained on large-scale query-document pairs giving much better performance. The use of the convolutional neural network for text processing, central to our DSSM, was also described in Collobert et al. (2011) and Shen et al. (2014) but with very different applications. The DSSM described in Section 3 can be viewed as a variant of the deep neural network models used in these previous studies.

7 Conclusions

Modeling interestingness is fundamental to many online recommendation systems. We obtain naturally occurring interest signals by observing Web browsing transitions where users click from one webpage to another. We propose to model this "interestingness" with a deep semantic similarity model (DSSM), based on deep neural networks with special convolutional-pooling structure, mapping source-target document pairs to feature vectors in a latent semantic space. We train the DSSM using browsing transitions between documents. Finally, we demonstrate the effectiveness of our model on two interestingness tasks: automatic highlighting and contextual entity search. Our results on large-scale, real-world datasets show that the semantics of documents computed by the DSSM are important for modeling interestingness and that the new model leads to significant improvements on both tasks. DSSM is shown to outperform not only the classic document models that do not use (latent) semantics but also state-of-the-art topic models that do not have the deep and convolutional architecture characterizing the DSSM.

One area of future work is to extend our method to model interestingness given an entire user session, which consists of a sequence of browsing events. We believe that the prior browsing and interaction history recorded in the session provides additional signals for predicting interestingness. To capture such signals, our model needs to be extended to adequately represent time series (e.g., causal relations and consequences of actions). One potentially effective model for such a purpose is based on the architecture of recurrent neural networks (e.g., Mikolov et al. 2010; Chen and Deng, 2014), which can be incorporated into the deep semantic model proposed in this paper.

Abstract

This work presents two different translation models using recurrent neural networks. The first one is a word-based approach using word alignments. Second, we present phrase-based translation models that are more consistent with phrase-based decoding. Moreover, we introduce bidirectional recurrent neural models to the problem of machine translation, allowing us to use the full source sentence in our models, which is also of theoretical interest. We demonstrate that our translation models are capable of improving strong baselines already including recurrent neural language models on three tasks: IWSLT 2013 German→English, BOLT Arabic→English and Chinese→English. We obtain gains up to 1.6% BLEU and 1.7% TER by rescoring 1000-best lists.

1 Introduction

Neural network models have recently experienced unprecedented attention in research on statistical machine translation (SMT). Several groups have reported strong improvements over state-of-the-art baselines using feedforward neural network-based language models (Schwenk et al., 2006; Vaswani et al., 2013), as well as translation models (Le et al., 2012; Schwenk, 2012; Devlin et al., 2014). Different from the feedforward design, *recurrent* neural networks (RNNs) have the advantage of being able to take into account an unbounded history of previous observations. In theory, this enables them to model long-distance dependencies of arbitrary length. However, while previous work on translation modeling with recurrent neural networks shows its effectiveness on standard baselines, so far no notable gains have been presented on top of recurrent language models (Auli et al., 2013; Kalchbrenner and Blunsom, 2013; Hu et al., 2014).

In this work, we present two novel approaches to recurrent neural translation modeling: word-based and phrase-based. The word-based approach assumes one-to-one aligned source and target sentences. We evaluate different ways of resolving alignment ambiguities to obtain such alignments. The phrase-based RNN approach is more closely tied to the underlying translation paradigm. It models actual phrasal translation probabilities while avoiding sparsity issues by using single words as input and output units. Furthermore, in addition to the unidirectional formulation, we are the first to propose a bidirectional architecture which can take the full source sentence into account for all predictions. Our experiments show that these models can improve state-of-the-art baselines containing a recurrent language model on three tasks. For our competitive IWSLT 2013 German→English system, we observe gains of up to 1.6% BLEU and 1.7% TER. Improvements are also demonstrated on top of our evaluation systems for BOLT Arabic→English and Chinese→English, which also include recurrent neural language models.

The rest of this paper is structured as follows. In Section 2 we review related work and in Section 3 an overview of long short-term memory (LSTM) neural networks, a special type of recurrent neural networks we make use of in this work, is given. Section 4 describes our novel translation models. Finally, experiments are presented in Section 5 and we conclude with Section 6.

2 Related Work

In this Section we contrast previous work to ours, where we design RNNs to model bilingual dependencies, which are applied to rerank n-best lists after decoding.

To the best of our knowledge, the earliest attempts to apply neural networks in machine translation (MT) are presented in (Castaño et al., 1997; Castaño and Casacuberta, 1997; Castaño and Casacuberta, 1999), where they were used for example-based MT.

Recently, Le et al. (2012) presented translation models using an output layer with classes and a shortlist for rescoring using feedforward networks. They compare between word-factored and tuple-factored n-gram models, obtaining their best results using the word-factored approach, which is less amenable to data sparsity issues. Both of our word-based and phrase-based models eventually work on the word level. Kalchbrenner and Blunsom (2013) use recurrent neural networks with full source sentence representations. The continuous representations are obtained by applying a sequence of convolutions, and the result is fed into the hidden layer of a recurrent language model. Rescoring results indicate no improvements over the state of the art. Auli et al. (2013) also include source sentence representations built either using Latent Semantic Analysis or by concatenating word embeddings. This approach produced no notable gain over systems using a recurrent language model. On the other hand, our proposed bidirectional models include the full source sentence relying on recurrency, yielding improvements over competitive baselines already including a recurrent language model.

RNNs were also used with minimum translation units (Hu et al., 2014), which are phrase pairs undergoing certain constraints. At the input layer, each of the source and target phrases are modeled as a bag of words, while the output phrase is predicted word-by-word assuming conditional independence. The approach seeks to alleviate data sparsity problems that would arise if phrases were to be uniquely distinguished. Our proposed phrase-based models maintain word order within phrases, but the phrases are processed in a word-pair manner, while the phrase boundaries remain implicitly encoded in the way the words are presented to the network. Schwenk (2012) proposed a feedforward network that predicts phrases of a fixed maximum length, such that all phrase words are predicted at once. The prediction is conditioned on the source phrase. Since our phrase-based model predicts one word at a time, it does not assume any phrase length. Moreover, our model's predictions go beyond phrase boundaries and cover unbounded history and future contexts.

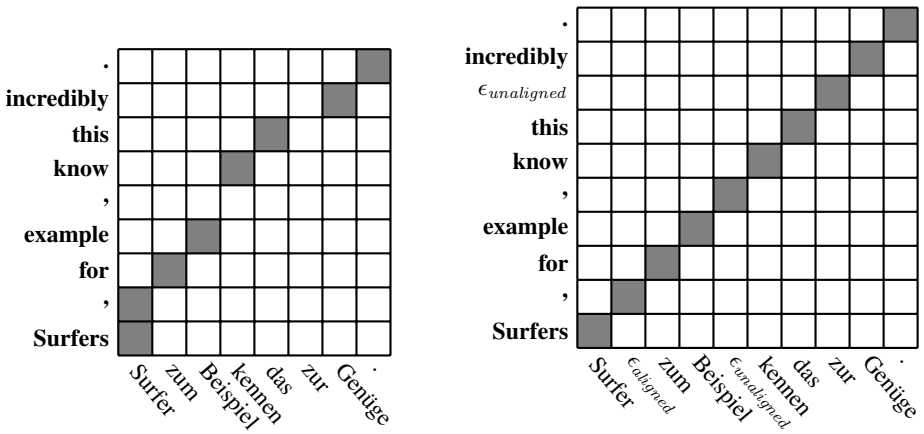
Using neural networks during decoding requires tackling the costly output normalization step. Vaswani et al. (2013) avoid this step by training feedforward neural language models using *noise contrastive estimation*, while Devlin et al. (2014) augment the training objective function to produce approximately normalized scores directly. The latter work makes use of translation and joint models, and pre-computes the first hidden layer beforehand, resulting in large speedups. They report major improvements over strong baselines. The speedups achieved by both works allowed to integrate feedforward neural networks into the decoder.

3 LSTM Recurrent Neural Networks

Our work is based on recurrent neural networks. In related fields like e. g. language modeling, this type of neural network has been shown to perform considerably better than standard feedforward architectures (Mikolov et al., 2011; Arisoy et al., 2012; Sundermeyer et al., 2013; Liu et al., 2014).

Most commonly, recurrent neural networks are trained with stochastic gradient descent (SGD), where the gradient of the training criterion is computed with the backpropagation through time algorithm (Rumelhart et al., 1986; Werbos, 1990; Williams and Zipser, 1995). However, the combination of RNN networks with conventional backpropagation training leads to conceptual difficulties which are known as the vanishing (or exploding) gradient problem, described e. g. in (Bengio et al., 1994). To remedy this problem, in (Hochreiter and Schmidhuber, 1997) it was suggested to modify the architecture of a standard RNN in such a way that vanishing and exploding gradients are avoided during backpropagation. In particular, no modification of the training algorithm is necessary. The resulting architecture is referred to as long short-term memory (LSTM) neural network.

Bidirectional recurrent neural networks (BRNNs) were first proposed in (Schuster and Paliwal, 1997) and applied to speech recognition tasks. They have been since applied to different



(a) Original

(b) One-to-one alignment

Figure 1: Example sentence from the German→English IWSLT data. The one-to-one alignment is created by introducing $\epsilon_{aligned}$ and $\epsilon_{unaligned}$ tokens.

tasks like parsing (Henderson, 2004) and spoken language understanding (Mesnil et al., 2013). Bidirectional long short-term memory (BLSTM) networks are BRNNs using LSTM hidden layers (Graves and Schmidhuber, 2005). This work introduces BLSTMs to the problem of machine translation, allowing powerful models that employ unlimited history and future information to make predictions.

While the proposed models do not make any assumptions about the type of RNN used, all of our experiments make use of recurrent LSTM neural networks, where we include later LSTM extensions proposed in (Gers et al., 2000; Gers et al., 2003). The cross-entropy error criterion is used for training. Further details on LSTM neural networks can be found in (Graves and Schmidhuber, 2005; Sundermeyer et al., 2012).

4 Translation Modeling with RNNs

In the following we describe our word- and phrase-based translation models in detail. We also show how bidirectional RNNs can enable such models to include full source information.

4.1 Resolving Alignment Ambiguities

Our word-based recurrent models are only defined for one-to-one-aligned source-target sentence pairs. In this work, we always evaluate the model in the order of the target sentence. However, we experiment with several different ways to resolve ambiguities due to unaligned or multiply aligned words. To that end, we introduce two additional tokens, $\epsilon_{aligned}$ and $\epsilon_{unaligned}$. Unaligned words are either removed or aligned to an extra $\epsilon_{unaligned}$ token on the opposite side. If an $\epsilon_{unaligned}$ is introduced on the target side, its position is determined by the aligned source word that is closest to the unaligned source word in question, preferring left to right. To resolve one-to-many alignments, we use an IBM-1 translation table to decide for one of the alignment connections to be kept. The remaining words are also either deleted or aligned to additionally introduced $\epsilon_{aligned}$ tokens on the opposite side. Fig. 1 shows an example sentence from the IWSLT data, where all ϵ tokens are introduced.

In a short experiment, we evaluated 5 different setups with our unidirectional RNN translation model (cf. next Section): without any ϵ tokens, without $\epsilon_{unaligned}$, source identity, target identity and using all ϵ tokens. Source identity means we

	dev		test	
	BLEU	TER	BLEU	TER
baseline	33.5	45.8	30.9	48.4
w/o ϵ	34.2	45.3	31.8	47.7
w/o $\epsilon_{unaligned}$	34.4	44.8	31.7	47.4
source identity	34.5	45.0	31.9	47.5
target identity	34.5	44.6	31.9	47.0
all ϵ	34.6	44.5	32.0	47.1

Table 1: Comparison of including different sets of ϵ tokens into the one-to-one alignment on the IWSLT 2013 German→English task using the unidirectional RNN translation model.

introduce no ϵ tokens on source side, but all on target side. Target identity is defined analogously. The results can be found in Tab. 1. We use the setup with all ϵ tokens in all following experiments, which showed the best BLEU performance.

4.2 Word-based RNN Models

Given a pair of source sequence $f_1^I = f_1 \dots f_I$ and target sequence $e_1^I = e_1 \dots e_I$, where we assume a direct correspondence between f_i and e_i, we define the posterior translation probability by factorizing on the target words:

$$p(e_1^I|f_1^I) = \prod_{i=1}^{I} p(e_i|e_1^{i-1}, f_1^I) \quad (1)$$

$$\approx \prod_{i=1}^{I} p(e_i|e_1^{i-1}, f_1^{i+d}) \quad (2)$$

$$\approx \prod_{i=1}^{I} p(e_i|f_1^{i+d}). \quad (3)$$

We denote the formulation (1) as the bidirectional joint model (BJM). This model can be simplified by several independence assumptions. First, we drop the dependency on the future source information, receiving what we denote as the unidirectional joint model (JM) in (2). Here, $d \in \mathbb{N}_0$ is a delay parameter, which is set to $d = 0$ for all experiments, except for the comparative results reported in Fig. 7. Finally, assuming conditional independence from the previous target sequence, we receive the unidirectional translation model (TM) in (3). Analogously, we can define a bidirectional translation model (BTM) by keeping the dependency on the full source sentence f_1^I, but dropping the previous target sequence e_1^{i-1}:

$$p(e_1^I|f_1^I) \approx \prod_{i=1}^{I} p(e_i|f_1^I). \quad (4)$$

Fig. 2 shows the dependencies of the word-based neural translation and joint models. The alignment points are traversed in target order and at each time step one target word is predicted. The pure translation model (TM) takes only source words as input, while the joint model (JM) takes the preceding target words as an additional input. A delay of $d > 0$ is implemented by shifting the target sequence by d time steps and filling the first d target positions and the last d source positions with a dedicated $\epsilon_{padding}$ symbol. The RNN architecture for the unidirectional word-based models

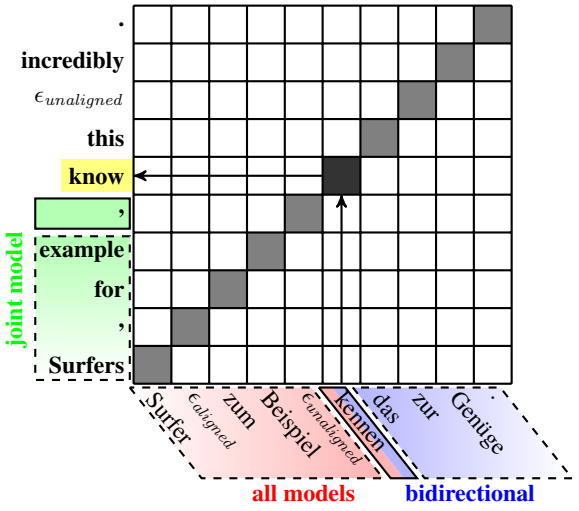


Figure 2: Dependencies modeled within the word-based RNN models when predicting the target word 'know'. Directly processed information is depicted with solid rectangles, and information available through recurrent connections is marked with dashed rectangles.

is illustrated in Fig. 3, which corresponds to the following set of equations:

$$\begin{aligned} y_i &= A_1 \hat{f}_i + A_2 \hat{e}_{i-1} \\ z_i &= \xi(y_i; A_3, y_1^{i-1}) \\ p\big(c(e_i)|e_1^{i-1}, f_1^i\big) &= \varphi_{c(e_i)}(A_4 z_i) \\ p\big(e_i|c(e_i), e_1^{i-1}, f_1^i\big) &= \varphi_{e_i}(A_{c(e_i)} z_i) \\ p(e_i|e_1^{i-1}, f_1^i) &= p\big(e_i|c(e_i), e_1^{i-1}, f_1^i\big) \cdot \\ &\quad p\big(c(e_i)|e_1^{i-1}, f_1^i\big) \end{aligned}$$

Here, by $\hat{f}_i$ and $\hat{e}_{i-1}$ we denote the one-hot encoded vector representations of the source and target words f_i and e_{i-1}. The outgoing activation values of the projection layer and the LSTM layer are y_i and z_i, respectively. The matrices A_j contain the weights of the neural network layers. By $\xi(\cdot\,; A_3, y_1^{i-1})$ we denote the LSTM formalism that we plug in at the third layer. As the LSTM layer is recurrent, we explicitly include the dependence on the previous layer activations y_1^{i-1}. Finally, φ is the widely-used softmax function to obtain normalized probabilities, and c denotes a word class mapping from any target word to its unique word class. For the bidirectional model, the equations can be defined analogously.

Due to the use of word classes, the output layer consists of two parts. The class probability $p\big(c(e_i)|e_1^{i-1}, f_1^i\big)$ is computed first, and then

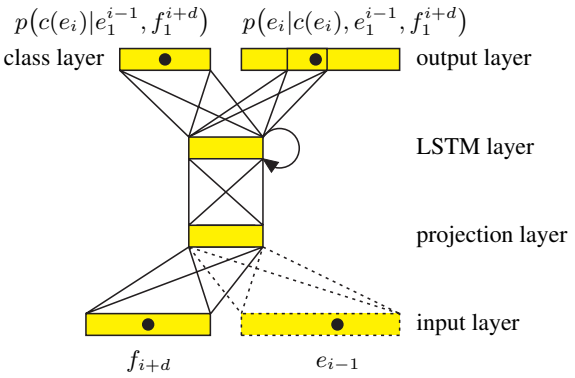

Figure 3: Architecture of a recurrent unidirectional translation model. By including the dashed parts, a *joint* model is obtained.

the word probability $p(e_i|c(e_i), e_1^{i-1}, f_1^i)$ is obtained given the word class. This trick helps avoiding the otherwise computationally expensive normalization sum, which would be carried out over all words in the target vocabulary. In a class-factorized output layer where each word belongs to a single class, the normalization is carried out over all classes, whose number is typically much less than the vocabulary size. The other normalization sum needed to produce the word probability is limited to the words belonging to the same class (Goodman, 2001; Morin and Bengio, 2005).

4.3 Phrase-based RNN Models

One of the conceptual disadvantages of word-based modeling as introduced in the previous section is that there is a mismatch between training and testing conditions: During neural network training, the vocabulary has to be extended by additional ϵ tokens, and a one-to-one alignment is used which does not reflect the situation in decoding. In phrase-based machine translation, more complex alignments in terms of multiple words on both the source and the target sides are used, which allow the decoder to make use of richer short-distance dependencies and are crucial for the performance of the resulting system.

From this perspective, it seems interesting to standardize the alignments used in decoding, and in training the neural network. However, it is difficult to use the phrases themselves as the vocabulary of the RNN. Usually, the huge number of potential phrases in comparison to the relatively small amount of training data makes the learning of continuous phrase representations difficult

Surfers Surfer	, for example , zum Beispiel	know kennen	this das	incredibly zur Genüge	. .

Figure 4: Example phrase alignment for a sentence from the IWSLT training data.

due to data sparsity. This is confirmed by results presented in (Le et al., 2012), which show that a word-factored translation model outperforms the phrase-factored version. Therefore, in this work we continue relying on source and target word vocabularies for building our phrase representations. However, we no longer use a direct correspondence between a source and a target word, as enforced in our word-based models.

Fig. 4 shows an example phrase alignment, where a sequence of source words $\tilde{f}_i$ is directly mapped to a sequence of target words $\tilde{e}_i$ for $1 \leq i \leq \tilde{I}$. By $\tilde{I}$, we denote the number of phrases in the alignment. We decompose the target sentence posterior probability in the following way:

$$p(e_1^I|f_1^J) = \prod_{i=1}^{\tilde{I}} p(\tilde{e}_i|\tilde{e}_1^{i-1}, \tilde{f}_1^{\tilde{I}}) \quad (5)$$

$$\approx \prod_{i=1}^{\tilde{I}} p(\tilde{e}_i|\tilde{e}_1^{i-1}, \tilde{f}_1^{i}) \quad (6)$$

where the joint model in Eq. 5 would correspond to a bidirectional RNN, and Eq. 6 only requires a unidirectional RNN. By leaving out the conditioning on the target side, we obtain a phrase-based *translation* model.

As there is no one-to-one correspondence between the words within a phrase, the basic idea of our phrase-based approach is to let the neural network learn the dependencies itself, and present the full source side of the phrase to the network before letting it predict target side words. Then the probability for the target side of a phrase can be computed, in case of Eq. 6, by:

$$p(\tilde{e}_i|\tilde{e}_1^{i-1}, \tilde{f}_1^{\tilde{I}}) = \prod_{j=1}^{|\tilde{e}_i|} p\big((\tilde{e}_i)_j|(\tilde{e}_i)_1^{j-1}, \tilde{e}_1^{i-1}, \tilde{f}_1^{i}\big),$$

and analogously for the case of Eq. 5. Here, $(\tilde{e}_i)_j$ denotes the j-th word of the i-th aligned target phrase.

We feed the source side of a phrase into the neural network one word at a time. Only when the

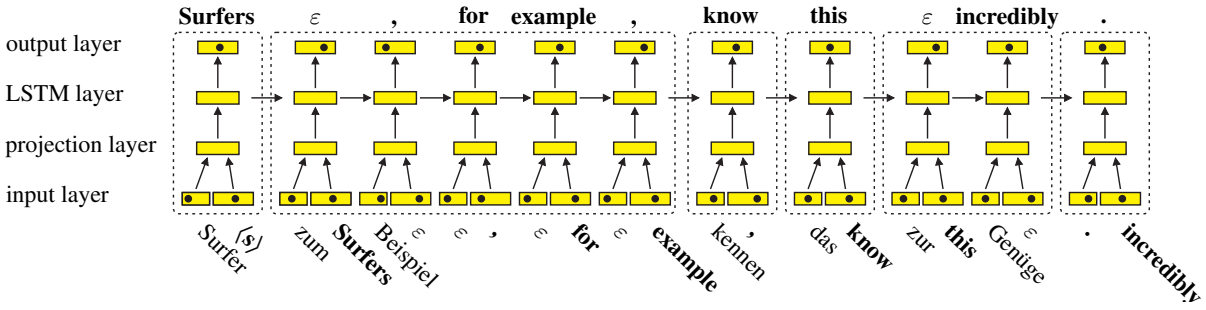

Figure 5: A recurrent phrase-based joint translation model, unfolded over time. Source words are printed in normal face, while target words are printed in bold face. Dashed lines indicate phrases from the example sentence. For brevity, we omit the precise handling of sentence begin and end tokens.

presentation of the source side is finished we start estimating probabilities for the target side. Therefore, we do not let the neural network learn a target distribution until the very last source word is considered. In this way, we break up the conventional RNN training scheme where an input sample is directly followed by its corresponding teacher signal. Similarly, the presentation of the source side of the next phrase only starts after the prediction of the current target side is completed.

To this end, we introduce a no-operation token, denoted by ε, which is not part of the vocabulary (which means it cannot be input to or predicted by the RNN). When the ε token occurs as input, it indicates that no input needs to be processed by the RNN. When the ε token occurs as a teacher signal for the RNN, the output layer distribution is ignored, and does not even have to be computed. In both cases, all the other layers are still processed during forward and backward passes such that the RNN state can be advanced even without additional input or output.

Fig. 5 depicts the evaluation of a phrase-based joint model for the example alignment from Fig. 4. For a source phrase $\tilde{f}_i$, we include $(|\tilde{e}_i|-1)$ many ε symbols at the end of the phrase. Conversely, for a target phrase $\tilde{e}_i$, we include $(|\tilde{f}_i| - 1)$ many ε symbols at the beginning of the phrase.

E. g., in the figure, the second dashed rectangle from the left depicts the training of the English phrase "*, for example ,*" and its German translation "*zum Beispiel*". At the input layer, we feed in the source words one at a time, while we present ε tokens at the target side input layer and the output layer (with the exception of the very first time step, where we still have the last target word from the previous phrase as input instead of ε). With the last word of the source phrase "*Beispiel*" being presented to the network, the full source phrase is stored in the hidden layer, and the neural network is then trained to predict the target phrase words at the output layer. Subsequently, the source input is ε, and the target input is the most recent target side history word.

To obtain a phrase-aligned training sequence for the phrase-based RNN models, we force-align the training data with the application of leave-one-out as described in (Wuebker et al., 2010).

4.4 Bidirectional RNN Architecture

While the unidirectional RNNs include an unbounded sentence history, they are still limited in the number of future source words they include. Bidirectional models provide a flexible means to also include an unbounded future context, which, unlike the delayed unidirectional models, require no tuning to determine the amount of delay.

Fig. 6 illustrates the bidirectional model architecture, which is an extension of the unidirectional model of Fig. 3. First, an additional recurrent hidden layer is added in parallel to the existing one. This layer will be referred to as the backward layer, since it processes information in backward time direction. This hidden layer receives source word input only, while target words in the case of a joint model are fed to the forward layer as in the unidirectional case. Due to the backward recurrency, the backward layer will make the information f_i^I available when predicting the target word e_i, while the forward layer takes care of the source history f_1^i. Jointly, the forward and backward branches include the full source sentence f_1^I, as indicated in Fig. 2. Fig. 6 shows the "deep" variant of the bidirectional model, where the for-

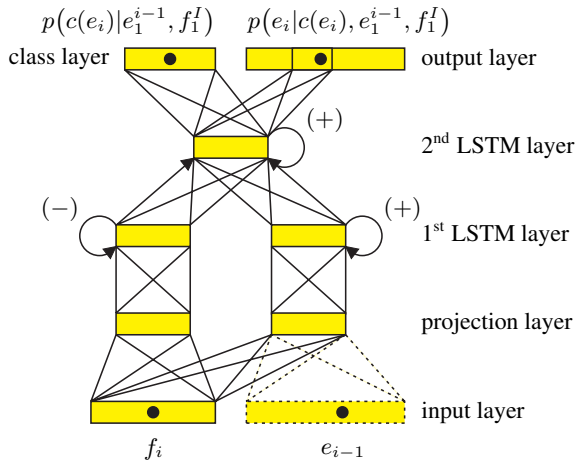

Figure 6: Architecture of a recurrent bidirectional translation model. By $(+)$ and $(-)$, we indicate a processing in forward and backward time directions, respectively. The inclusion of the dashed parts leads to a bidirectional *joint* model. One source projection matrix is used for the forward and backward branches.

ward and backward layers converge into a hidden layer. A shallow variant can be obtained if the parallel layers converge into the output layer directly[1].

Due to the full dependence on the source sequence, evaluating bidirectional networks requires computing the forward pass of the forward and backward layers for the full sequence, before being able to evaluate the next layers. In the backward pass of backpropagation, the forward and backward recurrent layers are processed in decreasing and increasing time order, respectively.

5 Experiments

5.1 Setup

All translation experiments are performed with the *Jane* toolkit (Vilar et al., 2010; Wuebker et al., 2012). The largest part of our experiments is carried out on the IWSLT 2013 German→English shared translation task.[2] The baseline system is trained on all available bilingual data, 4.3M sentence pairs in total, and uses a 4-gram LM with modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998), trained with the SRILM toolkit (Stolcke, 2002). As additional data sources for the LM we selected parts of the Shuffled News and LDC English Gigaword corpora based on cross-entropy difference (Moore and Lewis, 2010), resulting in a total of 1.7 billion running words for LM training. The state-of-the-art baseline is a standard phrase-based SMT system (Koehn et al., 2003) tuned with MERT (Och, 2003). It contains a hierarchical reordering model (Galley and Manning, 2008) and a 7-gram word cluster language model (Wuebker et al., 2013). Here, we also compare against a feed-forward joint model as described by Devlin et al. (2014), with a source window of 11 words and a target history of three words, which we denote as *BBN-JM*. Instead of POS tags, we predict word classes trained with `mkcls`. We use a shortlist of size 16K and 1000 classes for the remaining words. All neural networks are trained on the TED portion of the data (138K segments) and are applied in a rescoring step on 1000-best lists.

To confirm our results, we run additional experiments on the Arabic→English and Chinese→English tasks of the DARPA BOLT project. In both cases, the neural network models are added on top of our most competitive evaluation system. On Chinese→English, we use a hierarchical phrase-based system trained on 3.7M segments with 22 dense features, including an advanced orientation model (Huck et al., 2013). For the neural network training, we selected a subset of 9M running words. The Arabic→English system is a standard phrase-based decoder trained on 6.6M segments, using 17 dense features. The neural network training was performed using a selection amounting to 15.5M running words. For both tasks we apply the neural networks by rescoring 1000-best lists and evaluate results on two data sets from the 'discussion forum' domain, `test1` and `test2`. The sizes of the data sets for the Arabic→English system are: 1219 (`dev`), 1510 (`test1`), and 1137 (`test2`) segments, and for the Chinese→English system are: 5074 (`dev`), 1844 (`test1`), and 1124 (`test2`) segments. All results are measured in case-insensitive BLEU [%] (Papineni et al., 2002) and TER [%] (Snover et al., 2006) on a single reference.

5.2 Results

Our results on the IWSLT German→English task are summarized in Tab. 2. At this point, we do not include a recurrent neural network lan-

[1] In our implementation, the forward and backward layers converge into an intermediate identity layer, and the aggregate is weighted and fed to the next layer.

guage model yet. Here, the delay parameter d from Equations 2 and 3 is set to zero. We observe that for all recurrent translation models, we achieve substantial improvements over the baseline on the test data, ranging from 0.9 BLEU up to 1.6 BLEU. These results are also consistent with the improvements in terms of TER, where we achieve reductions by 0.8 TER up to 1.8 TER.

These numbers can be directly compared to the case of feedforward neural network-based translation modeling as proposed in (Devlin et al., 2014) which we include in the very last row of the table. Nearly all of our recurrent models outperform the feedforward approach, where the RNN model performing best on the dev data is better on test by 0.3 BLEU and 1.0 TER.

Interestingly, for the recurrent word-based models, on the test data it can be seen that TMs perform better than JMs, even though TMs do not take advantage of the target side history words. However, exploiting this extra information does not always need to result in a better model, as the target side words are only derived from the given source side, which is available to both TMs and JMs. On the other hand, including future source words in a bidirectional model clearly improves the performance further. By adding another LSTM

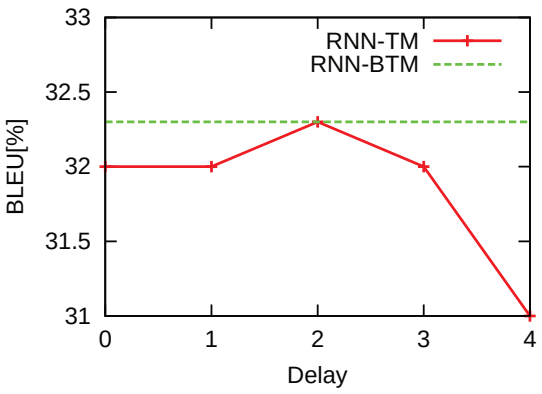

Figure 7: BLEU scores on the IWSLT test set with different delays for the unidirectional RNN-TM and the bidirectional RNN-BTM.

layer that combines forward and backward time directions (indicated as 'deep' in the table), we obtain our overall best model.

In Fig. 7 we compare the word-based bidirectional TM with a unidirectional TM that uses different time delays $d = 0, \ldots, 4$. For a delay $d = 2$, the same performance is obtained as with the bidirectional model, but this comes at the price of tuning the delay parameter.

In comparison to the unidirectional word-based models, phrase-based models perform similarly. In the tables, we include those phrase-based variants which perform best on the dev data, where phrase-based JMs always are at least as good or better than the corresponding TMs in terms of BLEU. Therefore, we mainly report JM results for the phrase-based networks. A phrase-based model can also be trained on multiple variants for the phrase alignment. For our experiments, we tested 10-best alignments against the single best alignment, which resulted in a small improvement of 0.2 TER on both dev and test. We did not observe consistent gains by using an additional hidden layer or bidirectional models. To some extent, future information is already considered in unidirectional phrase-based models by feeding the complete source side before predicting the target side.

Tab. 3 shows different model combination results for the IWSLT task, where a recurrent language model is included in the baseline. Adding a deep bidirectional TM or JM to the recurrent language model improves the RNN-LM baseline by 1.2 BLEU or 1.1 BLEU, respectively. A phrase-based model substantially improves over

the RNN-LM baseline, but performs not as good as its word-based counterparts. By adding four different translation models, including models in reverse word order and reverse translation direction, we are able to improve these numbers even further. However, especially on the test data, the gains from model combination saturate quickly.

Apart from the IWSLT track, we also analyze the performance of our translation models on the BOLT Chinese→English and Arabic→English translation tasks. Due to the large amount of training data, we concentrate on models of high performance in the IWSLT experiments. The results can be found in Tab. 4 and 5. In both cases, we see consistent improvements over the recurrent neural network language model baseline, improving the Arabic→English system by 0.6 BLEU and 0.5 TER on test1. This can be compared to the rescoring results for the same task reported by (Devlin et al., 2014), where they achieved 0.3 BLEU, despite the fact that they used multiple references for scoring, whereas in our experiments we rely on a single reference only. The models are also able to improve the Chinese→English system by 0.5 BLEU and 0.5 TER on test2.

5.3 Analysis

To investigate whether bidirectional models benefit from future source information, we compare the single-best output of a system reranked with a unidirectional model to the output reranked with a bidirectional model. We choose the models to be translation models in both cases, as they predict target words independent of previous predictions, given the source information (cf. Eqs. (3, 4)). This makes it easier to detect the effect of including future source information or the lack thereof. The examples are taken from the IWSLT task, where we include the one-to-one source information, reordered according to the target side.

source: nicht **so wie** ich
reference: not **like** me
Hypothesis 1:
1-to-1 source: **so** ich ϵ nicht **wie**
1-to-1 target: **so** I do n't **like**
Hypothesis 2:
1-to-1 source: nicht **so wie** ich
1-to-1 target: not ϵ **like** me

In this example, the German phrase "*so wie*" translates to "*like*" in English. The bidirectional model prefers hypothesis 2, making use of the future word "*wie*" when translating the German word "*so*" to ϵ, because it has future insight that this move will pay off later when translating

BJM (deep)	18.5	**63.1**	17.2	**62.3**
RNN-LM	18.8	63.3	17.2	62.8
+ BTM (deep)	**18.9**	**63.1**	**17.7**	**62.3**
+ BJM (deep)	18.8	63.3	17.5	62.5

Table 5: Results for the BOLT Chinese→English task with different RNN models. The "+" sign in the last two rows indicates that either of the corresponding deep models (BTM and BJM) are added to the baseline including the recurrent language model (i.e. they are not applied at the same time). T: translation, B: bidirectional.

the rest of the sentence. This information is not available to the unidirectional model, which prefers hypothesis 1 instead.

> *source*: das taten wir dann auch und verschafften uns so **eine Zeit lang** einen Wettbewerbs Vorteil .
> *reference*: and we actually did that and it gave us a competitive advantage **for a while** .
> **Hypothesis 1**:
> *1-to-1 source*: das ϵ ϵ ϵ wir dann auch taten und verschafften uns so **eine Zeit lang** einen Wettbewerbs Vorteil .
> *1-to-1 target*: that 's just what we ϵ ϵ did and gave us ϵ a **time ,** a competitive advantage .
> **Hypothesis 2**:
> *1-to-1 source*: das ϵ ϵ ϵ wir dann auch taten und verschafften uns so einen Wettbewerbs Vorteil ϵ **eine Zeit lang** .
> *1-to-1 target*: that 's just what we ϵ ϵ did and gave us ϵ a competitive advantage **for a ϵ while** .

Here, the German phrase "*eine Zeit lang*" translates to "*for a while*" in English. Bidirectional scoring favors hypothesis 2, while unidirectional scoring favors hypothesis 1. It seems that the unidirectional model translates "*Zeit*" to "*time*" as the object of the verb "*give*" in hypothesis 1, being blind to the remaining part "*lang*" of the phrase which changes the meaning. The bidirectional model, to its advantage, has the full source information, allowing it to make the correct prediction.

6 Conclusion

We developed word- and phrase-based RNN translation models. The former is simple and performs well in practice, while the latter is more consistent with the phrase-based paradigm. The approach inherently evades data sparsity problems as it works on words in its lowest level of processing. Our experiments show the models are able to achieve notable improvements over baselines containing a recurrent LM.

In addition, and for the first time in statistical machine translation, we proposed a bidirectional neural architecture that allows modeling past and future dependencies of any length. Besides its good performance in practice, the bidirectional architecture is of theoretical interest as it allows the exact modeling of posterior probabilities.

A Neural Network Approach to Selectional Preference Acquisition

Tim Van de Cruys
IRIT & CNRS
Toulouse, France
tim.vandecruys@irit.fr

Abstract

This paper investigates the use of neural networks for the acquisition of selectional preferences. Inspired by recent advances of neural network models for NLP applications, we propose a neural network model that learns to discriminate between felicitous and infelicitous arguments for a particular predicate. The model is entirely unsupervised – preferences are learned from unannotated corpus data. We propose two neural network architectures: one that handles standard two-way selectional preferences and one that is able to deal with multi-way selectional preferences. The model's performance is evaluated on a pseudo-disambiguation task, on which it is shown to achieve state of the art performance.

1 Introduction

Predicates often have a semantically motivated preference for particular arguments. Compare for example the sentences in (1) and (2).

(1) The vocalist sings a ballad.

(2) The exception sings a tomato.

Most language users would have no problems accepting the first sentence as well-formed: a vocalist can be expected to sing, and a ballad is something that can be sung. The same language users, however, would likely consider the second sentence to be ill-formed: an exception is not supposed to sing, nor is a tomato something that is typically sung. Within the field of natural language processing, this inclination of predicates to select for particular arguments is known as *selectional preference*.

The automatic acquisition of selectional preferences has been a popular research subject within the field of natural language processing. An automatically acquired selectional preference resource is a versatile tool for numerous NLP applications, such as semantic role labeling (Gildea and Jurafsky, 2002), word sense disambiguation (McCarthy and Carroll, 2003), and metaphor processing (Shutova et al., 2013).

Models for selectional preference need to adequately deal with the consequences of Zipf's law: language is inherently sparse, and the majority of language utterances occur very infrequently. As a consequence, models that are based on corpus data need to properly generalize beyond the mere co-occurrence frequencies of sparse corpus data, taking into account the semantic similarity of both predicates and arguments. Researchers have come up with various approaches to this generalization step. Earlier approaches to selectional preference acquisition mostly rely on hand-crafted resources such as WordNet (Resnik, 1996; Li and Abe, 1998; Clark and Weir, 2001), while later approaches tend to take advantage of unsupervised learning machinery, such as latent variable models (Rooth et al., 1999; Ó Séaghdha, 2010) and distributional similarity metrics (Erk, 2007; Padó et al., 2007).

This paper investigates the use of neural networks for the acquisition of selectional preferences. Inspired by recent advances of neural network models for NLP applications (Collobert and Weston, 2008; Mikolov et al., 2013), we propose a neural network model that learns to discriminate between felicitous and infelicitous arguments for a particular predicate. The model is entirely unsupervised – preferences are learned from unannotated corpus data. Positive training instances are constructed from attested corpus data, while negative instances are constructed from randomly corrupted instances. We propose two neural network architectures: one that handles standard two-way selectional preferences and one that is able to deal with multi-way selectional preferences, where the interaction be-

tween multiple verb arguments is taken into account. The model's performance is evaluated on a pseudo-disambiguation task, on which it is shown to achieve state of the art performance.

The contributions of this paper are twofold. First of all, we apply and evaluate a neural network approach to the problem of standard (two-way) selectional preference acquisition. Selectional preference acquisition using neural networks has not yet been explored in the literature. Secondly, we propose a novel network architecture and training objective for the acquisition of multi-way selectional preferences, where the interaction between a verb and its various arguments is captured at the same time.

The remainder of this paper is as follows. Section 2 first discusses related work with respect to selectional preference acquisition and neural network modeling. Section 3 describes our neural network architecture and its training procedure. Section 4 evaluates the model's performance, comparing it to other existing models for selectional preference acquisition. Finally, section 5 concludes and indicates a number of avenues for future work.

2 Related Work

2.1 Selectional preferences

One of the first approaches to the automatic induction of selectional preferences from corpora was the one by Resnik (1996). Resnik (1996) relies on WordNet synsets in order to generate generalized noun clusters. The *selectional preference strength* of a specific verb v in a particular relation is calculated by computing the Kullback-Leibler divergence between the cluster distribution of the verb and the prior cluster distribution.

$$S_{R(v)} = \sum_c \mathrm{p}(c|v) \log \frac{\mathrm{p}(c|v)}{\mathrm{p}(c)} \quad (1)$$

where c stands for a noun cluster, and R stands for a given predicate-argument relation. The *selectional association* of a particular noun cluster is then the contribution of that cluster to the verb's preference strength.

$$A_{R(v,c)} = \frac{\mathrm{p}(c|v) \log \frac{\mathrm{p}(c|v)}{\mathrm{p}(c)}}{S_{R(v)}} \quad (2)$$

The model's generalization relies entirely on WordNet, and there is no generalization among the verbs.

Other researchers have equally relied on WordNet in order to generalize over arguments. Li and Abe (1998) use the principle of Minimum Description Length in order to find a suitable generalization level within the lexical WordNet hierarchy. A same intuition is used by Clark and Weir (2001), but they use hypothesis testing instead to find the appropriate level of generalization. A recent approach that makes use of WordNet (in combination with Bayesian modeling) is the one by Ó Séaghdha and Korhonen (2012).

Most researchers, however, acknowledge the shortcomings of hand-crafted resources, and focus on the acquisition of selectional preferences from corpus data. Rooth et al. (1999) propose an Expectation-Maximization (EM) clustering algorithm for selectional preference acquisition based on a probabilistic latent variable model. The idea is that both predicate v and argument o are generated from a latent variable c, where the latent variables represent clusters of tight verb-argument interactions.

$$\mathrm{p}(v,o) = \sum_{c \in C} \mathrm{p}(c,v,o) = \sum_{c \in C} \mathrm{p}(c)\mathrm{p}(v|c)\mathrm{p}(o|c) \quad (3)$$

The use of latent variables allows the model to generalize to predicate-argument tuples that have not been seen during training. The latent variable distribution – and the probabilities of predicates and argument given the latent variables – are automatically induced from data using EM. We will compare against their model for evaluation purposes.

Erk (2007) and Erk et al. (2010) describe a method that uses corpus-driven distributional similarity metrics for the induction of selectional preferences. The key idea is that a predicate-argument tuple (v,o) is felicitous if the predicate v appears in the training corpus with arguments o' that are similar to o, i.e.

$$S(v,o) = \sum_{o' \in O_v} \frac{wt(v,o')}{Z(v)} \cdot sim(o,o') \quad (4)$$

where O_v represents the set of arguments that have been attested with predicate v, $wt(\cdot)$ represents an appropriate weighting function (such as the frequency of the (v,o') tuple), and Z is a normalization factor. We equally compare to their model for evaluation purposes.

Bergsma et al. (2008) present a discriminative approach to selectional preference acquisition. Positive examples are taken from observed predicate-

argument pairs, while negative examples are constructed from unobserved combinations. An SVM classifier is used to distinguish the positive from the negative instances. The training procedure used in their model is based on an intuition that is similar to ours, although it is implemented using different techniques.

A number of researchers presented models that are based on the framework of topic modeling. Ó Séaghdha (2010) describes three models for selectional preference induction based on Latent Dirichlet Allocation, which model the selectional preference of a predicate and a single argument. Ritter et al. (2010) equally present a selectional preference model based on topic modeling, but they tackle multi-way selectional preferences (of transitive predicates, which take two arguments) instead.

Finally, in previous work (Van de Cruys, 2009) we presented a model for multi-way selectional preference induction based on tensor factorization. Three-way co-occurrences of subjects, verbs, and objects are represented as a three-way tensor (the generalization of a matrix), and a latent factorization model is applied in order to generalize to unseen instances. We will compare our neural network based-approach for multi-way selectional preference acquisition to this tensor-based factorization model.

2.2 Neural networks

In the last few years, neural networks have become increasingly popular in NLP applications. In particular, neural language models (Bengio et al., 2003; Mnih and Hinton, 2007; Collobert and Weston, 2008) have demonstrated impressive performance at the task of language modeling. By incorporating distributed representations for words that model their similarity, neural language models are able to overcome the problem of data sparseness that standard n-gram models are confronted with. Also related to our work is the approach by Tsubaki et al. (2013), who successfully use a neural network to model co-compositionality.

Our model for selectional preference acquisition uses a network architecture that is similar to the abovementioned models. Its training objective is also similar to the ranking-loss training objective proposed by Collobert and Weston (2008), but we present a novel, modified version in order to deal with multi-way selectional preferences.

3 Methodology

3.1 Neural network architecture

Our model computes the score for a predicate i and an argument j as follows. First, the selectional preference tuple (i, j) is represented as the concatenation of the vectors $\mathbf{v}_i$ and $\mathbf{o}_j$, i.e.

$$\mathbf{x} = [\mathbf{v}_i, \mathbf{o}_j] \tag{5}$$

Vectors $\mathbf{v}_i$ and $\mathbf{o}_j$ are extracted from two embedding matrices, $\mathbf{V} \in \mathbb{R}^{N \times I}$ (the predicate matrix, where I represents the number of elements in the predicate vocabulary) and $\mathbf{O} \in \mathbb{R}^{N \times J}$ (the argument matrix, where J represents the number of elements in the argument vocabulary). N is a parameter setting of the model, representing the vector size of the embeddings. Matrices $\mathbf{V}$ and $\mathbf{O}$ will be automatically learned during training.

Vector $\mathbf{x}$ then serves as input vector to our neural network. We use a feed-forward neural network architecture with one hidden layer:

$$\mathbf{a}_1 = f(\mathbf{W}_1\mathbf{x} + \mathbf{b}_1) \tag{6}$$

$$y = \mathbf{W}_2\mathbf{a}_1 \tag{7}$$

where $\mathbf{x} \in \mathbb{R}^{2N}$ is our input vector, $\mathbf{a}_1 \in \mathbb{R}^H$ represents the activation of the hidden layer with H hidden nodes, $\mathbf{W}_1 \in \mathbb{R}^{H \times 2N}$ and $\mathbf{W}_2 \in \mathbb{R}^{1 \times H}$ respectively represent the first and second layer weights, $\mathbf{b}_1$ represents the first layer's bias, $f(\cdot)$ represents the element-wise activation function tanh, and y is our final selectional preference score. The left-hand picture of figure 1 gives a graphical representation of our standard neural network architecture.

3.2 Training the network

A proper estimation of a neural network's parameters requires a large amount of training data. To be able to use non-annotated corpus data for training, we use the method proposed by Collobert and Weston (2008). The authors present a method for training a neural network language model from unlabeled data by corrupting actual attested n-grams with a random word. They then define a ranking-type cost function, which allows the network to learn to discriminate between good and bad word sequences. We adopt the same method for our selectional preference model as follows.

Let (i, j) be our proper, attested predicate-argument tuple. The goal of our model is to discriminate the correct tuple (i, j) from other, non-attested tuples (i, j'), in which the correct predicate

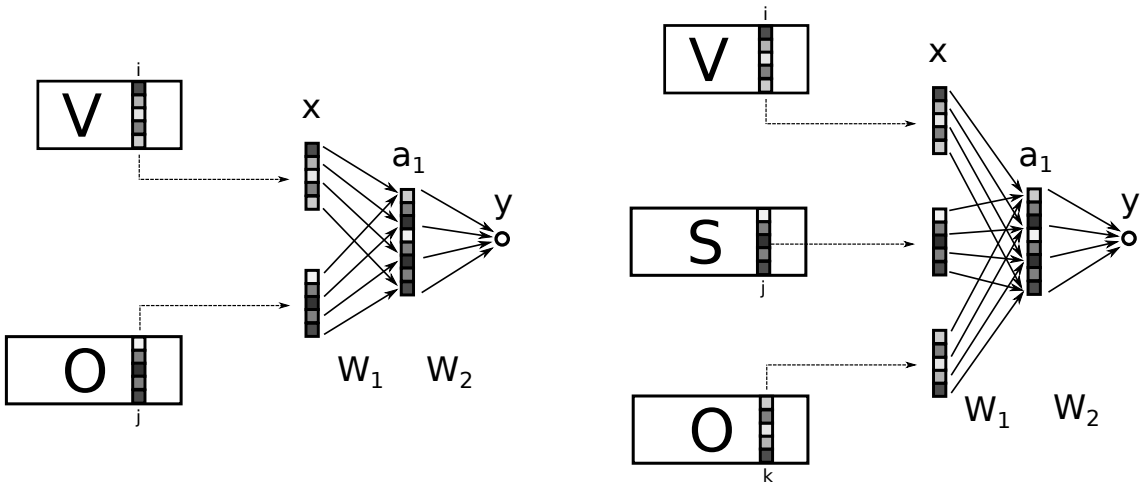

Figure 1: Neural network architectures for selectional preference acquisition. The left-hand picture shows the architecture for two-way selectional preferences, the right-hand picture shows the architecture for three-way selectional preferences. In both cases, vector **x** is constructed from the appropriate predicate and argument vectors from the embedding matrices, and fed forward through the network to yield a preference score y.

j has been replaced with a random predicate j'. We require the score for the correct tuple to be larger than the score for the corrupt tuple by a margin of one. For one tuple (i, j), this corresponds to minimizing the objective function in (8)

$$\sum_{j' \in J} \max(0, 1 - g[(i, j)] + g[(i, j')]) \qquad (8)$$

where J represents the predicate vocabulary, and $g[\cdot]$ represents our neural network scoring function presented in the previous section.

In line with Collobert and Weston (2008), the gradient of the objective function is sampled by randomly picking one corrupt argument j' from the argument vocabulary for each attested predicate-argument tuple (i, j). The derivative of the cost with respect to the model's parameters (weight matrices $\mathbf{W}_1$ and $\mathbf{W}_2$, bias vector $\mathbf{b}_1$, and embedding matrices $\mathbf{V}$ and $\mathbf{O}$) is computed, and the appropriate parameters are updated through backpropagation.

3.3 Multi-way selectional preferences

The model presented in the previous section is only able to deal with two-way selectional preferences. In this section, we present an extension of the model that is able to handle multi-way selectional preferences.[1]

[1]We exemplify the model using three-way selectional preferences for transitive predicates, but the model can be straightforwardly generalized to other multi-way selectional preferences.

In order to model the selectional preference of a transitive verb for its subject and direct object, we start out in a similar fashion to the two-way case. Instead of having only one embedding matrix, we now have two embedding matrices $\mathbf{S} \in \mathbb{R}^{N \times J}$ and $\mathbf{O} \in \mathbb{R}^{N \times K}$, representing the two different argument slots of a transitive predicate. Our input vector can now be represented as

$$\mathbf{x} = (\mathbf{v}_i, \mathbf{s}_j, \mathbf{o}_k) \qquad (9)$$

Note that $\mathbf{x} \in \mathbb{R}^{3N}$ and $\mathbf{W}_1 \in \mathbb{R}^{H \times 3N}$. The rest of our neural network architecture stays exactly the same. The right-hand picture of figure 1 presents a graphical representation.

For the multi-way case, we present an adapted version of the training objective. Given an attested subject-verb-object tuple (i, j, k), the goal of our network is now to discriminate this correct tuple from other, corrupted tuples (i, j, k'), (i, j', k) and (i, j', k'), where the correct arguments have been replaced by random subjects j' and random objects k'. Note that we do not only want the network to learn the infelicity of tuples in which both the subject and object slot are corrupted; we also want our network to learn the infelicity of tuples in which either the subject or object slot is corrupt, while the other slot contains the correct, attested argument. This leads us to the objective function represented in (10).

$$\sum_{k' \in K} \max(0, 1 - g[(i,j,k)] + g[(i,j,k')])$$
$$+ \sum_{j' \in J} \max(0, 1 - g[(i,j,k)] + g[(i,j',k)])$$
$$+ \sum_{\substack{j' \in J \\ k' \in K}} \max(0, 1 - g[(i,j,k)] + g[(i,j',k')]) \quad (10)$$

As in the two-way case, the gradient of the objective function is sampled by randomly picking one corrupted subject j' and one corrupted object k' for each tuple (i, j, k). All of the model's parameters are again updated through backpropagation.

4 Evaluation

4.1 Implementational details

We evaluate our neural network approach to selectional preference acquisition using verb-object tuples for the two-way model, and subject-verb-object tuples for the multi-way model.

Our model has been applied to English, using the UKWaC corpus (Baroni et al., 2009), which covers about 2 billion words of web text. The corpus has been part of speech tagged and lemmatized with Stanford Part-Of-Speech Tagger (Toutanova et al., 2003), and parsed with MaltParser (Nivre et al., 2006), so that dependency tuples could be extracted.

For the two-way model, we select all verbs and objects that appear within a predicate-argument relation with a frequency of at least 50. This gives us a total of about 7K verbs and 30K objects. For the multi-way model, we select the 2K most frequent verbs, together with the 10K most frequent subjects and the 10K most frequent objects (that appear within a transitive frame).

All words are converted to lowercase. We use the lemmatized forms, and only keep those forms that contain alphabetic characters. Furthermore, we require each tuple to appear at least three times in the corpus.

We set N, the size of our embedding matrices, to 50, and H, the number of units in the hidden layer, to 100. Following Huang et al. (2012), we use mini-batch L-BFGS (Liu and Nocedal, 1989) with 1000 pairs of good and corrupt tuples per batch for training, and train for 10 epochs.

4.2 Evaluation Setup

4.2.1 Task

Our models are quantitatively evaluated using a pseudo-disambiguation task (Rooth et al., 1999), which bears some resemblance to our training procedure. The task provides an adequate test of the generalization capabilities of our models. For the two-way case, the task is to judge which object (o or o') is more likely for a particular verb v, where (v, o) is a tuple attested in the corpus, and o' is a direct object randomly drawn from the object vocabulary. The tuple is considered correct if the model prefers the attested tuple (v, o) over (v, o'). For the three-way case, the task is to judge which subject (s or s') and direct object (o or o') are more likely for a particular verb v, where (v, s, o) is the attested tuple, and s' and o' are a random subject and object drawn from their respective vocabularies. The tuple is considered correct if the model prefers the attested tuple (v, s, o) over the alternatives (v, s, o'), (v, s', o), and (v, s', o'). Tables 1 and 2 respectively show a number of examples from the two-way and three-way pseudo-disambiguation task.

v	o	o'
perform	*play*	*geometry*
buy	*wine*	*renaissance*
read	*introduction*	*peanut*

Table 1: Pseudo-disambiguation examples for two-way verb-object tuples

v	s	o	s'	o'
win	*team*	*game*	*diversity*	*egg*
publish	*government*	*document*	*grid*	*priest*
develop	*company*	*software*	*breakfast*	*landlord*

Table 2: Pseudo-disambiguation examples for three-way subject-verb-object tuples

The models are evaluated using 10-fold cross validation. All tuples from our corpus are randomly divided into 10 equal parts. Next, for each fold, 9 parts are used for training, and the remaining part is used for testing. In order to properly test the generalization capability of our models, we make sure that all instances of a particular tuple appear in one part only. This way, we make sure that tuples used for testing are never seen during training.

For the two-way model, our corpus consists of about 70M tuple instances (1.9M types), so in each

fold, about 63M tuple instances are used for training and about 7M (190K types) are used for testing. For the three-way model, our corpus consists of about 5,5M tuple instances (750K types), so in each fold, about 5M tuples are used for training and about 500K (75K types) are used for testing. Note that our training procedure is instance-based, while our evaluation is type-based: during training, the neural network sees a tuple as many times as it appears in the training set, while for testing each individual tuple is only evaluated once.

4.2.2 Comparison models

We compare our neural network model to a number of other models for selectional preference acquisition.

For the two-way case, we compare our model to the EM-based clustering technique presented by Rooth et al. (1999),[2] and to Erk et al.'s (2010) similarity-based model. For Rooth et al.'s model, we set the number of latent factors to 50. Using a larger number of latent factors does not increase performance. For Erk et al.'s model, we create a dependency-based similarity model from the UKWaC corpus using our 30K direct objects as instances and 100K dependency relations as features. The resulting matrix is weighted using pointwise mutual information (Church and Hanks, 1990). Similarity values are computed using cosine. Furthermore, we use a sampling procedure in the testing phase: we sample 5000 predicate-argument pairs for each fold, as testing Erk et al.'s model on the complete test sets proved prohibitively expensive.

For the three-way case, we compare our model to the tensor factorization model we developed in previous work (Van de Cruys, 2009). We set the number of latent factors to 300.[3]

4.3 Results

4.3.1 Two-way model

Table 3 compares the results of our neural network architecture for two-way selectional preferences to the results of Rooth et al.'s (1999) model and Erk et al.'s (2010) model.

[2]Our own implementation of Rooth et al.'s (1999) algorithm is based on non-negative matrix factorization (Lee and Seung, 2000). Non-negative matrix factorization with Kullback-Leibler divergence has been shown to minimize the same objective function as EM (Li and Ding, 2006).

[3]The best scoring model presented by Van de Cruys (2009) also uses 300 latent factors; using more factors does not improve the results.

model	accuracy ($\mu \pm \sigma$)
Rooth et al. (1999)	.720 $\pm$ .002
Erk et al. (2010)	**.887** $\pm$ .004
2-way neural network	.880 $\pm$ .001

Table 3: Comparison of model results for two-way selectional preference acquisition – mean accuracy and standard deviations of 10-fold cross-validation results

The results indicate that our neural network approach outperforms Rooth et al.'s (1999) method by a large margin (16%). Clearly, the neural network architecture is able to model selectional preferences more profoundly than Rooth et al.'s latent variable approach. The difference between the models is highly statistically significant (paired t-test, $p < .01$), as the standard deviations already indicate.

Erk et al.'s model reaches a slightly better score than our model, and this result is also statistically significant (paired t-test, $p < .01$). However, Erk et al.'s model does not provide full coverage, whereas the other two models are able to compute scores for all pairs in the test set. In addition, Erk et al.'s model is much more expensive to compute. Our model computes selectional preference scores for the test set in a matter of seconds, whereas for Erk et al.'s model, we ended up sampling from the test set, as computing preference values for the complete test set proved prohibitively expensive.

4.3.2 Three-way model

Table 4 compares the results of our neural network architecture for three-way selectional preference acquisition to the results of the tensor-based factorization method (Van de Cruys, 2009).

model	accuracy ($\mu \pm \sigma$)
Van de Cruys (2009)	.874 $\pm$ .001
3-way neural network	**.889** $\pm$ .001

Table 4: Comparison of model results for three-way selectional preference acquisition – mean accuracy and standard deviations of 10-fold cross-validation results

The results indicate that the neural network approach slightly outperforms the tensor-based factorization method. Again the model difference is sta-

tistically significant (paired t-test, $p < 0.01$). Using our adapted training objective, the neural network is clearly able to learn a rich model of three-way selectional preferences, reaching state of the art performance.

4.4 Examples

We conclude our results section by briefly presenting a number of examples that illustrate the kind of semantics present in our models. Similar to neural language models, the predicate and argument embedding matrices of our neural network contain distributed word representations, that capture the similarity of predicates and arguments to other words.

Tables 5 and 6 contain a number of nearest neighbour similarity examples for predicate and arguments from our two-way neural network model. The nearest neighbours were calculated using standard cosine similarity.

DRINK	PROGRAM	INTERVIEW	FLOOD
SIP	RECOMPILE	RECRUIT	INUNDATE
BREW	UNDELETE	PERSUADE	RAVAGE
MINCE	CODE	INSTRUCT	SUBMERGE
FRY	IMPORT	PESTER	COLONIZE

Table 5: Nearest neighbours of 4 verbs, calculated using the distributed word representations of embedding matrix **V** from our two-way neural network model

Table 5 indicates that the network is effectively able to capture a semantics for verbs. The first column – verbs similar to DRINK – all have to do with food consumption. The second column contains verbs related to computer programming. The third column is related to human communication; and the fourth column seems to illustrate the network's comprehension of FLOOD having to do with invasion and water.

PAPER	RASPBERRY	SECRETARY	DESIGNER
BOOK	COURGETTE	PRESIDENT	PLANNER
JOURNAL	LATTE	MANAGER	PAINTER
ARTICLE	LEMONADE	POLICE	SPECIALIST
CODE	OATMEAL	EDITOR	SPEAKER

Table 6: Nearest neighbours of 4 direct objects, calculated using the distributed word representations of embedding matrix **O** from our two way neural network model

Similarly, table 6 shows the network's ability to capture the meaning of nouns that appear as direct objects to the verbs. Column one contains things that can be read. Column two contains things that can be consumed. Column three seems to hint at supervising professions, while column four seems to capture creative professions.

A similar kind of semantics is present in the embedding matrices of the three-way neural network model. Tables 7, 8, and 9 again illustrate this using word similarity calculations.

SEARCH	DIMINISH	CONFIGURE	PROSECUTE
CLICK	LESSEN	AUTOMATE	CRITICISE
BROWSE	DISTORT	SCROLL	URGE
SCROLL	HEIGHTEN	PROGRAM	DEPLORE
UPLOAD	DEGRADE	INSTALL	CONDEMN

Table 7: Nearest neighbours of 4 verbs, calculated using the distributed word representations of embedding matrix **V** from our three-way neural network model

Table 7 shows the network's verb semantics for the three-way case. The first column is related to internet usage, the second column contains verbs of scalar change, column three is again related to computer usage, and column four seems to capture 'mending' verbs.

FLOWER	COLLEGE	PRESIDENT	SONG
FISH	UNIVERSITY	BUSH	FILM
BIRD	INSTITUTE	BLAIR	ALBUM
SUN	DEPARTMENT	MP	PLAY
TREE	CENTRE	CHAIRMAN	MUSIC

Table 8: Nearest neighbours of 4 subjects, calculated using the distributed word representations of embedding matrix **S** from our three way neural network model

Table 8 illustrates the semantics for the subject slot of our three-way model. The first column captures nature terms, the second column contains university-related terms, the third column contains politicians/government terms, and the fourth column contains art expressions.

Finally, table 9 demonstrates the semantics of our three-way model's object slot. Column one generally contains housing terms, column two contains various locations, column three contains dining occasions, and column four contains textual expressions.

WALL	PARK	LUNCH	THESIS
FLOOR	STUDIO	DINNER	QUESTIONNAIRE
CEILING	VILLAGE	MEAL	DISSERTATION
ROOF	HALL	BUFFET	PERIODICAL
METRE	MUSEUM	BREAKFAST	DISCOURSE

Table 9: Nearest neighbours of 4 direct objects, calculated using the distributed word representations of embedding matrix **O** from our three way neural network model

Note that the embeddings for the subject and the object slot is different, although they mostly contain the same words. This allows the model to capture specific semantic characteristics for words given their argument position. *Virus*, for example, is in subject position more similar to active words like *animal*, whereas in object position, it is more similar to passive words like *cell*, *device*. Similarly, *mouse* in subject position tends to be similar to words like *animal*, *rat* whereas in object position it is similar to words like *web*, *browser*.

These examples, although anecdotal, illustrate that our neural network model is able to capture a rich semantics for predicates and arguments, which subsequently allows the network to make accurate predictions with regard to selectional preference.

5 Conclusion and future work

In this paper, we presented a neural network approach to the acquisition of selectional preferences. Inspired by recent work on neural language models, we proposed a neural network model that learns to discriminate between felicitous and infelicitous arguments for a particular predicate. The model is entirely unsupervised, as preferences are learned from unannotated corpus data. Positive training instances are constructed from attested corpus data, while negative instances are constructed from randomly corrupted instances. Using designated network architectures, we are able to handle standard two-way selectional preferences as well as multi-way selectional preferences. A quantitative evaluation on a pseudo-disambiguation task shows that our models achieve state of the art performance. The results for our two-way neural network are on a par with Erk et al.'s (2010) similarity-based approach, while our three-way neural network slightly outperforms the tensor-based factorization model (Van de Cruys, 2009) for multi-way selectional preference induction.

We conclude with a number of issues for future work. First of all, we would like to investigate how our neural network approach might be improved by incorporating information from other sources. In particular, we think of initializing our embedding matrices with distributed representations that come from a large-scale neural language model (Mikolov et al., 2013). We also want to further investigate the advantages and disadvantages of having different embedding matrices for different argument positions in our multi-way neural network. In our results section, we demonstrated that such an approach allows for more flexibility, but it also adds a certain level of redundancy. We want to investigate the benefit of our approach, compared to a model that shares the distributed word representation among different argument positions. Finally, we want to investigate more advanced neural network architectures for the acquisition of selectional preferences. In particular, neural tensor networks (Yu et al., 2013) have recently demonstrated impressive results in related fields like speech recognition, and might provide the necessary machinery to model multi-way selectional preferences in a more profound way.

Abstract

We construct multi-modal concept representations by concatenating a skip-gram linguistic representation vector with a visual concept representation vector computed using the feature extraction layers of a deep convolutional neural network (CNN) trained on a large labeled object recognition dataset. This transfer learning approach brings a clear performance gain over features based on the traditional bag-of-visual-word approach. Experimental results are reported on the WordSim353 and MEN semantic relatedness evaluation tasks. We use visual features computed using either ImageNet or ESP Game images.

1 Introduction

Recent works have shown that multi-modal semantic representation models outperform unimodal linguistic models on a variety of tasks, including modeling semantic relatedness and predicting compositionality (Feng and Lapata, 2010; Leong and Mihalcea, 2011; Bruni et al., 2012; Roller and Schulte im Walde, 2013; Kiela et al., 2014). These results were obtained by combining linguistic feature representations with robust visual features extracted from a set of images associated with the concept in question. This extraction of visual features usually follows the popular computer vision approach consisting of computing local features, such as SIFT features (Lowe, 1999), and aggregating them as bags of visual words (Sivic and Zisserman, 2003).

Meanwhile, deep transfer learning techniques have gained considerable attention in the computer vision community. First, a deep convolutional neural network (CNN) is trained on a large labeled dataset (Krizhevsky et al., 2012). The convolutional layers are then used as mid-level feature extractors on a variety of computer vision tasks (Oquab et al., 2014; Girshick et al., 2013; Zeiler and Fergus, 2013; Donahue et al., 2014). Although transferring convolutional network features is not a new idea (Driancourt and Bottou, 1990), the simultaneous availability of large datasets and cheap GPU co-processors has contributed to the achievement of considerable performance gains on a variety computer vision benchmarks: *"SIFT and HOG descriptors produced big performance gains a decade ago, and now deep convolutional features are providing a similar breakthrough"* (Razavian et al., 2014).

This work reports on results obtained by using CNN-extracted features in multi-modal semantic representation models. These results are interesting in several respects. First, these superior features provide the opportunity to increase the performance gap achieved by augmenting linguistic features with multi-modal features. Second, this increased performance confirms that the multimodal performance improvement results from the information contained in the images and not the information used to select which images to use to represent a concept. Third, our evaluation reveals an intriguing property of the CNN-extracted features. Finally, since we use the skip-gram approach of Mikolov et al. (2013) to generate our linguistic features, we believe that this work represents the first approach to multimodal distributional semantics that exclusively relies on deep learning for both its linguistic and visual components.

2 Related work

2.1 Multi-Modal Distributional Semantics

Multi-modal models are motivated by parallels with human concept acquisition. Standard se-

* This work was carried out while Douwe Kiela was an intern at Microsoft Research, New York.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 36–45,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

mantic space models extract meanings solely from linguistic data, even though we know that human semantic knowledge relies heavily on perceptual information (Louwerse, 2011). That is, there exists substantial evidence that many concepts are *grounded* in the perceptual system (Barsalou, 2008). One way to do this grounding in the context of distributional semantics is to obtain representations that combine information from linguistic corpora with information from another modality, obtained from e.g. property norming experiments (Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013) or from processing and extracting features from images (Feng and Lapata, 2010; Leong and Mihalcea, 2011; Bruni et al., 2012). This approach has met with quite some success (Bruni et al., 2014).

2.2 Multi-modal Deep Learning

Other examples that apply multi-modal deep learning use restricted Boltzmann machines (Srivastava and Salakhutdinov, 2012; Feng et al., 2013), auto-encoders (Wu et al., 2013) or recursive neural networks (Socher et al., 2014). Multimodal models with deep learning components have also successfully been employed in cross-modal tasks (Lazaridou et al., 2014). Work that is closely related in spirit to ours is by Silberer and Lapata (2014). They use a stacked auto-encoder to learn combined embeddings of textual and visual input. Their visual inputs consist of vectors of visual attributes obtained from learning SVM classifiers on attribute prediction tasks. In contrast, our work keeps the modalities separate and follows the standard multi-modal approach of concatenating linguistic and visual representations in a single semantic space model. This has the advantage that it allows for separate data sources for the individual modalities. We also learn visual representations directly from the images (i.e., we apply deep learning directly to the images), as opposed to taking a higher-level representation as a starting point. Frome et al. (2013) jointly learn multimodal representations as well, but apply them to a visual object recognition task instead of concept meaning.

2.3 Deep Convolutional Neural Networks

A flurry of recent results indicates that image descriptors extracted from deep convolutional neural networks (CNNs) are very powerful and consistently outperform highly tuned state-of-the-art systems on a variety of visual recognition tasks (Razavian et al., 2014). Embeddings from state-of-the-art CNNs (such as Krizhevsky et al. (2012)) have been applied successfully to a number of problems in computer vision (Girshick et al., 2013; Zeiler and Fergus, 2013; Donahue et al., 2014). This contribution follows the approach described by Oquab et al. (2014): they train a CNN on 1512 ImageNet synsets (Deng et al., 2009), use the first seven layers of the trained network as feature extractors on the Pascal VOC dataset, and achieve state-of-the-art performance on the Pascal VOC classification task.

3 Improving Multi-Modal Representations

Figure 1 illustrates how our system computes multi-modal semantic representations.

3.1 Perceptual Representations

The perceptual component of standard multi-modal models that rely on visual data is often an instance of the bag-of-visual-words (BOVW) representation (Sivic and Zisserman, 2003). This approach takes a collection of images associated with words or tags representing the concept in question. For each image, keypoints are laid out as a dense grid. Each keypoint is represented by a vector of robust local visual features such as SIFT (Lowe, 1999), SURF (Bay et al., 2008) and HOG (Dalal and Triggs, 2005), as well as pyramidal variants of these descriptors such as PHOW (Bosch et al., 2007). These descriptors are subsequently clustered into a discrete set of "visual words" using a standard clustering algorithm like k-means and quantized into vector representations by comparing the local descriptors with the cluster centroids. Visual representations are obtained by taking the average of the BOVW vectors for the images that correspond to a given word. We use BOVW as a baseline.

Our approach similarly makes use of a collection of images associated with words or tags representing a particular concept. Each image is processed by the first seven layers of the convolutional network defined by Krizhevsky et al. (2012) and adapted by Oquab et al. (2014)[1]. This network takes 224×224 pixel RGB images and applies five successive convolutional layers followed by three fully connected layers. Its eighth and last

[1] http://www.di.ens.fr/willow/research/cnn/

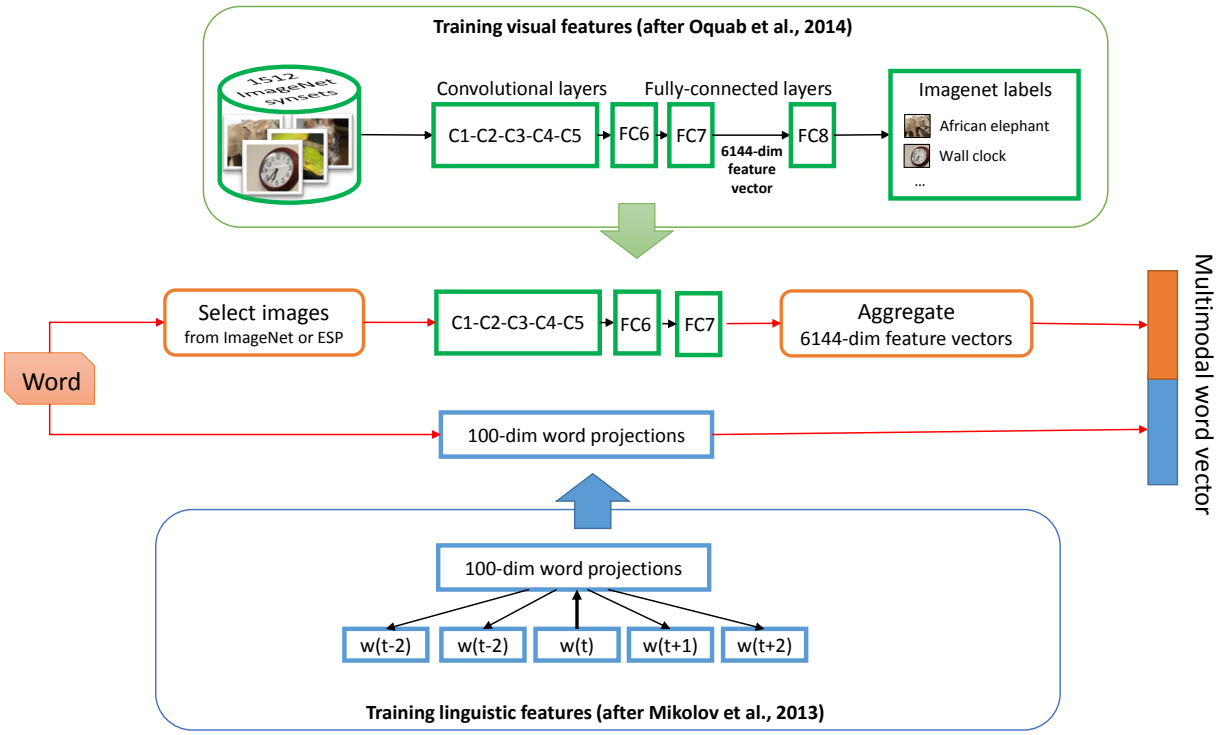

Figure 1: Computing word feature vectors.

layer produces a vector of 1512 scores associated with 1000 categories of the ILSVRC-2012 challenge and the 512 additional categories selected by Oquab et al. (2014). This network was trained using about 1.6 million ImageNet images associated with these 1512 categories. We then freeze the trained parameters, chop the last network layer, and use the remaining seventh layer as a filter to compute a 6144-dimensional feature vector on arbitrary 224×224 input images.

We consider two ways to aggregate the feature vectors representing each image.

1. The first method (**CNN-Mean**) simply computes the average of all feature vectors.

2. The second method (**CNN-Max**) computes the component-wise maximum of all feature vectors. This approach makes sense because the feature vectors extracted from this particular network are quite sparse (about 22% non-zero coefficients) and can be interpreted as bags of visual properties.

3.2 Linguistic representations

For our linguistic representations we extract 100-dimensional continuous vector representations using the log-linear skip-gram model of Mikolov et al. (2013) trained on a corpus consisting of the 400M word Text8 corpus of Wikipedia text[2] together with the 100M word British National Corpus (Leech et al., 1994). We also experimented with dependency-based skip-grams (Levy and Goldberg, 2014) but this did not improve results. The skip-gram model learns high quality semantic representations based on the distributional properties of words in text, and outperforms standard distributional models on a variety of semantic similarity and relatedness tasks. However we note that Bruni et al. (2014) have recently reported an even better performance for their linguistic component using a standard distributional model, although this may have been tuned to the task.

3.3 Multi-modal Representations

Following Bruni et al. (2014), we construct multi-modal semantic representations by concatenating the centered and L_2-normalized linguistic and perceptual feature vectors $\vec{v}_{ling}$ and $\vec{v}_{vis}$,

$$\vec{v}_{concept} = \alpha \times \vec{v}_{ling} \,||\, (1-\alpha) \times \vec{v}_{vis}\,, \quad (1)$$

where $||$ denotes the concatenation operator and α is an optional tuning parameter.

[2] http://mattmahoney.net/dc/textdata.html

Figure 2: Examples of *dog* in the ESP Game dataset.

Figure 3: Examples of *golden retriever* in ImageNet.

4 Experimental Setup

We carried out experiments using visual representations computed using two canonical image datasets. The resulting multi-modal concept representations were evaluated using two well-known semantic relatedness datasets.

4.1 Visual Data

We carried out experiments using two distinct sources of images to compute the visual representations.

The **ImageNet** dataset (Deng et al., 2009) is a large-scale ontology of images organized according to the hierarchy of WordNet (Fellbaum, 1999). The dataset was constructed by manually re-labelling candidate images collected using web searches for each WordNet synset. The images tend to be of high quality with the designated object roughly centered in the image. Our copy of ImageNet contains about 12.5 million images organized in 22K synsets. This implies that ImageNet covers only a small fraction of the existing 117K WordNet synsets.

The **ESP Game** dataset (Von Ahn and Dabbish, 2004) was famously collected as a "game with a purpose", in which two players must independently and rapidly agree on a correct word label for randomly selected images. Once a word label has been used sufficiently frequently for a given image, that word is added to the image's tags. This dataset contains 100K images, but with every image having on average 14 tags, that amounts to a coverage of 20,515 words. Since players are encouraged to produce as many terms per image, the dataset's increased coverage is at the expense of accuracy in the word-to-image mapping: a dog in a field with a house in the background might be a *golden retriever* in ImageNet and could have tags *dog, golden retriever, grass, field, house, door* in the ESP Dataset. In other words, images in the ESP dataset do not make a distinction between objects in the foreground and in the background, or between the relative size of the objects (tags for images are provided in a random order, so the top tag is not necessarily the best one).

Figures 2 and 3 show typical examples of images belonging to these datasets. Both datasets have attractive properties. On the one hand, ImageNet has higher quality images with better labels. On the other hand, the ESP dataset has an interesting coverage because the MEN task (see section 4.4) was specifically designed to be covered by the ESP dataset.

4.2 Image Selection

Since ImageNet follows the WordNet hierarchy, we would have to include almost all images in the dataset to obtain representations for high-level concepts such as *entity*, *object* and *animal*. Doing so is both computationally expensive and unlikely to improve the results. For this reason, we randomly sample up to N distinct images from the subtree associated with each concept. When this returns less than N images, we attempt to increase coverage by sampling images from the subtree of the concept's hypernym instead. In order to allow for a fair comparison, we apply the same method of sampling up to N on the ESP Game dataset. In all following experiments, $N = 1.000$. We used the WordNet lemmatizer from NLTK (Bird et al., 2009) to lemmatize tags and concept words so as to further improve the dataset's coverage.

4.3 Image Processing

The ImageNet images were preprocessed as described by (Krizhevsky et al., 2012). The largest centered square contained in each image is resam-

pled to form a 256×256 image. The CNN input is then formed by cropping 16 pixels off each border and subtracting 128 to the image components. The ESP Game images were preprocessed slightly differently because we do not expect the objects to be centered. Each image was rescaled to fit inside a 224×224 rectangle. The CNN input is then formed by centering this image into the 224×224 input field, subtracting 128 to the image components, and zero padding.

The BOVW features were obtained by computing DSIFT descriptors using VLFeat (Vedaldi and Fulkerson, 2008). These descriptors were subsequently clustered using mini-batch k-means (Sculley, 2010) with 100 clusters. Each image is then represented by a bag of clusters (visual words) quantized as a 100-dimensional feature vector. These vectors were then combined into visual concept representations by taking their mean.

4.4 Evaluation

We evaluate our multi-modal word representations using two semantic relatedness datasets widely used in distributional semantics (Agirre et al., 2009; Feng and Lapata, 2010; Bruni et al., 2012; Kiela and Clark, 2014; Bruni et al., 2014).

WordSim353 (Finkelstein et al., 2001) is a selection of 353 concept pairs with a similarity rating provided by human annotators. Since this is probably the most widely used evaluation dataset for distributional semantics, we include it for comparison with other approaches. WordSim353 has some known idiosyncracies: it includes named entities, such as *OPEC*, *Arafat*, and *Maradona*, as well as abstract words, such as *antecedent* and *credibility*, for which it may be hard to find corresponding images. Multi-modal representations are often evaluated on an unspecified subset of WordSim353 (Feng and Lapata, 2010; Bruni et al., 2012; Bruni et al., 2014), making it impossible to compare the reported scores. In this work, we report scores on the full WordSim353 dataset (**W353**) by setting the visual vector $\vec{v}_{vis}$ to zero for concepts without images. We also report scores on the subset (**W353-Relevant**) of pairs for which both concepts have both ImageNet and ESP Game images using the aforementioned selection procedure.

MEN (Bruni et al., 2012) was in part designed to alleviate the WordSim353 problems. It was constructed in such a way that only frequent words with at least 50 images in the ESP Game dataset were included in the evaluation pairs. The MEN dataset has been found to mirror the aggregate score over a variety of tasks and similarity datasets (Kiela and Clark, 2014). It is also much larger, with 3000 words pairs consisting of 751 individual words. Although MEN was constructed so as to have at least a minimum amount of images available in the ESP Game dataset for each concept, this is not the case for ImageNet. Hence, similarly to WordSim353, we also evaluate on a subset (**MEN-Relevant**) for which images are available in both datasets.

We evaluate the models in terms of their Spearman ρ correlation with the human relatedness ratings. The similarity between the representations associated with a pair of words is calculated using the cosine similarity:

$$\cos(v_1, v_2) = \frac{v_1 \cdot v_2}{\|v_1\| \, \|v_2\|} \tag{2}$$

5 Results

We evaluate on the two semantic relatedness datasets using solely linguistic, solely visual and multi-modal representations. In the case of MEN-Relevant and W353-Relevant, we report scores for BOVW, CNN-Mean and CNN-Max visual representations. For all datasets we report the scores obtained by BOVW, CNN-Mean and CNN-Max multi-modal representations. Since we have full coverage with the ESP Game dataset on MEN, we are able to report visual representation scores for the entire dataset as well. The results can be seen in Table 1.

There are a number of questions to ask. First of all, do CNNs yield better visual representations? Second, do CNNs yield better multi-modal representations? And third, is there a difference between the high-quality low-coverage ImageNet and the low-quality higher-coverage ESP Game dataset representations?

5.1 Visual Representations

In all cases, CNN-generated visual representations perform better or as good as BOVW representations (we report results for BOVW-Mean, which performs slightly better than taking the element-wise maximum). This confirms the motivation outlined in the introduction: by applying state-of-the-art approaches from computer vision to multi-modal semantics, we obtain a signficant perfor-

Dataset	Linguistic	Visual			Multi-modal		
		BOVW	CNN-Mean	CNN-Max	BOVW	CNN-Mean	CNN-Max
ImageNet visual features							
MEN	0.64	-	-	-	0.64	**0.70**	0.67
MEN-Relevant	0.62	0.40	0.64	0.63	0.64	**0.72**	0.71
W353	0.57	-	-	-	0.58	0.59	**0.60**
W353-Relevant	0.51	0.30	0.32	0.30	0.55	0.56	**0.57**
ESP game visual features							
MEN	0.64	0.17	0.51	0.20	0.64	**0.71**	0.65
MEN-Relevant	0.62	0.35	0.58	0.57	0.63	0.69	**0.70**
W353	0.57	-	-	-	0.58	0.59	**0.60**
W353-Relevant	0.51	0.38	0.44	0.56	0.52	0.55	**0.61**

Table 1: Results (see sections 4 and 5).

mance increase over standard multi-modal models.

5.2 Multi-modal Representations

Higher-quality perceptual input leads to better-performing multi-modal representations. In all cases multi-modal models with CNNs outperform multi-modal models with BOVW, occasionally by quite a margin. In all cases, multi-modal representations outperform purely linguistic vectors that were obtained using a state-of-the-art system. This re-affirms the importance of multi-modal representations for distributional semantics.

5.3 The Contribution of Images

Since the ESP Game images come with a multitude of word labels, one could question whether a performance increase of multi-modal models based on that dataset comes from the images themselves, or from overlapping word labels. It might also be possible that similar concepts are more likely to occur in the same image, which encodes relatedness information without necessarily taking the image data itself into account. In short, it is a natural question to ask whether the performance gain is due to image data or due to word label associations? We conclusively show that the image data matters in two ways: (a) using a different dataset (ImageNet) also results in a performance boost, and (b) using higher-quality image features on the ESP game images increases the performance boost without changing the association between word labels.

5.4 Image Datasets

It is important to ask whether the source image dataset has a large impact on performance. Although the scores for the visual representation in some cases differ, performance of multi-modal representations remains close for both image datasets. This implies that our method is robust over different datasets. It also suggests that it is beneficial to train on high-quality datasets like ImageNet and to subsequently generate embeddings for other sets of images like the ESP Game dataset that are more noisy but have better coverage. The results show the benefit of transfering convolutional network features, corroborating recent results in computer vision.

5.5 Semantic Similarity/Relatedness Datasets

There is an interesting discrepancy between the two types of network with respect to dataset performance: CNN-Mean multi-modal models tend to perform best on MEN and MEN-Relevant, while CNN-Max multi-modal models perform better on W353 and W353-Relevant. There also appears to be some interplay between the source corpus, the evaluation dataset and the best performing CNN: the performance leap on W353-

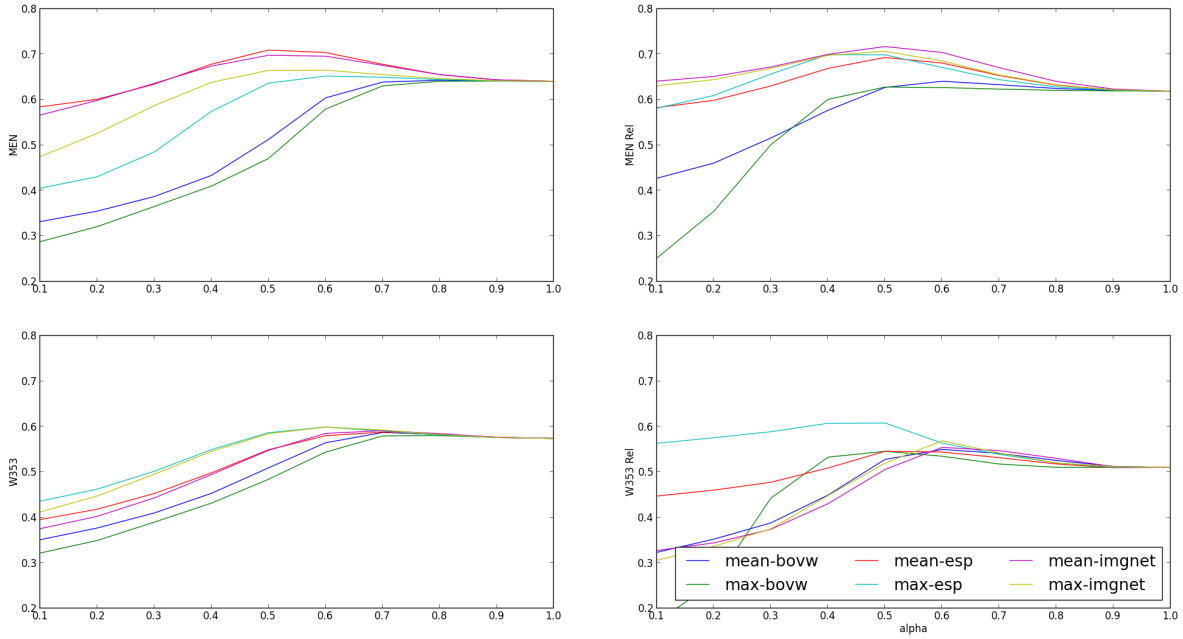

Figure 4: Varying the α parameter for MEN, MEN-Relevant, WordSim353 and WordSim353-Relevant, respectively.

Relevant for CNN-Max is much larger using ESP Game images than with ImageNet images.

We speculate that this is because CNN-Max performs better than CNN-Mean on a somewhat different type of similarity. It has been noted (Agirre et al., 2009) that WordSim353 captures both similarity (as in *tiger-cat*, with a score of 7.35) as well as relatedness (as in *Maradona-football*, with a score of 8.62). MEN, however, is explicitly designed to capture semantic relatedness only (Bruni et al., 2012). CNN-Max using sparse feature vectors means that we treat the dominant components as definitive of the concept class, which is more suited to similarity. CNN-Mean averages over all the feature components, and as such might be more suited to relatedness. We conjecture that the performance increase on WordSim353 is due to increased performance on the similarity subset of that dataset.

5.6 Tuning

The concatenation scheme in Equation 1 allows for a tuning parameter α to weight the relative contribution of the respective modalities. Previous work on MEN has found that the optimal parameter for that dataset is close to 0.5 (Bruni et al., 2014). We have found that this is indeed the case. On WordSim353, however, we have found the parameter for optimal performance to be shifted to the right, meaning that optimal performance is achieved when we include less of the visual input compared to the linguistic input. Figure 4 shows what happens when we vary alpha over the four datasets. There are a number of observations to be made here.

First of all, we can see that the performance peak for the MEN datastes is much higher than for the WordSim353 ones, and that its peak is relatively higher as well. This indicates that MEN is in a sense a more balanced dataset. There are two possible explanations: as indicated earlier, WordSim353 contains slightly idiosyncratic word pairs which may have a detrimental effect on performance; or, WordSim353 was not constructed with multi-modal semantics in mind, and contains a substantial amount of abstract words that would not benefit at all from including visual information.

Due to the nature of the datasets and the tasks at hand, it is arguably much more important that CNNs beat standard bag-of-visual-words representations on MEN than on W353, and indeed we see that there exists no α for which BOVW would beat any of the CNN networks.

6 Error Analysis

Table 2 shows the top 5 best and top 5 worst scoring word pairs for the two datasets using CNN-

W353-Relevant

dessert	tomato	0.66	0.14	dessert	soup	0.81	0.23

Table 2: The top 5 best and top 5 worst scoring pairs with respect to the gold standard.

Mean multi-modal vectors. The most accurate pairs are consistently the same across the two image datasets. There are some clear differences between the least accurate pairs, however. The MEN words *potatoes* and *tomato* probably have low quality ImageNet-derived representations, because they occur often in the bottom pairs for that dataset. The MEN words *dessert*, *bread* and *fruit* occur in the bottom 5 for both image datasets, which implies that their linguistic representations are probably not very good. For WordSim353, the bottom pairs on ImageNet could be said to be similarity mistakes; while the ESP Game dataset contains more relatedness mistakes (*king* and *queen* would evaluate similarity, while *stock* and *market* would evaluate relatedness). It is difficult to say anything conclusive about this discrepancy, but it is clearly a direction for future research.

7 Image embeddings

To facilitate further research on image embeddings and multi-modal semantics, we publicly release embeddings for all the image labels occurring in the ESP Game dataset. Please see the following web page: `http://www.cl.cam.ac.uk/~dk427/imgembed.html`

8 Conclusion

We presented a novel approach to improving multi-modal representations using deep convolutional neural network-extracted features. We reported high results on two well-known and widely-used semantic relatedness benchmarks, with increased performance both in the separate visual representations and in the combined multi-modal representations. Our results indicate that such multi-modal representations outperform both linguistic and standard bag-of-visual-words multi-modal representations. We have shown that our approach is robust and that CNN-extracted features from separate image datasets can succesfully be applied to semantic relatedness.

In addition to improving multi-modal representations, we have shown that the source of this improvement is due to image data and is not simply a result of word label associations. We have shown this by obtaining performance improvements on two different image datasets, and by obtaining

higher performance with higher-quality image features on the ESP game images, without changing the association between word labels.

In future work, we will investigate whether our system can be further improved by including concreteness information or a substitute metric such as image dispersion, as has been suggested by other work on multi-modal semantics (Kiela et al., 2014). Furthermore, a logical next step to increase performance would be to jointly learn multi-modal representations or to learn weighting parameters. Another interesting possibility would be to examine multi-modal distributional compositional semantics, where multi-modal representations are composed to obtain phrasal representations.

Acknowledgments

We would like to thank Maxime Oquab for providing the feature extraction code.

Abstract

In this paper, we present a novel approach for identifying argumentative discourse structures in persuasive essays. The structure of argumentation consists of several components (i.e. claims and premises) that are connected with argumentative relations. We consider this task in two consecutive steps. First, we identify the components of arguments using multiclass classification. Second, we classify a pair of argument components as either support or non-support for identifying the structure of argumentative discourse. For both tasks, we evaluate several classifiers and propose novel feature sets including structural, lexical, syntactic and contextual features. In our experiments, we obtain a macro F1-score of 0.726 for identifying argument components and 0.722 for argumentative relations.

1 Introduction

Argumentation is a crucial aspect of writing skills acquisition. The ability of formulating persuasive arguments is not only the foundation for convincing an audience of novel ideas but also plays a major role in general decision making and analyzing different stances. However, current writing support is limited to feedback about spelling, grammar, or stylistic properties and there is currently no system that provides feedback about written argumentation. By integrating argumentation mining in writing environments, students will be able to inspect their texts for plausibility and to improve the quality of their argumentation.

An *argument* consists of several components. It includes a claim that is supported or attacked by at least one premise. The *claim* is the central component of an argument. It is a controversial statement that should not be accepted by the reader without additional support.[1] The *premise* underpins the validity of the claim. It is a reason given by an author for persuading readers of the claim. *Argumentative relations* model the discourse structure of arguments. They indicate which argument components are related and constitute the structure of argumentative discourse. For example, the argument in the following paragraph contains four argument components: one claim (in bold face) and three premises (underlined).

> "(1) ***Museums and art galleries provide a better understanding about arts than Internet***. (2) *In most museums and art galleries, detailed descriptions in terms of the background, history and author are provided.* (3) *Seeing an artwork online is not the same as watching it with our own eyes, as* (4) *the picture online does not show the texture or three-dimensional structure of the art, which is important to study*."

In this example, the premises (2) and (3) support the claim (1) whereas premise (4) is a support for premise (3). Thus, this example includes three argumentative support relations holding between the components (2,1), (3,1) and (4,3) signaling that the source component is a justification of the target component. This illustrates two important properties of argumentative discourse structures. First, argumentative relations are often implicit (not indicated by discourse markers; e.g. the relation holding between (2) and (1)). Indeed, Marcu and Echihabi (2002) found that only 26% of the evidence relations in the RST Discourse Treebank (Carlson et al., 2001) include discourse markers.

[1]We use the term claim synonymously to *conclusion*. In our definition the differentiation between claims and premises does not indicate the validity of the statements but signals which components include the gist of an argument and which are given by the author as justification.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 46–56,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

Second, in contrast to Rhetorical Structure Theory (RST) (Mann and Thompson, 1987), argumentative relations also hold between non-adjacent sentences/clauses. For instance, in the corpus compiled by Stab and Gurevych (2014) only 37% of the premises appear adjacent to a claim. Therefore, existing approaches of discourse analysis, e.g. based on RST, do not meet the requirements of argumentative discourse structure identification, since they only consider discourse relations between adjacent sentences/clauses (Peldszus and Stede, 2013). In addition, there are no distinct argumentative relations included in common approaches like RST or the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), since they are focused on identifying general discourse structures (cp. section 2.2).

Most of the existing argumentation mining methods focus solely on the identification of argument components. However, identifying argumentative discourse structures is an important task (Sergeant, 2013) in particular for providing feedback about argumentation. First, argumentative discourse structures are essential for evaluating the quality of an argument, since it is not possible to examine how well a claim is justified without knowing which premises belong to it. Second, methods that recognize if a statement supports a given claim enable the collection of additional evidence from other sources. Third, the structure of argumentation is needed for recommending better arrangements of argument components and meaningful usage of discourse markers. Both foster argument comprehension and recall (Britt and Larson, 2003) and thus increase the argumentation quality. To the best of our knowledge, there is currently only one approach that aims at identifying argumentative discourse structures proposed by Mochales-Palau and Moens (2009). However, it relies on a manually created context-free grammar (CFG) and is tailored to the legal domain, which follows a standardized argumentation style. Therefore, it is likely that it will not achieve acceptable accuracy when applied to more general texts in which discourse markers are missing or even misleadingly used (e.g. student texts).

In this work, we present a novel approach for identifying argumentative discourse structures which includes two consecutive steps. In the first step, we focus on the identification of argument components using a multiclass classification approach. In the second step, we identify argumentative relations by classifying a pair of argument components as either support or non-support. In particular, the contributions of this work are the following: First, we introduce a novel approach for identifying argumentative discourse structures. Contrary to previous approaches, our approach is capable of identifying argumentative discourse structures even if discourse markers are missing or misleadingly used. Second, we present two novel feature sets for identifying argument components as well as argumentative relations. Third, we evaluate several classifiers and feature groups for identifying the best system for both tasks.

2 Related Work

2.1 Argumentation Mining

Previous research on argumentation mining spans several subtasks, including (1) the separation of argumentative from non-argumentative text units (Moens et al., 2007; Florou et al., 2013), (2) the classification of argument components or argumentation schemes (Rooney et al., 2012; Mochales-Palau and Moens, 2009; Teufel, 1999; Feng and Hirst, 2011), and (3) the identification of argumentation structures (Mochales-Palau and Moens, 2009; Wyner et al., 2010).

The separation of argumentative from non-argumentative text units is usually considered as a binary classification task and constitutes one of the first steps in an argumentation mining pipeline. Moens et al. (2007) propose an approach for identifying argumentative sentences in the Araucaria corpus (Reed et al., 2008). The argument annotations in Araucaria are based on a domain-independent argumentation theory proposed by Walton (1996). In their experiments, they obtain the best accuracy (73.75%) using a combination of word pairs, text statistics, verbs, and a list of keywords indicative for argumentative discourse. Florou et al. (2013) report a similar approach. They classify text segments crawled with a focused crawler as either containing an argument or not. Their approach is based on several discourse markers and features extracted from the tense and mood of verbs. They report an F1-score of 0.764 for their best performing system.

One of the first approaches focusing on the identification of argument components is *Argumentative Zoning* proposed by Teufel (1999). The underlying assumption of this work is that argu-

ment components extracted from a scientific article provide a good summary of its content. Each sentence is classified as one of seven rhetorical roles including claim, result or purpose. The approach obtained an F1-score of 0.46[2] using structural, lexical and syntactic features. Rooney et al. (2013) also focus on the identification of argument components but in contrast to the work of Teufel (1999) their scheme is not tailored to a particular genre. In their experiments, they identify claims, premises and non-argumentative text units in the Araucaria corpus and report an overall accuracy of 65%. Feng and Hirst (2011) also use the Araucaria corpus for their experiments but focus on the identification of *argumentation schemes* (Walton, 1996), which are templates for forms of arguments (e.g. argument from example or argument from consequence). Since their approach is based on features extracted from mutual information of claims and premises, it requires that the argument components are reliably identified in advance. In their experiments, they achieve an accuracy between 62.9% and 97.9% depending on the particular scheme and the classification setup.

In contrast to all approaches mentioned above, the work presented in this paper focuses besides the separation of argumentative from non-argumentative text units and the classification of argument components on the extraction of the argumentative discourse structure to identify which components of the argument belong together for achieving a more fine-grained and detailed analysis of argumentation. We are only aware of one approach (Mochales-Palau and Moens, 2009; Wyner et al., 2010) that also focuses on the identification of argumentative discourse structures. However, this approach is based on a manually created CFG that is tailored to documents from the legal domain, which follow a standardized argumentation style. Therefore, it does not accommodate ill-formatted arguments (Wyner et al., 2010), which are likely in argumentative writing support. In addition, the approach relies on discourse markers and is therefore not applicable for identifying implicit argumentative discourse structures.

2.2 Discourse Relations

Identifying argumentative discourse structures is closely related to discourse analysis. As illustrated in the initial example, the identification of argumentative relations postulates the identification of implicit as well as non-adjacent discourse relations. Marcu and Echihabi (2002) present the first approach focused on identifying implicit discourse relations. They exploit several discourse markers (e.g. *'because'* or *'but'*) for collecting large amounts of training data. For their experiments they remove the discourse markers and discover that word pair features are indicative for implicit discourse relations. Depending on the utilized corpus, they obtain accuracies between 64% and 75% for identifying a cause-explanation-evidence relation (the most similar relation of their work compared to argumentative relations).

With the release of the PDTB, the identification of discourse relations gained a lot of interest in the research community. The PDTB includes implicit as well as explicit discourse relations of different types, and there are multiple approaches aiming at automatically identifying implicit relations. Pitler et al. (2009) experiment with polarity tags, verb classes, length of verb phrases, modality, context and lexical features and found that word pairs with non-zero Information Gain yield best results. Lin et al. (2009) show that beside lexical features, production rules collected from parse trees yield good results, whereas Louis et al. (2010) found that features based on named-entities do not perform as well as lexical features. However, current approaches to discourse analysis like the RST or the PDTB are designed to analyze general discourse structures, and thus include a large set of generic discourse relations, whereas only a subset of those relations is relevant for argumentative discourse analysis. For instance, the argumentation scheme proposed by Peldszus and Stede (2013) includes three argumentative relations (support, attack and counter-attack), whereas Stab and Gurevych (2014) propose a scheme including only two relations (support and attack). The difference between argumentative relations and those included in general tagsets like RST and PDTB is best illustrated by the work of Biran and Rambow (2011), which is to the best of our knowledge the only work that focuses on the identification of argumentative relations. They argue that existing definitions of discourse relations are only relevant as a building block for identifying argumentative discourse and that existing approaches do not contain a single relation that corresponds to

[2]Calculated from the precision and recall scores provided for individual rhetorical roles in (Teufel, 1999, p. 225).

a distinct argumentative relation. Therefore, they consider a set of 12 discourse relations from the RST Discourse Treebank (Carlson et al., 2001) as a single argumentative relation in order to identify justifications for a given claim. They first extract a set of lexical indicators for each relation from the RST Discourse Treebank and create a word pair resource using the English Wikipedia. In their experiments, they use the extracted word pairs as features and obtain an F1-score of up to 0.51 using two different corpora. Although the approach considers non-adjacent relations, it is limited to the identification of relations between premises and claims and requires that claims are known in advance. In addition, the combination of several general relations to a single argumentative relation might lead to consistency problems and to noisy corpora (e.g. not each instance of a contrast relation is relevant for argumentative discourse).

3 Data

For our experiments, we use a corpus of persuasive essays compiled by Stab and Gurevych (2014). This corpus contains annotations of argument components at the clause-level as well as argumentative relations. In particular, it includes annotations of *major claims*, *claims* and *premises*, which are connected with argumentative *support* and *attack* relations. Argumentative relations are directed (there is a specified source and target component of each relation) and can hold between a premise and another premise, a premise and a (major-) claim, or a claim and a major claim. Except for the last one, an argumentative relation does not cross paragraph boundaries.

Three raters annotated the corpus with an inter-annotator agreement of $\alpha_U = 0.72$ (Krippendorff, 2004) for argument components and $\alpha = 0.81$ for argumentative relations. In total, the corpus comprises 90 essays including 1,673 sentences. Since it only contains a low number of attack relations, we focus in this work solely on the identification of argument components and argumentative support relations. However, the proposed approach can also be applied to identify attack relations in future work.

4 Identifying Argument Components

We consider the identification of argument components as a multiclass classification task. Each clause in the corpus is either classified as major claim, claim, premise or non-argumentative. So this task includes besides the classification of argument components also the separation of argumentative and non-argumentative text units. We label each sentence that does not contain an argument component as class *'none'*. Since many argument components cover an entire sentence (30%), this is not an exclusive feature of this class. In total, the corpus contains 1,879 instances.

Table 1 shows the class distribution among the instances. The corpus includes 90 major claims (each essay contains exactly one), 429 claims and 1,033 premises. This proportion between claims and premises is common in argumentation since claims are usually supported by several premises for establishing a stable standpoint.

MajorClaim	Claim	Premise	None
90 (4.8%)	429 (22.8%)	1,033 (55%)	327 (17.4%)

Table 1: Class distribution among the instances. The corpus contains 1552 argument components and 327 non-argumentative instances.

For our experiments, we randomly split the data into a 80% training set and a 20% test set with the same class distribution and determine the best performing system using 10-fold cross-validation on the training set only. In our experiments, we use several classifiers (see section 4.2) from the Weka data mining software (Hall et al., 2009). For preprocessing the corpus, we use the Stanford POS-Tagger (Toutanova et al., 2003) and Parser (Klein and Manning, 2003) included in the DKPro Framework (Gurevych et al., 2007). After these steps, we use the DKPro-TC text classification framework (Daxenberger et al., 2014) for extracting the features described in the following section.

4.1 Features

Structural features: We define structural features based on token statistics, the location and punctuations of the argument component and its covering sentence. Since Biran and Rambow (2011) found that premises are longer on the average than other sentences, we add the number of tokens of the argument component and its covering sentence to our feature set. In addition, we define the number of tokens preceding and following an argument component in the covering sentence, the token ratio between covering sentence and argument component, and a Boolean feature that indicates if the

argument component covers all tokens of its covering sentence as token statistics features.

For exploiting the structural properties of persuasive essays, we define a set of location-based features. First, we define four Boolean features that indicate if the argument component is present in the introduction or conclusion of an essay and if it is present in the first or the last sentence of a paragraph. Second, we add the position of the covering sentence in the essay as a numeric feature. Since major claims are always present in the introduction or conclusion of an essay and paragraphs frequently begin or conclude with a claim, we expect that these features are good indicators for classifying (major-) claims.

Further, we define structural features based on the punctuation: the number of punctuation marks of the covering sentence and the argument component, the punctuation marks preceding and following an argument component in its covering sentence and a Boolean feature that indicates if the sentence closes with a question mark.

Lexical features: We define n-grams, verbs, adverbs and modals as lexical features. We consider all n-grams of length 1-3 as a Boolean feature and extract them from the argument component including preceding tokens in the sentence that are not covered by another argument component. So, the n-gram features include discourse markers that indicate certain argument components but which are not included in the actual annotation of argument components.

Verbs and adverbs play an important role for identifying argument components. For instance, certain verbs like *'believe'*, *'think'* or *'agree'* often signal stance expressions which indicate the presence of a major claim and adverbs like *'also'*, *'often'* or *'really'* emphasize the importance of a premise. We model both verbs and adverbs as Boolean features.

Modal verbs like *'should'* and *'could'* are frequently used in argumentative discourse to signal the degree of certainty when expressing a claim. We use the POS tags generated during preprocessing to identify modals and define a Boolean feature which indicates if an argument component contains a modal verb.

Syntactic features: To capture syntactic properties of argument components, we define features extracted from parse trees. We adopt two features proposed by (Mochales-Palau and Moens, 2009): the number of sub-clauses included in the covering sentence and the depth of the parse tree. In addition, we extract *production rules* from the parse tree as proposed by Lin et al. (2009) to capture syntactic characteristics of an argument component. The production rules are collected for each function tag (e.g. VP, NN, S, etc.) in the subtree of an argument component. The feature set includes e.g. rules like $VP \rightarrow VBG, NP$ or $PP \rightarrow IN, NP$. We model each production rule as a Boolean feature and set it to true if it appears in the subtree of an argument component.

Since premises often refer to previous events and claims are usually in present tense, we capture the tense of the main verb of an argument component as proposed by Mochales-Palau and Moens (2009) and define a feature that indicates if an argument component is in the past or present tense.

Indicators: Discourse markers often indicate the components of an argument. For example, claims are frequently introduced with *'therefore'*, *'thus'* or *'consequently'*, whereas premises contain markers like *'because'*, *'reason'* or *'furthermore'*. We collected a list of discourse markers from the Penn Discourse Treebank 2.0 Annotation Manual (Prasad et al., 2007) and removed markers that do not indicate argumentative discourse (e.g. markers which indicate temporal discourse). In total, we collected 55 discourse markers and model each as a Boolean feature set to true if the particular marker precedes the argumentative component.

In addition, we define five Boolean features which denote a reference to the first person in the covering sentence of an argument component: *'I'*, *'me'*, *'my'*, *'mine'*, and *'myself'*. An additional Boolean feature indicates if one of them is present in the covering sentence. We expect that those features are good indicators of the major claim, since it is often introduced with expressions referring to the personal stance of the author.

Contextual features: The context plays a major role for identifying argument components. For instance, a premise can only be classified as such, if there is a corresponding claim. Therefore, we define the following features each extracted from the sentence preceding and following the covering sentence of an argument component: the number of punctuations, the number of tokens, the number of sub-clauses and a Boolean feature indicating the presence of modal verbs.

4.2 Results and Analysis

For identifying the best performing system, we conducted several experiments on the training set using stratified 10-fold cross-validation. We determine the evaluation scores by accumulating the confusion matrices of each fold into one confusion matrix, since it is the less biased method for evaluating cross-validation studies (Forman and Scholz, 2010). In a comparison of several classifiers (Support Vector Machine, Naïve Bayes, C4.5 Decision Tree and Random Forest), we found that each of the classifiers significantly outperforms a majority baseline (McNemar Test (McNemar, 1947) with $p = 0.05$) and that a Support Vector Machine (SVM) achieves the best results using 100 top features ranked by Information Gain.[3] It achieves an accuracy of 77.3% on the test set and outperforms the majority baseline with respect to overall accuracy as well as F1-score (table 2).

	Baseline	**Human**	**SVM**
Accuracy	0.55	0.877	0.773
Macro F1	0.177	0.871	0.726
Macro Precision	0.137	0.864	0.773
Macro Recall	0.25	0.879	0.684
F1 MajorClaim	0	0.916	0.625
F1 Claim	0	0.841	0.538
F1 Premise	0.709	0.911	0.826
F1 None	0	0.812	0.884

Table 2: Results of an SVM for argument component classification on the test set compared to a majority baseline and human performance.

The upper bound for this task constitutes the human performance which we determine by comparing each annotator to the gold standard. Since the boundaries of an argument component in the gold standard can differ from the boundaries identified by a human annotator (the annotation task included the identification of argument component boundaries), we label each argument component of the gold standard with the class of the maximum overlapping annotation of a human annotator for determining the human performance. We obtain a challenging upper bound of 87.7% (accuracy) by averaging the scores of all three annotators on the test set (table 2). So, our system achieves 88.1% of human performance (accuracy).

Feature influence: In subsequent experiments, we evaluate each of the defined feature groups on the entire data set using 10-fold cross-validation to find out which features perform best for identifying argument components. As assumed, structural features perform well for distinguishing claims and premises in persuasive essays. They also yield high results for separating argumentative from non-argumentative text units (table 3).

Feature group	**MajorClaim**	**Claim**	**Premise**	**None**
Structural	0.477	0.419	0.781	0.897
Lexical	0.317	0.401	0.753	0.275
Syntactic	0.094	0.292	0.654	0.427
Indicators	0.286	0.265	0.730	0
Contextual	0	0	0.709	0

Table 3: F1-scores for individual feature groups and classes (SVM with 10-fold cross-validation on the entire data set)

Interestingly, the defined indicators are not useful for separating argumentative from non-argumentative text units though they are helpful for classifying argument components. A reason for this could be that not each occurrence of an indicator distinctly signals argument components, since their sense is often ambiguous (Prasad et al., 2008). For example *'since'* indicates temporal properties as well as justifications, whereas *'because'* also indicates causal links. Syntactic features also contribute to the identification of argument components. They achieve an F1-score of 0.292 for claims and 0.654 for premises and also contribute to the separation of argumentative from non-argumentative text units. Contextual features do not perform well. However, they increase the accuracy by 0.7% in combination with other features. Nevertheless, this difference is not significant ($p = 0.05$).

Error analysis: The system performs well for separating argumentative and non-argumentative text units as well as for identifying premises. However, the identification of claims and major claims yields lower performance. The confusion matrix (table 4) reveals that the most common error is between claims and premises. In total, 193 claims are incorrectly classified as premise. In a manual assessment, we observed that many of these errors occur if the claim is present in the first paragraph sentence and exhibits preceding indicators like *'first(ly)'* or *'second(ly)'* which are also frequently used to enumerate premises. In these cases, the author introduces the claim of the argument as support for the major claim and thus its characteristic is similar to a premise. To prevent

[3] Although the Naïve Bayes classifier achieves lowest accuracy, it exhibits a slightly higher recall compared to SVM.

this type of error, it might help to define features representing the location of indicators or to disambiguate the function of indicators.

Actual \ *Predicted*	MC	Cl	Pr	No
MC	**38**	34	18	0
Cl	19	**210**	193	7
Pr	6	104	**904**	19
No	0	12	23	**292**

Table 4: Confusion matrix (SVM) for argument component classification (MC = Major Claim; Cl = Claim; Pr = Premise; No = None)

We also observed, that some of the misclassified claims cover an entire sentence and don't include indicators. For example, it is even difficult for humans to classify the sentences *'Competition helps in improvement and evolution'* as a claim without knowing the intention of the author. For preventing these errors, it might help to include more sophisticated contextual features.

5 Identifying Argumentative Relations

We consider the identification of argumentative relations as a binary classification task of argument component pairs and classify each pair as either support or non-support. For identifying argumentative relations, all possible combinations of argument components have to be tested. Since this results in a heavily skewed class distribution, we extract all possible combinations of argument components from each paragraph of an essay.[4] So, we omit argumentative relations between claims and major claims which are the only relations in the corpus that cross paragraph boundaries, but obtain a better distribution between true (support) and false (non-support) instances. In total, we obtain 6,330 pairs, of which 15.6% are support and 84.4% are non-support relations (table 5).

Support	Non-support
989 (15.6%)	5341 (84.4%)

Table 5: Class distribution of argument component pairs

Equivalent to the identification of argument components, we randomly split the data in a 80% training and a 20% test set and determine the best performing system using 10-fold cross-validation on the training set. We use the same preprocessing pipeline as described in section 4 and DKPro-TC for extracting the features described below.

5.1 Features

Structural features: We define structural features for each pair based on the source and target components, and on the mutual information of both. Three numeric features are based on token statistics. Two features represent the number of tokens of the source and target components and the third one represents the absolute difference in the number of tokens. Three additional numeric features count the number of punctuation marks of the source and target components as well as the absolute difference between both. We extract both types of features solely from the clause annotated as argument component and do not consider the covering sentence. In addition, we define nine structural features based on the position of both argument components: two of them represent the position of the covering sentences in the essay, four Boolean features indicate if the argument components are present in the first or last sentence of a paragraph, one Boolean feature for representing if the target component occurs before the source component, the sentence distance between the covering sentences, and a Boolean feature which indicates if both argument components are in the same sentence.

Lexical features: We define lexical features based on word pairs, first words and modals. It has been shown in previous work that word pairs are effective for identifying implicit discourse relations (Marcu and Echihabi, 2002). We define each pair of words between the source and target components as a Boolean feature and investigate word pairs containing stop words as well as stop word filtered word pairs.

In addition, we adopt the first word features proposed by Pitler et al. (2009). We extract the first word either from the argument component or from non-annotated tokens preceding the argument component in the covering sentence if present. So, the first word of an argument component is either the first word of the sentence containing the argument component, the first word following a preceding argument component in the same sentence or the first word of the actual argument component if it commences the sentence or directly follows another argument component.

[4] Only 4.6% of 28,434 possible pairs are true instances (support), if all combinations are considered.

So, we ensure that the first word of an argument component includes important discourse markers which are not included in the annotation. We define each first word of the source and target components as a Boolean feature and also add the pairs of first words to our feature set.

Further, we define a Boolean feature for the source as well as for the target component that indicates if they contain a modal verb and a numerical feature that counts the number of common terms of the two argument components.

Syntactic features: For capturing syntactic properties, we extract production rules from the source and target components. Equivalent to the features extracted for the argument component classification (section 4.1), we model each rule as a Boolean feature which is true if the corresponding argument component includes the rule.

Indicators: We use the same list of discourse markers introduced above (section 4.1) as indicator features. For each indicator we define a Boolean feature for the source as well as for the target component of the pair and set it to true if it is present in the argument component or in its preceding tokens.

Predicted type: The *argumentative type* (major claim, claim or premise) of the source and target components is a strong indicator for identifying argumentative relations. For example, there are no argumentative relations from claims to premises. Thus, if the type of the argument component is reliably identified many potential pairs can be excluded. Therefore, we define two features that represent the argumentative type of the source and target components identified in the first experiment.

5.2 Results and Analysis

The comparison of several classifiers reveals that an SVM achieves the best results. In our experiments, all classifiers except the C4.5 Decision Tree significantly outperform a majority baseline which classifies all pairs as non-support ($p = 0.05$). We also conducted several experiments using word pair features only and found in contrast to Pitler et al. (2009) that limiting the number of word pairs decreases the performance. In particular, we compared the top 100, 250, 500, 1000, 2500, 5000 word pairs ranked by Information Gain, non-zero Information Gain word pairs and non-filtered word pairs. The results show that non-filtered word pairs perform best (macro F1-score of 0.68). Our experiments also reveal that filtering stop words containing word pairs decreases the macro F1-score to 0.60. We obtain the best results using an SVM without any feature selection method. Due to the class imbalance, the SVM only slightly outperforms the accuracy of a majority baseline on the test set (table 6). However, the macro F1-score is more appropriate for evaluating the performance if the data is imbalanced since it assigns equal weight to the classes and not to the instances. The SVM achieves a macro F1-score of 0.722 and also outperforms the baseline with respect to the majority class.

	Baseline	**Human**	**SVM**
Accuracy	0.843	0.954	0.863
Macro F1	0.458	0.908	0.722
Macro Precision	0.422	0.937	0.739
Macro Recall	0.5	0.881	0.705
F1 Support	0	0.838	0.519
F1 Non-Support	0.915	0.973	0.92

Table 6: Results of an SVM for classifying argumentative relations on the test set compared to a majority baseline and human performance.

We determined the upper bound constituted by the human performance by comparing the annotations of all three annotators to the gold standard. The scores in table 6 are the average scores of all three annotators. Our system achieves 90.5% of human performance (accuracy).

Feature influence: A comparison of the defined feature groups using 10-fold cross-validation on the entire data set shows that lexical features perform best. They achieve an F1-score of 0.427 for support and 0.911 for non-support pairs (table 7). The syntactic features also perform well followed by the indicators. It turned out that structural features are not effective for identifying argumentative relations though they are the most effective features for identifying argument components (cp. section 4.2). However, when omitted from the entire feature set the performance significantly decreases by 0.018 macro F1-score ($p = 0.05$).

Interestingly, the predicted types from our first experiment are not effective at all. Although the argumentative type of the target component exhibits the highest Information Gain in each fold compared to all other features, the predicted type does not yield a significant difference when combined with all other features ($p = 0.05$). It only improves the macro F1-score by 0.001 when in-

cluded in the entire feature set.

Feature group	Support	Non-Support
Structural	0	0.915
Lexical	0.427	0.911
Syntactic	0.305	0.911
Indicators	0.159	0.916
Predicted types	0	0.915

Table 7: F1-scores for individual feature groups using an SVM and the entire data set

Error analysis: For identifying frequent error patterns, we manually investigated the mistakes of the classifier. Although our system identifies 97.5% of the non-support pairs from claim to premise correctly, there are still some false positives that could be prevented if the argument components had been classified more accurately. For instance, there are 18 non-support relations from claim to another claim, 32 from claim to premise, 5 from major claim to premise and 4 from major claim to claim among the false positives. However, the larger amount of errors is due to not identified support relations (false negatives). We found that some errors might be related to missing contextual information and unresolved coreferences. For instance, it might help to replace *'It'* with *'Exercising'* for classifying the pair *'It helps relieve tension and stress'* → *'Exercising improves self-esteem and confidence'* as support relation or to include contextual information for the premise *'This can have detrimental effects on health'* supporting the claim *'There are some serious problems springing from modern technology'*.

6 Discussion

In our experiments, we have investigated the classification of argument components as well as the identification of argumentative relations for recognizing argumentative discourse structures in persuasive essays. Both tasks are closely related and we assume that sharing mutual information between both tasks might be a promising direction for future research. On the one hand, knowing the type of argument components is a strong indicator for identifying argumentative relations and on the other hand, it is likely that information about the argumentative structure facilitates the identification of argument components. However, our experiments revealed that the current accuracy for identifying argument components is not sufficient for increasing the performance of argumentative relation identification. Nevertheless, we obtain almost human performance when including the types of argument components of the gold standard (macro F1-score >0.85) in our argument relation identification experiment and when including the number of incoming and outgoing support relations for each argument component in our first experiment (macro F1-score >0.9). Therefore, it can be assumed, that if the identification of argument components can be improved, the identification of argumentative relations will achieve better results and vice versa.

The results also show that the distinction between claims and premises is the major challenge for identifying argument components. It turned out that structural features are the most effective ones for this task. However, some of those features are unique to persuasive essays, and it is an open question if there are general structural properties of arguments which can be exploited for separating claims from premises.

Our experiments show that discourse markers yield only low accuracies. Using only our defined indicator features, we obtain an F1-score of 0.265 for identifying claims, whereas Mochales-Palau and Moens (2009) achieve 0.673 for the same task in legal documents using a CFG. This confirms our initial assumption that approaches relying on discourse markers are not applicable for identifying argumentative discourse structures in documents which do not follow a standardized form. In addition, it shows that discourse markers are either frequently missing or misleadingly used in student texts and that there is a need for argumentative writing support systems that assist students in employing discourse markers correctly.

7 Conclusion and Future Work

We presented a novel approach for identifying argumentative discourse structures in persuasive essays. Previous approaches on argument recognition suffer from several limitations: Existing approaches focus either solely on the identification of argument components or rely on manually created rules which are not able to identify implicit argumentative discourse structures. Our approach is the first step towards computational argument analysis in the educational domain and enables the identification of implicit argumentative discourse structures. The presented approach achieves 88.1% of human performance for identi-

fying argument components and 90.5% for identifying argumentative relations.

For future work, we plan to extend our studies to larger corpora, to integrate our classifiers in writing environments, and to investigate their effectiveness for supporting students.

Abstract

This paper proposes a Markov Decision Process and reinforcement learning based approach for domain selection in a multi-domain Spoken Dialogue System built on a distributed architecture. In the proposed framework, the domain selection problem is treated as sequential planning instead of classification, such that confirmation and clarification interaction mechanisms are supported. In addition, it is shown that by using a model parameter tying trick, the extensibility of the system can be preserved, where dialogue components in new domains can be easily plugged in, without re-training the domain selection policy. The experimental results based on human subjects suggest that the proposed model marginally outperforms a non-trivial baseline.

1 Introduction

Due to growing demand for natural human-machine interaction, over the last decade Spoken Dialogue Systems (SDS) have been increasingly deployed in various commercial applications ranging from traditional call centre automation (e.g. AT&T "Lets Go!" bus information system (Williams et al., 2010)) to mobile personal assistants and knowledge navigators (e.g. Apple's Siri®, Google Now™, Microsoft Cortana, etc.) or voice interaction for smart household appliance control (e.g. Samsung Evolution Kit for Smart TVs). Furthermore, latest progress in open-vocabulary Automatic Speech Recognition (ASR) is pushing SDS from traditional single-domain information systems towards more complex multi-domain speech applications, of which typical examples are those voice assistant mobile applications.

Recent advances in SDS have shown that statistical approaches to dialogue management can result in marginal improvement in both the naturalness and the task success rate for domain-specific dialogues (Lemon and Pietquin, 2012; Young et al., 2013). State-of-the-art statistical SDS treat the dialogue problem as a sequential decision making process, and employ established planning models, such as Markov Decision Processes (MDPs) (Singh et al., 2002) or Partially Observable Markov Decision Processes (POMDPs) (Thomson and Young, 2010; Young et al., 2010; Williams and Young, 2007), in conjunction with reinforcement learning techniques (Jurčíček et al., 2011; Jurčíček et al., 2012; Gašić et al., 2013a) to seek optimal dialogue policies that maximise long-term expected (discounted) rewards and are robust to ASR errors.

However, to the best of our knowledge, most of the existing multi-domain SDS in public use are rule-based (e.g. (Gruber et al., 2012; Mirkovic and Cavedon, 2006)). The application of statistical models in multi-domain dialogue systems is still preliminary. Komatani et al. (2006) and Nakano et al. (2011) utilised a distributed architecture (Lin et al., 1999) to integrate expert dialogue systems in different domains into a unified framework, where a central controller trained as a data-driven classifier selects a domain expert at each turn to address user's query. Alternatively, Hakkani-Tür et al. (2012) adopted the well-known Information State mechanism (Traum and Larsson, 2003) to construct a multi-domain SDS and proposed a discriminative classification model for more accurate state updates. More recently, Gašić et al. (2013b) proposed that by a simple expansion of the kernel function in Gaussian Process (GP) reinforcement learning (Engel et al., 2005; Gašić et al., 2013a), one can adapt pre-trained dialogue policies to handle unseen slots for SDS in extended domains.

In this paper, we use a voice assistant applica-

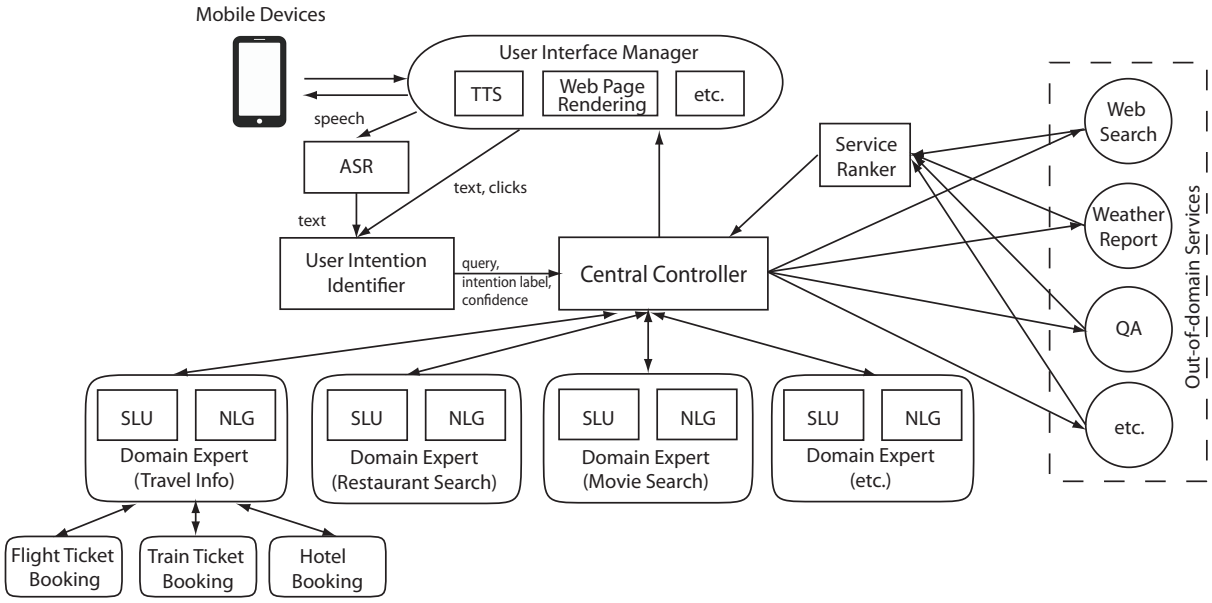

Figure 1: The distributed architecture of the voice assistant system (a simplified illustration).

tion (similar to Apple's Siri but in Chinese language) as an example to demonstrate a novel MDP-based approach for central interaction management in a complex multi-domain dialogue system. The voice assistant employs a distributed architecture similar to (Lin et al., 1999; Komatani et al., 2006; Nakano et al., 2011), and handles mixed interactions of multi-turn dialogues across different domains and single-turn queries powered by a collection of information access services (such as web search, Question Answering (QA), etc.). In our system, the dialogues in each domain are managed by an individual domain expert SDS, and the single-turn services are used to handle those so-called out-of-domain requests. We use featurised representations to summarise the current dialogue states in each domain (see Section 3 for more details), and let the central controller (the MDP model) choose one of the following system actions at each turn: (1) addressing user's query based on a domain expert, (2) treating it as an out-of-domain request, (3) asking user to confirm whether he/she wants to continue a domain expert's dialogue or to switch to out-of-domain services, and (4) clarifying user's intention between two domains. The Gaussian Process Temporal Difference (GPTD) algorithm (Engel et al., 2005; Gašić et al., 2013a) is adopted here for policy optimisation based on human subjects, where a parameter tying trick is applied to preserve the extensibility of the system, such that new domain experts (dialogue systems) can be flexibly plugged in without the need of re-training the central controller.

Comparing to the previous classification-based methods (Komatani et al., 2006; Nakano et al., 2011), the proposed approach not only has the advantage of action selection in consideration of long-term rewards, it can also yield more robust policies that allow clarifications and confirmations to mitigate ASR and Spoken Language Understanding (SLU) errors. Our human evaluation results show that the proposed system with a trained MDP policy achieves significantly better naturalness in domain switching tasks than a non-trivial baseline with a hand-crafted policy.

The remainder of this paper is organised as follows. Section 2 defines the terminology used throughout the paper. Section 3 briefly overviews the distributed architecture of our system. The MDP model and the policy optimisation algorithm are introduced in Section 4 and Section 5, respectively. After this, experimental settings and evaluation results are described in Section 6. Finally, we discuss some possible improvements in Section 7 and conclude ourselves in Section 8.

2 Terminology

A voice assistant application provides a unified speech interface to a collection of individual information access systems. It aims to collect and satisfy user requests in an interactive manner, where

different types of interactions can be involved. Here we focus ourselves on two interaction scenarios, i.e. task-oriented (multi-turn) dialogues and single-turn queries.

According to user intentions, the dialogue interactions in our voice assistant system can further be categorised into different *domains*, of which each is handled by a separate dialogue manager, namely a *domain expert*. Example domains include travel information, restaurant search, etc. In addition, some domains in our system can be further decomposed into sub-domains, e.g. the travel information domain consists of three sub-domains: flight ticket booking, train ticket booking and hotel reservation. We use an integrated domain expert to address queries in all its sub-domains, so that relevant information can be shared across those subdomains to allow intelligent induction in the dialogue flow.

For convenience of future reference, we call those single-turn information access systems *out-of-domain services* or simply *services* for short. The services integrated in our system include web search, semantic search, QA, system command execution, weather report, chat-bot, and many more.

3 System Architecture

The voice assistant system introduced in this paper is built on a distributed architecture (Lin et al., 1999), as shown in Figure 1, where the dialogue flow is processed as follows. Firstly, a user's query (either an ASR utterance or directly typed in text) is passed to a user intention identifier, which labels the raw query with a list of intention hypotheses with confidence scores. Here an intention label could be either a domain name or a service name. After this, the central controller distributes the raw query together with its intention labels and confidence scores to all the domain experts and the service modules, which will attempt to process the query and return their results to the central controller.

The domain experts in the current implementation of our system are all rule-based SDS following the RavenClaw framework proposed in (Bohus and Rudnicky, 2009). When receiving a query, a domain expert will use its own SLU module to parse the utterance or text input and try to update its dialogue state in consideration of both the SLU output and the intention labels. If the dialogue state in the domain expert can be updated given the query, it will return its output, internal session record and a confidence score to the central controller, where the output can be either a natural language utterance realised by its Natural Language Generation (NLG) module or a set of data records obtained from its database (if a database search operation is triggered), or both. If the domain expert cannot update its state using the current query, it will just return an empty result with a low confidence score. Similar procedures apply to those out-of-domain services as well, but there are no session records or confidence scores returned. Finally, given all the returned information, the central controller chooses, according to its policy, the module (either a domain expert or a service) whose results will be provided to the user.

When the central controller decides to pass a domain expert's output to the user, we regard the domain expert as being activated. Also note here, the updated state of a domain expert in a turn will not be physically stored, unless the domain expert is activated in that turn. This is a necessary mechanism to prevent an inactive domain expert being misled by ambiguous queries in other domains.

In addition, we use a well-engineered priority ranker to rank the services based on the numbers of results they returned as well as some prior knowledge about the quality of their data sources. When the central controller decides to show user the results from an out-of-domain service, it will choose the top one from the ranked list.

4 MDP Modelling of the Central Control Process

The main focus of this paper is to seek a policy for robustly switching the control flow among those domain experts and services (the service ranker in practice) during a dialogue, where the user may have multiple or compound goals (e.g. booking a flight ticket, booking a restaurant in the destination city and checking the weather report of the departure or destination city).

In order to make the system robust to ASR errors or ambiguous queries, the central controller should also have basic dialogue abilities for confirmation and clarification purposes. Here we define the confirmation as an action of asking whether a user wants to continue the dialogue in a certain domain. If the system receives a negative response at this point, it will switch to out-of-domain services. On the other hand, the clarification action is de-

fined between domains, in which case, the system will explicitly ask the user to choose between two domain candidates before continuing the dialogue.

Due to the confirmation and clarification mechanisms defined above, the central controller becomes a sequential decision maker that must take the overall smoothness of the dialogue into account. Therefore, we propose an MDP-based approach for learning an optimal central control policy in this section.

The potential state space of our MDP is huge, which in principle consists of the combinations of all possible situations of the domain experts and the out-of-domain services, therefore function approximation techniques must be employed to enable tractable computations. However, when developing such a complex application as the voice assistant here, one also needs to take the extensibility of the system into account, so that new domain experts can be easily integrated into the system without major re-training or re-engineering of the existing components. Essentially, it requires the state featurisation and the central control policy learnt here to be independent of the number of domain experts. In Section 4.3, we show that such a property can be achieved by a parameter tying trick in the definition of the MDP.

4.1 MDP Preliminaries

Let $\mathcal{P}_X$ denote the set of probability distributions over a set X. An MDP is defined as a five tuple $\langle S, A, T, R, \gamma \rangle$, where the components are defined as follows. S and A are the sets of system states and actions, respectively. $T : S \times A \rightarrow \mathcal{P}_S$ is the transition function, and $T(s'|s, a)$ defines the conditional probability of the system transiting from state $s \in S$ to state $s' \in S$ after taking action $a \in A$. $R : S \times A \rightarrow \mathcal{P}_{\mathbb{R}}$ is the reward function with $R(s, a)$ specifying the distribution of the immediate rewards for the system taking action a at state s. In addition, $0 \leq \gamma \leq 1$ is the discount factor on the summed sequence of rewards.

A finite-horizon MDP operates as follows. The system occupies a state s and takes an action a, which then will make it transit to a next state $s' \sim T(\cdot|s, a)$ and receive a reward $r \sim R(s, a)$. This process repeats until a terminal state is reached.

For a given policy $\pi : S \rightarrow A$, the value function V^π is defined to be the expected cumulative reward, as $V^\pi(s_0) = \mathbb{E}\left[\sum_{t=0}^{n} \gamma^t r_t|_{s_t, \pi(s_t)}\right]$, where s_0 is the starting state and n is the planning horizon. The aim of policy optimisation is to seek an optimal policy π^* that maximises the value function. If T and R are given, in conjunction with a Q-function, the optimal value V^* can be expressed by recursive equations as $Q(s, a) = R(s, a) + \gamma \sum_{s' \in S} T(s'|s, a)V^*(s')$ and $V^*(s) = \max_{a \in A} Q(s, a)$ (here we assume $R(s, a)$ is deterministic), which can be solved by dynamic programming (Bellman, 1957). For problems with unknown T or R, such as dialogue systems, the Q-values are usually estimated via reinforcement learning (Sutton and Barto, 1998).

4.2 Problem Definition

Let D denote the set of the domain experts in our voice assistant system, and s_d be the current dialogue state of domain expert $d \in D$ at a certain timestamp. We also define s_o as an abstract state to describe the current status of those out-of-domain services. Then mathematically we can represent the central control process as an MDP, where its state $\mathbf{s}$ is a joint set of the states of all the domain experts and the services, as $\mathbf{s} = \{s_d\}_{d \in D} \cup \{s_o\}$. Four types of system actions are defined as follows.

- `present(`d`)`: presenting the output of domain expert d to user;
- `present_ood(null)`: presenting the results of the top-ranked out-of-domain service given by the service ranker;
- `confirm(`d`)`: confirming whether user wants to continue with domain expert d (or to switch to out-of-domain services);
- `clarify(`d, d'`)`: asking user to clarify his/her intention between domains d and d'.

For convenience of notations, we use $a(x)$ to denote a system action of our MDP, where $a \in \{\texttt{present}, \texttt{present\_ood}, \texttt{confirm}, \texttt{clarify}\}$, $x \in \{d, \texttt{null}, (d, d')\}_{d,d' \in D, d \neq d'}$, $x = \texttt{null}$ only applies to `present_ood`, and $x = (d, d')$ only applies to `clarify` actions.

4.3 Function Approximation

Function approximation is a commonly used technique to estimate the Q-values when the state space of the MDP is huge. Concretely, in our case, we assume that:

$$Q(\mathbf{s}, a(x)) = f(\phi(\mathbf{s}, a(x)); \theta) \qquad (1)$$

where $\phi : S \times A \rightarrow \mathbb{R}^K$ is a feature function that maps a state-action pair to an K-dimensional feature vector, and $f : \mathbb{R}^K \rightarrow \mathbb{R}$ is a function of $\phi(\mathbf{s}, a(x))$ parameterised by θ. A frequent choice of f is the linear function, as:

$$Q(\mathbf{s}, a(x)) = \theta^\top \phi(\mathbf{s}, a(x)) \tag{2}$$

After this, the policy optimisation problem becomes learning the parameter θ to approximate the Q-values based on example dialogue trajectories.

However, a crucial problem with the standard formulation in Eq. (2) is that the feature function ϕ is defined over the entire state and action spaces. In this case, when a new domain expert is integrated into the system, both the state space and the action space will be changed, therefore one will have to re-define the feature function and consequentially re-train the model. In order to achieve an extensible system, we make some simplification assumptions and decompose the feature function as follows. Firstly, we let:

$$\begin{aligned} \phi(\mathbf{s}, a(x)) &= \phi_a(\mathbf{s}_x) \qquad (3) \\ &= \begin{cases} \phi_{\texttt{pr}}(s_d) & \text{if } a(x) = \texttt{present(}d\texttt{)} \\ \phi_{\texttt{ood}}(s_o) & \text{if } a(x) = \texttt{present\_ood()} \\ \phi_{\texttt{cf}}(s_d) & \text{if } a(x) = \texttt{confirm(}d\texttt{)} \\ \phi_{\texttt{cl}}(s_d, s_{d'}) & \text{if } a(x) = \texttt{clarify(}d\texttt{,}d'\texttt{)} \end{cases} \end{aligned}$$

where the feature function is reduced to only depend on the state of the action's operand, instead of the entire system state. Then, we make those actions $a(x)$ that have a same action type (a) but operate different domain experts (x) share the same parameter, i.e.:

$$Q(\mathbf{s}, a(x)) = \theta_a^\top \phi_a(\mathbf{s}_x) \tag{4}$$

This decomposition and parameter tying trick preserves the extensibility of the system, because both $\theta_a^\top$ and ϕ_a are independent of x, when there is a new domain expert $\tilde{d}$, we can directly substitute its state $s_{\tilde{d}}$ into Eq. (3) and (4) to compute its corresponding Q-values.

4.4 Features

Based on the problem formulation in Eq. (3) and (4), we shall only select high-level summary features to sketch the dialogue state and dialogue history of each domain expert, which must be applicable to all domain experts, regardless of their domain-specific characteristics or implementation differences. Suppose that the dialogue states of the domain experts can be represented as slot-value pairs[1], and for each domain there are required slots and optional slots, where all required slots must be filled before the domain expert can execute a database search operation. The features investigated in the proposed framework are listed in Table 1.

#	Feature	Range
1	the number of unfilled required slots of a domain expert	$\{0, \ldots, M\}$
2	the number of filled required slots of a domain expert	$\{0, \ldots, M\}$
3	the number of filled optional slots of a domain expert	$\{0, \ldots, L\}$
4	whether a domain expert has executed a database search	$\{0, 1\}$
5	the confidence score returned by a domain expert	$[0, 1.2]$
6	the total number of turns that a domain expert has been activated during a dialogue	$\mathbb{Z}^+$
7	e^{-t_a} where t_a denotes the relative turn of a domain expert being last activated, or 0 if not applicable	$[0, 1]$
8	e^{-t_c} where t_c denotes the relative turn of a domain expert being last confirmed, or 0 if not applicable	$[0, 1]$
9	the summed confidence score from the user intention identifier of a query being for out-of-domain services	$[0, 1.2N]$

Table 1: A list of all features used in our model. M and L respectively denote the maximum numbers of required and optional slots for the domain experts. N is the maximum number of hypotheses that the intention identifier can return. $\mathbb{Z}^+$ stands for the non-negative integer set.

Detailed featurisation in Eq. (3) is explained as follows. For $\phi_{\texttt{pr}}$, we choose the first 8 features plus a bias dimension that is always set to

[1]This is a rather general assumption. Informally speaking, for most task-oriented SDS, one can extract a slot-value representation from their dialogue models, of which examples include the RavenClaw architecture (Bohus and Rudnicky, 2009), the Information State dialogue engine (Traum and Larsson, 2003), MDP-SDS (Singh et al., 2002) or POMDP-SDS (Thomson and Young, 2010; Young et al., 2010; Williams and Young, 2007).

-1. Whilst, feature #9 plus a bias is used to define $\phi_{\texttt{ood}}$. All the features are used in $\phi_{\texttt{cf}}$, as to do a confirmation, one needs to consider the joint situation in and out of the domain. Finally, the feature function for a clarification action between two domains d and d' is defined as $\phi_{\texttt{cl}}(s_d, s_{d'}) = \exp\{-|\phi_{\texttt{pr}}(s_d) - \phi_{\texttt{pr}}(s_{d'})|\}$, where we use $|\cdot|$ to denote the element-wise absolute of a vector operand. The intuition here is that the more distinguishable the (featurised) states of two domain experts are, the less we tend to clarify them.

For those domain experts that have multiple sub-domains with different numbers of required and optional slots, the feature extraction procedure only applies to the latest active sub-domain.

In addition, note that, the confidence scores provided by the user intention identifier are only used as features for out-of-domain services. This is because in the current version of our system, the confidence estimation of the intention identifier for domain-dependent dialogue queries is less reliable due to the lack of context information. In contrast, the confidence scores returned by the domain experts will be more informative at this point.

5 Policy Learning with GPTD

In traditional statistical SDS, dialogue policies are usually trained using reinforcement learning based on simulated dialogue trajectories (Schatzmann et al., 2007; Keizer et al., 2010; Thomson and Young, 2010; Young et al., 2010). Although the evaluation of the simulators themselves could be an arguable issue, there are various advantages, e.g. hundreds of thousands of data examples can be easily generated for training and initial policy evaluation purposes, and different reinforcement learning models can be compared without incurring notable extra costs.

However, for more complex multi-domain SDS, particularly a voice assistant application like ours that aims at handling very complicated (ideally open-domain) dialogue scenarios, it would be difficult to develop a proper simulator that can reasonably mimic real human behaviours. Therefore, in this work, we learn the central control policy directly with human subjects, for which the following properties of the learning algorithm are required. Firstly and most importantly, the learner must be sample-efficient as the data collection procedure is costly. Secondly, the algorithm should support batch reinforcement learning. This is because when using function approximation, the learning process may not strictly converge, and the quality of the sequence of generated policies tends to oscillate after a certain number of improving steps at the beginning (Bertsekas and Tsitsiklis, 1996). If online reinforcement learning is used, we will be unable to evaluate the generated policy after each update, and hence will not know which policy to keep for the final evaluation. Therefore, we do a batch policy update and iterate the learning process for a number of batches, such that the data collection phase in a new iteration yields an evaluation of the policy obtained from the previous iteration at the same time.

To fulfill the above two requirements, the Gaussian Process Temporal Difference (GPTD) algorithm (Engel et al., 2005) is a proper choice, due to its sample efficiency (Fard et al., 2011) and batch learning ability (Engel et al., 2005), as well as its previous success in dialogue policy learning with human subjects (Gašić et al., 2013a). Note that, GPTD can also admit recursive (online) computations, but here we focus ourselves on the batch version.

A Gaussian Process (GP) is a generative model of Bayesian inference that can be used for function regression, and has the superiority of obtaining good posterior estimates with just a few observations (Rasmussen and Williams, 2006). GPTD models the Q-function as a zero mean GP which defines correlations in different parts of the featurised state and action spaces through a kernel function κ, as:

$$Q(\mathbf{s}, a(x)) \sim \mathcal{GP}(0, \kappa((\mathbf{s}_x, a), (\mathbf{s}_x, a))) \quad (5)$$

Given a sequence of t state-action pairs $\mathbf{X}_t = [(\mathbf{s}^0, a^0(x^0)), \ldots, (\mathbf{s}^t, a^t(x^t))]$ from a collection of dialogues and their corresponding immediate rewards $\mathbf{r}_t = [r^0, \ldots, r^t]$, the posterior of $Q(\mathbf{s}, a(x))$ for an arbitrary new state-action pair $(\mathbf{s}, a(x))$ can be computed as:

$$\begin{aligned} &Q(\mathbf{s}, a(x))|_{\mathbf{X}_t, \mathbf{r}_t} \\ &\quad \sim \mathcal{N}\left(\bar{Q}(\mathbf{s}, a(x)), \mathrm{cov}\left(\mathbf{s}, a(x)\right)\right) && (6) \\ &\bar{Q}(\mathbf{s}, a(x)) = \mathbf{k}_t(\mathbf{s}_x, a)^\top \mathbf{H}_t^\top \mathbf{G}_t^{-1} \mathbf{r}_t && (7) \\ &\mathrm{cov}\left(\mathbf{s}, a(x)\right) = \kappa((\mathbf{s}_x, a), (\mathbf{s}_x, a)) \\ &\quad - \mathbf{k}_t(\mathbf{s}_x, a)^\top \mathbf{H}_t^\top \mathbf{G}_t^{-1} \mathbf{H}_t \mathbf{k}_t(\mathbf{s}_x, a) && (8) \\ &\mathbf{G}_t = \mathbf{H}_t \mathbf{K}_t \mathbf{H}_t^\top + \sigma^2 \mathbf{H}_t \mathbf{H}_t^\top && (9) \end{aligned}$$

$$\mathbf{H}_t = \begin{bmatrix} 1 & -\gamma & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & \cdots & 0 & 1 & -\gamma \end{bmatrix} \quad (10)$$

where $\mathbf{K}_t$ is the Gram matrix with elements $\mathbf{K}_t(i,j) = \kappa((\mathbf{s}^i_{x^i}, a^i), (\mathbf{s}^j_{x^j}, a^j))$, $\mathbf{k}_t(\mathbf{s}_x, a) = [\kappa((\mathbf{s}^i_{x^i}, a^i), (\mathbf{s}_x, a))]^t_{i=0}$ is a vector, and σ is a hyperparameter specifying the diagonal covariance values of the zero-mean Gaussian noise. In addition, we use $\mathrm{cov}\,(\mathbf{s}, a(x))$ to denote (for short) the self-covariance $\mathrm{cov}\,(\mathbf{s}, a(x), \mathbf{s}, a(x))$.

In our case, as different feature functions ϕ_a are defined for different action types, the kernel function is defined to be:

$$\kappa((\mathbf{s}_x, a), (\mathbf{s}'_{x'}, a')) = [\![a = a']\!]\kappa_a(\mathbf{s}_x, \mathbf{s}'_{x'}) \quad (11)$$

where $[\![\cdot]\!]$ is an indicator function and κ_a is the kernel function defined corresponding to the feature function ϕ_a.

Given a state, a most straightforward policy is to select the action that corresponds to the maximum mean Q-value estimated by the GP. However, since the objective is to learn the Q-function associated with the optimal policy by interacting directly with users, the policy must exhibit some form of stochastic behaviour in order to explore alternatives during the process of learning. In this work, the strategy employed for the exploration-exploitation trade-off is that, during exploration, actions are chosen according to the variance of the GP estimate for the Q-function, and during exploitation, actions are chosen according to the mean. That is:

$$\pi(\mathbf{s}) = \begin{cases} \arg\max_{a(x)} \bar{Q}(\mathbf{s}, a(x)) : \text{w.p. } 1-\epsilon \\ \arg\max_{a(x)} \mathrm{cov}\,(\mathbf{s}, a(x)) : \text{w.p. } \epsilon \end{cases} \quad (12)$$

where $0 < \epsilon < 1$ is a pre-defined exploration rate, and will be exponentially reduced at each batch iteration during our learning process.

Note that, in practice, not all the actions are valid at every possible state. For example, if a domain expert d has never been activated during a dialogue and can neither process the user's current query, the actions with an operand d will be regarded as invalid at this state. When executing the policy, we only consider those valid actions for a given state.

Score	Interpretation
5	The domain selections are totally correct, and the entire dialogue flow is fluent.
4	The domain selections are totally correct, but the dialogue flow is slightly redundant.
3	There are accidental domain selections errors, or the dialogue flow is perceptually redundant.
2	There are frequent domain selections errors, or the dialogue flow is intolerably redundant.
1	Most domain selections are incorrect, or the dialogue is incompletable.

Table 2: The scoring standard in our experiments.

6 Experimental Results

6.1 Training

We use the batch version of GPTD as described in Section 5 to learn the central control policy with human subjects. There are three domain experts available in our current system, but during the training only two domains are used, which are the travel information domain and the restaurant search domain. We reserve a movie search domain for evaluating the generalisation property of the learnt policy (see Section 6.2). The learning process started from a hand-crafted policy. Then 15 experienced users[2] volunteered to contribute dialogue examples with multiple or compound goals (see Figure 4 for an instance), from whom we collected around 50∼70 dialogues per day for 5 days[3]. After each dialogue, the users were asked to score the system from 5 to 1 according to a scoring standard shown in Table 2. The scores were taken as the (delayed) rewards to train the GPTD model, where we set the rewards for intermediate turns to 0. The working policy was updated daily based on the data obtained up to that day. The data collected on the first day was used for preliminary experiments to choose the hyperparame-

[2]Overall user satisfactions may rely on various aspects of the entire system, e.g. the data source quality of the services, the performance of each domain expert, etc. It will be difficult to make non-experienced users to score the central controller isolatedly.

[3]Not all the users participated the experiments everyday. There were 311 valid dialogues received in total, with an average length of 9 turns.

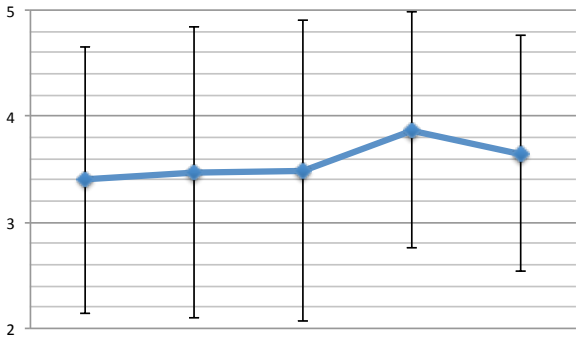

Figure 2: Average scores and standard deviations during policy iteration.

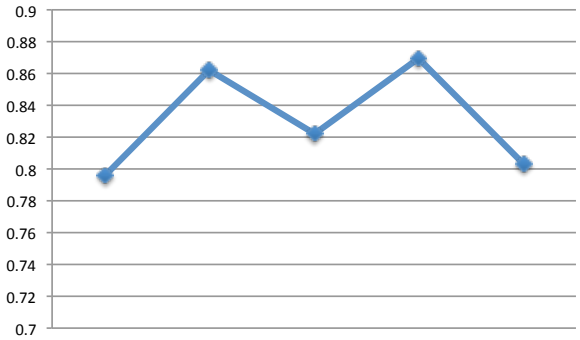

Figure 3: Domain selection accuracies during policy iteration.

ters of the model, such as the kernel function, the kernel parameters (if applicable), and σ and γ in the GPTD model. We initially experimented with linear, polynomial and Gaussian kernels, with different configurations of σ and γ values, as well as kernel parameter values. It was found that the linear kernel in combination with $\sigma = 5$ and $\gamma = 0.99$ works more appropriate than the other settings. This configuration was then fixed for the rest iterations.

The learning process was iterated for 4 days after the first one. On each day, we computed the mean and standard deviation of the user scores as an evaluation of the policy learnt on the previous day. The learning curve is illustrated in Figure 2. Note here, as we were actually executing a stochastic policy according to Eq. (12), to calculate the values in Figure 2 we ignored those dialogues that contain any actions selected due to the exploration. We also manually labelled the correctness of domain selection at every turn of the dialogues. The domain selection accuracies of the obtained policy sequence are shown in Figure 3, where similarly, those exploration actions as well as the clarification and confirmation actions were excluded from the calculations. Although the domain selection accuracy is not the target that our learning algorithm aims to optimise, it reflects the quality of the learnt policies from a different angle of view.

Scenario	Policy		p-value
	Baseline	GPTD	
(i)	4.5±0.8	4.2±0.8	0.387
(ii)	3.4±0.9	4.2±0.8	0.018
(iii)	4.1±1.0	4.3±1.0	0.0821
(iv)	3.9±1.1	4.5±0.8	0.0440

Table 3: Paired comparison experiments between the system with a trained GPTD policy and the rule-based baseline.

It can be found in Figure 2 that the best policy was obtained in the third iteration, and after that the policy quality oscillated. The same finding is indicated in Figure 3 as well, when we use the domain selection accuracy as the evaluation metric. Therefore, we kept the policy corresponding to the peak point of the learning curve for the comparison experiments below.

6.2 Comparison Experiments

We conducted paired comparison experiments in four scenarios to compare between the system with the GPTD-learnt central control policy and a non-trivial baseline. The baseline is a publicly deployed version of the voice assistant application. The central control policy of the baseline system is handcrafted, which has a separate list of semantic matching rules for each domain to enable domain switching.

The first two scenarios aim to test the performance of the two systems on (i) switching between a domain expert and out-of-domain services, and (ii) switching between two domain experts, where only the two training domains (travel information and restaurant search) were considered. Scenarios (iii) and (iv) are similar to scenarios (i) and (ii) respectively, but at this time, the users were required to carry out the tests surrounding the movie search domain (which is addressed by a new domain expert not used in the training phase). There were 13 users who participated this experiment. In each scenario, every user was required to test the two systems with an identical goal and similar queries. After each test, the users were asked to

score the two systems separately according to the scoring standard in Table 2.

The average scores received by the two systems are shown in Table 3, where we also compute the statistical significance (the p-values) of the results based on paired t-tests. It can be found that the learnt policy works significantly better than the rule-based policy in scenarios (ii) and (iv), but in scenarios (i) and (iii) the differences between two systems are statistically insignificant. Moreover, the learnt policy preserves the extensibility of the entire system as expected, of which strong evidences are given by the results in scenarios (iii) and (iv).

6.3 Policy Analysis

To better understand the policy learnt by the GPTD model, we look into the obtained weight vectors, as shown in Table 4. It can be found that confidence score (#5) is an informative feature for all the system actions, while the relative turn of a domain being last activated (#7) is an additional strong evidence for a confirmation decision. In addition, the similarity between the dialogue completion status (#1 & #2) of two ambiguous domain experts and the relative turns of them being last confirmed (#8) tend to be extra dominating features for clarification decisions, besides the closeness of the confidence scores returned by the two domain experts.

A less noticeable but important phenomenon is observed for feature #6, i.e. the total number of active turns of a domain expert during a dialogue. Concretely, feature #6 has a small negative effect on presentation actions but a small positive contribution to confirmation actions. Such weights could correspond to the discount factor's penalty to long dialogues in the value function. However, it implies an unexpected effect in extreme cases, which we explain in detail as follows. Although the absolute weights for feature #6 are tiny for both presentation and confirmation actions, the feature value will grow linearly during a dialogue. Therefore, when a dialogue in a certain domain last rather long, there tend to be very frequent confirmations. A possible solution to this problem could be either ignoring feature #6 or twisting it to some nonlinear function, such that its value stops increasing at a certain threshold point. In addition, to cover sufficient amount of those "extreme" examples in the training phase could also be an alternative solution, as our current training set contains very few examples that exhibit extraordinary long domain persistence.

#	Feature Weights			
	present	confirm	clarify	
1	0.09	0.02	0.60	present_ood
2	0.20	0.29	0.53	
3	0.18	0.29	0.16	
4	-0.10	0.16	0.25	
5	0.75	0.57	0.54	
6	-0.02	0.11	0.13	
7	0.25	1.19	0.36	
8	-0.22	-0.19	0.69	
9	–	0.20	–	0.47
Bias	-1.79	–	–	-2.42

7 Further Discussions

The proposed approach is a rather general framework to learn extensible central control policies for multi-domain SDS based on distributed architectures. It does not rely on any internal representations of those individual domain experts, as long as a unified featurisation of their dialogue states can be achieved.

However, from the entire system point of view, the current implementation is still preliminary. Particularly, the confirmation and clarification mechanisms are isolated, for which the surface realisations sometimes may sound stiff. This phenomenon explains one of the reasons that make the proposed system slightly less preferred by the users than the baseline in scenario (i), when the interaction flows are relative simple. A possible improvement here could be associating the confirmation and clarification actions in the central controller to the error handling mechanisms within each domain expert, and letting domain experts generate their own utterances on receiving a confirmation/clarification request from the central controller.

Online reinforcement learning with real user cases will be another undoubted direction of further improvement of our system. The key challenge here is to automatically estimate user's satisfactions, which will be transformed to the rewards for the reinforcement learners. Strong feedbacks such as clicks or actual order placements can be

collected. But to regress user's true satisfaction, other environment features must also be taken into account. Practical solutions are still an open issue at this stage, and are left to our future work.

8 Conclusion

In this paper, we introduce an MDP framework for learning domain selection policies in a complex multi-domain SDS. Standard problem formulation is modified with tied model parameters, so that the entire system is extensible and new domain experts can be easily integrated without re-training the policy. This expectation is confirmed by empirical experiments with human subjects, where the proposed system marginally beats a non-trivial baseline and demonstrates proper extensibility. Several possible improvements are discussed, which will be the central arc of our future research.

A Constituent-Based Approach to Argument Labeling with Joint Inference in Discourse Parsing

Abstract

Discourse parsing is a challenging task and plays a critical role in discourse analysis. In this paper, we focus on labeling full argument spans of discourse connectives in the Penn Discourse Treebank (PDTB). Previous studies cast this task as a linear tagging or subtree extraction problem. In this paper, we propose a novel constituent-based approach to argument labeling, which integrates the advantages of both linear tagging and subtree extraction. In particular, the proposed approach unifies intra- and inter-sentence cases by treating the immediately preceding sentence as a special constituent. Besides, a joint inference mechanism is introduced to incorporate global information across arguments into our constituent-based approach via integer linear programming. Evaluation on PDTB shows significant performance improvements of our constituent-based approach over the best state-of-the-art system. It also shows the effectiveness of our joint inference mechanism in modeling global information across arguments.

1 Introduction

Discourse parsing determines the internal structure of a text and identifies the discourse relations between its text units. It has attracted increasing attention in recent years due to its importance in text understanding, especially since the release of the Penn Discourse Treebank (PDTB) corpus (Prasad et al., 2008), which adds a layer of discourse annotations on top of the Penn Treebank (PTB) corpus (Marcus et al., 1993). As the largest available discourse corpus, the PDTB corpus has become the defacto benchmark in recent studies on discourse parsing.

Compared to connective identification and discourse relation classification in discourse parsing, the task of labeling full argument spans of discourse connectives is much harder and thus more challenging. For connective identification, Lin et al. (2014) achieved the performance of 95.76% and 93.62% in F-measure using gold-standard and automatic parse trees, respectively. For discourse relation classification, Lin et al. (2014) achieved the performance of 86.77% in F-measure on classifying discourse relations into 16 level 2 types. However, for argument labeling, Lin et al. (2014) only achieved the performance of 53.85% in F-measure using gold-standard parse trees and connectives, much lower than the inter-annotation agreement of 90.20% (Miltsakaki et al., 2004).

In this paper, we focus on argument labeling in the PDTB corpus. In particular, we propose a *novel* constituent-based approach to argument labeling which views constituents as candidate arguments. Besides, our approach unifies intra- and inter-sentence cases by treating the immediately preceding sentence as a special constituent. Finally, a joint inference mechanism is introduced to incorporate global information across arguments via integer linear programming. Evaluation on the PDTB corpus shows the effectiveness of our approach.

The rest of this paper is organized as follows. Section 2 briefly introduces the PDTB corpus. Related work on argument labeling is reviewed in Section 3. In Section 4, we describe our constituent-based approach to argument labeling. In Section 5, we present our joint inference mechanism via integer linear programming (ILP). Section 6 gives the experimental results and analysis. Finally, we conclude in Section 7.

2 Penn Discourse Treebank

As the first large-scale annotated corpus that follows the lexically grounded, predicate-argument approach in D-LTAG (Lexicalized Tree Adjoining Grammar for Discourse) (Webber, 2004), the PDTB regards a connective as the predicate of a discourse relation which takes exactly two text spans as its arguments. In particular, the text span that the connective is syntactically attached to is called Arg2, and the other is called Arg1.

Although discourse relations can be either explicitly or implicitly expressed in PDTB, this paper focuses only on explicit discourse relations that are explicitly signaled by discourse connectives. Example (1) shows an explicit discourse relation from the article wsj_2314 with connective so underlined, Arg1 span *italicized*, and Arg2 span **bolded**.

(1) *But its competitors have much broader business interests* **and** so **are better cushioned against price swings .**

Note that a connective and its arguments can appear in any relative order, and an argument can be arbitrarily far away from its corresponding connective. Although the position of Arg2 is fixed once the connective is located, Arg1 can occur in the same sentence as the connective (SS), in a sentence preceding that of the connective (PS), or in a sentence following that of the connective (FS), with proportions of 60.9%, 39.1%, and less than 0.1% respectively for explicit relations in the PDTB corpus (Prasad et al., 2008). Besides, out of all PS cases where Arg1 occurs in some preceding sentence, 79.9% of them are the exact immediately preceding sentence. As such, in this paper, we only consider the current sentence containing the connective and its immediately preceding sentence as the text span where Arg1 occurs, similar to what was done in (Lin et al., 2014).

3 Related Work

For argument labeling in discourse parsing on the PDTB corpus, the related work can be classified into two categories: locating parts of arguments, and labeling full argument spans.

As a representative on locating parts of arguments, Wellner and Pustejovsky (2007) proposed several machine learning approaches to identify the head words of the two arguments for discourse connectives. Following this work, Elwell and Baldridge (2008) combined general and connective specific rankers to improve the performance of labeling the head words of the two arguments. Prasad et al. (2010) proposed a set of heuristics to locate the position of the Arg1 sentences for inter-sentence cases. The limitation of locating parts of arguments, such as the positions and head words, is that it is only a partial solution to argument labeling in discourse parsing.

In comparison, labeling full argument spans can provide a complete solution to argument labeling in discourse parsing and has thus attracted increasing attention recently, adopting either a subtree extraction approach (Dinesh et al. (2005), Lin et al. (2014)) or a linear tagging approach (Ghosh et al. (2011)).

As a representative subtree extraction approach, Dinesh et al. (2005) proposed an automatic tree subtraction algorithm to locate argument spans for intra-sentential subordinating connectives. However, only dealing with intra-sentential subordinating connectives is not sufficient since they constitute only 40.93% of all cases. Instead, Lin et al. (2014) proposed a two-step approach. First, an argument position identifier was employed to locate the position of Arg1. For the PS case, it directly selects the immediately preceding sentence as Arg1. For other cases, an argument node identifier was employed to locate the Arg1- and Arg2-nodes. Next, a tree subtraction algorithm was used to extract the arguments. However, as pointed out in Dinesh et al. (2005), it is not necessarily the case that a connective, Arg1, or Arg2 is dominated by a single node in the parse tree (that is, it can be dominated by a set of nodes). Figure 1 shows the gold-standard parse tree corresponding to Example (1). It shows that Arg1 includes three nodes: [$_{CC}$ But], [$_{NP}$ its competitors], [$_{VP}$ have much broader business interests], and Arg2 includes two nodes: [$_{CC}$ and], [$_{VP}$ are better cushioned against price swings]. Therefore, such an argument node identifier has inherent shortcomings in labeling arguments. Besides, the errors propagated from the upstream argument position classifier may adversely affect the performance of the downstream argument node identifier.

As a representative linear tagging approach, Ghosh et al. (2011) cast argument labeling as a linear tagging task using conditional random fields. Ghosh et al. (2012) further improved the perfor-

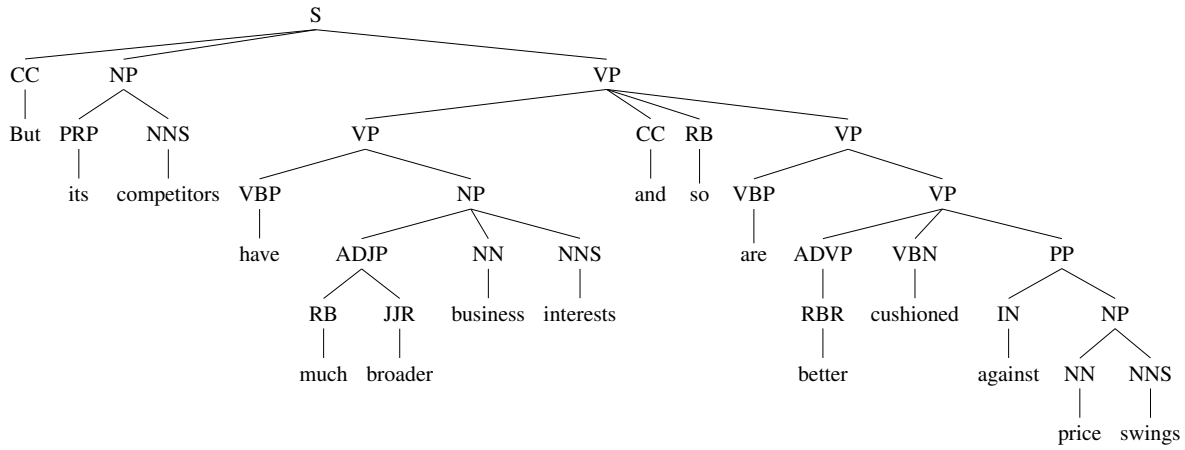

Figure 1: The gold-standard parse tree corresponding to Example (1)

mance with integration of the n-best results.

While the subtree extraction approach locates argument spans based on the nodes of a parse tree and is thus capable of using rich syntactic information, the linear tagging approach works on the tokens in a sentence and is thus capable of capturing local sequential dependency between tokens. In this paper, we take advantage of both subtree extraction and linear tagging approaches by proposing a novel constituent-based approach. Furthermore, intra- and inter-sentence cases are unified by treating the immediately preceding sentence as a special constituent. Finally, a joint inference mechanism is proposed to add global information across arguments.

4 A Constituent-Based Approach to Argument Labeling

Our constituent-based approach works by first casting the constituents extracted from a parse tree as argument candidates, then determining the role of every constituent as part of Arg1, Arg2, or NULL, and finally, merging all the constituents for Arg1 and Arg2 to obtain the Arg1 and Arg2 text spans respectively. Obviously, the key to the success of our constituent-based approach is constituent-based argument classification, which determines the role of every constituent argument candidate.

As stated above, the PDTB views a connective as the predicate of a discourse relation. Similar to semantic role labeling (SRL), for a given connective, the majority of the constituents in a parse tree may not be its arguments (Xue and Palmer, 2004). This indicates that negative instances (constituents marked NULL) may overwhelm positive instances. To address this problem, we use a simple algorithm to prune out these constituents which are clearly not arguments to the connective in question.

4.1 Pruning

The pruning algorithm works recursively in preprocessing, starting from the target connective node, i.e. the lowest node dominating the connective. First, all the siblings of the connective node are collected as candidates, then we move on to the parent of the connective node and collect its siblings, and so on until we reach the root of the parse tree. In addition, if the target connective node does not cover the connective exactly, the children of the target connective node are also collected.

For the example shown in Figure 1, we can locate the target connective node [$_{RB}$ so] and return five constituents — [$_{VP}$ have much broader business interests], [$_{CC}$ and], [$_{VP}$ are better cushioned against price swings], [$_{CC}$ But], and [$_{NP}$ its competitors] — as argument candidates.

It is not surprising that the pruning algorithm works better on gold parse trees than automatic parse trees. Using gold parse trees, our pruning algorithm can recall 89.56% and 92.98% (489 out of 546 Arg1s, 808 out of 869 Arg2s in the test data) of the Arg1 and Arg2 spans respectively and prune out 81.96% (16284 out of 19869) of the nodes in the parse trees. In comparison, when automatic parse trees (based on the Charniak parser (Charniak, 2000)) are used, our pruning algorithm can recall 80.59% and 89.87% of the Arg1 and Arg2 spans respectively and prune out 81.70% (16190

Feature	Description	Example
CON-Str	The string of the given connective (case-sensitive)	so
CON-LStr	The lowercase string of the given connective	so
CON-Cat	The syntactic category of the given connective: subordinating, coordinating, or discourse adverbial	Subordinating
CON-iLSib	Number of left siblings of the connective	2
CON-iRSib	Number of right siblings of the connective	1
NT-Ctx	The context of the constituent. We use POS combination of the constituent, its parent, left sibling and right sibling to represent the context. When there is no parent or siblings, it is marked NULL.	VP-VP-NULL-CC
CON-NT-Path	The path from the parent node of the connective to the node of the constituent	$RB \uparrow VP \downarrow VP$
CON-NT-Position	The position of the constituent relative to the connective: left, right, or previous	left
CON-NT-Path-iLsib	The path from the parent node of the connective to the node of the constituent and whether the number of left siblings of the connective is greater than one	$RB \uparrow VP \downarrow VP$:>1

Table 1: Features employed in argument classification.

out of 19816) of the nodes in the parse trees.

4.2 Argument Classification

In this paper, a multi-category classifier is employed to determine the role of an argument candidate (i.e., Arg1, Arg2, or NULL). Table 1 lists the features employed in argument classification, which reflect the properties of the connective and the candidate constituent, and the relationship between them. The third column of Table 1 shows the features corresponding to Figure 1, considering [$_{RB}$ so] as the given connective and [$_{VP}$ have much broader business interests] as the constituent in question.

Similar to Lin et al. (2014), we obtained the syntactic category of the connectives from the list provided in Knott (1996). However, different from Lin et al. (2014), only the siblings of the root path nodes (i.e., the nodes occurring in the path of the connective to root) are collected as the candidate constituents in the pruning stage, and the value of the relative position can be left or right, indicating that the constituent is located on the left- or right-hand of the root path respectively. Besides, we view the root of the previous sentence as a special candidate constituent. For example, the value of the feature CON-NT-Position is *previous* when the current constituent is the root of the previous sentence. Finally, we use the part-of-speech (POS) combination of the constituent itself, its parent node, left sibling node and right sibling node to represent the context of the candidate constituent. Intuitively, this information can help determine the role of the constituent.

For the example shown in Figure 1, we first employ the pruning algorithm to get the candidate constituents, and then employ our argument classifier to determine the role for every candidate. For example, if the five candidates are labeled as Arg1, Arg2, Arg2, Arg1, and Arg1, respectively, we merge all the Arg1 constituents to obtain the Arg1 text span (i.e., *But its competitors have much broader business interests*). Similarly, we merge the two Arg2 constituents to obtain the Arg2 text span (i.e., **and are better cushioned against price swings**).

5 Joint Inference via Integer Linear Programming

In the above approach, decisions are always made for each candidate independently, ignoring global information across candidates in the final output. For example, although an argument span can be split into multiple discontinuous segments (e.g., the Arg2 span of Example (1) contains two discontinuous segments, **and**, **are better cushioned against price swings**), the number of discontinuous segments is always limited. Statistics on the PDTB corpus shows that the number of discontin-

uous segments for both Arg1 and Arg2 is generally ($>= 99\%$) at most 2. For Example (1), from left to right, we can obtain the list of constituent candidates: [$_{CC}$ But], [$_{NP}$ its competitors], [$_{VP}$ have much broader business interests], [$_{CC}$ and], [$_{VP}$ are better cushioned against price swings]. If our argument classifier wrongly determines the roles as Arg1, Arg2, Arg1, Arg2, and Arg1 respectively, we can find that the achieved Arg1 span contains three discontinuous segments. Such errors may be corrected from a global perspective.

In this paper, a joint inference mechanism is introduced to incorporate various kinds of knowledge to resolve the inconsistencies in argument classification to ensure global legitimate predictions. In particular, the joint inference mechanism is formalized as a constrained optimization problem, represented as an integer linear programming (ILP) task. It takes as input the argument classifiers' confidence scores for each constituent candidate along with a list of constraints, and outputs the optimal solution that maximizes the objective function incorporating the confidence scores, subject to the constraints that encode various kinds of knowledge.

In this section, we meet the requirement of ILP with focus on the definition of variables, the objective function, and the problem-specific constraints, along with ILP-based joint inference integrating multiple systems.

5.1 Definition of Variables

Given an input sentence, the task of argument labeling is to determine what labels should be assigned to which constituents corresponding to which connective. It is therefore natural that encoding the output space of argument labeling requires various kinds of information about the connectives, the argument candidates corresponding to a connective, and their argument labels.

Given an input sentence s, we define following variables:

(1) P: the set of connectives in a sentence.

(2) $p \in P$: a connective in P.

(3) $C(p)$: the set of argument candidates corresponding to connective p. (i.e., the parse tree nodes obtained in the pruning stage).

(4) $c \in C(p)$: an argument candidate.

(5) L: the set of argument labels {Arg1, Arg2, NULL }.

(6) $l \in L$: an argument label in L.

In addition, we define the integer variables as follows:

$$Z^l_{c,p} \in \{0, 1\} \tag{1}$$

If $Z^l_{c,p} = 1$, the argument candidate c, which corresponds to connective p, should be assigned the label l. Otherwise, the argument candidate c is not assigned this label.

5.2 The Objective Function

The objective of joint inference is to find the best arguments for all the connectives in one sentence. For every connective, the pruning algorithm is first employed to determine the set of corresponding argument candidates. Then, the argument classifier is used to assign a label to every candidate. For an individual labeling $Z^l_{c,p}$, we measure the quality based on the confidence scores, $f_{l,c,p}$, returned by the argument classifier. Thus, the objective function can be defined as

$$\max \sum_{l,c,p} f_{l,c,p} Z^l_{c,p} \tag{2}$$

5.3 Constraints

As the key to the success of ILP-based joint inference, the following constraints are employed:

Constraint 1: The arguments corresponding to a connective cannot overlap with the connective. Let $c_1, c_2..., c_k$ be the argument candidates that correspond to the same connective and overlap with the connective in a sentence.[1] Then this constraint ensures that none of them will be assigned as Arg1 or Arg2.

$$\sum_{i=1}^{k} Z^{NULL}_{c_i,p} = k \tag{3}$$

Constraint 2: There are no overlapping or embedding arguments. Let $c_1, c_2..., c_k$ be the argument candidates that correspond to the same connective and cover the same word in a sentence.[2]

[1] Only when the target connective node does not cover the connective exactly and our pruning algorithm collects all the children of the target connective node as part of constituent candidates, such overlap can be introduced.

[2] This constraint only works in system combination of Section 5.4, where additional phantom candidates may introduce such overlap.

Then this constraint ensures that at most one of the constituents can be assigned as Arg1 or Arg2. That is, at least $k-1$ constituents should be assigned the special label NULL.

$$\sum_{i=1}^{k} Z_{c_i,p}^{NULL} \geq k-1 \quad (4)$$

Constraint 3: For a connective, there is at least one constituent candidate assigned as Arg2.

$$\sum_{c} Z_{c,p}^{Arg2} \geq 1 \quad (5)$$

Constraint 4: Since we view the previous complete sentence as a special Arg1 constituent candidate, denoted as m, there is at least one candidate assigned as Arg1 for every connective.

$$\sum_{c} Z_{c,p}^{Arg1} + Z_{m,p}^{Arg1} \geq 1 \quad (6)$$

Constraint 5: The number of discontinuous constituents assigned as Arg1 or Arg2 should be at most 2. That is, if argument candidates $c_1, c_2..., c_k$ corresponding to the same connective are discontinuous, this constraint ensures that at most two of the constituents can be assigned the same label Arg1 or Arg2.

$$\sum_{i=1}^{k} Z_{c_i,p}^{Arg1} \leq 2, and \sum_{i=1}^{k} Z_{c_i,p}^{Arg2} \leq 2 \quad (7)$$

5.4 System Combination

Previous work shows that the performance of argument labeling heavily depends on the quality of the syntactic parser. It is natural that combining different argument labeling systems on different parse trees can potentially improve the overall performance of argument labeling.

To explore this potential, we build two argument labeling systems — one using the Berkeley parser (Petrov et al., 2006) and the other the Charniak parser (Charniak, 2000). Previous studies show that these two syntactic parsers tend to produce different parse trees for the same sentence (Zhang et al., 2009). For example, our preliminary experiment shows that applying the pruning algorithm on the output of the Charniak parser produces a list of candidates with recall of 80.59% and 89.87% for Arg1 and Arg2 respectively, while achieving recall of 78.6% and 91.1% for Arg1 and Arg2 respectively on the output of the Berkeley parser. It also shows that combining these two candidate lists significantly improves recall to 85.7% and 93.0% for Arg1 and Arg2, respectively.

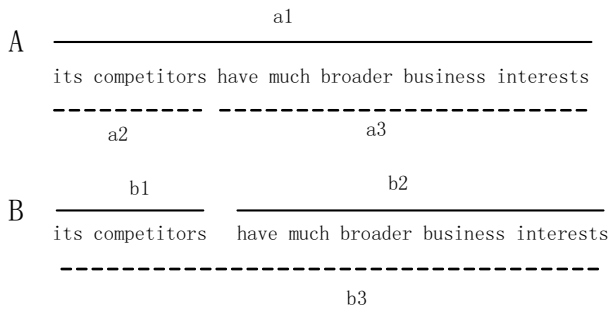

Figure 2: An example on unifying different candidates.

In subsection 5.2, we only consider the confidence scores returned by an argument classifier. Here, we proceed to combine the probabilities produced by two argument classifiers. There are two remaining problems to resolve:

- How do we unify the two candidate lists? In principle, constituents spanning the same sequence of words should be viewed as the same candidate. That is, for different candidates, we can unify them by adding phantom candidates. This is similar to the approach proposed by Punyakanok et al. (2008) for the semantic role labeling task. For example, Figure 2 shows the candidate lists generated by our pruning algorithm based on two different parse trees given the segment "its competitors have much broader business interests". Dashed lines are used for phantom candidates and solid lines for true candidates. Here, system A produces one candidate a1, with two phantom candidates a2 and a3 added. Analogously, phantom candidate b3 is added to the candidate list output by System B. In this way, we can get the unified candidate list: "its competitors have much broader business interests", "its competitors", "have much broader business interests".

- How do we compute the confidence score for every decision? For every candidate in the unified list, we first determine whether it is a true candidate based on the specific parse tree. Then, for a true candidate, we extract the features from the corresponding parse

tree. On this basis, we can determine the confidence score using our argument classifier. For a phantom candidate, we set the same prior distribution as the confidence score. In particular, the probability of the "NULL" class is set to 0.55, following (Punyakanok et al., 2008), and the probabilities of Arg1 and Arg2 are set to their occurrence frequencies in the training data. For the example shown in Figure 2, since System A returns "its competitors have much broader business interests" as a true candidate, we can obtain its confidence score using our argument classifier. For the two phantom candidates — "its competitors" and "have much broader business interests" — we use the prior distributions directly. This applies to the candidates for System B. Finally, we simply average the estimated probabilities to determine the final probability estimate for every candidate in the unified list.

6 Experiments

In this section, we systematically evaluate our constituent-based approach with a joint inference mechanism to argument labeling on the PDTB corpus.

6.1 Experimental settings

All our classifiers are trained using the OpenNLP maximum entropy package[3] with the default parameters (i.e. without smoothing and with 100 iterations). As the PDTB corpus is aligned with the PTB corpus, the gold parse trees and sentence boundaries are obtained from PTB. Under the automatic setting, the NIST sentence segmenter[4] and the Charniak parser[5] are used to segment and parse the sentences, respectively. lp_solve[6] is used for our joint inference.

This paper focuses on automatically labeling the full argument spans of discourse connectives. For a fair comparison with start-of-the-art systems, we use the NUS PDTB-style end-to-end discourse parser[7] to perform other subtasks of discourse parsing except argument labeling, which includes connective identification, non-explicit discourse relation identification and classification.

Finally, we evaluate our system on two aspects: (1) the dependence on the parse trees (GS/Auto, using gold standard or automatic parse trees and sentence boundaries); and (2) the impact of errors propagated from previous components (noEP/EP, using gold annotation or automatic results from previous components). In combination, we have four different settings: GS+noEP, GS+EP, Auto+noEP and Auto+EP. Same as Lin et al. (2014), we report exact match results under these four settings. Here, exact match means two spans match identically, except beginning or ending punctuation symbols.

6.2 Experimental results

We first evaluate the effectiveness of our constituent-based approach by comparing our system with the state-of-the-art systems, ignoring the joint inference mechanism. Then, the contribution of the joint inference mechanism to our constituent-based approach, and finally the contribution of our argument labeling system to the end-to-end discourse parser are presented.

Effectiveness of our constituent-based approach

By comparing with two state-of-the-art argument labeling approaches, we determine the effectiveness of our constituent-based approach.

Comparison with the linear tagging approach

As a representative linear tagging approach, Ghosh et al. (2011; 2012; 2012) only reported the exact match results for Arg1 and Arg2 using the evaluation script for chunking evaluation[8] under GS+noEP setting with Section 02–22 of the PDTB corpus for training, Section 23–24 for testing, and Section 00–01 for development. It is also worth mentioning that an argument span can contain multiple discontinuous segments (i.e., chunks), so chunking evaluation only shows the exact match of every argument segment but not the exact match of every argument span. In order to fairly compare our system with theirs, we evaluate our system using both the exact metric and the chunking evaluation. Table 2 compares the results of our system without joint inference and the results reported by Ghosh et al. (2012) on the same data split. We can find that our system performs much bet-

[3] http://maxent.sourceforge.net/

[4] http://duc.nist.gov/duc2004/software/duc2003.breakSent.tar.gz

[5] ftp://ftp.cs.brown.edu/pub/nlparser/

[6] http://lpsolve.sourceforge.net/

[7] http://wing.comp.nus.edu.sg/ linzihen/parser/

[8] http://www.cnts.ua.ac.be/conll2000/chunking/conlleval.txt

ter than Ghosh's on both Arg1 and Arg2, even on much stricter metrics.

Systems	Arg1	Arg2
ours using exact match	65.68	84.50
ours using chunking evaluation	67.48	88.08
reported by Ghosh et al. (2012)	59.39	79.48

Table 2: Performance (F1) comparison of our argument labeling approach with the linear tagging approach as adopted in Ghosh et al. (2012)

Comparison with the subtree extracting approach

For a fair comparison, we also conduct our experiments on the same data split of Lin et al. (2014) with Section 02 to 21 for training, Section 22 for development, and Section 23 for testing. Table 3 compares our labeling system without joint inference with Lin et al. (2014), a representative subtree extracting approach. From the results, we find that the performance of our argument labeling system significantly improves under all settings. This is because Lin et al. (2014) considered all the internal nodes of the parse trees, whereas the pruning algorithm in our approach can effectively filter out those unlikely constituents when determining Arg1 and Arg2.

	Setting	Arg1	Arg2	Arg1&2
ours	GS+noEP	62.84	84.07	55.69
	GS+EP	61.46	81.30	54.31
	Auto+EP	56.04	76.53	48.89
Lin's	GS+noEP	59.15	82.23	53.85
	GS+EP	57.64	79.80	52.29
	Auto+EP	47.68	70.27	40.37

Table 3: Performance (F1) comparison of our argument labeling approach with the subtree extraction approach as adopted in Lin et al. (2014)

As justified above, by integrating the advantages of both linear tagging and subtree extraction, our constituent-based approach can capture both rich syntactic information from parse trees and local sequential dependency between tokens. The results show that our constituent-based approach indeed significantly improves the performance of argument labeling, compared to both linear tagging and subtree extracting approaches.

Contribution of Joint Inference

Same as Lin et al. (2014), we conduct our experiments using Section 02 to 21 for training, Section 22 for development, and Section 23 for testing. Table 4 lists the performance of our argument labeling system without and with ILP inference under four different settings, while Table 5 reports the contribution of system combination. It shows the following:

- On the performance comparison of Arg1 and Arg2, the performance on Arg2 is much better than that on Arg1 with the performance gap up to 8% under different settings. This is due to the fact that the relationship between Arg2 and the connective is much closer. This result is also consistent with previous studies on argument labeling.

- On the impact of error propagation from connective identification, the errors propagated from connective identification reduce the performance of argument labeling by less than 2% in both Arg1 and Arg2 F-measure under different settings.

- On the impact of parse trees, using automatic parse trees reduces the performance of argument labeling by about 5.5% in both Arg1 and Arg2 F-measure under different settings. In comparison with the impact of error propagation, parse trees have much more impact on argument labeling.

- On the impact of joint inference, it improves the performance of argument labeling, especially on automatic parse trees by about 2%.[9]

- On the impact of system combination, the performance is improved by about 1.5%.

	Setting	Arg1	Arg2	Arg1&2
without Joint Inference	GS+noEP	62.84	84.07	55.69
	GS+EP	61.46	81.30	54.31
	Auto+noEP	57.75	79.85	50.27
	Auto+EP	56.04	76.53	48.89
with Joint Inference	GS+noEP	65.76	83.86	58.18
	GS+EP	63.96	81.19	56.37
	Auto+noEP	60.24	79.74	52.55
	Auto+EP	58.10	76.53	50.73

Table 4: Performance (F1) of our argument labeling approach.

Contribution to the end-to-end discourse parser

[9]Unless otherwise specified, all the improvements in this paper are significant with $p < 0.001$.

Systems	Setting	Arg1	Arg2	Arg1&2
Charniak	noEP	60.24	79.74	52.55
	EP	58.10	76.53	50.73
Berkeley	noEP	60.78	80.07	52.98
	EP	58.80	77.21	51.43
Combined	noEP	61.97	80.61	54.50
	EP	59.72	77.55	52.52

Table 5: Contribution of System Combination in Joint Inference.

Lastly, we focus on the contribution of our argument labeling approach to the overall performance of the end-to-end discourse parser. This is done by replacing the argument labeling model of the NUS PDTB-style end-to-end discourse parser with our argument labeling model. Table 6 shows the results using gold parse trees and automatic parse trees, respectively.[10] From the results, we find that using gold parse trees, our argument labeling approach significantly improves the performance of the end-to-end system by about 1.8% in F-measure, while using automatic parse trees, the improvement significantly enlarges to 6.7% in F-measure.

Setting	New d-parser	Lin et al.'s (2014)
GS	34.80	33.00
Auto	27.39	20.64

Table 6: Performance (F1) of the end-to-end discourse parser.

7 Conclusion

In this paper, we focus on the problem of automatically labeling the full argument spans of discourse connectives. In particular, we propose a constituent-based approach to integrate the advantages of both subtree extraction and linear tagging approaches. Moreover, our proposed approach integrates inter- and intra-sentence argument labeling by viewing the immediately preceding sentence as a special constituent. Finally, a joint inference mechanism is introduced to incorporate global information across arguments into our constituent-based approach via integer linear programming.

[10]Further analysis found that the error propagated from sentence segmentation can reduce the performance of the end-to-end discourse parser. Retraining the NIST sentence segmenter using Section 02 to 21 of the PDTB corpus, the original NUS PDTB-style end-to-end discourse parser can achieve the performance of 25.25% in F-measure, while the new version (i.e. replace the argument labeling model with our argument labeling model) can achieve the performance of 30.06% in F-measure.

Abstract

We present STIR (STrongly Incremental Repair detection), a system that detects speech repairs and edit terms on transcripts incrementally with minimal latency. STIR uses information-theoretic measures from n-gram models as its principal decision features in a pipeline of classifiers detecting the different stages of repairs. Results on the Switchboard disfluency tagged corpus show utterance-final accuracy on a par with state-of-the-art incremental repair detection methods, but with better incremental accuracy, faster time-to-detection and less computational overhead. We evaluate its performance using incremental metrics and propose new repair processing evaluation standards.

1 Introduction

Self-repairs in spontaneous speech are annotated according to a well established three-phase structure from (Shriberg, 1994) onwards, and as described in Meteer et al. (1995)'s Switchboard corpus annotation handbook:

$$\text{John} \underbrace{[\ \text{likes}}_{\text{reparandum}} + \underbrace{\{\text{uh}\}}_{\text{interregnum}} \underbrace{\text{loves}\ ]}_{\text{repair}} \text{Mary} \quad (1)$$

From a dialogue systems perspective, detecting repairs and assigning them the appropriate structure is vital for robust natural language understanding (NLU) in interactive systems. Downgrading the commitment of *reparandum* phases and assigning appropriate *interregnum* and *repair* phases permits computation of the user's intended meaning.

Furthermore, the recent focus on *incremental* dialogue systems (see e.g. (Rieser and Schlangen, 2011)) means that repair detection should operate without unnecessary processing overhead, and function efficiently within an incremental framework. However, such left-to-right operability on its own is not sufficient: in line with the principle of strong incremental interpretation (Milward, 1991), a repair detector should give *the best results possible as early as possible*. With one exception (Zwarts et al., 2010), there has been no focus on evaluating or improving the *incremental performance* of repair detection.

In this paper we present STIR (Strongly Incremental Repair detection), a system which addresses the challenges of incremental accuracy, computational complexity and latency in self-repair detection, by making local decisions based on relatively simple measures of fluency and similarity. Section 2 reviews state-of-the-art methods; Section 3 summarizes the challenges and explains our general approach; Section 4 explains STIR in detail; Section 5 explains our experimental set-up and novel evaluation metrics; Section 6 presents and discusses our results and Section 7 concludes.

2 Previous work

Qian and Liu (2013) achieve the state of the art in Switchboard corpus self-repair detection, with an F-score for detecting reparandum words of 0.841 using a three-step weighted Max-Margin Markov network approach. Similarly, Georgila (2009) uses Integer Linear Programming post-processing of a CRF to achieve F-scores over 0.8 for reparandum start and repair start detection. However neither approach can operate incrementally.

Recently, there has been increased interest in left-to-right repair detection: Rasooli and Tetreault (2014) and Honnibal and Johnson (2014) present dependency parsing systems with reparandum detection which perform similarly, the latter equalling Qian and Liu (2013)'s F-score at 0.841. However, while operating left-to-right, these systems are not designed or evaluated for their *incremental* performance. The use of beam search over

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 78–89,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

different repair hypotheses in (Honnibal and Johnson, 2014) is likely to lead to unstable repair label sequences, and they report repair hypothesis 'jitter'. Both of these systems use a non-monotonic dependency parsing approach that immediately removes the reparandum from the linguistic analysis of the utterance in terms of its dependency structure and repair-reparandum correspondence, which from a downstream NLU module's perspective is undesirable. Heeman and Allen (1999) and Miller and Schuler (2008) present earlier left-to-right operational detectors which are less accurate and again give no indication of the incremental performance of their systems. While Heeman and Allen (1999) rely on repair structure template detection coupled with a multi-knowledge-source language model, the rarity of the tail of repair structures is likely to be the reason for lower performance: Hough and Purver (2013) show that only 39% of repair alignment structures appear at least twice in Switchboard, supported by the 29% reported by Heeman and Allen (1999) on the smaller TRAINS corpus. Miller and Schuler (2008)'s encoding of repairs into a grammar also causes sparsity in training: repair is a general processing strategy not restricted to certain lexical items or POS tag sequences.

The model we consider most suitable for incremental dialogue systems so far is Zwarts et al. (2010)'s incremental version of Johnson and Charniak (2004)'s noisy channel repair detector, as it incrementally applies structural repair analyses (rather than just identifying reparanda) and is evaluated for its incremental properties. Following (Johnson and Charniak, 2004), their system uses an n-gram language model trained on roughly 100K utterances of reparandum-excised ('cleaned') Switchboard data. Its channel model is a statistically-trained S-TAG parser whose grammar has simple reparandum-repair alignment rule categories for its non-terminals (copy, delete, insert, substitute) and words for its terminals. The parser hypothesises all possible repair structures for the string consumed so far in a chart, before pruning the unlikely ones. It performs equally well to the non-incremental model by the end of each utterance (F-score = 0.778), and can make detections early via the addition of a speculative next-word repair completion category to their S-TAG non-terminals. In terms of incremental performance, they report the novel evaluation metric of *time-to-detection* for correctly identified repairs, achieving an average of 7.5 words from the start of the reparandum and 4.6 from the start of the repair phase. They also introduce *delayed accuracy*, a word-by-word evaluation against gold-standard disfluency tags up to the word before the current word being consumed (in their terms, the *prefix boundary*), giving a measure of the stability of the repair hypotheses. They report an F-score of 0.578 at one word back from the current prefix boundary, increasing word-by-word until 6 words back where it reaches 0.770. These results are the point-of-departure for our work.

3 Challenges and Approach

In this section we summarize the challenges for incremental repair detection: computational complexity, repair hypothesis stability, latency of detection and repair structure identification. In 3.1 we explain how we address these.

Computational complexity Approaches to detecting repair structures often use chart storage (Zwarts et al., 2010; Johnson and Charniak, 2004; Heeman and Allen, 1999), which poses a computational overhead: if considering all possible boundary points for a repair structure's 3 phases beginning on any word, for prefixes of length n the number of hypotheses can grow in the order $O(n^4)$. Exploring a subset of this space is necessary for assigning entire repair structures as in (1) above, rather than just detecting reparanda: the (Johnson and Charniak, 2004; Zwarts et al., 2010) noisy-channel detector is the only system that applies such structures but the potential runtime complexity in decoding these with their S-TAG repair parser is $O(n^5)$. In their approach, complexity is mitigated by imposing a maximum repair length (12 words), and also by using beam search with re-ranking (Lease et al., 2006; Zwarts and Johnson, 2011). If we wish to include full decoding of the repair's structure (as argued by Hough and Purver (2013) as necessary for full interpretation) whilst taking a strictly incremental and time-critical perspective, reducing this complexity by minimizing the size of this search space is crucial.

Stability of repair hypotheses and latency Using a beam search of n-best hypotheses on a word-by-word basis can cause 'jitter' in the detector's output. While utterance-final accuracy is desired,

for a truly incremental system good intermediate results are equally important. Zwarts et al. (2010)'s time-to-detection results show their system is only certain about a detection after processing the entire repair. This may be due to the string alignment-inspired S-TAG that matches repair and reparanda: a 'rough copy' dependency only becomes likely once the entire repair has been consumed. The latency of 4.6 words to detection and a relatively slow rise to utterance-final accuracy up to 6 words back is undesirable given repairs have a mean reparandum length of ≈1.5 words (Hough and Purver, 2013; Shriberg and Stolcke, 1998).

Structural identification Classifying repairs has been ignored in repair processing, despite the presence of distinct categories (e.g. repeats, substitutions, deletes) with different pragmatic effects (Hough and Purver, 2013).[1] This is perhaps due to lack of clarity in definition: even for human annotators, verbatim repeats withstanding, agreement is often poor (Hough and Purver, 2013; Shriberg, 1994). Assigning and evaluating repair (not just reparandum) structures will allow repair interpretation in future; however, work to date evaluates only reparandum detection.

3.1 Our approach

To address the above, we propose an alternative to (Johnson and Charniak, 2004; Zwarts et al., 2010)'s noisy channel model. While the model elegantly captures intuitions about parallelism in repairs and modelling fluency, it relies on string-matching, motivated in a similar way to automatic spelling correction (Brill and Moore, 2000): it assumes a speaker chooses to utter fluent utterance X according to some prior distribution $P(X)$, but a noisy channel causes them instead to utter a noisy Y according to channel model $P(Y \mid X)$. Estimating $P(Y \mid X)$ directly from observed data is difficult due to sparsity of repair instances, so a transducer is trained on the rough copy alignments between reparandum and repair. This approach succeeds because repetition and simple substitution repairs are very common; but repair as a psychological process is not driven by string alignment, and deletes, restarts and rarer substitution forms are not captured. Furthermore, the noisy channel model assumes an inherently utterance-global process for generating (and therefore finding) an underlying 'clean' string — much as similar spelling correction models are word-global — we instead take a very local perspective here.

In accordance with psycholinguistic evidence (Brennan and Schober, 2001), we assume characteristics of the repair onset allow hearers to detect it very quickly and solve the *continuation problem* (Levelt, 1983) of integrating the repair into their linguistic context immediately, before processing or even hearing the end of the repair phase. While repair onsets may take the form of interregna, this is not a reliable signal, occurring in only ≈15% of repairs (Hough and Purver, 2013; Heeman and Allen, 1999). Our repair onset detection is therefore driven by departures from fluency, via information-theoretic features derived incrementally from a language model in line with recent psycholinguistic accounts of incremental parsing – see (Keller, 2004; Jaeger and Tily, 2011).

Considering the time-linear way a repair is processed and the fact speakers are exponentially less likely to trace one word further back in repair as utterance length increases (Shriberg and Stolcke, 1998), backwards search seems to be the most efficient reparandum extent detection method.[2] Features determining the detection of the reparandum extent in the backwards search can also be information-theoretic: entropy measures of distributional parallelism can characterize not only rough copy dependencies, but distributionally similar or dissimilar correspondences between sequences. Finally, when detecting the repair end and structure, distributional information allows computation of the similarity between reparandum and repair. We argue a local-detection-with-backtracking approach is more cognitively plausible than string-based left-to-right repair labelling, and using this insight should allow an improvement in incremental accuracy, stability and time-to-detection over string-alignment driven approaches in repair detection.

4 STIR: Strongly Incremental Repair detection

Our system, STIR (Strongly Incremental Repair detection), therefore takes a local incremental ap-

[1] Though see (Germesin et al., 2008) for one approach, albeit using idiosyncratic repair categories.

[2] We acknowledge a purely position-based model for reparandum extent detection under-estimates prepositions, which speakers favour as the retrace start and over-estimates verbs, which speakers tend to avoid retracing back to, preferring to begin the utterance again, as (Healey et al., 2011)'s experiments also demonstrate.

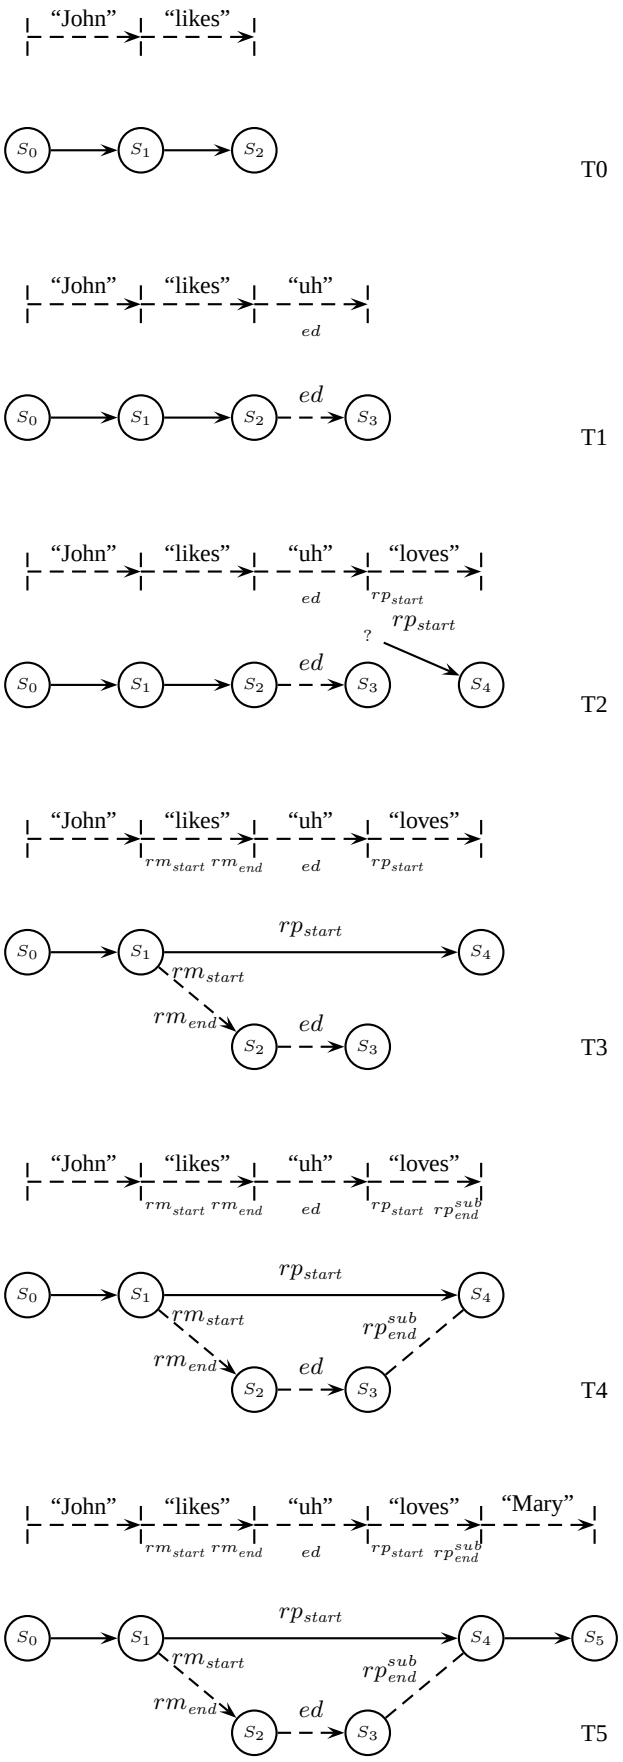

Figure 1: Strongly Incremental Repair Detection

proach to detecting repairs and isolated edit terms, assigning words the structures in (2). We include interregnum recognition in the process, due to the inclusion of interregnum vocabulary within edit term vocabulary (Ginzburg, 2012; Hough and Purver, 2013), a useful feature for repair detection (Lease et al., 2006; Qian and Liu, 2013).

$$\begin{cases} ...[rm_{start}...rm_{end} + \{ed\}rp_{start}...rp_{end}]... \\ ...\{ed\}... \end{cases} \quad (2)$$

Rather than detecting the repair structure in its left-to-right string order as above, STIR functions as in Figure 1: first detecting edit terms (possibly interregna) at step T1; then detecting repair onsets rp_{start} at T2; if one is found, backwards searching to find rm_{start} at T3; then finally finding the repair end rp_{end} at T4. Step T1 relies mainly on lexical probabilities from an edit term language model; T2 exploits features of divergence from a fluent language model; T3 uses fluency of hypothesised repairs; and T4 the similarity between distributions after reparandum and repair. However, each stage integrates these basic insights via multiple related features in a statistical classifier.

4.1 Enriched incremental language models

We derive the basic information-theoretic features required using n-gram language models, as they have a long history of information theoretic analysis (Shannon, 1948) and provide reproducible results without forcing commitment to one particular grammar formalism. Following recent work on modelling grammaticality judgements (Clark et al., 2013), we implement several modifications to standard language models to develop our basic measures of fluency and uncertainty.

For our main fluent language models we train a trigram model with Kneser-Ney smoothing (Kneser and Ney, 1995) on the words and POS tags of the standard Switchboard training data (all files with conversation numbers beginning sw2*,sw3* in the Penn Treebank III release), consisting of ≈100K utterances, ≈600K words. We follow (Johnson and Charniak, 2004) by cleaning the data of disfluencies (i.e. edit terms and reparanda), to approximate a 'fluent' language model. We call these probabilities p^{lex}_{kn}, p^{pos}_{kn} below.[3]

[3]We suppress the ^{pos} and ^{lex} superscripts below where we refer to measures from either model.

We then derive *surprisal* as our principal default lexical uncertainty measurement s (equation 3) in both models; and, following (Clark et al., 2013), the (unigram) Weighted Mean Log trigram probability (WML, eq. 4)– the trigram logprob of the sequence divided by the inverse summed logprob of the component unigrams (apart from the first two words in the sequence, which serve as the first trigram history). As here we use a local approach we restrict the WML measures to single trigrams (weighted by the inverse logprob of the final word). While use of standard n-gram probability conflates syntactic with lexical probability, WML gives us an approximation to *incremental syntactic probability* by factoring out lexical frequency.

$$s(w_{i-2} \dots w_i) = -\log_2 p_{kn}(w_i \mid w_{i-2}, w_{i-1}) \quad (3)$$

$$WML(w_0 \dots w_n) = \frac{\sum_{i=2}^{i=n} \log_2 p_{kn}(w_i \mid w_{i-2}, w_{i-1})}{-\sum_{j=2}^{n} \log_2 p_{kn}(w_j)} \quad (4)$$

Distributional measures To approximate uncertainty, we also derive the entropy $H(w \,|\, c)$ of the possible word continuations w given a context c, from $p(w_i \,|\, c)$ for all words w_i in the vocabulary – see (5). Calculating distributions over the entire lexicon incrementally is costly, so we approximate this by constraining the calculation to words which are observed at least once in context c in training, $w_c = \{w | count(c, w) \geq 1\}$, assuming a uniform distribution over the unseen suffixes by using the appropriate smoothing constant, and subtracting the latter from the former – see eq. (6).

Manual inspection showed this approximation to be very close, and the trie structure of our n-gram models allows efficient calculation. We also make use of the Zipfian distribution of n-grams in corpora by storing entropy values for the 20% most common trigram contexts observed in training, leaving entropy values of rare or unseen contexts to be computed at decoding time with little search cost due to their small or empty w_c sets.

$$H(w \mid c) = -\sum_{w \in Vocab} p_{kn}(w \mid c) \log_2 p_{kn}(w \mid c) \quad (5)$$

$$\begin{aligned} H(w \mid c) \approx & \left[-\sum_{w \in w_c} p_{kn}(w \mid c) \log_2 p_{kn}(w \mid c) \right] \\ & - [n \times \lambda \log_2 \lambda] \\ & \text{where } n = |Vocab| - |w_c| \\ & \text{and } \lambda = \frac{1 - \sum_{w \in w_c} p_{kn}(w \mid c)}{n} \end{aligned} \quad (6)$$

Given entropy estimates, we can also similarly approximate the Kullback-Leibler (KL) divergence (relative entropy) between distributions in two different contexts c_1 and c_2, i.e. $\theta(w|c_1)$ and $\theta(w|c_2)$, by pair-wise computing $p(w|c_1) \log_2(\frac{p(w|c_1)}{p(w|c_2)})$ only for words $w \in w_{c_1} \cap w_{c_2}$, then approximating unseen values by assuming uniform distributions. Using p_{kn} smoothed estimates rather than raw maximum likelihood estimations avoids infinite KL divergence values. Again, we found this approximation sufficiently close to the real values for our purposes. All such probability and distribution values are stored in incrementally constructed directed acyclic graph (DAG) structures (see Figure 1), exploiting the Markov assumption of n-gram models to allow efficient calculation by avoiding re-computation.

4.2 Individual classifiers

This section details the features used by the 4 individual classifiers. To investigate the utility of the features used in each classifier we obtain values on the standard Switchboard heldout data (PTB III files sw4[5-9]*: 6.4K utterances, 49K words).

4.2.1 Edit term detection

In the first component, we utilise the well-known observation that edit terms have a distinctive vocabulary (Ginzburg, 2012), training a bigram model on a corpus of all edit words annotated in Switchboard's training data. The classifier simply uses the surprisal s^{lex} from this edit word model, and the trigram surprisal s^{lex} from the standard fluent model of Section 4.1. At the current position w_n, one, both or none of words w_n and w_{n-1} are classified as edits. We found this simple approach effective and stable, although some delayed decisions occur in cases where s^{lex} and WML^{lex} are high in both models before the end of the edit, e.g. "I like" $\rightarrow$ "I $\{like\}$ want...". Words classified as ed are removed from the incremental processing graph (indicated by the dotted line transition in Figure 1) and the stack updated if repair hypotheses are cancelled due to a delayed edit hypothesis of w_{n-1}.

4.2.2 Repair start detection

Repair onset detection is arguably the most crucial component: the greater its accuracy, the better the input for downstream components and the lesser the overhead of filtering false positives required.

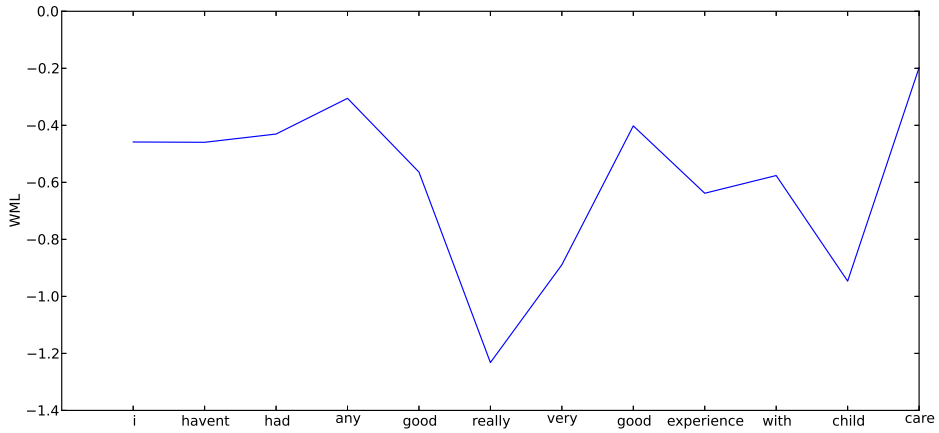

Figure 2: WML^{lex} values for trigrams for a repaired utterance exhibiting the drop at the repair onset

We use Section 4.1's information-theoretic features s, WML, H for words and POS, and introduce 5 additional information-theoretic features: ΔWML is the difference between the WML values at w_{n-1} and w_n; ΔH is the difference in entropy between w_{n-1} and w_n; $InformationGain$ is the difference between expected entropy at w_{n-1} and observed s at w_n, a measure that factors out the effect of naturally high entropy contexts; $BestEntropyReduce$ is the best reduction in entropy possible by an early rough hypothesis of reparandum onsets within 3 words; and $BestWMLBoost$ similarly speculates on the best improvement of WML possible by positing rm_{start} positions up to 3 words back. We also include simple alignment features: binary features which indicate if the word w_{i-x} is identical to the current word w_i for $x \in \{1, 2, 3\}$. With 6 alignment features, 16 N-gram features and a single logical feature $edit$ which indicates the presence of an edit word at position w_{i-1}, rp_{start} detection uses 23 features– see Table 1.

We hypothesised repair onsets rp^{start} would have significantly lower p^{lex} (lower lexical-syntactic probability) and WML^{lex} (lower syntactic probability) than other fluent trigrams. This was the case in the Switchboard heldout data for both measures, with the biggest difference obtained for WML^{lex} (non-repair-onsets: -0.736 (sd=0.359); repair onsets: -1.457 (sd=0.359)). In the POS model, entropy of continuation H^{pos} was the strongest feature (non-repair-onsets: 3.141 (sd=0.769); repair onsets: 3.444 (sd=0.899)). The trigram WML^{lex} measure for the repaired utterance "I haven't had any [good + really very good] experience with child care" can be seen in Figure 2. The steep drop at the repair onset shows the usefulness of WML features for fluency measures.

To compare n-gram measures against other local features, we ranked the features by Information Gain using 10-fold cross validation over the Switchboard heldout data– see Table 1. The language model features are far more discriminative than the alignment features, showing the potential of a general information-theoretic approach.

4.2.3 Reparandum start detection

In detecting rm_{start} positions given a hypothesised rp_{start} (stage T3 in Figure 1), we use the noisy channel intuition that removing the reparandum (from rm_{start} to rp_{start}) increases fluency of the utterance, expressed here as $WMLboost$ as described above. When using gold standard input we found this was the case on the heldout data, with a mean $WMLboost$ of 0.223 (sd=0.267) for reparandum onsets and -0.058 (sd=0.224) for other words in the 6-word history- the negative boost for non-reparandum words captures the intuition that backtracking from those points would make the utterance less grammatical, and conversely the boost afforded by the correct rm_{start} detection helps solve the continuation problem for the listener (and our detector).

Parallelism in the onsets of rp_{start} and rm_{start} can also help solve the continuation problem, and in fact the KL divergence between $\theta^{pos}(w \mid rm_{start}, rm_{start-1})$ and $\theta^{pos}(w \mid rp_{start}, rp_{start-1})$ is the second most useful feature with average merit 0.429 (+- 0.010) in cross-

validation. The highest ranked feature is ΔWML (0.437 (+- 0.003)) which here encodes the drop in the $WMLboost$ from one backtracked position to the next. In ranking the 32 features we use, again information-theoretic ones are higher ranked than the logical features.

average merit	average rank	attribute
0.139 (+- 0.002)	1 (+- 0.00)	H^{pos}
0.131 (+- 0.001)	2 (+- 0.00)	WML^{pos}
0.126 (+- 0.001)	3.4 (+- 0.66)	WML^{lex}
0.125 (+- 0.003)	4 (+- 1.10)	s^{pos}
0.122 (+- 0.001)	5.9 (+- 0.94)	$w_{i-1} = w_i$
0.122 (+- 0.001)	5.9 (+- 0.70)	BestWMLBoost^{lex}
0.122 (+- 0.002)	5.9 (+- 1.22)	InformationGain^{pos}
0.119 (+- 0.001)	7.9 (+- 0.30)	BestWMLBoost^{pos}
0.098 (+- 0.002)	9 (+- 0.00)	H^{lex}
0.08 (+- 0.001)	10.4 (+- 0.49)	ΔWML^{pos}
0.08 (+- 0.003)	10.6 (+- 0.49)	ΔH^{pos}
0.072 (+- 0.001)	12 (+- 0.00)	$POS_{i-1} = POS_i$
0.066 (+- 0.003)	13.1 (+- 0.30)	s^{lex}
0.059 (+- 0.000)	14.2 (+- 0.40)	ΔWML^{lex}
0.058 (+- 0.005)	14.7 (+- 0.64)	BestEntropyReduce^{pos}
0.049 (+- 0.001)	16.3 (+- 0.46)	InformationGain^{lex}
0.047 (+- 0.004)	16.7 (+- 0.46)	BestEntropyReduce^{lex}
0.035 (+- 0.004)	18 (+- 0.00)	ΔH^{lex}
0.024 (+- 0.000)	19 (+- 0.00)	$w_{i-2} = w_i$
0.013 (+- 0.000)	20 (+- 0.00)	$POS_{i-2} = POS_i$
0.01 (+- 0.000)	21 (+- 0.00)	$w_{i-3} = w_i$
0.009 (+- 0.000)	22 (+- 0.00)	edit
0.006 (+- 0.000)	23 (+- 0.00)	$POS_{i-3} = POS_i$

Table 1: Feature ranker (Information Gain) for rp_{start} detection- 10-fold x-validation on Switchboard heldout data.

4.2.4 Repair end detection and structure classification

For rp_{end} detection, using the notion of parallelism, we hypothesise an effect of divergence between θ^{lex} at the reparandum-final word rm_{end} and the repair-final word rp_{end}: for repetition repairs, KL divergence will trivially be 0; for substitutions, it will be higher; for deletes, even higher. Upon inspection of our feature ranking this KL measure ranked 5th out of 23 features (merit= 0.258 (+- 0.002)).

We introduce another feature encoding parallelism $ReparandumRepairDifference$: the difference in probability between an utterance cleaned of the reparandum and the utterance with its repair phase substituting its reparandum. In both the POS (merit=0.366 (+- 0.003)) and word (merit=0.352 (+- 0.002)) LMs, this was the most discriminative feature.

4.3 Classifier pipeline

STIR effects a pipeline of classifiers as in Figure 3, where the ed classifier only permits non ed words to be passed on to rp_{start} classification and for rp_{end} classification of the active repair hypotheses, maintained in a stack. The rp_{start} classifier passes positive repair hypotheses to the rm_{start} classifier, which backwards searches up to 7 words back in the utterance. If a rm_{start} is classified, the output is passed on for rp_{end} classification at the end of the pipeline, and if not rejected this is pushed onto the repair stack. Repair hypotheses are are popped off when the string is 7 words beyond its rp_{start} position. Putting limits on the stack's storage space is a way of controlling for processing overhead and complexity. Embedded repairs whose rm_{start} coincide with another's rp_{start} are easily dealt with as they are added to the stack as separate hypotheses.[4]

Classifiers Classifiers are implemented using Random Forests (Breiman, 2001) and we use different error functions for each stage using MetaCost (Domingos, 1999). The flexibility afforded by implementing adjustable error functions in a pipelined incremental processor allows control of the trade-off of immediate accuracy against runtime and stability of the sequence classification.

Processing complexity This pipeline avoids an exhaustive search all repair hypotheses. If we limit the search to within the $\langle rm_{start}, rp_{start} \rangle$ possibilities, this number of repairs grows approximately in the triangular number series– i.e. $\frac{n(n+1)}{2}$, a nested loop over previous words as n gets incremented – which in terms of a complexity class is a quadratic $O(n^2)$. If we allow more than one $\langle rm_{start}, rp_{start} \rangle$ hypothesis per word, the complexity goes up to $O(n^3)$, however in the tests that we describe below, we are able to achieve good detection results without permitting this extra search space. Under our assumption that reparandum onset detection is only triggered after repair onset detection, and repair extent detection is dependent on positive reparandum onset detection, a pipeline with accurate components will allow us to limit processing to a small subset of this search space.

[4]We constrain the problem not to include embedded deletes which may share their rp_{start} word with another repair – these are in practice very rare.

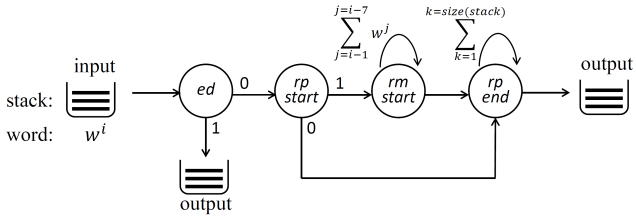

Figure 3: Classifier pipeline

5 Experimental set-up

We train STIR on the Switchboard data described above, and test it on the standard Switchboard test data (PTB III files 4[0-1]*). In order to avoid overfitting of classifiers to the basic language models, we use a cross-fold training approach: we divide the corpus into 10 folds and use language models trained on 9 folds to obtain feature values for the 10th fold, repeating for all 10. Classifiers are then trained as standard on the resulting feature-annotated corpus. This resulted in better feature utility for n-grams and better F-score results for detection in all components in the order of 5-6%.[5]

Training the classifiers Each Random Forest classifier was limited to 20 trees of maximum depth 4 nodes, putting a ceiling on decoding time. In making the classifiers cost-sensitive, MetaCost resamples the data in accordance with the cost functions: we found using 10 iterations over a resample of 25% of the training data gave the most effective trade-off between training time and accuracy.[6] We use 8 different cost functions in rp_{start} with differing costs for false negatives and positives of the form below, where R is a repair element word and F is a fluent onset:

$$\begin{array}{c} \\ R^{gold} \\ F^{gold} \end{array} \begin{array}{c} \begin{array}{cc} R^{hyp} & F^{hyp} \end{array} \\ \begin{pmatrix} 0 & 2 \\ 1 & 0 \end{pmatrix} \end{array}$$

We adopt a similar technique in rm_{start} using 5 different cost functions and in rp_{end} using 8 different settings, which when combined gives a total of 320 different cost function configurations. We hypothesise that higher recall permitted in the pipeline's first components would result in better overall accuracy as these hypotheses become refined, though at the cost of the stability of the hypotheses of the sequence and extra downstream processing in pruning false positives.

We also experiment with the number of repair hypotheses permitted per word, using limits of 1-best and 2-best hypotheses. We expect that allowing 2 hypotheses to be explored per rp_{start} should allow greater final accuracy, but with the trade-off of greater decoding and training complexity, and possible incremental instability.

As we wish to explore the incrementality versus final accuracy trade-off that STIR can achieve we now describe the evaluation metrics we employ.

5.1 Incremental evaluation metrics

Following (Baumann et al., 2011) we divide our evaluation metrics into *similarity metrics* (measures of equality with or similarity to a gold standard), *timing metrics* (measures of the timing of relevant phenomena detected from the gold standard) and *diachronic metrics* (evolution of incremental hypotheses over time).

Similarity metrics For direct comparison to previous approaches we use the standard measure of overall accuracy, the F-score over reparandum words, which we abbreviate $\mathbf{F_{rm}}$ (see 7):

$$\begin{aligned} \text{precision} &= \frac{rm^{correct}}{rm^{hyp}} \\ \text{recall} &= \frac{rm^{correct}}{rm^{gold}} \\ \text{F}_{rm} &= 2 \times \frac{\text{precision} \times \text{recall}}{\text{precision} + \text{recall}} \end{aligned} \tag{7}$$

We are also interested in repair structural classification, we also measure F-score over *all* repair components (rm words, ed words as interregna and rp words), a metric we abbreviate $\mathbf{F_s}$. This is not measured in standard repair detection on Switchboard. To investigate incremental accuracy we evaluate the *delayed accuracy* (**DA**) introduced by (Zwarts et al., 2010), as described in section 2 against the utterance-final gold standard disfluency annotations, and use the mean of the 6 word F-scores.

[5] Zwarts and Johnson (2011) take a similar approach on Switchboard data to train a re-ranker of repair analyses.

[6] As (Domingos, 1999) demonstrated, there are only relatively small accuracy gains when using more than this, with training time increasing in the order of the re-sample size.

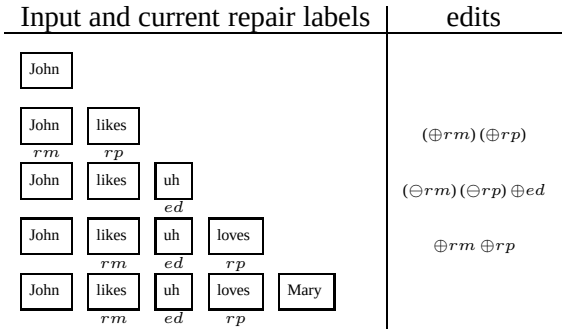

Figure 4: Edit Overhead- 4 unnecessary edits

	1	2	3	4	5	6
Best delayed acc.	0.587	0.710	0.747	0.755	0.757	0.754
Best rm F-score	0.550	0.671	0.726	0.743	0.749	0.752
Zwarts et al. 2010	0.578	0.633	0.697	0.725	0.758	0.770

Figure 6: Delayed Accuracy Curves

Timing and resource metrics Again for comparative purposes we use Zwarts et al's *time-to-detection* metrics, that is the two average distances (in numbers of words) consumed before first detection of gold standard repairs, one from rm_{start}, $\mathbf{TD_{rm}}$ and one from rp_{start}, $\mathbf{TD_{rp}}$. In our 1-best detection system, before evaluation we know a priori TD_{rp} will be 1 token, and TD_{rm} will be 1 more than the average length of $rm_{start} - rp_{start}$ repair spans correctly detected. However when we introduce a beam where multiple rm_{start}s are possible per rp_{start} with the most likely hypothesis committed as the current output, the latency may begin to increase: the initially most probable hypothesis may not be the correct one. In addition to output timing metrics, we account for intrinsic processing complexity with the metric *processing overhead* (**PO**), which is the number of classifications made by all components per word of input.

Diachronic metrics To measure stability of repair hypotheses over time we use (Baumann et al., 2011)'s *edit overhead* (**EO**) metric. EO measures the proportion of edits (add, revoke, substitute) applied to a processor's output structure that are unnecessary. STIR's output is the repair label sequence shown in Figure 1, however rather than evaluating its EO against the current gold standard labels, we use a new mark-up we term the *incremental repair gold standard*: this does not penalise lack of detection of a reparandum word rm as a bad edit until the corresponding rp_{start} of that rm has been consumed. While F_{rm}, F_s and DA evaluate against what Baumann et al. (2011) call the *current gold standard*, the incremental gold standard reflects the repair processing approach we set out in 3. An example of a repaired utterance with an EO of 44% ($\frac{4}{9}$) can be seen in Figure 4: of the 9 edits (7 repair annotations and 2 correct fluent words), 4 are unnecessary (bracketed). Note the final $\oplus rm$ is not counted as a bad edit for the reasons just given.

6 Results and Discussion

We evaluate on the Switchboard test data; Table 2 shows results of the best performing settings for each of the metrics described above, together with the setting achieving the highest total score (**TS**)– the average % achieved of the best performing system's result in each metric.[7] The settings found to achieve the highest $\text{F}_{\mathbf{rm}}$ (the metric standardly used in disfluency detection), and that found to achieve the highest TS for each stage in the pipeline are shown in Figure 5.

Our experiments showed that different system settings perform better in different metrics, and no individual setting achieved the best result in all of them. Our best utterance-final F_{rm} reaches 0.779, marginally though not significantly exceeding (Zwarts et al., 2010)'s measure and STIR achieves 0.736 on the previously unevaluated F_s. The setting with the best DA improves on (Zwarts et al., 2010)'s result significantly in terms of mean values (0.718 vs. 0.694), and also in terms of the steepness of the curves (Figure 6). The fastest average time to detection is 1 word for TD_{rp} and 2.6 words for TD_{rm} (Table 3), improving dramatically on the noisy channel model's 4.6 and 7.5 words.

Incrementality versus accuracy trade-off We aimed to investigate how well a system could do in terms of achieving both good final accuracy and incremental performance, and while the best F_{rm} setting had a large PO and relatively slow DA increase, we find STIR can find a good trade-off set-

[7] We do not include time-to-detection scores in TS as it did not vary enough between settings to be significant, however there was a difference in this measure between the 1-best stack condition and the 2-best stack condition – see below.

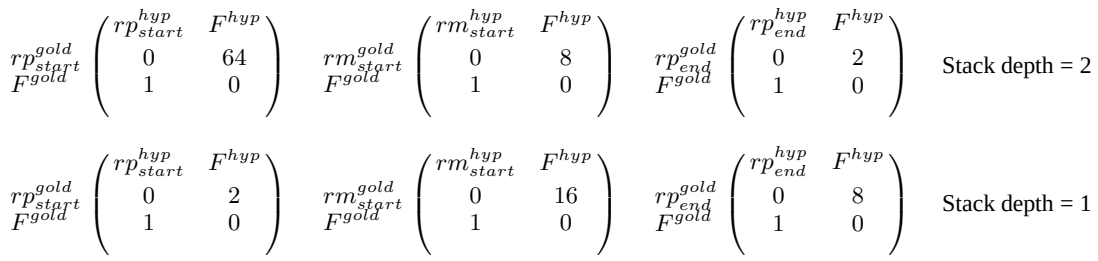

Figure 5: The cost function settings for the MetaCost classifiers for each component, for the best F_{rm} setting (top row) and best total score (TS) setting (bottom row)

	F_{rm}	F_s	DA	EO	PO
Best Final rm F-score (F_{rm})	**0.779**	0.735	0.698	3.946	1.733
Best Final repair structure F-score (F_s)	0.772	**0.736**	0.707	4.477	1.659
Best Delayed Accuracy of rm (DA)	0.767	0.721	**0.718**	1.483	1.689
Best (lowest) Edit Overhead (EO)	0.718	0.674	0.675	**0.864**	1.230
Best (lowest) Processing Overhead (PO)	0.716	0.671	0.673	0.875	**1.229**
Best Total Score (mean % of best scores) (TS)	*0.754*	*0.708*	*0.711*	*0.931*	*1.255*

Table 2: Comparison of the best performing system settings using different measures

	F_{rm}	F_s	DA	EO	PO	TD_{rp}	TD_{rm}
1-best rm_{start}	0.745	0.707	0.699	3.780	1.650	1.0	2.6
2-best rm_{start}	0.758	0.721	0.701	4.319	1.665	1.1	2.7

Table 3: Comparison of performance of systems with different stack capacities

ting: the highest TS scoring setting achieves an F_{rm} of 0.754 whilst also exhibiting a very good DA (0.711) – over 98% of the best recorded score – and low PO and EO rates – over 96% of the best recorded scores. See the bottom row of Table 2. As can be seen in Figure 5, the cost functions for these winning settings are different in nature. The best non-incremental F_{rm} measure setting requires high recall for the rest of the pipeline to work on, using the highest cost, 64, for false negative rp_{start} words and the highest stack depth of 2 (similar to a wider beam); but the best overall TS scoring system uses a less permissive setting to increase incremental performance.

We make a preliminary investigation into the effect of increasing the stack capacity by comparing stacks with 1-best rm_{start} hypotheses per rp_{start} and 2-best stacks. The average differences between the two conditions is shown in Table 3. Moving to the 2-stack condition results in gain in overall accuracy in F_{rm} and F_s, but at the cost of EO and also time-to-detection scores TD_{rm} and TD_{rp}. The extent to which the stack can be increased without increasing jitter, latency and complexity will be investigated in future work.

7 Conclusion

We have presented STIR, an incremental repair detector that can be used to experiment with incremental performance and accuracy trade-offs. In future work we plan to include probabilistic and distributional features from a top-down incremental parser e.g. Roark et al. (2009), and use STIR's distributional features to classify repair type.

Semi-Supervised Chinese Word Segmentation Using Partial-Label Learning With Conditional Random Fields

Abstract

There is rich knowledge encoded in online web data. For example, punctuation and entity tags in Wikipedia data define some word boundaries in a sentence. In this paper we adopt partial-label learning with conditional random fields to make use of this valuable knowledge for semi-supervised Chinese word segmentation. The basic idea of partial-label learning is to optimize a cost function that marginalizes the probability mass in the constrained space that encodes this knowledge. By integrating some domain adaptation techniques, such as EasyAdapt, our result reaches an F-measure of 95.98% on the CTB-6 corpus, a significant improvement from both the supervised baseline and a previous proposed approach, namely *constrained decode*.

1 Introduction

A general approach for supervised Chinese word segmentation is to formulate it as a character sequence labeling problem, to label each character with its location in a word. For example, Xue (2003) proposes a four-label scheme based on some linguistic intuitions: 'B' for the beginning character of a word, 'I' for the internal characters, 'E' for the ending character, and 'S' for single-character word. Thus the word sequence "洽谈会很 成功" can be turned into a character sequence with labels as 洽\B 谈\I 会\E 很\S 成\B 功\E. A machine learning algorithm for sequence labeling, such as conditional random fields (CRF) (Lafferty et al., 2001), can be applied to the labelled training data to learn a model.

Labelled data for supervised learning of Chinese word segmentation, however, is usually expensive and tends to be of a limited amount. Researchers are thus interested in semi-supervised learning, which is to make use of unlabelled data to further improve the performance of supervised learning. There is a large amount of unlabelled data available, for example, the Gigaword corpus in the LDC catalog or the Chinese Wikipedia on the web.

Faced with the large amount of unlabelled data, an intuitive idea is to use self-training or EM, by first training a baseline model (from the supervised data) and then iteratively decoding the unlabelled data and updating the baseline model. Jiao et al. (2006) and Mann and McCallum (2007) further propose to minimize the entropy of the predicted label distribution on unlabeled data and use it as a regularization term in CRF (i.e. *entropy regularization*). Beyond these ideas, Liang (2005) and Sun and Xu (2011) experiment with deriving a large set of statistical features such as mutual information and accessor variety from unlabelled data, and add them to supervised discriminative training. Zeng et al. (2013b) experiment with graph propagation to extract information from unlabelled data to regularize the CRF training. Yang and Vozila (2013), Zhang et al. (2013), and Zeng et al. (2013a) experiment with co-training for semi-supervised Chinese word segmentation. All these approaches only leverage the distribution of the unlabelled data, yet do not make use of the knowledge that the unlabelled data might have integrated in.

There could be valuable information encoded within the unlabelled data that researchers can take advantage of. For example, punctuation creates natural word boundaries (Li and Sun, 2009): the character before a comma can only be labelled as either 'S' or 'E', while the character after a comma can only be labelled as 'S' or 'B'. Furthermore, entity tags (HTML tags or Wikipedia tags) on the web, such as emphasis and cross reference, also provide rich information for word segmentation: they might define a word or at least

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 90–98,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

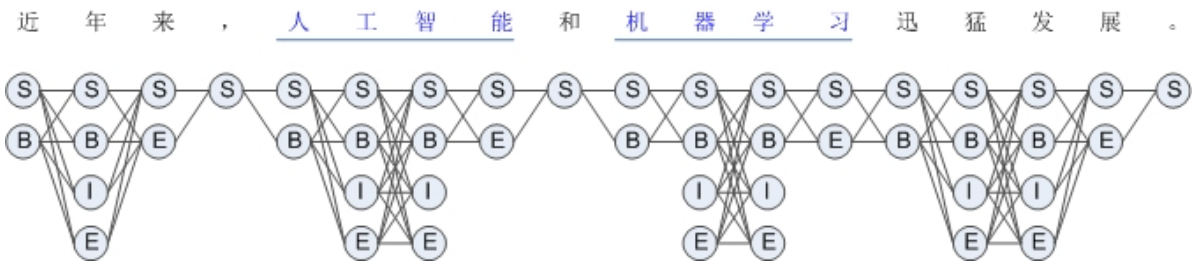

Figure 1: Sausage constraint (partial labels) from natural annotations and punctuation

give word boundary information similar to punctuation. Jiang et al. (2013) refer to such structural information on the web as natural annotations, and propose that they encode knowledge for NLP. For Chinese word segmentation, natural annotations and punctuation create a sausage[1] constraint for the possible labels, as illustrated in Figure 1. In the sentence "近年来，人工智能和机器学习迅猛发展。", the first character 近 can only be labelled with 'S' or 'B'; and the characters 来 before the comma and 展 before the Chinese period can only be labelled as 'S' or 'E'. "人工智能" and "机器学习" are two Wikipedia entities, and so they define the word boundaries before the first character and after the last character of the entities as well. The single character 和 between these two entities has only one label 'S'. This sausage constraint thus encodes rich information for word segmentation.

To make use of the knowledge encoded in the sausage constraint, Jiang et al. (2013) adopt a constrained decode approach. They first train a baseline model with labelled data, and then run constrained decode on the unlabelled data by binding the search space with the sausage; and so the decoded labels are consistent with the sausage constraint. The unlabelled data, together with the labels from constrained decode, are then selectively added to the labelled data for training the final model. This approach, using constrained decode as a middle step, provides an indirect way of leaning the knowledge. However, the middle step, constrained decode, has the risk of reinforcing the errors in the baseline model: the decoded labels added to the training data for building the final model might contain errors introduced from the baseline model. The knowledge encoded in the data carrying the information from punctuation and natural annotations is thus polluted by the errorful re-decoded labels.

A sentence where each character has exactly one label is fully-labelled; and a sentence where each character receives all possible labels is zero-labelled. A sentence with sausage-constrained labels can be viewed as partially-labelled. These partial labels carry valuable information that researchers would like to learn in a model, yet the normal CRF training typically uses fully-labelled sentences. Recently, Täckström et al. (2013) propose an approach to train a CRF model directly from partial labels. The basic idea is to marginalize the probability mass of the constrained sausage in the cost function. The normal CRF training using fully-labelled sentences is a special case where the sausage constraint is a linear line; while on the other hand a zero-labelled sentence, where the sausage constraint is the full lattice, makes no contribution in the learning since the sum of probabilities is deemed to be one. This new approach, without the need of using constrained re-decoding as a middle step, provides a direct means to learn the knowledge in the partial labels.

In this research we explore using the partial-label learning for semi-supervised Chinese word segmentation. We use the CTB-6 corpus as the labelled training, development and test data, and use the Chinese Wikipedia as the unlabelled data. We first train a baseline model with labelled data only, and then selectively add Wikipedia data with partial labels to build a second model. Because the Wikipedia data is out of domain and has distribution bias, we also experiment with two domain adaptation techniques: model interpolation and EasyAdapt (Daumé III, 2007). Our result reaches an F-measure of 95.98%, an absolute improvement of 0.72% over the very strong base-

[1] Also referred to as confusion network.

line (corresponding to 15.19% relative error reduction), and 0.33% over the constrained decode approach (corresponding to 7.59% relative error reduction). We conduct a detailed error analysis, illustrating how partial-label learning excels constrained decode in learning the knowledge encoded in the Wikipedia data. As a note, our result also out-performs (Wang et al., 2011) and (Sun and Xu, 2011).

2 Partial-Label Learning with CRF

In this section, we review in more detail the partial-label learning algorithm with CRF proposed by (Täckström et al., 2013). CRF is an exponential model that expresses the conditional probability of the labels given a sequence, as Equation 1, where y denotes the labels, x denotes the sequence, $\Phi(x, y)$ denotes the feature functions, and θ is the parameter vector. $Z(x) = \sum_y \exp(\theta^T \Phi(x, y))$ is the normalization term.

$$p_\theta(y|x) = \frac{\exp(\theta^T \Phi(x, y))}{Z(x)} \quad (1)$$

In full-label training, where each item in the sequence is labelled with exactly one tag, maximum likelihood is typically used as the optimization target. We simply sum up the log-likelihood of the n labelled sequences in the training set, as shown in Equation 2.

$$\begin{aligned} L(\theta) &= \sum_{i=1}^{n} log\ p_\theta(y|x) \\ &= \sum_{i=1}^{n} (\theta^T \Phi(x_i, y_i) - log\ Z(x_i)) \end{aligned} \quad (2)$$

The gradient is calculated as Equation 3, in which the first term $\frac{1}{n}\sum_{i=1}^{n}\Phi_j$ is the empirical expectation of feature function Φ_j, and the second term $E[\Phi_j]$ is the model expectation. Typically a forward-backward process is adopted for calculating the latter.

$$\frac{\partial}{\partial\theta_j} L(\theta) = \frac{1}{n}\sum_{i=1}^{n}\Phi_j - E[\Phi_j] \quad (3)$$

In partial-label training, each item in the sequence receives multiple labels, and so for each sequence we have a sausage constraint, denoted as $\hat{Y}(x, \tilde{y})$. The marginal probability of the sausage is defined as Equation 4.

$$p_\theta(\hat{Y}(x, \tilde{y})|x) = \sum_{y \in \hat{Y}(x,\tilde{y})} p_\theta(y|x) \quad (4)$$

The optimization target thus is to maximize the probability mass of the sausage, as shown in Equation 5.

$$L(\theta) = \sum_{i=1}^{n} log p_\theta(\hat{Y}(x_i, \tilde{y_i})|x_i) \quad (5)$$

A gradient-based approach such as L-BFGS (Liu and Nocedal, 1989) can be employed to optimize Equation 5. The gradient is calculated as Equation 6, where $E_{\hat{Y}(x,\tilde{y})}[\Phi_j]$ is the empirical expectation of feature function Φ_j constrained by the sausage, and $E[\Phi_j]$ is the same model expectation as in standard CRF. $E_{\hat{Y}(x,\tilde{y})}[\Phi_j]$ can be calculated via a forward-backward process in the constrained sausage.

$$\frac{\partial}{\partial\theta_j} L(\theta) = E_{\hat{Y}(x,\tilde{y})}[\Phi_j] - E[\Phi_j] \quad (6)$$

For fully-labelled sentences, $E_{\hat{Y}(x,\tilde{y})}[\Phi_j] = \frac{1}{n}\sum_{i=1}^{n}\Phi_j$, and so the standard CRF is actually a special case of the partial-label learning.

3 Experiment setup

In this section we describe the basic setup for our experiments of semi-supervised Chinese word segmentation.

3.1 Data

We use the CTB-6 corpus as the labelled data. We follow the official CTB-6 guideline in splitting the corpus into a training set, a development set, and a test set. The training set has 23420 sentences; the development set has 2079 sentences; and the test set has 2796 sentences. These are fully-labelled data.

For unlabelled data we use the Chinese Wikipedia. The Wikipedia data is quite noisy and asks for a lot of cleaning. We first filter out references and lists etc., and sentences with obviously bad segmentations, for example, where every character is separated by a space. We also remove sentences that contain mostly English words. We then convert all characters into full-width. We also convert traditional Chinese characters into simplified characters using the tool

mediawiki-zhconverter[2]. We then randomly select 7737 sentences and reserve them as the test set.

To create the partial labels in the Wikipedia data, we use the information from cross-reference, emphasis, and punctuation. In our pilot study we found that it's beneficial to force a cross-reference or emphasis entity as a word when the item has 2 or 3 characters. That is, if an entity in the Wikipedia has three characters it receives the labels of "BIE"; and if it has two characters it is labelled as "BE".[3]

3.2 Supervised baseline model

We create the baseline supervised model by using an order-1 linear CRF with L2 regularization, to label a character sequence with the four candidate labels "BIES". We use the tool wapiti (Lavergne et al., 2010).

Following Sun et al. (2009), Sun (2010), and Low et al. (2005), we extract two types of features: character-level features and word-level features. Given a character c_0 in the character sequence ...$c_{-2}c_{-1}c_0c_1c_2$...:

Character-level features :

- Character unigrams: c_{-2}, c_{-1}, c_0, c_1, c_2
- Character bigrams: $c_{-2}c_{-1}$, $c_{-1}c_{-0}$, c_0c_1, c_1c_2
- Consecutive character equivalence: $?c_{-2} = c_{-1}$, $?c_{-1} = c_{-0}$, $?c_0 = c_1$, $?c_1 = c_2$
- Separated character equivalence: $?c_{-3} = c_{-1}$, $?c_{-2} = c_0$, $?c_{-1} = c_1$, $?c_0 = c_2$, $?c_1 = c_3$
- Whether the current character is a punctuation: $?Punct(c_0)$
- Character sequence pattern: $T(C_{-2})T(C_{-1})T(C_0)T(C_1)T(C_2)$. We classify all characters into four types. Type one has three characters '年' (year) '月' (month) '日' (date). Type two includes number characters. Type three includes English characters. All others are Type four characters. Thus "去年三月S" would generate the character sequence pattern "41213".

Word-level features :

- The identity of the string $c[s:i]$ ($i-6 < s < i$), if it matches a word from the list of word unigrams; multiple features could be generated.
- The identity of the string $c[i:e]$ ($i < e < i+6$), if it matches a word; multiple features could be generated.
- The identity of the bi-gram $c[s:i-1]c[i:e]$ ($i-6 < s, e < i+6$), if it matches a word bigram; multiple features could be generated.
- The identity of the bi-gram $c[s:i]c[i+1:e]$ ($i-6 < s, e < i+6$), if it matches a word bigram; multiple features could be generated.
- Idiom. We use the idiom list from (Sun and Xu, 2011). If the current character c_0 and its surrounding context compose an idiom, we generate a feature for c_0 of its position in the idiom. For example, if $c_{-1}c_0c_1c_2$ is an idiom, we generate feature "Idiom-2" for c_0.

The above features together with label bigrams are fed to wapiti for training. The supervised baseline model is created with the CTB-6 corpus without the use of Wikipedia data.

3.3 Partial-label learning

The overall process of applying partial-label learning to Wikipedia data is shown in Algorithm 1. Following (Jiang et al., 2013), we first train the supervised baseline model, and use it to estimate the potential contribution for each sentence in the Wikipedia training data. We label the sentence with the baseline model, and then compare the labels with the constrained sausage. For each character, a consistent label is defined as an element in the constrained labels. For example, if the constrained labels for a character are "SB", the label 'S' or 'B' is consistent but 'I' or 'E' is not. The number of inconsistent labels for each sentence is then used as its potential contribution to the partial-label learning: higher number indicates that the partial-labels for the sentence contain more knowledge that the baseline system does not integrate, and so have higher potential contribution. The Wikipedia training sentences are then ranked by their potential contribution, and the top

[2]https://github.com/tszming/mediawiki-zhconverter

[3]Another possibility is to label it as "SS" but we find that it's very rare the case.

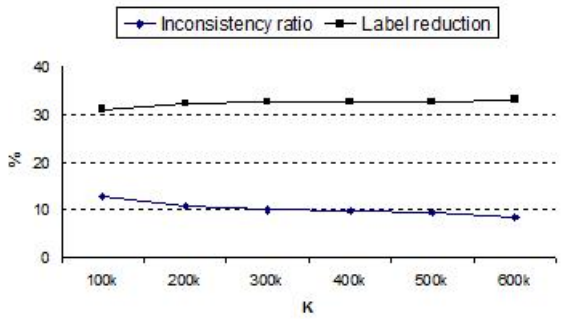

Figure 2: Encoded knowledge: inconsistency ratio and label reduction

K sentences together with their partial labels are then added to the CTB-6 training data to build a new model, using partial-label learning.[4] In our experiments, we try six data points with K = 100k, 200k, 300k, 400k, 500k, 600k. Figure 2 gives a rough idea of the knowledge encoded in Wikipedia for these data points with inconsistency ratio and label reduction. Inconsistency ratio is the percentage of characters that have inconsistent labels; and label reduction is the percentage of the labels reduced in the full lattice.

We modify wapiti to implement the partial-label learning as described in Section 2. Same as baseline, L2 regularization is adopted.

Algorithm 1 Partial-label learning

1. Train supervised baseline model M_0
2. For each sentence x in Wiki-Train:
3. $y \leftarrow$ Decode(x, M_0)
4. diff $\leftarrow$ Inconsistent(y, $\hat{Y}(x, \tilde{y})$)
5. if diff > 0:
6. C $\leftarrow$ C $\cup$ ($\hat{Y}(x, \tilde{y})$, diff)
7. Sort(C, diff, reverse)
8. Train model M^{pl} with CTB-6 and top K sentences in C using partial-label learning

3.4 Constrained decode

Jiang et al. (2013) implement the constrained decode algorithm with perceptron. However, CRF is generally believed to out-perform perceptron, yet the comparison of CRF vs perceptron is out of the scope of this paper. Thus for fair comparison, we re-implement the constrained decode algorithm with CRF.

Algorithm 2 shows the constrained decode implementation. We first train the baseline model with the CTB-6 data. We then use this baseline model to run normal decode and constrained decode for each sentence in the Wikipedia training set. If the normal decode and constrained decode have different labels, we add the constrained decode together with the number of different labels to the filtered Wikipedia training corpus. The filtered Wikipedia training corpus is then sorted using the number of different labels, and the top K sentences with constrained decoded labels are then added to the CTB-6 training data for building a new model using normal CRF.

Algorithm 2 Constrained decode

1. Train supervised baseline model M_0
2. For each sentence x in Wiki-Train:
3. $y \leftarrow$ Decode(x, M_0)
4. $\bar{y} \leftarrow$ ConstrainedDecode(x, M_0)
5. diff $\leftarrow$ Difference(y, $\bar{y}$)
6. if diff > 0:
7. C $\leftarrow$ C $\cup$ ($\bar{y}$, diff)
8. Sort(C, diff, reverse)

4 Evaluation on Wikipedia test set

In order to determine how well the models learn the encoded knowledge (i.e. partial labels) from the Wikipedia data, we first evaluate the models against the Wikipedia test set. The Wikipedia test set, however, is only partially-labelled. Thus the metric we use here is *consistent label accuracy*, similar to how we rank the sentences in Section 3.3, defined as whether a predicted label for a character is an element in the constrained labels. Because partial labels are only sparsely distributed in the test data, a lot of characters receive all four labels in the constrained sausage. Evaluating against characters with all four labels do not really represent the models' difference as it is deemed to be consistent. Thus beyond evaluating against all characters in the Wikipedia test set (referred to as *Full* measurement), we also evaluate against characters that are only constrained with less than four labels (referred to as *Label* measurement). The *Label* measurement focuses on en-

[4] Knowledge is sparsely distributed in the Wikipedia data. Using the Wikipedia data without the CTB-6 data for partial-label learning does not necessarily guarantee convergence. Also the CTB-6 training data helps to learn that certain label transitions, such as "B B" or "E E", are not legal.

coded knowledge in the test set and so can better represent the model's capability of learning from the partial labels.

Results are shown in Figure 3 with the *Full* measurement and in Figure 4 with the *Label* measurement. The x axes are the size of Wikipedia training data, as explained in Section 3.3. As can be seen, both constrained decode and partial-label learning perform much better than the baseline supervised model that is trained from CTB-6 data only, indicating that both of them are learning the encoded knowledge from the Wikipedia training data. Also we see the trend that the performance improves with more data in training, also suggesting the learning of encoded knowledge. Most importantly, we see that partial-label learning consistently out-performs constrained decode in all data points. With the *Label* measurement, partial-label learning gives 1.7% or higher absolute improvement over constrained decode across all data points. At the data point of 600k, constrained decode gives an accuracy of 97.14%, while partial-label learning gives 98.93% (baseline model gives 87.08%). The relative gain (from learning the knowledge) of partial-label learning over constrained decode is thus 18% $((98.93 - 97.14)/(97.14 - 87.08))$. These results suggest that partial-label learning is more effective in learning the encoded knowledge in the Wikipedia data than constrained decode.

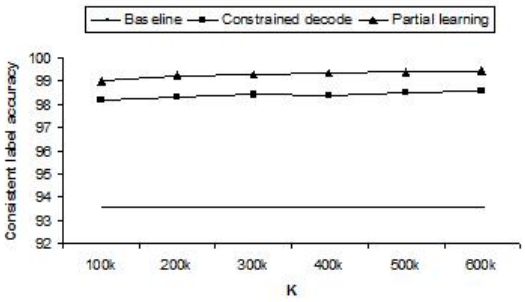

Figure 3: Wiki label evaluation results: Full

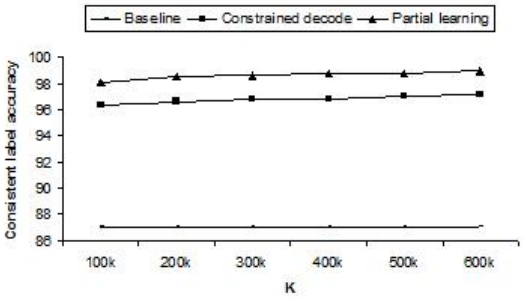

Figure 4: Wiki label evaluation results: Label

5 CTB evaluation

5.1 Model adaptation

Our ultimate goal, however, is to determine whether we can leverage the encoded knowledge in the Wikipedia data to improve the word segmentation in CTB-6. We run our models against the CTB-6 test set, with results shown in Figure 5. Because we have fully-labelled sentences in the CTB-6 data, we adopt the F-measure as our evaluation metric here. The baseline model achieves 95.26% in F-measure, providing a state-of-the-art supervised performance. Constrained decode is able to improve on this already very strong baseline performance, and we see the nice trend of higher performance with more unlabeled data for training, indicating that constrained decode is making use of the encoded knowledge in the Wikipedia data to help CTB-6 segmentation.

When we look at the partial-label model, however, the results tell a totally different story.

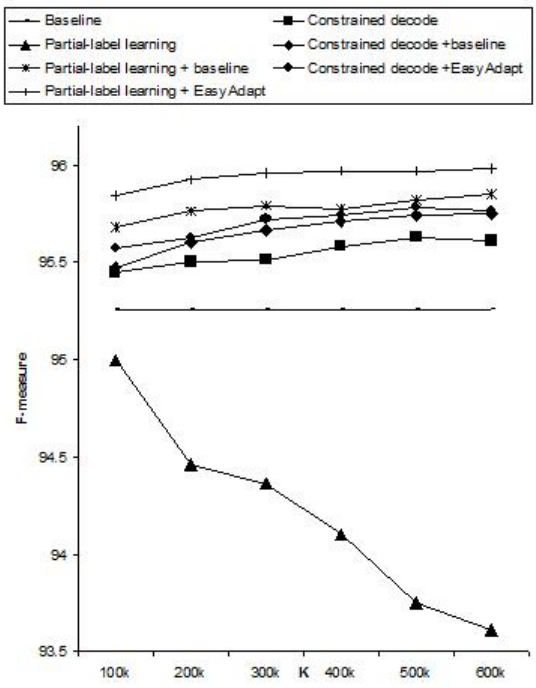

Figure 5: CTB evaluation results

First, it actually performs worse than the baseline model, and the more data added to training, the worse the performance is. In the previous section we show that partial-label learning is more effective in learning the encoded knowledge in Wikipedia data than constrained decode. So, what goes wrong? We hypothesize that there is an out-of-domain distribution bias in the partial labels, and so the more data we add, the worse the in-domain performance is. Constrained decode actually helps to smooth out the out-of-domain distribution bias by using the re-decoded labels with the in-domain supervised baseline model. For example, both the baseline model and constrained decode correctly give the segmentation "提供/了/运输/和/**给排水**/之/便", while partial-label learning gives incorrect segmentation "提供/了/运输/和/**给/排水**/之/便". Looking at the Wikipedia training data, 排水 is tagged as an entity 13 times; and 给排水, although occurs 13 times in the data, is never tagged as an entity. Partial-label learning, which focuses on the tagged entities, thus overrules the segmentation of 给排水. Constrained decode, on the other hand, by using the correctly re-decoded labels from the baseline model, observes enough evidence to correctly segment 给排水 as a word.

To smooth out the out-of-domain distribution bias, we experiment with two approaches: model interpolation and EasyAdapt (Daumé III, 2007).

5.1.1 Model interpolation

We linearly interpolate the model of partial-label learning M^{pl} with the baseline model M_0 to create the final model M_+^{pl}, as shown in Equation 7. The interpolation weight is optimized via a grid search between 0.0 and 1.0 with a step of 0.1, tuned on the CTB-6 development set. Again we modify wapiti so that it takes two models and an interpolation weight as input. For each model it creates a search lattice with posteriors, and then linearly combines the two lattices using the interpolation weight to create the final search space for decoding. As shown in Figure 5, model M_+^{pl} consistently out-performs constrained decode in all data points. We also see the trend of better performance with more training data.

$$M_+^{pl} = \lambda * M_0 + (1 - \lambda) * M^{pl} \qquad (7)$$

5.1.2 EasyAdapt

EasyAdapt is a straightforward technique but has been shown effective in many domain adaptation tasks (Daumé III, 2007). We train the model M_{ea}^{pl} with feature augmentation. For each out-of-domain training instance $< x_o, y_o >$, where x_o is the input features and y_o is the (partial) labels, we copy the features and file them as an additional feature set, and so the training instance becomes $< x_o, x_o, y_o >$. The in-domain training data remains the same. Consistent with (Daumé III, 2007), EasyAdapt gives us the best performance, as show in Figure 5. Furthermore, unlike in (Jiang et al., 2013) where they find a plateau, our results show no harm adding more training data for partial-label learning when integrated with domain adaptation, although the performance seems to saturate after 400k sentences.

Finally, we search for the parameter setting of best performance on the CTB-6 development set, which is to use EasyAdapt with $K = 600k$ sentences of Wikipedia data. With this setting, the performance on the CTB-6 test set is 95.98% in F-measure. This is 0.72% absolute improvement over supervised baseline (corresponding to 15.19% relative error reduction), and 0.33% absolute improvement over constrained decode (corresponding to 7.59% relative error reduction); the differences are both statistically significant ($p < 0.001$).[5] As a note, this result out-performs (Sun and Xu, 2011) (95.44%) and (Wang et al., 2011) (95.79%), and the differences are also statistically significant ($p < 0.001$).

5.2 Analysis with examples

To better understand why partial-label learning is more effective in learning the encoded knowledge, we look at cases where M_0 and M^{cd} have the incorrect segmentation while M^{pl} (and its domain adaptation variance M_+^{pl} and M_{ea}^{pl}) have the correct segmentation. We find that the majority is due to the error in re-decoded labels outside of encoded knowledge. For example, M_0 and M^{cd} give the segmentation "地震/为/**里/氏**/6.9/ 级", yet the correct segmentation given by partial-label learning is "地震/为/**里 氏**/6.9/ 级". Looking at the Wikipedia training data, there are 38 tagged entities of 里氏, but there are another 190 mentions of

[5] Statistical significance is evaluated with z-test using the standard deviation of $\sqrt{F * (1 - F)/N}$, where F is the F-measure and N is the number of words.

里氏 that are not tagged as an entity. Thus for constrained decode it sees 38 cases of "里\B 氏\E" and 190 cases of "里\S 氏\S" in the Wikipedia training data. The former comes from the encoded knowledge while the latter comes from re-decoded labels by the baseline model. The much bigger number of incorrect labels from the baseline re-decoding badly pollute the encoded knowledge. This example illustrates that constrained decode reinforces the errors from the baseline. On the other hand, the training materials for partial-label learning are purely the encoded knowledge, which is not impacted by the baseline model error. In this example, partial-label learning focuses only on the 38 cases of "里\B 氏\E" and so is able to learn that 里氏 is a word.

As a final remark, we want to make a point that, although the re-decoded labels serve to smooth out the distribution bias, the Wikipedia data is indeed not the ideal data set for such a purpose, because it itself is out of domain. The performance tends to degrade when we apply the baseline model to re-decode the out-of-domain Wikipedia data. The errorful re-decoded labels, when being used to train the model M^{cd}, could lead to further errors. For example, the baseline model M_0 is able to give the correct segmentation "电脑/**元器件**" in the CTB-6 test set. However, when it is applied to the Wikipedia data for constrained decode, for the seven occurrences of 元器件, three of which are correctly labelled as "元\B 器\I 件\E", but the other four have incorrect labels. The final model M^{cd} trained from these labels then gives incorrect segmentation "两/市/生产/的/电脑/**元/器件**/大量/销往/世界/各地" in the CTB-6 test set. On the other hand, model interpolation or EasyAdapt with partial-label learning, focusing only on the encoded knowledge and not being impacted by the errorful re-decoded labels, performs correctly in this case. For a more fair comparison between partial-label learning and constrained decode, we have also plotted the results of model interpolation and EasyAdapt for constrained decode in Figure 5. As can be seen, they improve on constrained decode a bit but still fall behind the correspondent domain adaptation approach of partial-label learning.

6 Conclusion and future work

There is rich information encoded in online web data. For example, punctuation and entity tags define some word boundaries. In this paper we show the effectiveness of partial-label learning in digesting the encoded knowledge from Wikipedia data for the task of Chinese word segmentation. Unlike approaches such as constrained decode that use the errorful re-decoded labels, partial-label learning provides a direct means to learn the encoded knowledge. By integrating some domain adaptation techniques such as EasyAdapt, we achieve an F-measure of 95.98% in the CTB-6 corpus, a significant improvement from both the supervised baseline and constrained decode. Our results also beat (Wang et al., 2011) and (Sun and Xu, 2011).

In this research we employ a sausage constraint to encode the knowledge for Chinese word segmentation. However, a sausage constraint does not reflect the legal label sequence. For example, in Figure 1 the links between label 'B' and label 'S', between 'S' and 'E', and between 'E' and 'I' are illegal, and can confuse the machine learning. In our current work we solve this issue by adding some fully-labelled data into training. Instead we can easily extend our work to use a lattice constraint by removing the illegal transitions from the sausage. The partial-label learning stands the same, by executing the forward-backward process in the constrained lattice. In future work we will examine partial-label learning with this more enforced lattice constraint in depth.

Abstract

Microblogs have recently received widespread interest from NLP researchers. However, current tools for Japanese word segmentation and POS tagging still perform poorly on microblog texts. We developed an annotated corpus and proposed a joint model for overcoming this situation. Our annotated corpus of microblog texts enables not only training of accurate statistical models but also quantitative evaluation of their performance. Our joint model with lexical normalization handles the orthographic diversity of microblog texts. We conducted an experiment to demonstrate that the corpus and model substantially contribute to boosting accuracy.

1 Introduction

Microblogs, such as Twitter[1] and Weibo[2], have recently become an important target of NLP technology. Since microblogs offer an instant way of posting textual messages, they have been given increasing attention as valuable sources for such actions as mining opinions (Jiang et al., 2011) and detecting sudden events such as earthquake (Sakaki et al., 2010).

However, many studies have reported that current NLP tools do not perform well on microblog texts (Foster et al., 2011; Gimpel et al., 2011). In the case of Japanese text processing, the most serious problem is poor accuracy of word segmentation and POS tagging. Since these two tasks are positioned as the fundamental step in the text processing pipeline, their accuracy is vital for all downstream applications.

[1]https://twitter.com
[2]https://www.weibo.com

1.1 Development of annotated corpus

The main obstacle that makes word segmentation and POS tagging in the microblog domain challenging is the lack of annotated corpora. Because current annotated corpora are from other domains, such as news articles, it is difficult to train models that perform well on microblog texts. Moreover, system performance cannot be evaluated quantitatively.

We remedied this situation by developing an annotated corpus of Japanese microblogs. We collected 1831 sentences from Twitter and manually annotated these sentences with word boundaries, POS tags, and normalized forms of words (*c.f.*, Section 1.2).

We, for the first time, present a comprehensive empirical study of Japanese word segmentation and POS tagging on microblog texts by using this corpus. Specifically, we investigated how well current models trained on existing corpora perform in the microblog domain. We also explored performance gains achieved by using our corpus for training, and by jointly performing lexical normalization (*c.f.*, Section 1.2).

1.2 Joint modeling with lexical normalization

Orthographic diversity in microblog texts causes a problem when training a statistical model for word segmentation and POS tagging. Microblog texts frequently contain informal words that are spelled in a non-standard manner, *e.g.*, "*oredi* (*already*)", "*b4* (*before*)", and "*talkin* (*talking*)" (Han and Baldwin, 2011). Such words, hereafter referred to as *ill-spelled words*, are so productive that they considerably increase the vocabulary size. This makes training of statistical models difficult.

We address this problem by jointly conducting lexical normalization. Although a wide variety of ill-spelled words are used in microblog texts, many can be normalized into *well-spelled equivalents*, which conform to standard rules of spelling.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 99–109,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

A joint model with lexical normalization is able to handle orthographic diversity by exploiting information obtainable from the well-spelled equivalents.

The proposed joint model was empirically evaluated on the microblog corpus we developed. Our experiment demonstrated that the proposed model can perform word segmentation and POS tagging substantially better than current state-of-the-art models.

1.3 Summary

Contributions of this paper are the following:

- We developed a microblog corpus that enables not only training of accurate models but also quantitative evaluation for word segmentation and POS tagging in the microblog domain.[3]
- We propose a joint model with lexical normalization for better handling of orthographic diversity in microblog texts. In particular, we present a new method of training the joint model using a partially annotated corpus (*c.f.*, Section 7.4).
- We, for the first time, present a comprehensive empirical study of word segmentation and POS tagging for microblogs. The experimental results demonstrated that both the microblog corpus and joint model greatly contributes to training accurate models for word segmentation and POS tagging.

The remainder of this paper is organized as follows. Section 2 reviews related work. Section 3 discusses the task of lexical normalization and introduces terminology. Section 4 presents our microblog corpus and results of our corpus analysis. Section 5 presents an overview of our joint model with lexical normalization, and Sections 6 and 7 provide details of the model. Section 8 presents experimental results and discussions, and Section 9 presents concluding remarks.

2 Related Work

Researchers have recently developed various microblog corpora annotated with rich linguistic information. Gimpel et al. (2011) and Foster et al. (2011) annotated English microblog posts with POS tags. Han and Baldwin (2011) released a microblog corpus annotated with normalized forms of words. A Chinese microblog corpus annotated with word boundaries was developed for SIGHAN bakeoff (Duan et al., 2012). However, there are no microblog corpora annotated with word boundaries, POS tags, and normalized sentences.

There has been a surge of interest in lexical normalization with the advent of microblogs (Han and Baldwin, 2011; Liu et al., 2012; Han et al., 2012; Wang and Ng, 2013; Zhang et al., 2013; Ling et al., 2013; Yang and Eisenstein, 2013; Wang et al., 2013). However, these studies did not address enhancing word segmentation.

Wang et al. (2013) proposed a method of joint ill-spelled word recognition and word segmentation. With their method, informal spellings are merely recognized and not normalized. Therefore, they did not investigate how to exploit the information obtainable from well-spelled equivalents to increase word segmentation accuracy.

Some studies also explored integrating the lexical normalization process into word segmentation and POS tagging (Ikeda et al., 2009; Sasano et al., 2013). A strength of our joint model is that it uses rich character-level and word-level features used in state-of-the-art models of joint word segmentation and POS tagging (Kudo et al., 2004; Neubig et al., 2011; Kaji and Kitsuregawa, 2013). Thanks to these features, our model performed much better than Sasano et al.'s system, which is the only publicly available system that jointly conducts lexical normalization, in the experiments (see Section 8). Another advantage is that our model can be trained on a partially annotated corpus. Furthermore, we present a comprehensive evaluation in terms of precision and recall on our microblog corpus. Such an evaluation has not been conducted in previous work due to the lack of annotated corpora.[4]

3 Lexical Normalization Task

This section explains the task of lexical normalization addressed in this paper. Since lexical normalization is a relatively new research topic, there are no precise definitions of a lexical normalization task that are widely accepted by researchers.

[3] Please contact the first author for this corpus.

[4] Very recently, Saito et al. (2014) conducted similar empirical evaluation on microblog corpus. However, they used biased dataset, in which every sentence includes at least one ill-spelled words.

Table 1: Examples of our target ill-spelled words and their well-spelled equivalents. Phonemes are shown between slashes. English translations are provided in parentheses.

Ill-spelled word	Well-spelled equivalent
すげえ /sugee/	すごい /sugoi/ (great)
戻ろ /modoro/	戻ろう /modorou/ (going to return)
うまいいいい /umaiiii/	うまい /umai/ (yummy)

Therefore, it is important to clarify our task setting before discussing our joint model.

3.1 Target ill-spelled words

Many studies on lexical normalization have pointed out that phonological factors are deeply involved in the process of deriving ill-spelled words. Xia et al. (2006) investigated a Chinese chat corpus and reported that 99.2% of the ill-spelled words were derived by phonetic mapping from well-spelled equivalents. Wang and Ng (2013) analyzed 200 Chinese messages from Weibo and 200 English SMS messages from the NUS SMS corpus (How and Kan, 2005). Their analysis revealed that most ill-spelled words were derived from well-spelled equivalents based on pronunciation similarity.

On top of these investigations, we focused on ill-spelled words that are derived by phonological mapping from well-spelled words by assuming that such ill-spelled words are dominant in Japanese microblogs as well. We also assume that these ill-spelled words can be normalized into well-spelled equivalents on a word-to-word basis, as assumed in a previous study (Han and Baldwin, 2011). The validity of these two assumptions is empirically assessed in Section 4.

Table 1 lists examples of our target ill-spelled words, their well-spelled equivalents, and their phonemes. The ill-spelled word in the first row is formed by changing the continuous two vowels from /oi/ to /ee/. This type of change in pronunciation is often observed in Japanese spoken language. The second row presents contractions. The last vowel character "う" /u/ of the well-spelled word is dropped. The third row illustrates word lengthening. The ill-spelled word is derived by repeating the vowel character "い" /i/.

3.2 Terminology

We now introduce the terminology that will be used throughout the remainder of this paper. The term *word surface form* (or *surface form* for short) is used to refer to the word form observed in an actual text, while *word normal form* (or *normal form*) refers to the normalized word form. Note that surface forms of well-spelled words are always identical to their normal forms.

It is possible that the word surface form and normal form have distinct POS tags, although they are identical in most cases. Take the ill-spelled word "戻ろ" /modoro/ as an example (the second row of Table 1). According to the JUMAN POS tag set,[5] POS of its surface form is CONTRACTED VERB, while that of its normal form is VERB.[6] To handle such a case, we strictly distinguish between these two POS tags by referring to them as *surface POS tags* and *normal POS tags*, respectively.

Given these terms, the tasks addressed in this paper can be stated as follows. Word segmentation is a task of segmenting a sentence into a sequence of word surface forms, and POS tagging is a task of providing surface POS tags. The task of joint lexical normalization, word segmentation, and POS tagging is to map a sentence into a sequence of quadruplets: word surface form, surface POS tag, normal form, and normal POS tag.

4 Microblog Corpus

This section introduces our microblog corpus. We first explain the process of developing the corpus then present the results of our agreement study and corpus analysis.

4.1 Data collection and annotation

The corpus was developed by manually annotating text messages posted to Twitter.

The posts to be annotated were collected as follows. 171,386 Japanese posts were collected using the Twitter API[7] on December 6, 2013. Among these, 1000 posts were randomly selected then manually split into sentences. As a result, we obtained 1831 sentences as a source of the corpus.

Two human participants annotated the 1831 sentences with surface forms and surface POS tags. Since much effort has already been done to annotate corpora with this information, the annotation process here follows the guidelines used to

[5] http://nlp.ist.i.kyoto-u.ac.jp/index.php?JUMAN

[6] In this paper, we use simplified POS tags for explanation purposes. Remind that these tags are different from the original ones defined in JUMAN POS tag set.

[7] https://stream.twitter.com/1.1/statuses/sample.json

develop such corpora in previous studies (Kurohashi and Nagao, 1998; Hashimoto et al., 2011).

The two participants also annotated ill-spelled words with their normal forms and normal POS tags. Although this paper targets only informal phonological variations (*c.f.*, Section 3), other types of ill-spelled words were also annotated to investigate their frequency distribution in microblog texts. Specifically, besides informal phonological variations, spelling errors and Twitter-specific abbreviations were annotated. As a result, 833 ill-spelled words were identified (Table 2). They were all annotated with normal forms and normal POS tags.

4.2 Agreement study

We investigated the inter-annotator agreement to check the reliability of the annotation. During the annotation process, the two participants collaboratively annotated around 90% of the sentences (specifically, 1647 sentences) with normal forms and normal POS tags, and elaborated an annotation guideline through discussion. They then independently annotated the remaining 184 sentences (1431 words), which were used for the agreement study. Our annotation guideline is shown in the supplementary material.

We first explored the extent to which the two participants agreed in distinguishing between well-spelled words and ill-spelled words. For this task, we observed Cohen's kappa of 0.96 (almost perfect agreement). This results show that it is easy for humans to distinguish between these two types of words.

Next, we investigated whether the two participants could give ill-spelled words with the same normal forms and normal POS tags. For this purpose, we regarded the normal forms and normal POS tags annotated by one participant as goldstandards and calculated precision and recall achieved by the other participant. We observed moderate agreement between the two participants: 70% (56/80) precision and 73% (56/76) recall. We manually analyzed the conflicted examples and found that there were more than one acceptable normal form in many of these cases. Therefore, we would like to note that the precision and recall reported above are rather pessimistic estimations.

4.3 Analysis

We conducted corpus analysis to confirm the feasibility of our approach.

Table 2: Frequency distribution over three types of ill-spelled words in corpus.

Type	Frequency
Informal phonological variation	804 (92.9%)
Spelling error	27 (3.1%)
Twitter-specific abbreviation	34 (3.9%)
Total	865 (100%)

Table 2 illustrates that phonological variations constitute a vast majority of ill-spelled words in Japanese microblog texts. In addition, analysis of the 804 phonological variations showed that 793 of them can be normalized into single words. These represent the validity of the two assumptions we made in Section 3.1.

We then investigated whether lexical normalization can decrease the number of out-of-vocabulary words. For the 793 ill-spelled words, we counted how many of their surface forms and normal forms were not registered in the JUMAN dictionary.[8] The result suggests that 411 (51.8%) and 74 (9.3%) are not registered in the dictionary. This indicates the effectiveness of lexical normalization for decreasing out-of-vocabulary words.

5 Overview of Joint Model

This section gives an overview of our joint model with lexical normalization for accurate word segmentation and POS tagging.

5.1 Lattice-based approach

A lattice-based approach has been commonly adopted to perform joint word segmentation and POS tagging (Jiang et al., 2008; Kudo et al., 2004; Kaji and Kitsuregawa, 2013). In this approach, an input sentence is transformed into a word lattice in which the edges are labeled with surface POS tags (Figure 1). Given such a lattice, word segmentation and POS tagging can be performed at the same time by traversing the lattice. A discriminative model is typically used for the traversal.

An advantage of this approach is that, while the lattice can represent an exponentially large number of candidate analyses, it can be quickly traversed using dynamic programming (Kudo et al., 2004; Kaji and Kitsuregawa, 2013) or beam search (Jiang et al., 2008). In addition, a discriminative model allows the use of rich word-level features to find the correct analysis.

[8] http://nlp.ist.i.kyoto-u.ac.jp/index.php?JUMAN

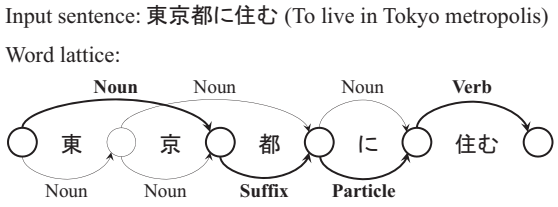

Figure 1: Example lattice (Kudo et al., 2004; Kaji and Kitsuregawa, 2013). Circle and arrow represent node and edge, respectively. Bold edges represent correct analysis.

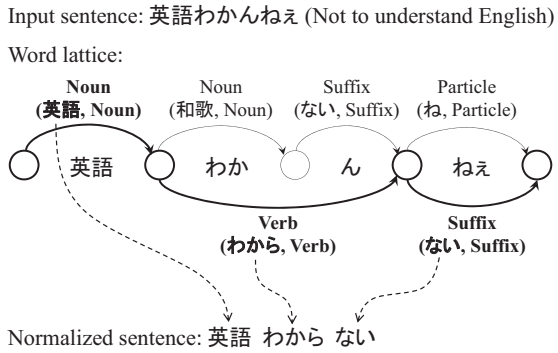

Figure 2: Lattice used to perform joint task. Normal forms and normal POS tags are shown in parentheses. As indicated by dotted arrows, normalized sentence can be obtained by concatenating normal forms associated with edges in correct analysis.

We propose extending the lattice-based approach to jointly perform lexical normalization, word segmentation, and POS tagging. We transform an input sentence into a word lattice in which the edges are labeled with not only surface POS tags but normal forms and normal POS tags (Figure 2). By traversing such a lattice, the three tasks can be performed at the same time. This approach can not only exploit rich information obtainable from word normal forms, but also achieve efficiency similar to the original lattice-based approach.

5.2 Issues

Issues on how to develop this lattice-based approach is detailed in Sections 6 and 7.

Section 6 describes how to generate a word lattice from an input sentence. This is done using a hybrid approach that combines a statistical model and *normalization dictionary*. The normalization dictionary is specifically a list of quadruplets: word surface form, surface POS tag, normal form, and normal POS tag (Table 3).

Table 3: Normalization dictionary. Columns represent entry ID, surface form, surface POS, normal form, and normal POS, respectively.

ID	Surf.	Surf. POS	Norm.	Norm. POS
A	すごい	ADJECTIVE	すごい	ADJECTIVE
B	すげえ	ADJECTIVE	すごい	ADJECTIVE
C	戻ろう	VERB	戻ろう	VERB
D	戻ろ	CONTR. VERB	戻ろう	VERB
E	うまい	ADJECTIVE	うまい	ADJECTIVE
F	うまいいいい	ADJECTIVE	うまい	ADJECTIVE

Table 4: Tag dictionary.

ID	Surf. form	Surf. POS
a	すごい (great)	ADJECTIVE
b	戻ろう (going to return)	VERB
c	戻ろ (gonna return)	CONTR. VERB
d	うまい (yummy)	ADJECTIVE

Section 7 describes a discriminative model for the lattice traversal. Our feature design as well as two training methods are presented.

6 Word Lattice Generation

In this section, we first describe a method of constructing a normalization dictionary then present a method of generating a word lattice from an input sentence.

6.1 Construction of normalization dictionary

Although large-scale normalization dictionaries are difficult to obtain, *tag dictionaries*, which list pairs of word surface forms and their surface POS tags (Table 4), are widely available in many languages including Japanese. Therefore, we use an existing tag dictionary to construct the normalization dictionary.

Due to space limitations, we give only a brief overview of our construction method, omitting its details. We note that our method uses hand-crafted rules similar to those used in (Sasano et al., 2013); hence, the proposal of this method is not an important contribution. To make our experimental results reproducible, our normalization dictionary, as well as a tool for constructing it, is released as supplementary material.

Our method of constructing the normalization dictionary takes three steps. The following explains each step using Tables 3 and 4 as running examples.

Step 1 A tag dictionary generally contains a small number of ill-spelled words, although well-spelled words constitute a vast majority. We identify such ill-spelled words by using a manually-tailored list of surface POS tags indicative of informal spelling (*e.g.*, CONTRACTED VERB). For example, entry (c) in Table 4 is identified as an ill-spelled word in this step.

Step 2 The tag dictionary is augmented with normal forms and normal POS tags to construct a small normalization dictionary. For ill-spelled words identified in step 1, the normal forms and normal POS tags are determined by hand-crafted rules. For example, the normal form is derived by appending the vowel character "う" /u/ to the surface form, if the surface POS tag is CONTRACTED VERB. This rule derives entry (D) in Table 3 from entry (c) in Table 4. For well-spelled words, on the other hand, the normal forms and normal POS tags are simply set the same as the surface forms and surface POS tags. For example, entries (A), (C), and (E) in Table 3 are generated from entries (a), (b), and (d) in Table 4, respectively.

Step 3 Because the normalization dictionary constructed in step 2 contains only a few ill-spelled words, it is expanded in this step. For this purpose, we use hand-crafted rules to derive ill-spelled words from the entries already registered in the normalization dictionary. Some rules are taken from (Sasano et al., 2013), while the others are newly tailored. In Table 3, for example, entry (B) is derived from entry (A) by applying the rule that substitutes "ごい" /goi/ with "げえ" /gee/.

A small problem that arises in step 3 is how to handle lengthened words, such as entry (F) in Table 3. While lengthened words can be easily derived using simple rules (Brody and Diakopoulos, 2011; Sasano et al., 2013), such rules infinitely increase the number of entries because an unlimited number of lengthened words can be derived by repeating characters. To address this problem, no lengthened words are added to the normalization dictionary in step 3. We instead use rules to skip repetitive characters in an input sentence when performing dictionary match.

6.2 A hybrid approach

A word lattice is generated using both a statistical method (Kaji and Kitsuregawa, 2013) and the normalization dictionary.

We begin by generating a word lattice which encodes only word surface forms and surface POS tags (*c.f.*, Figure 1) using the statistical method proposed by Kaji and Kitsuregawa (2013). Interested readers may refer to their paper for details.

Each edge in the lattice is then labeled with normal forms and normal POS tags. Note that a single edge can have more than one candidate normal form and normal POS tag. In such a case, new edges are accordingly added to the lattice.

The edges are labeled with normal forms and normal POS tags in the following manner. First, every edge is labeled with a normal form and normal POS tag that are identical with the surface form and surface POS tag. This is based on our observation that most words are well-spelled ones. The edge is not provided with further normal forms and normal POS tags, if the normalization dictionary contains a well-spelled word that has the same surface form as the edge. Otherwise, we allow the edge to have all pairs of normal forms and normal POS tags that are obtained by using the normalization dictionary.

7 Discriminative Lattice Traversal

This section explains a discriminative model for traversing the word lattice. The lattice traversal with a discriminative model can formally be written as

$$(\boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s}) = \underset{(\boldsymbol{w},\boldsymbol{t},\boldsymbol{v},\boldsymbol{s}) \in \mathcal{L}(x)}{\arg\max} \boldsymbol{f}(x, \boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s}) \cdot \boldsymbol{\theta}.$$

Here, x denotes an input sentence, $\boldsymbol{w}$, $\boldsymbol{t}$, $\boldsymbol{v}$, and $\boldsymbol{s}$ denote a sequence of word surface forms, surface POS tags, normal forms, and normal POS tags, respectively, $\mathcal{L}(x)$ represents a set of candidate analyses represented by the word lattice, and $\boldsymbol{f}(\cdot)$ and $\boldsymbol{\theta}$ are feature and weight vectors.

We now describe features, a decoding method, and two training methods.

7.1 Features

We use character-level and word-level features used for word segmentation and POS tagging in (Kaji and Kitsuregawa, 2013). To take advantage of joint model with lexical normalization, the word-level features are extracted from not only surface forms but also normal forms. See (Kaji and Kitsuregawa, 2013) for the original features.

In addition, several new features are introduced in this paper. We use the quadruplets (w_i, t_i, v_i, s_i)

and pairs of surface and normal POS tags (t_i, s_i) as binary features to capture probable mappings between ill-spelled words and their well-spelled equivalents. We use another binary feature indicating whether a quadruplet (w_i, t_i, v_i, s_i) is registered in the normalization dictionary. Also, we use a bigram language model feature, which prevents sentences from being normalized into ungrammatical and/or incomprehensible ones. The language model features are associated with normalized bigrams, $(v_{i-1}, s_{i-1}, v_i, s_i)$, and take as the values the logarithmic frequency $\log_{10}(f+1)$, where f represents the bigram frequency (Kaji and Kitsuregawa, 2011). Since it is difficult to obtain a precise value of f, it is approximated by the frequency of the surface bigram, $(w_{i-1}, t_{i-1}, w_i, t_i)$, calculated from a large raw corpus automatically analyzed using a system of joint word segmentation and POS tagging. See Section 8.1 for the raw corpus and system used in the experiments.

7.2 Decoding

It is easy to find the best analysis $(\boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s})$ among the candidates represented by the word lattice. Although we use several new features, we can still locate the best analysis by using the same dynamic programming algorithm as in previous studies (Kudo et al., 2004; Kaji and Kitsuregawa, 2013).

7.3 Training on a fully annotated corpus

It is straightforward to train the joint model provided with a fully annotated corpus, which is labeled with word surface forms, surface POS tags, normal forms, and normal POS tags.

We use structured perceptron (Collins, 2002) for the training (Algorithm 1). The training begins by initializing $\boldsymbol{\theta}$ as a zero vector (line 1). It then reads the annotated corpus $\mathcal{C}$ (line 2-9). Given a training example, $(x, \boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s}) \in \mathcal{C}$, the algorithm locates the best analysis, $(\hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}})$, based on the current weight vector (line 4). If the best analysis differs from the oracle analysis, $(\boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s})$, the weight vector is updated (line 5-7). After going through the annotated corpus m times (m=10 in our experiment), the averaged weight vector is returned (line 10).

7.4 Training on a partially annotated corpus

Although the training with the perceptron algorithm requires a fully annotated corpus, it is labor-intensive to fully annotate sentences. This consideration motivates us to explore training our model with less supervision. We specifically explore using a corpus annotated with only word boundaries and POS tags.

Algorithm 1 Perceptron training

1: $\boldsymbol{\theta} \leftarrow \mathbf{0}$
2: **for** $i = 1 \ldots m$ **do**
3: **for** $(x, \boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s}) \in \mathcal{C}$ **do**
4: $(\hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}}) \leftarrow \textsc{Decoding}(x, \boldsymbol{\theta})$
5: **if** $(\boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s}) \neq (\hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}})$ **then**
6: $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \boldsymbol{f}(x, \boldsymbol{w}, \boldsymbol{t}, \boldsymbol{v}, \boldsymbol{s}) - \boldsymbol{f}(x, \hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}})$
7: **end if**
8: **end for**
9: **end for**
10: **return** $\textsc{Average}(\boldsymbol{\theta})$

Algorithm 2 Latent perceptron training

1: $\boldsymbol{\theta} \leftarrow \mathbf{0}$
2: **for** $i = 1 \ldots m$ **do**
3: **for** $(x, \boldsymbol{w}, \boldsymbol{t}) \in \mathcal{C}'$ **do**
4: $(\hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}}) \leftarrow \textsc{Decoding}(x, \boldsymbol{\theta})$
5: $(\boldsymbol{w}, \boldsymbol{t}, \bar{\boldsymbol{v}}, \bar{\boldsymbol{s}}) \leftarrow \textsc{ConstrainedDecoding}(x, \boldsymbol{\theta})$
6: **if** $\boldsymbol{w} \neq \hat{\boldsymbol{w}}$ or $\boldsymbol{t} \neq \hat{\boldsymbol{t}}$ **then**
7: $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \boldsymbol{f}(x, \boldsymbol{w}, \boldsymbol{t}, \bar{\boldsymbol{v}}, \bar{\boldsymbol{s}}) - \boldsymbol{f}(x, \hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}})$
8: **end if**
9: **end for**
10: **end for**
11: **return** $\textsc{Average}(\boldsymbol{\theta})$

We use the latent perceptron algorithm (Sun et al., 2013) to train the joint model from such a partially annotated corpus (Algorithm 2). In this scenario, a training example is a sentence x paired with a sequence of word surface forms $\boldsymbol{w}$ and surface POS tags $\boldsymbol{t}$ (*c.f.*, line 3). Similarly to the perceptron algorithm, we locate the best analysis $(\hat{\boldsymbol{w}}, \hat{\boldsymbol{t}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{s}})$ for a given training example, (line 4). We also locate the best analysis, $(\boldsymbol{w}, \boldsymbol{t}, \bar{\boldsymbol{v}}, \bar{\boldsymbol{s}})$, among those having the same surface forms $\boldsymbol{w}$ and surface POS tags $\boldsymbol{t}$ as the training example (line 5). If the surface forms and surface POS tags of the former analysis differ from the annotations of the training example, parameter is updated by regarding the latter analysis as an oracle (line 6-8).

8 Experiments

We conducted experiments to investigate how the microblog corpus and joint model contribute to improving accuracy of word segmentation and POS tagging in the microblog domain.

8.1 Setting

We constructed the normalization dictionary from the JUMAN dictionary 7.0.[9] While JUMAN dic-

[9] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN

tionary contains 750,156 entries, the normalization dictionary contains 112,458,326 entries.

Some features taken from the previous study (Kaji and Kitsuregawa, 2013) are induced using a tag dictionary. For this we used two tag dictionaries. One is JUMAN dictionary 7.0 and the other is a tag dictionary constructed by listing surface forms and surface POS tags in the normalization dictionary.

To compute the language model features, one billion sentences from Twitter posts were analyzed using MeCab 0.996.[10] We used all bigrams appearing at least 10 times in the auto-analyzed sentences.

8.2 Results of word segmentation and POS tagging

We first investigated the performance of models trained on an existing annotated corpus form news texts. For this experiment, our joint model as well as three state-of-the-art models (Kudo et al., 2004)[11](Neubig et al., 2011)[12](Kaji and Kitsuregawa, 2013) were trained on Kyoto University Text corpus 4.0 (Kurohashi and Nagao, 1998). Since this training corpus is not annotated with normal forms and normal POS tags, our model was trained using the latent perceptron. Table 5 summarizes the word-level F_1-scores (Kudo et al., 2004) on our microblog corpus. The two columns represent the results for word segmentation (**Seg**) and joint word segmentation and POS tagging (**Seg+Tag**), respectively.

We also conducted 5-fold crossvalidation on our microblog corpus to evaluate performance improvement when these models are trained on microblog texts (Table 6). In addition to the models in Table 5, results of a rule-based system (Sasano et al., 2013)[13] and our joint model trained using the perceptron algorithm are also presented. Notice that **Proposed** and **Proposed (latent)** represent our model trained using perceptron and latent perceptron, respectively.

From Tables 5 and 6, as expected, we see that the models trained on news texts performed poorly on microblog texts, while their performance significantly boosted when trained on the microblog texts. This demonstrates the importance of corpus annotation. An exception was **Kudo04**. Its performance improved only slightly, even when it was trained on the microblog texts. We believe this is because their model uses dictionary-based rules to prune candidate analyses; thus, it could not perform well in the microblog domain, where out-of-vocabulary words are abundant.

Table 5: Performance of models trained on the news articles.

	Seg	Seg+Tag
Kudo04	81.8	71.0
Neubig11	80.5	69.1
Kaji13	**83.2**	73.1
Proposed (latent)	83.0	**73.9**

Table 6 also illustrates that our joint models achieved F_1-score better than the state-of-the-art models trained on the microblog texts. This shows that modeling the derivation process of ill-spelled words makes training easier. We conducted bootstrap resampling (with 1000 samples) to investigate the significance of the improvements achieved with our joint model. The results showed that all improvements over the baselines were statistically significant ($p < 0.01$). The difference between **Proposed** and **Proposed (latent)** were also statistically significant ($p < 0.01$).

The results of **Proposed (latent)** are interesting. Table 5 illustrates that our joint model performs well even when it is trained on a news corpus that rarely contains ill-spelled words and is not at all annotated with normal forms and normal POS tags. This indicates the robustness of our training method and the importance of modeling word derivation process in the microblog domain. In Table 6, we observed that **Proposed (latent)**, which uses less supervision, performed better than **Proposed**. The reason for this will be examined later.

In summary, we can conclude that both the microblog corpus and joint model significantly contribute to training accurate models for word segmentation and POS tagging in the microblog domain.

8.3 Results of lexical normalization

While the main goal with this study was to enhance word segmentation and POS tagging in the microblog domain, it is interesting to explore how well our joint model can normalize ill-spelled words.

Table 7 illustrates precision, recall, and F_1-score for the lexical normalization task. To put

Table 6: Results of 5-fold cross-validation on microblog corpus.

	Seg	Seg+Tag
Kudo04	82.7	71.7
Neubig11	88.6	75.9
Kaji13	90.9	82.1
Sasano13	82.7	73.3
Proposed	91.3	83.2
Proposed (latent)	**91.4**	**83.7**

Table 7: Results of lexical normalization task in terms of precision, recall, and F_1-score.

	Precision	Recall	F_1
Neubig11	69.2	35.9	47.3
Proposed	**77.1**	**44.6**	**56.6**
Proposed (latent)	53.7	24.7	33.9

the results into context, we report on the baseline results of a tagging model proposed by Neubig et al. (2011). This baseline conducts lexical normalization by regarding it as two independent tagging tasks (*i.e.*, tasks of tagging normal forms and normal POS tags). The result of the baseline model is also obtained using 5-fold crossvalidation.

Table 7 illustrates that **Proposed** performed significantly better than the simple tagging model, **Neubig11**. This suggests the effectiveness of our joint model. On the other hand, **Proposed (latent)** performed poorly in this task. From this result, we can argue that **Proposed (latent)** can achieve superior performance in word segmentation and POS tagging (Table 6) because it gave up correctly normalizing ill-spelled words, focusing on word segmentation and POS tagging.

The experimental results so far suggest the following strategy for training our joint model. If accuracy of word segmentation and POS tagging is the main concern, we can use the latent perceptron. This approach has the advantage of being able to use a partially annotated corpus. On the other hand, if performance of lexical normalization is crucial, we have to use the standard perceptron algorithm.

8.4 Error analysis

We manually analyzed erroneous outputs and observed several tendencies.

We found that a word lattice sometimes missed the correct output. Such an error was, for example, observed in a sentence including many ill-spelled words, e.g., '周囲の目が、キニナリマス！ (be nervous about what other people think!)', where the part 'キニナリマス' is in ill-spelled words. Improving the lattice generation algorithm is considered necessary to achieve further performance gain.

Even if the correct analysis appears in the word lattice, our model sometimes failed to handle ill-spelled words, incorrectly analyzing them as out-of-vocabulary words. For example, the proposed method treated the phrase 'おやつたーいむ (snack time)' as a single out-of-vocabulary word, even though the correct analysis was found in the word lattice. More sophisticated features would be required to accurately distinguish between ill-spelled and out-of-vocabulary words.

9 Conclusion and Future Work

We presented our attempts towards developing an accurate model for word segmentation and POS tagging in the microblog domain. To this end, we, for the first time, developed an annotated corpus of microblogs. We also proposed a joint model with lexical normalization to handle orthographic diversity in the microblog text. Intensive experiments demonstrated that we could successfully improve the performance of word segmentation and POS tagging on microblog texts. We believe this study will have a large practical impact on a various research areas that target microblogs.

One limitation of our approach is that it cannot handle certain types of ill-spelled words. For example, the current model cannot handle the cases in which there are no one-to-one-mappings between well-spelled and ill-spelled words. Also, our model cannot handle spelling errors, which are considered relatively frequent in the microblog than news domains. The treatment of these problems would require further research.

Another future research is to speed-up our model. Since the joint model with lexical normalization significantly increases the search space, it is much slower than the original lattice-based model for word segmentation and POS tagging.

Acknowledgments

The authors would like to thank Naoki Yoshinaga for his help in developing the microblog corpus as well as fruitful discussions.

Abstract

Recent work has shown success in using continuous word embeddings learned from unlabeled data as features to improve supervised NLP systems, which is regarded as a simple semi-supervised learning mechanism. However, fundamental problems on effectively incorporating the word embedding features within the framework of linear models remain. In this study, we investigate and analyze three different approaches, including a new proposed *distributional prototype* approach, for utilizing the embedding features. The presented approaches can be integrated into most of the classical linear models in NLP. Experiments on the task of named entity recognition show that each of the proposed approaches can better utilize the word embedding features, among which the *distributional prototype* approach performs the best. Moreover, the combination of the approaches provides additive improvements, outperforming the dense and continuous embedding features by nearly 2 points of F1 score.

1 Introduction

Learning generalized representation of words is an effective way of handling data sparsity caused by high-dimensional lexical features in NLP systems, such as named entity recognition (NER) and dependency parsing. As a typical low-dimensional and generalized word representation, Brown clustering of words has been studied for a long time. For example, Liang (2005) and Koo et al. (2008) used the Brown cluster features for semi-supervised learning of various NLP tasks and achieved significant improvements.

*Email correspondence.

Recent research has focused on a special family of word representations, named "word embeddings". Word embeddings are conventionally defined as dense, continuous, and low-dimensional vector representations of words. Word embeddings can be learned from large-scale unlabeled texts through context-predicting models (e.g., neural network language models) or spectral methods (e.g., canonical correlation analysis) in an unsupervised setting.

Compared with the so-called *one-hot* representation where each word is represented as a sparse vector of the same size of the vocabulary and only one dimension is on, word embedding preserves rich linguistic regularities of words with each dimension hopefully representing a latent feature. Similar words are expected to be distributed close to one another in the embedding space. Consequently, word embeddings can be beneficial for a variety of NLP applications in different ways, among which the most simple and general way is to be fed as features to enhance existing supervised NLP systems.

Previous work has demonstrated effectiveness of the continuous word embedding features in several tasks such as chunking and NER using generalized linear models (Turian et al., 2010).[1] However, there still remain two fundamental problems that should be addressed:

- Are the continuous embedding features fit for the generalized linear models that are most widely adopted in NLP?
- How can the generalized linear models better utilize the embedding features?

According to the results provided by Turian et

[1]Generalized linear models refer to the models that describe the data as a combination of linear basis functions, either directly in the input variables space or through some transformation of the probability distributions (e.g., *log-linear* models).

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 110–120,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

al. (2010), the embedding features brought significantly less improvement than Brown clustering features. This result is actually not reasonable because the expressing power of word embeddings is theoretically stronger than clustering-based representations which can be regarded as a kind of *one-hot* representation but over a low-dimensional vocabulary (Bengio et al., 2013).

Wang and Manning (2013) showed that linear architectures perform better in high-dimensional discrete feature space than non-linear ones, whereas non-linear architectures are more effective in low-dimensional and continuous feature space. Hence, the previous method that directly uses the continuous word embeddings as features in linear models (CRF) is inappropriate. Word embeddings may be better utilized in the linear modeling framework by smartly transforming the embeddings to some relatively higher dimensional and discrete representations.

Driven by this motivation, we present three different approaches: *binarization* (Section 3.2), *clustering* (Section 3.3) and a new proposed *distributional prototype* method (Section 3.4) for better incorporating the embeddings features. In the *binarization* approach, we directly binarize the continuous word embeddings by dimension. In the *clustering* approach, we cluster words based on their embeddings and use the resulting word cluster features instead. In the *distributional prototype* approach, we derive *task-specific* features from word embeddings by utilizing a set of automatically extracted *prototypes* for each target label.

We carefully compare and analyze these approaches in the task of NER. Experimental results are promising. With each of the three approaches, we achieve higher performance than directly using the continuous embedding features, among which the *distributional prototype* approach performs the best. Furthermore, by putting the most effective two of these features together, we finally outperform the continuous embedding features by nearly 2 points of F1 Score (86.21% vs. 88.11%).

The major contribution of this paper is twofold. (1) We investigate various approaches that can better utilize word embeddings for semi-supervised learning. (2) We propose a novel *distributional prototype* approach that shows the great potential of word embedding features. All the presented approaches can be easily integrated into most of the classical linear NLP models.

2 Semi-supervised Learning with Word Embeddings

Statistical modeling has achieved great success in most NLP tasks. However, there still remain some major unsolved problems and challenges, among which the most widely concerned is the data sparsity problem. Data sparsity in NLP is mainly caused by two factors, namely, the lack of labeled training data and the Zipf distribution of words. On the one hand, large-scale labeled training data are typically difficult to obtain, especially for structure prediction tasks, such as syntactic parsing. Therefore, the supervised models can only see limited examples and thus make biased estimation. On the other hand, the natural language words are Zipf distributed, which means that most of the words appear a few times or are completely absent in our texts. For these low-frequency words, the corresponding parameters usually cannot be fully trained.

More foundationally, the reason for the above factors lies in the high-dimensional and sparse lexical feature representation, which completely ignores the similarity between features, especially word features. To overcome this weakness, an effective way is to learn more generalized representations of words by exploiting the numerous unlabeled data, in a semi-supervised manner. After which, the generalized word representations can be used as extra features to facilitate the supervised systems.

Liang (2005) learned Brown clusters of words (Brown et al., 1992) from unlabeled data and use them as features to promote the supervised NER and Chinese word segmentation. Brown clusters of words can be seen as a generalized word representation distributed in a discrete and low-dimensional vocabulary space. Contextually similar words are grouped in the same cluster. The Brown clustering of words was also adopted in dependency parsing (Koo et al., 2008) and POS tagging for online conversational text (Owoputi et al., 2013), demonstrating significant improvements.

Recently, another kind of word representation named "word embeddings" has been widely studied (Bengio et al., 2003; Mnih and Hinton, 2008). Using word embeddings, we can evaluate the similarity of two words straightforward by computing the dot-product of two numerical vectors in the Hilbert space. Two *similar* words are expected to

be distributed close to each other.[2]

Word embeddings can be useful as input to an NLP model (mostly non-linear) or as additional features to enhance existing systems. Collobert et al. (2011) used word embeddings as input to a deep neural network for multi-task learning. Despite of the effectiveness, such non-linear models are hard to build and optimize. Besides, these architectures are often specialized for a certain task and not scalable to general tasks. A simple and more general way is to feed word embeddings as augmented features to an existing supervised system, which is similar to the semi-supervised learning with Brown clusters.

As discussed in Section 1, Turian et al. (2010) is the pioneering work on using word embedding features for semi-supervised learning. However, their approach cannot fully exploit the potential of word embeddings. We revisit this problem in this study and investigate three different approaches for better utilizing word embeddings in semi-supervised learning.

3 Approaches for Utilizing Embedding Features

3.1 Word Embedding Training

In this paper, we will consider a context-predicting model, more specifically, the *Skip-gram* model (Mikolov et al., 2013a; Mikolov et al., 2013b) for learning word embeddings, since it is much more efficient as well as memory-saving than other approaches.

Let's denote the embedding matrix to be learned by $C_{d\times N}$, where N is the vocabulary size and d is the dimension of word embeddings. Each column of C represents the embedding of a word. The *Skip-gram* model takes the current word w as input, and predicts the probability distribution of its context words within a fixed window size. Concretely, w is first mapped to its embedding v_w by selecting the corresponding column vector of C (or multiplying C with the *one-hot* vector of w). The probability of its context word c is then computed using a log-linear function:

$$P(c|w;\theta) = \frac{exp({v_c}^\top v_w)}{\sum_{c'\in V} exp({v_{c'}}^\top v_w)} \qquad (1)$$

where V is the vocabulary. The parameters θ are v_{w_i}, v_{c_i} for $w, c \in V$ and $i = 1, ..., d$. Then, the log-likelihood over the entire training dataset D can be computed as:

$$J(\theta) = \sum_{(w,c)\in D} \log p(c|w;\theta) \qquad (2)$$

The model can be trained by maximizing $J(\theta)$.

Here, we suppose that the word embeddings have already been trained from large-scale unlabeled texts. We will introduce various approaches for utilizing the word embeddings as features for semi-supervised learning. The main idea, as introduced in Section 1, is to transform the continuous word embeddings to some relatively higher dimensional and discrete representations. The direct use of continuous embeddings as features (Turian et al., 2010) will serve as our baseline setting.

3.2 Binarization of Embeddings

One fairly natural approach for converting the continuous-valued word embeddings to discrete values is binarization by dimension.

Formally, we aim to convert the continuous-valued embedding matrix $C_{d\times N}$, to another matrix $M_{d\times N}$ which is discrete-valued. There are various conversion functions. Here, we consider a simple one. For the i^{th} dimension of the word embeddings, we divide the corresponding row vector C_i into two halves for positive (C_{i+}) and negative (C_{i-}), respectively. The conversion function is then defined as follows:

$$M_{ij} = \phi(C_{ij}) = \begin{cases} U_+, & if\ C_{ij} \geq mean(C_{i+}) \\ B_-, & if\ C_{ij} \leq mean(C_{i-}) \\ 0, & otherwise \end{cases}$$

where $mean(v)$ is the mean value of vector v, U_+ is a string feature which turns on when the value (C_{ij}) falls into the upper part of the positive list. Similarly, B_- refers to the bottom part of the negative list. The insight behind ϕ is that we only consider the features with strong opinions (i.e., positive or negative) on each dimension and omit the values close to zero.

3.3 Clustering of Embeddings

Yu et al. (2013) introduced clustering embeddings to overcome the disadvantage that word embeddings are not suitable for linear models. They suggested that the high-dimensional cluster features make samples from different classes better separated by linear models.

[2] The term *similar* should be viewed depending on the specific task.

In this study, we again investigate this approach. Concretely, each word is treated as a single sample. The batch k-means clustering algorithm (Sculley, 2010) is used,[3] and each cluster is represented as the mean of the embeddings of words assigned to it. Similarities between words and clusters are measured by Euclidean distance.

Moreover, different number of clusters n contain information of different granularities. Therefore, we combine the cluster features of different ns to better utilize the embeddings.

3.4 Distributional Prototype Features

We propose a novel kind of embedding features, named distributional prototype features for supervised models. This is mainly inspired by *prototype-driven learning* (Haghighi and Klein, 2006) which was originally introduced as a primarily unsupervised approach for sequence modeling. In *prototype-driven learning*, a few prototypical examples are specified for each target label, which can be treated as an injection of prior knowledge. This sparse prototype information is then propagated across an unlabeled corpus through distributional similarities.

The basic motivation of the distributional prototype features is that similar words are supposed to be tagged with the same label. This hypothesis makes great sense in tasks such as NER and POS tagging. For example, suppose *Michael* is a prototype of the named entity (NE) type `PER`. Using the distributional similarity, we could link similar words to the same prototypes, so the word *David* can be linked to *Michael* because the two words have high similarity (exceeds a threshold). Using this link feature, the model will push *David* closer to `PER`.

To derive the distributional prototype features, first, we need to construct a few canonical examples (prototypes) for each target annotation label. We use the normalized pointwise mutual information (NPMI) (Bouma, 2009) between the label and word, which is a smoothing version of the standard PMI, to decide the prototypes of each label. Given the annotated training corpus, the NPMI between a label and word is computed as follows:

$$\lambda_n(label, word) = \frac{\lambda(label, word)}{-\ln p(label, word)} \quad (3)$$

[3] `code.google.com/p/sofia-ml`

NE Type	Prototypes
B-PER	Mark, Michael, David, Paul
I-PER	Akram, Ahmed, Khan, Younis
B-ORG	Reuters, U.N., Ajax, PSV
I-ORG	Newsroom, Inc, Corp, Party
B-LOC	U.S., Germany, Britain, Australia
I-LOC	States, Republic, Africa, Lanka
B-MISC	Russian, German, French, British
I-MISC	Cup, Open, League, OPEN
O	., ,, the, to

Table 1: Prototypes extracted from the CoNLL-2003 NER training data using NPMI.

where,

$$\lambda(label, word) = \ln \frac{p(label, word)}{p(label)p(word)} \quad (4)$$

is the standard PMI.

For each target label l (e.g., `PER`, `ORG`, `LOC`), we compute the NPMI of l and all words in the vocabulary, and the top m words are chosen as the prototypes of l. We should note that the prototypes are extracted fully automatically, without introducing additional human prior knowledge.

Table 1 shows the top four prototypes extracted from the NER training corpus of CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003), which contains four NE types, namely, `PER`, `ORG`, `LOC`, and `MISC`. Non-NEs are denoted by `O`. We convert the original annotation to the standard BIO-style. Thus, the final corpus contains nine labels in total.

Next, we introduce the prototypes as features to our supervised model. We denote the set of prototypes for all target labels by S_p. For each prototype $z \in S_p$, we add a predicate $proto = z$, which becomes active at each w if the distributional similarity between z and w ($DistSim(z, w)$) is above some threshold. $DistSim(z, w)$ can be efficiently calculated through the *cosine* similarity of the embeddings of z and w. Figure 1 gives an illustration of the distributional prototype features. Unlike previous embedding features or Brown clusters, the distributional prototype features are *task-specific* because the prototypes of each label are extracted from the training data.

Moreover, each prototype word is also its own prototype (since a word has maximum similarity to itself). Thus, if the prototype is closely related to a label, all the words that are distributionally

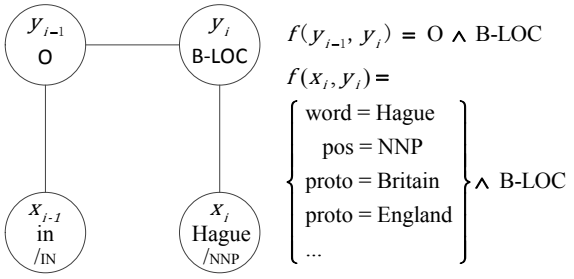

Figure 1: An example of distributional prototype features for NER.

similar to that prototype are pushed towards that label.

4 Supervised Evaluation Task

Various tasks can be considered to compare and analyze the effectiveness of the above three approaches. In this study, we partly follow Turian et al. (2010) and Yu et al. (2013), and take NER as the supervised evaluation task.

NER identifies and classifies the named entities such as the names of persons, locations, and organizations in text. The state-of-the-art systems typically treat NER as a sequence labeling problem, where each word is tagged either as a BIO-style NE or a non-NE category.

Here, we use the linear chain CRF model, which is most widely used for sequence modeling in the field of NLP. The CoNLL-2003 shared task dataset from the Reuters, which was used by Turian et al. (2010) and Yu et al. (2013), was chosen as our evaluation dataset. The training set contains 14,987 sentences, the development set contains 3,466 sentences and is used for parameter tuning, and the test set contains 3,684 sentences.

The baseline features are shown in Table 2.

4.1 Embedding Feature Templates

In this section, we introduce the embedding features to the baseline NER system, turning the supervised approach into a semi-supervised one.

Dense embedding features. The dense continuous embedding features can be fed directly to the CRF model. These embedding features can be seen as heterogeneous features from the existing baseline features, which are discrete. There is no effective way for dense embedding features to be combined internally or with other discrete features. So we only use the unigram embedding features following Turian et al. (2010). Concretely, the embedding feature template is:

Baseline NER Feature Templates
00: $w_{i+k}, -2 \leq k \leq 2$
01: $w_{i+k} \circ w_{i+k+1}, -2 \leq k \leq 1$
02: $t_{i+k}, -2 \leq k \leq 2$
03: $t_{i+k} \circ t_{i+k+1}, -2 \leq k \leq 1$
04: $chk_{i+k}, -2 \leq k \leq 2$
05: $chk_{i+k} \circ chk_{i+k+1}, -2 \leq k \leq 1$
06: $Prefix(w_{i+k}, l), -2 \leq k \leq 2, 1 \leq l \leq 4$
07: $Suffix(w_{i+k}, l), -2 \leq k \leq 2, 1 \leq l \leq 4$
08: $Type(w_{i+k}), -2 \leq k \leq 2$
Unigram Features
$y_i \circ 00 - 08$
Bigram Features
$y_{i-1} \circ y_i$

Table 2: Features used in the NER system. t is the POS tag. chk is the chunking tag. $Prefix$ and $Suffix$ are the first and last l characters of a word. $Type$ indicates if the word is all-capitalized, is-capitalized, all-digits, etc.

- $de_{i+k}[d]$, $-2 \leq k \leq 2$, d ranges over the dimensions of the dense word embedding de.

Binarized embedding features. The binarized embedding feature template is similar to the dense one. The only difference is that the feature values are discrete and we omit dimensions with zero value. Therefore, the feature template becomes:

- $bi_{i+k}[d]$, $-2 \leq k \leq 2$, where $bi_{i+k}[d] \neq 0$, d ranges over the dimensions of the binarized vector bi of word embedding.

In this way, the dimension of the binarized embedding feature space becomes $2 \times d$ compared with the originally d of the dense embeddings.

Compound cluster features. The advantage of the cluster features is that they can be combined internally or with other features to form compound features, which can be more discriminative. Furthermore, the number of resulting clusters n can be tuned, and different ns indicate different granularities. Concretely, the compound cluster feature template for each specific n is:

- $c_{i+k}, -2 \leq k \leq 2$.
- $c_{i+k} \circ c_{i+k+1}, -2 \leq k \leq 1$.
- $c_{i-1} \circ c_{i+1}$.

Distributional prototype features. The set of prototypes is again denoted by S_p, which is de-

cided by selecting the top m (NPMI) words as prototypes of each label, where m is tuned on the development set. For each word w_i in a sequence, we compute the distributional similarity between w_i and each prototype in S_p and select the prototypes zs that $DistSim(z, w) \geq \delta$. We set $\delta = 0.5$ without manual tuning. The distributional prototype feature template is then:

- $\{proto_{i+k}{=}z \mid DistSim(w_{i+k}, z) \geq \delta \;\&\; z \in S_p\}, -2 \leq k \leq 2$.

We only use the unigram features, since the number of active distributional prototype features varies for different words (positions). Hence, these features cannot be combined effectively.

4.2 Brown Clustering

Brown clustering has achieved great success in various NLP applications. At most time, it provides a strong baseline that is difficult to beat (Turian et al., 2010). Consequently, in our study, we conduct comparisons among the embedding features and the Brown clustering features, along with further investigations of their combination.

The Brown algorithm is a hierarchical clustering algorithm which optimizes a class-based bigram language model defined on the word clusters (Brown et al., 1992). The output of the Brown algorithm is a binary tree, where each word is uniquely identified by its path from the root. Thus each word can be represented as a bit-string with a specific length.

Following the setting of Owoputi et al. (2013), we will use the prefix features of hierarchical clusters to take advantage of the word similarity in different granularities. Concretely, the Brown cluster feature template is:

- bc_{i+k}, $-2 \leq k \leq 2$.
- $prefix(bc_{i+k}, p)$, $p \in \{2,4,6,...,16\}$, $-2 \leq k \leq 2$. $prefix$ takes the p-length prefix of the Brown cluster coding bc_{i+k}.

5 Experiments

5.1 Experimental Setting

We take the English Wikipedia until August 2012 as our unlabeled data to train the word embeddings.[4] Little pre-processing is conducted for the training of word embeddings. We remove paragraphs that contain non-roman characters and all MediaWiki markups. The resulting text is tokenized using the Stanford tokenizer,[5] and every word is converted to lowercase. The final dataset contains about 30 million sentences and 1.52 billion words. We use a dictionary that contains 212,779 most common words (frequency ≥ 80) in the dataset. An efficient open-source implementation of the *Skip-gram* model is adopted.[6] We apply the negative sampling[7] method for optimization, and the asynchronous stochastic gradient descent algorithm (Asynchronous SGD) for parallel weight updating. In this study, we set the dimension of the word embeddings to 50. Higher dimension is supposed to bring more improvements in semi-supervised learning, but its comparison is beyond the scope of this paper.

For the cluster features, we tune the number of clusters n from 500 to 3000 on the development set, and finally use the combination of $n = 500, 1000, 1500, 2000, 3000$, which achieves the best results. For the distributional prototype features, we use a fixed number of prototype words (m) for each target label. m is tuned on the development set and is finally set to 40.

We induce 1,000 brown clusters of words, the setting in prior work (Koo et al., 2008; Turian et al., 2010). The training data of brown clustering is the same with that of training word embeddings.

5.2 Results

Table 3 shows the performances of NER on the test dataset. Our baseline is slightly lower than that of Turian et al. (2010), because they use the BILOU encoding of NE types which outperforms BIO encoding (Ratinov and Roth, 2009).[8] Nonetheless, our conclusions hold. As we can see, all of the three approaches we investigate in this study achieve better performance than the direct use of the dense continuous embedding features.

To our surprise, even the binarized embedding features (BinarizedEmb) outperform the continuous version (DenseEmb). This provides clear evidence that directly using the dense continuous embeddings as features in CRF indeed cannot fully

Table 3: The performance of semi-supervised NER on the CoNLL-2003 test data, using various embedding features. † DenseEmb refers to the method used by Turian et al. (2010), i.e., the direct use of the dense and continuous embeddings.

exploit the potential of word embeddings. The compound cluster features (ClusterEmb) also outperform the DenseEmb. The same result is also shown in (Yu et al., 2013). Further, the distributional prototype features (DistPrototype) achieve the best performance among the three approaches (1.23% higher than DenseEmb).

We should note that the feature templates used for BinarizedEmb and DistPrototype are merely unigram features. However, for ClusterEmb, we form more complex features by combining the clusters of the context words. We also consider different number of clusters n, to take advantage of the different granularities. Consequently, the dimension of the cluster features is much higher than that of BinarizedEmb and DistPrototype.

We further combine the proposed features to see if they are complementary to each other. As shown in Table 3, the cluster and distributional prototype features are the most complementary, whereas the binarized embedding features seem to have large overlap with the distributional prototype features. By combining the cluster and distributional prototype features, we further push the performance to 88.11%, which is nearly two points higher than the performance of the dense embedding features (86.21%).[9]

We also compare the proposed features with the Brown cluster features. As shown in Table 3, the distributional prototype features alone achieve comparable performance with the Brown clusters. When the cluster and distributional prototype features are used together, we outperform the Brown clusters. This result is inspiring because we show that the embedding features indeed have stronger expressing power than the Brown clusters, as desired. Finally, by combining the Brown cluster features and the proposed embedding features, the performance can be improved further (88.58%). The binarized embedding features are not included in the final compound features because they are almost overlapped with the distributional prototype features in performance.

We also summarize some of the reported benchmarks that utilize unlabeled data (with no gazetteers used), including the Stanford NER tagger (Finkel et al. (2005) and Krishnan and Manning (2006)) with distributional similarity features. Ando and Zhang (2005) use unlabeled data for constructing auxiliary problems that are expected to capture a good feature representation of the target problem. Collobert et al. (2011) adjust the feature embeddings according to the specific task in a deep neural network architecture. We can see that both Ando and Zhang (2005) and Collobert et al. (2011) learn *task-specific* lexical features, which is similar to the proposed *distributional prototype* method in our study. We suggest this to be the main reason for the superiority of these methods.

Another advantage of the proposed discrete features over the dense continuous features is tagging efficiency. Table 4 shows the running time using different kinds of embedding features. We achieve a significant reduction of the tagging time per sentence when using the discrete features. This is mainly due to the dense/sparse battle. Although the dense embedding features are low-dimensional, the feature vector for each word is much denser than in the sparse and discrete feature space. Therefore, we actually need much more computation during decoding. Similar results can be observed in the comparison of the DistPrototype and ClusterEmb features, since the density of the DistPrototype features is higher. It is possible

[9] Statistical significant with p-value < 0.001 by two-tailed t-test.

to accelerate the DistPrototype, by increasing the threshold of $DistSim(z, w)$. However, this is indeed an issue of trade-off between efficiency and accuracy.

5.3 Analysis

In this section, we conduct analyses to show the reasons for the improvements.

5.3.1 Rare words

As discussed by Turian et al. (2010), much of the NER F1 is derived from decisions regarding rare words. Therefore, in order to show that the three proposed embedding features have stronger ability for handling rare words, we first conduct analysis for the tagging errors of words with different frequency in the unlabeled data. We assign the word frequencies to several buckets, and evaluate the per-token errors that occurred in each bucket. Results are shown in Figure 2. In most cases, all three embedding features result in fewer errors on rare words than the direct use of dense continuous embedding features.

Interestingly, we find that for words that are extremely rare (0–256), the binarized embedding features incur significantly fewer errors than other approaches. As we know, the embeddings for the rare words are close to their initial value, because they received few updates during training. Hence, these words are not fully trained. In this case, we would like to omit these features because their embeddings are not even trustable. However, all embedding features that we proposed except BinarizedEmb are unable to handle this.

In order to see how much we have utilized the embedding features in BinarizedEmb, we calculate the sparsity of the binarized embedding vectors, i.e., the ratio of zero values in each vector (Section 3.2). As demonstrated in Figure 3, the sparsity-frequency curve has good properties: higher sparsity for very rare words and very frequent words, while lower sparsity for mid-frequent words. It indicates that for words that are very rare or very frequent, BinarizedEmb just omit most of the features. This is reasonable also for the very frequent words, since they usually have rich and diverse context distributions and their embeddings cannot be well learned by our models (Huang et al., 2012).

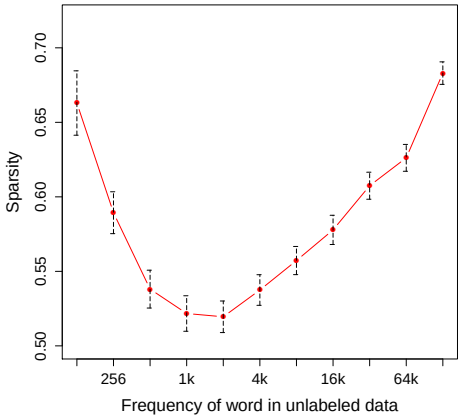

Figure 3: Sparsity (with confidence interval) of the binarized embedding vector w.r.t. word frequency in the unlabeled data.

Figure 2(b) further supports our analysis. BinarizedEmb also reduce much of the errors for the highly frequent words (32k-64k).

As expected, the distributional prototype features produce fewest errors in most cases. The main reason is that the prototype features are *task-specific*. The prototypes are extracted from the training data and contained indicative information of the target labels. By contrast, the other embedding features are simply derived from general word representations and are not specialized for certain tasks, such as NER.

5.3.2 Linear Separability

Another reason for the superiority of the proposed embedding features is that the high-dimensional discrete features are more linear separable than the low-dimensional continuous embeddings. To verify the hypothesis, we further carry out experiments to analyze the linear separability of the proposed discrete embedding features against dense continuous embeddings.

We formalize this problem as a binary classification task, to determine whether a word is an NE or not (NE identification). The linear support vector machine (SVM) is used to build the classifiers, using different embedding features respec-

Table 5: Performance of the NE/non-NE classification on the CoNLL-2003 development dataset using different embedding features.

tively. We use the LIBLINEAR tool (Fan et al., 2008) as our SVM implementation. The penalty parameter C is tuned from 0.1 to 1.0 on the development dataset. The results are shown in Table 5. As we can see, NEs and non-NEs can be better separated using ClusterEmb or DistPrototype features. However, the BinarizedEmb features perform worse than the direct use of word embedding features. The reason might be inferred from the third column of Table 5. As demonstrated in Wang and Manning (2013), linear models are more effective in high-dimensional and discrete feature space. The dimension of the BinarizedEmb features remains small (500), which is merely twice the DenseEmb. By contrast, feature dimensions are much higher for ClusterEmb and DistPrototype, leading to better linear separability and thus can be better utilized by linear models.

We notice that the DistPrototype features perform significantly worse than ClusterEmb in NE identification. As described in Section 3.4, in previous experiments, we automatically extracted prototypes for each label, and propagated the information via distributional similarities. Intuitively, the prototypes we used should be more effective in determining fine-grained NE types than identifying whether a word is an NE. To verify this, we extract new prototypes considering only two labels, namely, NE and non-NE, using the same metric in Section 3.4. As shown in the last row of Table 5, higher performance is achieved.

6 Related Studies

Semi-supervised learning with generalized word representations is a simple and general way of improving supervised NLP systems. One common approach for inducing generalized word representations is to use clustering (e.g., Brown clustering) (Miller et al., 2004; Liang, 2005; Koo et al., 2008; Huang and Yates, 2009).

Aside from word clustering, word embeddings have been widely studied. Bengio et al. (2003) propose a feed-forward neural network based language model (NNLM), which uses an embedding layer to map each word to a dense continuous-valued and low-dimensional vector (parameters), and then use these vectors as the input to predict the probability distribution of the next word. The NNLM can be seen as a joint learning framework for language modeling and word representations.

Alternative models for learning word embeddings are mostly inspired by the feed-forward NNLM, including the Hierarchical Log-Bilinear Model (Mnih and Hinton, 2008), the recurrent neural network language model (Mikolov, 2012), the C&W model (Collobert et al., 2011), the log-linear models such as the CBOW and the Skip-

gram model (Mikolov et al., 2013a; Mikolov et al., 2013b).

Aside from the NNLMs, word embeddings can also be induced using spectral methods, such as latent semantic analysis and canonical correlation analysis (Dhillon et al., 2011). The spectral methods are generally faster but much more memory-consuming than NNLMs.

There has been a plenty of work that exploits word embeddings as features for semi-supervised learning, most of which take the continuous features directly in linear models (Turian et al., 2010; Guo et al., 2014). Yu et al. (2013) propose compound k-means cluster features based on word embeddings. They show that the high-dimensional discrete cluster features can be better utilized by linear models such as CRF. Wu et al. (2013) further apply the cluster features to transition-based dependency parsing.

7 Conclusion and Future Work

This paper revisits the problem of semi-supervised learning with word embeddings. We present three different approaches for a careful comparison and analysis. Using any of the three embedding features, we obtain higher performance than the direct use of continuous embeddings, among which the distributional prototype features perform the best, showing the great potential of word embeddings. Moreover, the combination of the proposed embedding features provides significant additive improvements.

We give detailed analysis about the experimental results. Analysis on rare words and linear separability provides convincing explanations for the performance of the embedding features.

For future work, we are exploring a novel and a theoretically more sounding approach of introducing embedding kernel into the linear models.

Acknowledgments

We are grateful to Mo Yu for the fruitful discussion on the implementation of the cluster-based embedding features. We also thank Ruiji Fu, Meishan Zhang, Sendong Zhao and the anonymous reviewers for their insightful comments and suggestions. Abstract

Punctuation prediction and disfluency prediction can improve downstream natural language processing tasks such as machine translation and information extraction. Combining the two tasks can potentially improve the efficiency of the overall pipeline system and reduce error propagation. In this work[1], we compare various methods for combining punctuation prediction (PU) and disfluency prediction (DF) on the Switchboard corpus. We compare an isolated prediction approach with a cascade approach, a rescoring approach, and three joint model approaches. For the cascade approach, we show that the soft cascade method is better than the hard cascade method. We also use the cascade models to generate an n-best list, use the bi-directional cascade models to perform rescoring, and compare that with the results of the cascade models. For the joint model approach, we compare mixed-label Linear-chain Conditional Random Field (LCRF), cross-product LCRF and 2-layer Factorial Conditional Random Field (FCRF) with soft-cascade LCRF. Our results show that the various methods linking the two tasks are not significantly different from one another, although they perform better than the isolated prediction method by 0.5–1.5% in the F1 score. Moreover, the clique order of features also shows a marked difference.

1 Introduction

The raw output from automatic speech recognition (ASR) systems does not have sentence boundaries or punctuation symbols. Spontaneous speech also contains a significant proportion of disfluency. Researchers have shown that splitting input sequences into sentences and adding in punctuation symbols improve machine translation (Favre et al., 2008; Lu and Ng, 2010). Moreover, disfluencies in speech also introduce noise in downstream tasks like machine translation and information extraction (Wang et al., 2010). Thus, punctuation prediction (PU) and disfluency prediction (DF) are two important post-processing tasks for automatic speech recognition because they improve not only the readability of ASR output, but also the performance of downstream Natural Language Processing (NLP) tasks.

The task of punctuation prediction is to insert punctuation symbols into conversational speech texts. Punctuation prediction on long, unsegmented texts also achieves the purpose of sentence boundary prediction, because sentence boundaries are identified by sentence-end punctuation symbols: periods, question marks, and exclamation marks. Consider the following example,

How do you feel about the Viet Nam War ? Yeah , I saw that as well .

The question mark splits the sequence into two sentences. This paper deals with this task which is more challenging than that on text that has already been split into sentences.

The task of disfluency prediction is to identify word tokens that are spoken incorrectly due to speech disfluency. There are two main types of disfluencies: filler words and edit words. Filler words mainly include filled pauses (e.g., 'uh', 'um') and discourse markers (e.g., "I mean", "you know"). As they are insertions in spontaneous speech to indicate pauses or mark boundaries in discourse, they do not convey useful content information. Edit words are words that are spoken wrongly and then corrected by the speaker. For example, consider the following utterance:

[1]The research reported in this paper was carried out as part of the PhD thesis research of Xuancong Wang at the NUS Graduate School for Integrated Sciences and Engineering.

Edit Filler Repair

I want a flight ~~*to Boston*~~ *uh I mean* to Denver

The phrase "to Boston" forms the edit region to be replaced by "to Denver". The words "uh I mean" are filler words that serve to cue the listener about the error and subsequent corrections.

The motivation of combining the two tasks can be illustrated by the following two utterances:

~~*I am uh*~~ *I am not going with you .*

I am sorry . I am not going with you .

Notice that the bi-gram *"I am"* is repeated in both sentences. For the first utterance, if punctuation prediction is performed first, it might break the utterance both before and after "uh" so that the second-stage disfluency prediction will treat the whole utterance as three sentences, and thus may not be able to detect any disfluency because each one of the three sentences is legitimate on its own. On the other hand, for the second utterance, if disfluency prediction is performed first, it might mark *"I am sorry"* as disfluent in the first place and remove it before passing into the second-stage punctuation prediction. Therefore, no matter which task is performed first, certain utterances can always cause confusion.

There are many ways to combine the two tasks. For example, we can perform one task first followed by another, which is called the cascade approach. We can also mix the labels, or take the cross-product of the labels, or use joint prediction models. In this paper, we study the mutual influence between the two tasks and compare a variety of common state-of-the-art joint prediction techniques on this joint task.

In Section 2, we briefly introduce previous work on the two tasks. In Section 3, we describe our baseline system which performs punctuation and disfluency prediction separately (i.e., in isolation). In Section 4, we compare the soft cascade approach with the hard cascade approach. We also examine the effect of task order, i.e., performing which task first benefits more. In Section 5, we compare the cascade approach with bi-directional n-best rescoring. In Section 6, we compare the 2-layer Factorial CRF (Sutton et al., 2007) with the cross-product LCRF (Ng and Low, 2004), mixed-label LCRF (Stolcke et al., 1998), the cascade approach, and the baseline isolated prediction. Section 7 gives a summary of our overall findings. Section 8 gives the conclusion.

2 Previous Work

There were many works on punctuation prediction or disfluency prediction as an isolated task. For punctuation prediction, Huang and Zweig (2002) used maximum entropy model; Christensen et al. (2001) used finite state and multi-layer perceptron method; Liu et al. (2005) used conditional random fields; Lu and Ng (2010) proposed using dynamic conditional random fields for joint sentence boundary type and punctuation prediction; Wang et al. (2012) has added prosodic features for the dynamic conditional random field approach and Zhang et al. (2013) used transition-based parsing.

For disfluency prediction, Shriberg et al. (1997) uses purely prosodic features to perform the task. Johnson and Charniak (2004) proposed a TAG-based (Tree-Adjoining Grammar) noisy channel model. Maskey et al. (2006) proposed a phrase-level machine translation approach for this task. Georgila (2009) used integer linear programming (ILP) which can incorporate local and global constraints. Zwarts and Johnson (2011) has investigated the effect of using extra language models as features in the reranking stage. Qian and Liu (2013) proposed using weighted Max-margin Markov Networks (M3N) to balance precision and recall to further improve the F1-score. Wang et al. (2014) proposed a beam-search decoder which integrates M3N and achieved further improvements.

There were also some works that addressed both tasks. Liu et al. (2006) and Baron et al. (1998) carried out sentence unit (SU) and disfluency prediction as separate tasks. The difference between SU prediction and punctuation prediction is only in the non-sentence-end punctuation symbols such as commas. Stolcke et al. (1998) mixed sentence boundary labels with disfluency labels so that they do not predict punctuation on disfluent tokens. Kim (2004) performed joint SU and Interruption Point (IP) prediction, deriving edit and filler word regions from predicted IPs using a rule-based system as a separate step.

In this paper, we treat punctuation prediction and disfluency prediction as a joint prediction task, and compare various state-of-the-art joint prediction methods on this task.

3 The Baseline System

3.1 Experimental Setup

We use the Switchboard corpus (LDC99T42) in our experiment with the same train/develop/test split as (Qian and Liu, 2013) and (Johnson and Charniak, 2004). The corpus statistics are shown in Table 1. Since the proportion of exclamation marks and incomplete SU boundaries is too small, we convert all exclamation marks to periods and remove all incomplete SU boundaries (treat as no punctuation). In the Switchboard corpus, the utterances of each speaker have already been segmented into short sentences when used in (Qian and Liu, 2013; Johnson and Charniak, 2004). In our work, we concatenate the utterances of each speaker to form one long sequence of words for use as the input to punctuation prediction and disfluency prediction. This form of input where, utterances are not pre-segmented into short sentences, better reflects the real-world scenarios and provides a more realistic test setting for punctuation and disfluency prediction. Punctuation prediction also gives rise to sentence segmentation in this setting.

Data set	train	develop	test
# of tokens	1.3M	85.9K	65.5K
# of sentences	173.7K	10.1K	7.9K
# of sequences*	1854	174	134
# of edit words	63.6K	4.7K	3.7K
# of filler words	137.1K	9.6K	7.3K
# of Commas	52.7K	1.8K	2.1K
# of Periods	97.6K	6.5K	4.5K
# of Questions	6.8K	363	407
# of Exclamations	67	4	1
# of Incomplete	189	2	0

Table 1: Corpus statistics for all the experiments. *: each conversation produces two long/sentence-joined sequences, one from each speaker.

Our baseline system uses M3N (Taskar et al., 2004), one M3N for punctuation prediction and the other for disfluency prediction. We use the same set of punctuation and disfluency labels (as shown in Table 2) throughout this paper. To compare the various isolated, cascade, and joint prediction models, we use the same feature templates for both tasks as listed in Table 3. Since some of the feature templates require predicted filler labels and part-of-speech (POS) tags, we have trained a POS tagger and a filler predictor both using CRF (i.e., using the same approach as that in Qian and Liu (2013)). The same predicted POS tags and fillers are used for feature extraction in all the experiments in this paper for a fair comparison. The degradation on disfluency prediction due to the concatenation of utterances of each speaker is shown in Table 4. The pause duration features are extracted by running forced alignment on the corresponding Switchboard speech corpus (LDC97S62).

Task	Label	Meaning
Disfluency prediction	*E*	edit word
	F	filler word
	O	otherwise / fluent
Punctuation prediction	*Comma*	comma
	Period	full-stop
	QMark	question mark
	None	no punctuation

Table 2: Labels for punctuation prediction and disfluency prediction.

3.2 Features

We use the standard NLP features such as $F(w_{-1}w_0$='so that'), i.e., the word tokens at the previous and current node position are 'so' and 'that' respectively. Each feature is associated with a *clique order*. For example, since the clique order of this feature template is 2 (see Table 3), its feature functions can be $f(w_{-1}w_0$='so that', y_0='*F*', y_{-1}='*O*', $t)$. The example has a value of 1 only when the words at node $t-1$ and t are 'so that', and the labels at node t and $t-1$ are *'F'* and *'O'* respectively. The maximum length of the y history is called the *clique order* of the feature (in this feature function, it is 2 since only y_0 and y_{-1} are covered). The feature templates are listed in Table 3. w_i refers to the word at the i^{th} position relative to the current node; *window size* is the maximum span of words centered at the current word that the template covers, e.g., $w_{-1}w_0$ with a window size of 9 means $w_{-4}w_{-3}$, $w_{-3}w_{-2}$, ..., w_3w_4; p_i refers to the POS tag at the i^{th} position relative to the current node; $w_{i\sim j}$ refers to any word from the i^{th} position to the j^{th} position relative to the current node, this template can capture word pairs which can potentially indicate a repair, e.g., "was ... is ...", the speaker may have spoken any

word(s) in between and it is very difficult for the standard n-gram features to capture all possible variations; $w_{i,\neq F}$ refers to the i^{th} non-filler word with respect to the current position, this template can extract n-gram features skipping filler words; the multi-pair comparison function $I(a, b, c, ...)$ indicates whether each pair (a and b, b and c, and so on) is identical, for example, if $a = b \neq c = d$, it will output "101" ('1' for being equal, '0' for being unequal), this feature template can capture consecutive word/POS repetitions which can further improve upon the standard repetition features; and *ngram-score* features are the natural logarithm of the following 8 probabilities: $P(w_{-3}, w_{-2}, w_{-1}, w_0)$, $P(w_0|w_{-3}, w_{-2}, w_{-1})$, $P(w_{-3}, w_{-2}, w_{-1})$, $P(\langle/s\rangle|w_{-3}, w_{-2}, w_{-1})$, $P(w_{-3})$, $P(w_{-2})$, $P(w_{-1})$ and $P(w_0)$ (where "$\langle/s\rangle$" denotes sentence-end).

Feature Template	Window Size	Clique Order
w_0	9	1
$w_{-1}w_0$	9	2
$w_{-2}w_{-1}w_0$	9	2
p_0	9	1
$p_{-1}p_0$	9	2
$p_{-2}p_{-1}p_0$	9	2
$w_0w_{-6\sim-1}$, $w_0w_{1\sim6}$	1	1
$I(w_i, w_j)$	21	2
$I(w_i, w_j, w_{i+1}, w_{j+1})$	21	2
$I(w_i, w_j)(w_i$ if w_i=$w_j)$	21	2
$I(p_i, p_j)$	21	3
$I(p_i, p_j, p_{i+1}, p_{j+1})$	21	3
$I(p_i, p_j)(p_i$ if p_i=$p_j)$	21	3
$p_{-1}w_0$	5	2
$w_{-1}p_0$	5	2
$w_{-2,\neq F}w_{-1,\neq F}$	1	2
$w_{-3,\neq F}w_{-2,\neq F}w_{-1,\neq F}$	1	2
$p_{-2,\neq F}p_{-1,\neq F}$	1	2
$p_{-3,\neq F}p_{-2,\neq F}p_{-1,\neq F}$	1	2
ngram-score features	1	3
pause duration before w_0	1	3
pause duration after w_0	1	3
transitions	1	3

Table 3: Feature templates for disfluency prediction, or punctuation prediction, or joint prediction for all the experiments in this paper.

The performance of the system can be further improved by adding additional prosodic features (Savova and Bachenko, 2003; Shriberg et al., 1998; Christensen et al., 2001) apart from pause durations. However, since in this work we focus on model-level comparison, we do not use other prosodic features for simplicity.

3.3 Evaluation and Results

Experiment	F1 (PU)	F1 (DF)
Short sentences, with precision/recall balancing, clique order of features up to 3, and labels {*E,F,O*}	N.A.	84.7
Short sentences, with precision/recall balancing, clique order of features up to 3, and labels {*E,O*}	N.A.	84.3
Join utterances into long sentences	71.1	79.2
Join utterances into long sentences + remove precision/recall balancing	71.1	78.2
Join utterances into long sentences + remove precision/recall balancing + reduce clique order of all features	68.5	76.4

Table 4: Baseline results showing the degradation by joining utterances into long sentences, removing precision/recall balancing, and reducing the clique order of features. All models are trained using M3N.

We use the standard F1 score as our evaluation metric and this is similar to that in Qian and Liu (2013). For training, we set the frequency pruning threshold to 5 to control the number of parameters. The regularization parameter is tuned on the development set. Since the toolkits used to run different experiments have slightly different limitations, in order to make fair comparisons across different toolkits, we do not use weighting to balance precision and recall when training M3N and we have reduced the clique order of transition features to two and all the other features to one in some of our experiments. Since the performance of filler word prediction on this dataset is already very high, (>97%), we only focus on the F1 score of edit word prediction in this paper when reporting the performance of disfluency prediction. Table 4 shows our baseline results. Our preliminary study shows the following gen-

eral trends: (i) for disfluency prediction: joining utterances into long sentences will cause a 5–6% drop in F1 score; removing precision/recall balance in M3N will cause about 1% drop in F1 score; and reducing the clique order in Table 3 will cause about 1–2% drop in F1 score; and (ii) for punctuation prediction: removing precision/recall balance in M3N will cause negligible drop in F1 score; and reducing clique order will cause about 2–3% drop in F1 score. Conventionally, the degradation from reducing the clique orders can be mostly compensated by using the BIES (Begin, Inside, End, and Single) labeling scheme. In this work, for consistency and comparability across various experiments, we will stick to the same set of labels in Table 2.

4 The Cascade Approach

Instead of decomposing the joint prediction of punctuation and disfluency into two independent tasks, the cascade approach considers one task to be conditionally dependent on the other task such that the predictions are performed in sequence, where the results from the first step is used in the second step. In this paper, we compare two types of cascade: hard cascade versus soft cascade.

4.1 Hard Cascade

For the hard cascade, we use the output from the first step to modify the input sequence *before* extracting features for the second step. For PU→DF (PUnctuation prediction followed by DisFluency prediction), we split the input sequence into sentences according to the sentence-end punctuation symbols predicted by the first step, and then perform the DF prediction on the short/sentence-split sequences in the second step. For DF→PU, we remove the edit and filler words predicted by the first step, and then predict the punctuations using the cleaned-up input sequence. The hard cascade method may be helpful because the disfluency prediction on short/sentence-split sequences is better than on long/sentence-joined sequences (see the second and third rows in Table 4). On the other hand, the punctuation prediction on fluent text is more accurate than that on non-fluent text based on our preliminary study.

For this experiment, four models are trained using M3N without balancing precision/recall. For the first step, two models are trained on long/sentence-joined sequences with disfluent tokens - one for PU prediction and the other for DF prediction. These are simply the isolated baseline systems. For the second step, the DF prediction model is trained on the short/sentence-split sequences with disfluent tokens while the PU prediction model is trained on the long/sentence-joined sequences with disfluent tokens removed. Note that in the second step of DF→PU, punctuation labels are predicted only for the fluent tokens since the disfluent tokens predicted by the first step has already been removed. Therefore, during evaluation, if the first step makes a false positive by predicting a fluent token as an edit or filler, we set its punctuation label to the neutral label, *None*. All the four models are trained using the same feature templates as shown in Table 3. The regularization parameter is tuned on the development set.

4.2 Soft Cascade

For the soft cascade method, we use the labels predicted from the first step as additional features for the second step. For PU→DF, we model the joint probability as:

$$P(\text{DF}, \text{PU}|\mathbf{x}) = P(\text{PU}|\mathbf{x}) \times P(\text{DF}|\text{PU}, \mathbf{x}) \quad (1)$$

Likewise, we model the joint probability for DF→PU as:

$$P(\text{DF}, \text{PU}|\mathbf{x}) = P(\text{DF}|\mathbf{x}) \times P(\text{PU}|\text{DF}, \mathbf{x}) \quad (2)$$

For this experiment, four models are trained using M3N without balancing precision/recall. As with the case of hard cascade, the two models used in the first step are simply the isolated baseline systems. For the second step, in addition to the feature templates in Table 3, we also pass on the labels (at the previous, current and next position) predicted by the first step as three third-order-clique features. We also tune the regularization parameter on the development set to obtain the best model.

4.3 Experimental Results

Table 5 compares the performance of the hard and soft cascade methods with the isolated baseline systems. In addition, we have also included the results of using the true labels in place of the labels predicted by the first step to indicate the upper-bound performance of the cascade approaches. The results show that both the hard and soft cascade methods outperform the baseline systems, with the latter giving a better performance

Experiment	F1 for PU	F1 for DF
isolated baseline	71.1	78.2
hard cascade	71.2	79.1
hard cascade (using true labels)	72.6	83.5
soft cascade	71.6	79.6
soft cascade (using true labels)	72.1	82.7

Table 5: Performance comparison between the hard cascade method and the soft cascade method with respect to the baseline isolated prediction. All models are trained using M3N without balancing precision and recall.

(statistical significance at p=0.01). However, hard cascade has a higher upper-bound than soft cascade. This observation can be explained as follows.

For hard cascade, the input sequence is modified prior to feature extraction. Therefore, many of the features generated by the feature templates given in Table 3 will be affected by these modifications. So, provided that the modifications are based on the correct information, the resulting features will not contain unwanted artefacts caused by the absence of the sentence boundary information for the presence of disfluencies. For example, in *"do you do you feel that it was worthy"*, the punctuation prediction system tends to insert a sentence-end punctuation after the first *"do you"* because the speaker restarts the sentence.

If the disfluency was correctly predicted in the first step, then the hard cascade method would have removed the first *"do you"* and eliminated the confusion. Similarly, in "*I 'm sorry . I 'm not going with you tomorrow .* ", the first "*I 'm*" is likely to be incorrectly detected as disfluent tokens since consecutive repetitions are a strong indication of disfluency. In the case of hard cascade, PU→DF, the input sequence would have been split into sentences and the repetition feature would not be activated. However, since the hard cascade method has a greater influence on the features for the second step, it is also more sensitive to the prediction errors from the first step.

Another observation from Table 5 is that the improvement of the soft cascade over the isolate baseline is much larger on DF (1.4% absolute) than that on PU (only 0.5% absolute). The same holds true for the hard cascade, despite the fact that there are more DF labels than PU labels in this corpus (see Table 1) and the first step prediction is more accurate on DF than on PU. This suggests that their mutual influence is not symmetrical, in the way that the output from punctuation prediction provides more useful information for disfluency prediction than the other way round.

5 The Rescoring Approach

In Section 4, we have described that the two tasks can be cascaded in either order, i.e., PU→DF and DF→PU. However, the performance of the second step greatly depends on that of the first step. In order to reduce sensitivity to the errors made in the first step, one simple approach is to propagate multiple hypotheses from the first step to the second step to obtain a list of joint hypotheses (with both the DF and PU labels). We then rerank these hypotheses based on the joint probability and pick the best. We call this the rescoring approach. From (1) and (2), the joint probabilities can be expressed in terms of the probabilities generated by four models: $P(\text{PU}|\mathbf{x})$, $P(\text{DF}|\text{PU}, \mathbf{x})$, $P(\text{DF}|\mathbf{x})$, and $P(\text{PU}|\text{DF}, \mathbf{x})$. We can combine the four models to form the following joint probability function for rescoring:

$$P(\text{DF}, \text{PU}|\mathbf{x}) = P(\text{DF}|\mathbf{x})^{\alpha_1} \times P(\text{PU}|\text{DF}, \mathbf{x})^{\alpha_2} \times P(\text{PU}|\mathbf{x})^{\beta_1} \times P(\text{DF}|\text{PU}, \mathbf{x})^{\beta_2}$$

where α_1, α_2, β_1, and β_2 are used to weight the relative importance between (1) and (2); and between the first and second steps. In practice, the probabilities are computed in the log domain where the above expression becomes a weighted sum of the log probabilities. A similar rescoring approach using two models is described in Shi and Wang (2007).

The experimental framework is shown in Figure 1. For PU→DF, we first use $P(\text{PU}|\mathbf{x})$ to generate an n-best list. Then, for each hypothesis in the n-best list, we use $P(\text{DF}|\text{PU}, \mathbf{x})$ to obtain another n-best list. So we have n^2-best joint hypotheses. We do the same for DF→PU to obtain another n^2-best joint hypotheses. We rescore the $2n^2$-best list using the four models. The four weights α_1, α_2, β_1, and β_2 are tuned to optimize the overall F1 score on the development set. We used the MERT (minimum-error-rate training, (Och, 2003)) algorithm to tune the weights. We also vary the size of n.

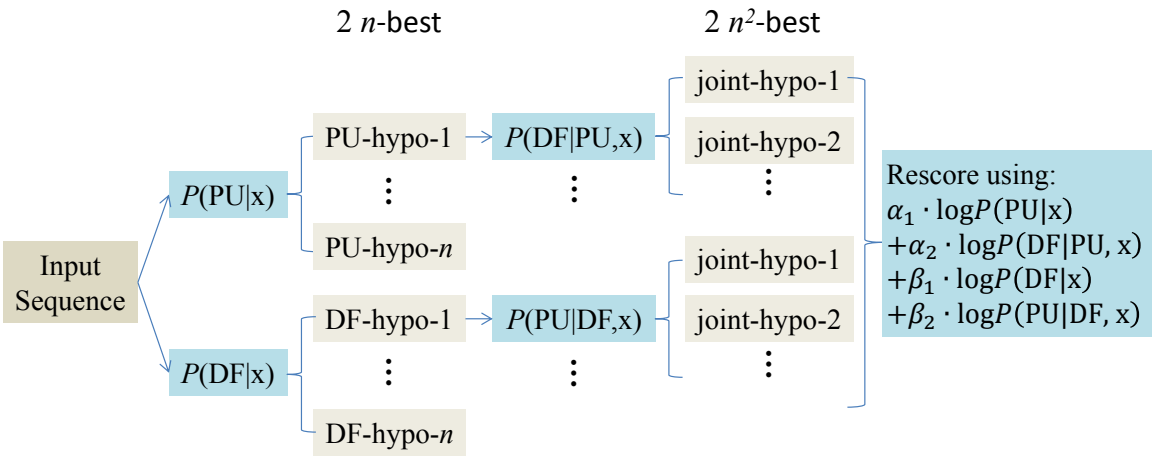

Figure 1: Illustration of the rescoring pipeline framework using the four M3N models used in the soft-cascade method: $P(\text{PU}|\mathbf{x})$, $P(\text{DF}|\text{PU}, \mathbf{x})$, $P(\text{DF}|\mathbf{x})$ and $P(\text{PU}|\text{DF}, \mathbf{x})$

The results shown in Table 6 suggest that the rescoring method does not improve over the soft-cascade baseline. This can be due to the fact that we are using the same four models for the soft-cascade and the rescoring methods. It may be possible that the information contained in the two models for the soft-cascade PU→DF mostly overlaps with the information contained in the other two models for the soft-cascade DF→PU since all the four models are trained using the same features. Thus, no additional information is gained by combining the four models.

6 The Joint Approach

In this section, we compare 2-layer FCRF (Lu and Ng, 2010) with mixed-label LCRF (Stolcke et al., 1998) and cross-product LCRF on the joint prediction task. For the 2-layer FCRF, we use punctuation labels for the first layer and disfluency labels for the second layer (see Table 2). For the mixed-label LCRF, we split the neutral label $\{O\}$ into $\{$*Comma, Period, QMark, None*$\}$ so that we have six labels in total, $\{$*E, F, Comma, Period, QMark, None*$\}$. In this approach, disfluent tokens do not have punctuation labels because in real applications, if we just want to get the cleaned-up/fluent text with punctuations, we do not need to predict punctuations on disfluent tokens as they will be removed during the clean-up process. Since this approach does not predict punctuation labels on disfluent tokens, its punctuation F1 score is only evaluated on those fluent tokens. For the cross-product LCRF, we compose each of the three disfluency labels with the four punctuation labels to get 12 PU-DF-joint labels (Ng and Low, 2004). Figure 2 shows a comparison of these three models in the joint prediction of punctuation and disfluency. All the LCRF and FCRF models are trained using the GRMM toolkit (Sutton, 2006). We use the same feature templates (Table 3) to generate all the features for the toolkit. However, to reduce the training time, we have set clique order to 2 for the transitions and 1 for all other features. We tune the Gaussian prior variance on the development set for all the experiments to obtain the best model for testing.

Table 7 shows the comparison of results. On DF alone, the improvement of the cross-product LCRF over the mixed-label LCRF, and the improvement of the mixed-label LCRF over the isolated baseline are not statistically significant. However, if we test the statistical significance on the overall performance of both PU and DF, both the 2-layer FCRF and the cross-product LCRF perform better than the mixed-label LCRF. And we also obtain the same conclusion as Stolcke et al. (1998) that mixed-label LCRF performs better than isolated prediction. However, for the comparison between the 2-layer FCRF and the cross-product LCRF, although the 2-layer FCRF performs better than the cross-product LCRF on disfluency prediction, it does worse on punctuation prediction. Overall, the two methods perform about the same, their difference is not statistically significant. In addition, both the 2-layer FCRF and the cross-product LCRF slightly outperform the soft cascade method (statistical significance at p=0.04).

Experiment	F1 for PU	F1 for DF
isolated baseline	71.1	78.2
soft-cascade	71.6	79.6
rescore n=1	71.5 (72.5)	79.3 (81.1)
rescore n=2	71.2 (73.0)	79.3 (81.8)
rescore n=3	71.2 (73.3)	79.9 (82.6)
rescore n=4	71.2 (73.6)	79.8 (82.8)
rescore n=5	71.2 (73.9)	79.4 (83.3)
rescore n=6	71.1 (74.0)	79.6 (83.5)
rescore n=8	71.2 (74.2)	79.8 (84.0)
rescore n=10 *	71.2 (74.4)	79.8 (84.3)
rescore n=12	71.1 (74.5)	79.7 (84.6)
rescore n=15	71.2 (74.8)	79.8 (84.9)
rescore n=18	71.1 (74.9)	79.7 (85.1)
rescore n=25	70.7 (75.2)	79.3 (85.5)

Table 6: Performance comparison between the rescoring method and the soft-cascade method with respect to the baseline isolated prediction. The rescoring is done on $2n^2$ hypotheses. All models are trained using M3N without balancing precision and recall. Figures in the bracket are the oracle F1 scores of the $2n^2$ hypotheses. *:on the development set, the best overall result is obtained at $n = 10$.

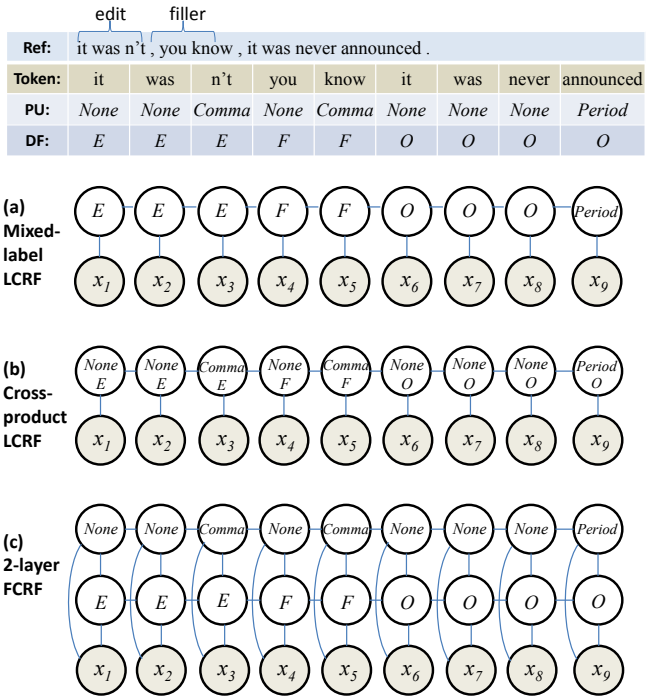

Figure 2: Illustration using (a) mixed-label LCRF; (b) cross-product LCRF; and (c) 2-layer FCRF, for joint punctuation (PU) and disfluency (DF) prediction. Shaded nodes are observations and unshaded nodes are variables to be predicted.

7 Discussion

In this section, we will summarise our observations based on the empirical studies that we have conducted in this paper.

Firstly, punctuation prediction and disfluency prediction do influence each other. The output from one task does provide useful information that can improve the other task. All the approaches studied in this work, which link the two tasks together, perform better than their corresponding isolated prediction baseline.

Experiment	F1 for PU	F1 for DF
isolated baseline	68.7	77.0
soft cascade	69.0	77.5
mixed-label LCRF	69.0	77.2
cross-product LCRF	69.9	77.3
2-layer FCRF	69.2	77.8

Table 7: Performance comparison among 2-layer FCRF, mixed-label LCRF and cross-product LCRF, with respect to the soft-cascade and the isolated prediction baseline. All models are trained using GRMM (Sutton, 2006), with reduced clique orders.

Secondly, as compared to the soft cascade, the hard cascade passes more information from the first step into the second step, and thus is much more sensitive to errors in the first step. In practice, unless the first step has very high accuracy, soft cascade is expected to do better than hard cascade.

Thirdly, if we train a model using a fine-grained label set but test it on the same coarse-grained label set, we are very likely to get improvement. For example:

- The edit word F1 for mixed edit and filler prediction using $\{E, F, O\}$ is better than that for edit prediction using $\{E, O\}$ (see the second and third rows in Table 4). This is because the former actually splits the O in the latter into F and O. Thus, it has a finer label granularity.

- Disfluency prediction using mixed-label LCRF (using label set $\{E, F, Comma, Period, Question, None\}$) performs better than that using isolated LCRF (using label set $\{E, F, O\}$) (see the second and fourth rows in Table 7). This is because the former dis-

tinguishes between different punctuations for fluent tokens and thus has a finer label granularity.

- Both the cross-product LCRF and 2-layer FCRF perform better than mixed-label LCRF because the former two distinguish between different punctuations for edit, filler and fluent tokens while the latter distinguishes between different punctuations only for fluent tokens. Thus, the former has a much finer label granularity.

From the above comparisons, we can see that increasing the label granularity can greatly improve the accuracy of a model. However, this may also increase the model complexity dramatically, especially when higher clique order is used. Although the joint approach (2-layer FCRF and cross-product LCRF) are better than the soft-cascade approach, they cannot be easily scaled up to using higher order cliques, which greatly limits their potential. In practice, the soft cascade approach offers a simpler and more efficient way to achieve a joint prediction of punctuations and disfluencies.

8 Conclusion

In general, punctuation prediction and disfluency prediction can improve downstream NLP tasks. Combining the two tasks can potentially improve the efficiency of the overall framework and minimize error propagation. In this work, we have carried out an empirical study on the various methods for combining the two tasks. Our results show that the various methods linking the two tasks perform better than the isolated prediction. This means that punctuation prediction and disfluency prediction do influence each other, and the prediction outcome in one task can provide useful information that helps to improve the other task. Specifically, we compare the cascade models and the joint prediction models. For the cascade approach, we show that soft cascade is less sensitive to prediction errors in the first step, and thus performs better than hard cascade. For joint model approach, we show that, when clique order of one is used, all the three joint model approaches perform significantly better than the isolated prediction baseline. Moreover, the 2-layer FCRF and the cross-product LCRF perform slightly better than the mix-label LCRF and the soft-cascade approach, suggesting that modelling at a finer label granularity is potentially beneficial. However, the soft cascade approach is more efficient than the joint approach when a higher clique order is used.

Abstract

We introduce submodular optimization to the problem of training data subset selection for statistical machine translation (SMT). By explicitly formulating data selection as a submodular program, we obtain fast scalable selection algorithms with mathematical performance guarantees, resulting in a unified framework that clarifies existing approaches and also makes both new and many previous approaches easily accessible. We present a new class of submodular functions designed specifically for SMT and evaluate them on two different translation tasks. Our results show that our best submodular method significantly outperforms several baseline methods, including the widely-used cross-entropy based data selection method. In addition, our approach easily scales to large data sets and is applicable to other data selection problems in natural language processing.

1 Introduction

SMT has made significant progress over the last decade, not least due to the availability of increasingly larger data sets. Large-scale SMT systems are now routinely trained on millions of sentences of parallel data, and billions of words of monolingual data for language modeling. Large data sets are often beneficial, but they do create certain other problems. First, they place higher demands on computational resources (storage and compute). Hence, existing software infrastructure may need to be adapted and optimized to handle such large data sets. Second, experimental turn-around time is increased as well, making it more difficult to quickly train, fine-tune, and evaluate novel modeling approaches. Most importantly, however, SMT performance does not increase linearly with the training data size but levels off after a certain point. This is because the additional training data may be noisy, irrelevant to the task at hand, or inherently redundant. Thus, a linear increase in the amount of training data typically leads to a sublinear increase in performance, an effect known as diminishing returns. Several recent papers (Bloodgood and Callison-Burch, 2010; Turchi et al., 2012a; Turchi et al., 2012b) have amply demonstrated this effect.

A way to counteract this is to perform *data subset selection*, i.e., choose a subset of the available training data to optimize a particular quality criterion. One scheme is to select a subset that expresses as much of the information in the original data set as possible - i.e., the data set should be "summarized" by excluding redundant information. Another scheme, popular in the context of SMT, is to subselect the original training set to match the properties of a particular test set.

In this paper, we introduce submodularity for subselecting SMT training data, a methodology that follows both of the above schemes.[1] Submodular functions (Fujishige, 2005) are a class of discrete set functions having the property of diminishing returns. They occur naturally in a wide range of problems in a diverse set of fields including economics, game theory, operations research, circuit theory, and more recently machine learning. Submodular functions share certain properties with convexity (e.g., naturalness and mathematical tractability) although submodularity is still quite distinct from convexity.

We present a novel class of submodular functions particularly suited for SMT subselection and evaluate it against state-of-the-art baseline methods on two different translation tasks, showing that our method outperforms them significantly in most cases. While many approaches to SMT data selection have been developed previously (a detailed overview is provided in Section 3), many of them are heuristic and do not offer performance guarantees. Certain previous approaches, however, have

[1] As far as we know, submodularity has not before been explicitly utilized for SMT subset selection.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 131–141,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

inadvertently made use of submodular methods. This, in addition to our own positive results, provides strong evidence that submodularity is a natural and practical framework for data subset selection in SMT and related fields.

An additional advantage of this framework is that many submodular programs (e.g., the greedy procedure reviewed in Section 2) are fast and scalable to large data sets. By contrast, trying to solve a submodular problem using, say, an integer-linear programming (ILP) procedure, would lead to impenetrable scalability problems.

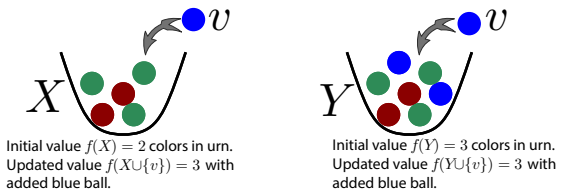

Figure 1: $f(Y)$ measures the number of distinct colors in the set of balls Y, and hence is submodular.

This paper makes several contributions: First, we present a brief overview of submodular functions (Section 2) and their potential application to natural language processing (NLP). Next we review previous approaches to MT data selection (Section 3) and analyze them with respect to their submodular properties. We find that some previous approaches are submodular in nature although this connection was not heretofore made explicit. Section 4 details our new approach. We discuss desirable properties of an SMT data selection objective and present a new class of submodular functions tailored towards this problem. Section 5 presents the data and systems used for the experiments, and results are reported in Section 6. Section 7 then concludes.

2 Submodular Functions/Optimization

Submodular functions (Edmonds, 1970; Fujishige, 2005), are widely used in mathematics, economics, circuit theory (Narayanan, 1997), and operations research. More recently, they have attracted much interest in machine learning (e.g., (Narasimhan and Bilmes, 2004; Kolmogorov and Zabih, 2004; Krause et al., 2008; Krause and Guestrin, 2011; Jegelka and Bilmes, 2011; Iyer and Bilmes, 2013)), where they have been applied to a variety of problems. In natural language and speech processing, they have been applied to document summarization (Lin and Bilmes, 2011; Lin and Bilmes, 2012) and speech data selection (Wei et al., 2013).

We are given a finite size-n set of objects V (i.e., $|V| = n$). A valuation function $f : 2^V \rightarrow \mathbb{R}_+$ is defined that returns a non-negative real value for any subset $X \subseteq V$. The function f is said to be *submodular* if it satisfies the property of diminishing returns: namely, for all $X \subseteq Y$ and $v \notin Y$, we must have:

$$f(X \cup \{v\}) - f(X) \geq f(Y \cup \{v\}) - f(Y). \quad (1)$$

This means that the incremental value (or gain) of element v decreases when the context in which v is considered grows from X to $Y \supseteq X$. We define the "gain" as $f(v|X) \triangleq f(X \cup \{v\}) - f(X)$. Hence, f is submodular if $f(v|X) \geq f(v|Y)$. We note that a function $m : 2^V \rightarrow \mathbb{R}_+$ is said to be *modular* if it satisfies the above with equality, meaning $m(v|X) = m(v|Y)$ for all $X \subseteq Y \subseteq V \setminus \{v\}$. If m is modular and $m(\emptyset) = 0$, it can be written as $m(X) = \sum_{x \in X} m(x)$ and, moreover, is seen simply as a n-dimensional vector $m \in \mathbb{R}^V$.

As an example, suppose we have a set V of balls and $f(X)$ counts the number of colors present in any subset $X \subseteq V$. In Figure 1, $|X| = 5$ and $f(X) = 2$, $|Y| = 7$ and $f(Y) = 3$, and $X \subset Y$. Adding v (a blue ball) to X has a unity gain $f(v|X) = 1$ but since a blue ball exists in Y, we have $f(v|Y) = 0 < f(v|X) = 1$.

Submodularity is a natural model for data subset selection in SMT. In this case, each $v \in V$ is a distinct training data sentence and V corresponds to a training set. An important characteristic of any good model for this problem is that we wish to decrease the "value" of a sentence $v \in V$ based on how much that sentence has in common with those sentences, say X, that have already been chosen. The value $f(v|X)$ of a given sentence v in a context of previously chosen sentences $X \subseteq V$ further diminishes as the context grows $Y \supseteq X$. When, for example, a sentence's value is represented as the value of its set of features (e.g., n-grams), it is natural for those features' values to be discounted based on how much representation of those features already exists in a previously chosen subset. This corresponds to submodularity, which can easily be expressed mathematically by functions such as Eqn. (4) below.

Not only are submodular functions natural for SMT subset selection, they can also be optimized efficiently and scalably such that the result has mathematical performance guarantees. In the remainder of this paper we will assume that f is not only submodular, but also non-negative ($f(X) \geq 0$ for all X), and *monotone non-decreasing* ($f(X) \leq f(Y)$ for all $X \subseteq Y$). Such functions are trivial to uselessly maximize, since $f(V)$ is the largest possible valuation. Typically, however, we wish to have

Algorithm 1: The Greedy Algorithm

Input: Submodular function $f : 2^V \rightarrow \mathbb{R}_+$, cost vector m, budget b, finite set V.
Output: X_k where k is the number of iterations.
Set $X_0 \leftarrow \emptyset$; $i \leftarrow 0$;
while $m(X_i) < b$ **do**
    Choose v_i as follows:
    $v_i \in \left\{ \text{argmax}_{v \in V \setminus X_i} \frac{f(\{v\}|X_i)}{m(v)} \right\}$;
    $X_{i+1} \leftarrow X_i \cup \{v_i\}$; $i \leftarrow i+1$;

a valuable subset of bounded and small cost, where cost is measured based on a modular function $m(X)$. For example, the cost $m(v)$ of a sentence $v \in V$ might be its length, so $m(X) = \sum_{x \in X} m(x)$ is a sum of sentence lengths. This leads to the following optimization problem:

$$X^* \in \underset{X \subseteq V, m(X) \leq b}{\text{argmax}} \; f(X), \tag{2}$$

where b is a known budget. Solving this problem exactly is NP-complete (Feige, 1998), and expressing it as an ILP procedure renders it impractical for large data sizes. When f is submodular the cost is just size ($m(X) = |X|$), then the simple greedy algorithm (detailed below) will have a **worst-case guarantee** of $f(\tilde{X}^*) \geq (1 - 1/e) f(X_{\text{opt}}) \approx 0.63 f(X_{\text{opt}})$ where X_{opt} is the optimal and $\tilde{X}^*$ is the greedy solution (Nemhauser et al., 1978).

This constant factor guarantee has practical importance. First, a constant factor guarantee stays the same as n grows, so the relative worst-case quality of the solution is the same for small and for big problem instances. Second, the worst-case result is achieved only by very contrived and unrealistic function instances — the typical case is almost always much better. Third, the worst-case guarantee improves depending on the "curvature" $\kappa \in [0,1]$ of the submodular function (Conforti and Cornuejols, 1984). When the submodular function is not fully curved ($\kappa < 1$, something true of the functions used in this paper), the worst case guarantee is better, namely $\frac{1}{\kappa}(1 - e^{-\kappa})$ (e.g., a function f with $\kappa = 0.2$ has a worst-case guarantee of 0.91). Lastly, when the cost m is not just cardinality but an arbitrary non-negative modular function, a greedy algorithm has similar guarantees (Sviridenko, 2004), and a scalable variant has a worst-case guarantee of $1 - 1/\sqrt{e}$ (Lin and Bilmes, 2010).

The basic greedy algorithm has a very simple form. Starting with $X \leftarrow \emptyset$, we repeat the operation $X \leftarrow X \cup \text{argmax}_{v \in V \setminus X} \frac{f(v|X)}{m(v)}$ until the budget is exceeded ($m(X) > b$) and then backoff to the previous iteration (complete details are given in Algorithm 1). While the algorithm has complexity $O(n^2)$, there is an accelerated instance of this algorithm (Minoux, 1978; Leskovec et al., 2007) that has empirical computational complexity of $O(n \log n)$ where $n = |V|$. The greedy algorithm, therefore, scales practically to very large n. Recently, still much faster (Wei et al., 2014) and also parallel distributed (Mirzasoleiman et al., 2013) greedy procedures have been advanced offering still better scalability.

There are many submodular functions that are appropriate for subset selection (Lin and Bilmes, 2011; Lin and Bilmes, 2012). Some of them are graph-based, where we are given a non-negative weighted graph $G = (V, E, w)$ and $w : E \rightarrow \mathbb{R}_+$ is a set of edge weights (i.e., $w(x,y)$ is a non-negative similarity score between sentences x and y). A submodular function is obtained via a *graph cut* function $f(X) = \sum_{x \in X, y \in V \setminus X} w(x,y)$ or via a *monotone truncated graph cut* function $f(X) = \sum_{v \in V} \min(C_v(X), \alpha C_v(V))$ where $\alpha \in (0,1)$ is a scalar parameter and $C_v(X) = \sum_{x \in X} w(v,x)$ is a v-specific modular function. Alternatively, the class of *facility location functions* $f(X) = \sum_{v \in V} \max_{x \in X} w(x,v)$ have been widely and successfully used in the field of operations research, and are also applicable here.

In the worse case, the required graph construction has a worst-case complexity of $O(n^2)$. While sparse graphs can be used, this can be prohibitive when $n = |V|$ gets large. Another class of submodular functions that does not have this problem is based on a weighted *bipartite* graph $G = (V, U, E, w)$ where V are the left vertices, U are the right vertices, $E \subseteq V \times U$ is a set of edges, and $w : U \rightarrow \mathbb{R}_+$ is a set of non-negative weights on the vertices U. For $X \subseteq V$, the *bipartite neighborhood* function is defined as:

$$f(X) = w(\{u \in U : \exists x \in X \text{ with } (x,u) \in E\}) \tag{3}$$

This function is interesting for NLP applications since U can be seen as a set of "features" of the elements $v \in V$ (i.e., if V is a set of sentences, U can be the collective set of n-grams for multiple values of n, and $f(X)$ is the weight of the n-grams contained collectively in sentences X).[2] Given a set $X \subseteq V$,

[2] To be consistent with standard notation in previous literature, we overload the use of n in "n-grams" and the size of our set "$n = |V|$", even though the two ns have no relationship with each other.

we get value from the features of the elements $x \in X$, but we get credit for each feature only one time — once a given object $x \in X$ has a given feature $u \in U$, any additions to X by elements also having feature u offer no further credit via that feature.

Another interesting class of submodular functions, allowing additional credit from an element even when its features already exist in X, are what we call *feature-based* submodular functions. They involve sums of non-decreasing concave functions applied to modular functions (Stobbe and Krause, 2010) and take the following form:

$$f(X) = \sum_{u \in U} w_u \phi_u(m_u(X)) \quad (4)$$

where $w_u > 0$ is a *feature weight*, $m_u(X) = \sum_{x \in X} m_u(x)$ is a non-negative modular function specific to feature u, $m_u(x)$ is a *relevance score* (a non-negative scalar score indicating the relevance of feature u in object x), and ϕ_u is a u-specific non-negative non-decreasing *concave function*. The gain is $f(v|X) = \sum_{u \in U} \Big(\phi(m_u(X \cup \{v\})) - \phi(m_u(X)) \Big)$, and thanks to ϕ_u's concavity, the term $\phi(m_u(X \cup \{v\})) - \phi(m_u(X))$ for each feature $u \in U$ is decaying as X grows. The rate of decay, and hence the degree of diminishing returns and ultimately the measure of redundancy of the information provided by the feature, is controlled by the concave function. The rate of decay is also related to the curvature κ of the submodular function (c.f. §2), with more aggressive decay having higher curvature (and a worse worst-case guarantee). The decay is a modeling choice that should be decided based on a given application.

Feature-based functions have the advantage that they do not require the construction of a pairwise graph; they have a cost of only $O(n|U|)$, which is **linear in the data size** and therefore scalable to large data set sizes.

We utilize this class for our subset selection experiments described in Section 4, where we use one global concave function $\phi_u = \phi$ for all $u \in U$. In this work we chose one particular set of features U. However, given the large body of research into NLP feature engineering (Jurafsky and Martin, 2009), this class is extensible beyond just this set, which makes it suitable for many other NLP applications.

Before describing our SMT-specific functions in detail, we review previous work on subset selection for SMT in the context of submodularity.

3 Previous Approaches

There have been many previous approaches to data subset selection in SMT. In this section, we show that some of them in fact correspond to submodular methods, thus introducing a connection between submodularity and the practical problem of SMT data selection. The fact that submodularity is implicitly and unintentionally used in previous work suggests that it is natural for this problem.

A currently widely-used data selection method in SMT (which we also use as a baseline in Section 6) uses the cross-entropy between two language models (Moore and Lewis, 2010), one trained on the test set of interest, and another trained on a large set of generic or out-of-domain training data. We call this the *cross-entropy method*. This method trains a test-set specific (or in-domain) language model, LM_{in}, and a generic (out-of- or mixed-domain) language model, LM_{out}. Each sentence $x \in V$ in the training data is given a probability score with both language models and then ranked in descending order based on the log ratio

$$m_{\text{ce}}(x) = \frac{1}{\ell(x)} \log[\Pr(x|\text{LM}_{\text{in}})/\Pr(x|\text{LM}_{\text{out}})] \quad (5)$$

where $\ell(x)$ is the length of sentence x. Finally, the top N sentences are chosen. In (Axelrod et al., 2011) this method is extended to take both sides of the parallel corpus into account rather than just the source side. The cross-entropy approach values each sentence individually, without regard to any interaction with already selected sentences. This approach, therefore, is modular (a special case of submodular) and values a set X via $m(X) = \sum_{x \in X} m(x)$. Moreover, the thresholding method for choosing a subset corresponds exactly to the optimization problem in Eqn. (2) where $f \leftarrow m$ and the budget b is set to the sum of the top N sentence scores. Thanks to modularity, the problem is no longer NP-complete, and the threshold method solves Eqn. (2) exactly. On the other hand, a modular function does not have the diminishing returns property, and thus has no chance to represent interaction or redundancy between sentences. The chosen subset, therefore, might have an enormous overrepresentation of one aspect of the training data while having minimal or no representation of another aspect, a major vulnerability of this approach.

Other methods use information retrieval (Hildebrand et al., 2005; Lü et al., 2007) which can also be described as modular function optimization (e.g., take the top k scoring sentences). Duplicate

sentence removal is easily represented by a feature-based submodular function, Equation (4), where there is one sentence-specific feature per sentence and where $\phi_u(m_u(X)) = \min(|X \cap \{u\}|, 1)$ — once a sentence is chosen, its contribution is saturated so any duplicate sentence has a gain of zero. Also, the unseen n-gram function of (Eck et al., 2005; Bloodgood and Callison-Burch, 2010) corresponds to a *bipartite neighborhood* submodular function, with a weight function defined based on n-gram counts. Moreover their functions are optimized using the greedy algorithm; hence they in fact have a $1-1/e$ guarantee. Other methods have noted and dealt with the existence of redundancy in phrase-based systems (Ittycheriah and Roukos, 2007) by limiting the set of phrases — submodular optimization inherently removes redundancy. Also, (Callison-Burch et al., 2005; Lopez, 2007) involve modular functions but where selection is over subsets of phrases (rather than sentences as in our current work) and where multiple selections occur, each specific to an individual test set sentence rather than the entire test set.

In the feature-decay method, presented in (Biçici, 2011; Biçici and Yuret, 2011; Biçici, 2013), the value of a sentence is based on its decomposition into a set of feature values. As sentences are added to a set, the feature decay approach in general diminishes the value of each feature depending on how much of that feature has already been covered by those sentences previously chosen — the papers define a set of *feature decay functions* for this purpose.

Our analysis of (Biçici, 2011; Biçici and Yuret, 2011; Biçici, 2013), from the perspective of submodularity, has revealed an interesting connection. The feature decay functions used in these papers turn out to be derivatives of non-decreasing concave functions. For example, in one case $\phi'(a) = 1/(1+a)$ which is the derivative of the concave function $\phi(a) = \ln(1+a)$. We are given a constant initialization w_u for feature $u \in U$ — in the papers, they set either $w_u \leftarrow 1$, or $w_u \leftarrow \log(m(V)/m_u(V))$, or $w_u \leftarrow \log(m(V)/(1+m_u(V)))$, where $m(V) = \sum_u m_u(V)$, and where $m_u(X) = \sum_{x \in X} m_u(x)$ is the count of feature u within the set of sentences $X \subseteq V$. This yields the submodular feature function $f_u(X) = w_u \phi(m_u(X))$. The value of sentence v as measured by feature u in the context of X is the gain $f_u(v|X)$, which is a discrete derivative corresponding to $w_u/(1+m_u(X \cup \{v\}))$. An alternative decay function they define is given as $\phi'(a) = 1/(1+b^a)$ for a base b (they set $b \leftarrow 2$) which is the derivative of the following non-decreasing concave function:

$$\phi(a) = \left[1 - \frac{1}{\ln(b)} \ln\Big(1 + \exp\big(-a \ln(b)\big)\Big)\right] \quad (6)$$

We note that this function is saturating, meaning that it quickly reaches its asymptote at its maximum possible value. We can, once again, define a function specific for feature $u \in U$ as $f_u(X) = w_u \phi(m_u(X))$ with a gain $f_u(v|X)$ being a discrete derivative corresponding to $w_u/(1+b^{m_u(X \cup \{v\})})$.

The connection between this work and submodularity is not complete, however, without considering the method used for optimization. In fact, Algorithm 1 of (Biçici and Yuret, 2011) is precisely the accelerated greedy algorithm of (Minoux, 1978) applied to the submodular function corresponding to $f(X) = \sum_{u \in U} f_u(X)$, and Algorithm 1 of (Biçici, 2013) is the cost-normalized variant of this greedy algorithm corresponding to a knapsack constraint (Sviridenko, 2004). Thus, our analysis shows that these methods also have a $1-1/e$ performance guarantee and also the $O(n \log n)$ empirical complexity mentioned in Section 2. This is an important connection, as it furthers the evidence that submodularity is natural for the problem of SMT subset selection. This also increases the accessibility of this method since we may view it as a special case of Equation (4).

Another class of approaches focuses on active learning. In (Haffari et al., 2009) a large corpus of noisy parallel data is created automatically; a smaller set of samples is then selected from this set that receive human translations. A combination of several "informativeness" scores is computed on a sentence-level basis, and samples are selected via hierarchical adaptive sampling (Dasgupta and Hsu, 2008). In (Mandal et al., 2008) a measure of disagreement between different MT systems, as well as an entropy-based criterion are used to select additional data for annotation. In (Bloodgood and Callison-Burch, 2010) and (Ambati et al., 2010), active learning is combined with crowd-sourced annotations to produce large, human-translated data sets that are as informative as possible. In (Cao and Khudanpur, 2012), samples are selected for discriminative training of an MT system according to a greedy algorithm that tries to maximize overall quality. These methods address a different scenario (data selection for annotation or discriminative training) than the one considered here; however, we also note that the actual selection techniques employed in these papers do not appear to be submodular.

4 Novel Submodular Functions for SMT

In this section, we design a parameterized class of submodular functions useful for SMT training data subset selection. By staying within the realm of submodularity, we retain the advantages of the greedy algorithm, its theoretical performance assurances, and its scalability properties. At the same time this opens the door to a general framework for quickly exploring a much larger class of functions (with the same desirable properties) than before.

It is important to note that we are using submodularity as a "model" of the selection process, and the submodular objective acts as a surrogate for the actual SMT objective function. Thus, the mathematical guarantee we have is in terms of the surrogate objective rather than the true SMT objective. Evaluating one point of the actual SMT objective would require the complete training and testing of an SMT system, so even an algorithm as efficient as Algorithm 1 would be infeasible, even on small data. It is therefore important to design a natural and scalable surrogate objective.

We do not consider the graph-based functions discussed in Section 2 here since they require a pairwise similarity matrix over all training sentences and thus have $O(n^2)$ worst-case complexity. For large tasks with millions or even billions of sentences, this eventually becomes impractical. Instead we focus on feature-based functions of the type presented in Eqn. (4), where each sentence is represented as a set of features rather than as a vertex in a graph. In this function there are four components to specify: 1) U, the *linguistic feature set*; 2) $m_u(x)$, the *relevance scores* for each feature u and sentence x; 3) w_u, the *feature weights*; and 4) ϕ, the *concave function* (we use one concave function, so $\phi_u = \phi$ for all $u \in U$).

Feature set: U is the set of n-grams from either the source language U^{src}, or from both the source and target language $U^{\text{src}} \cup U^{\text{tgt}}$ (see Section 6); since we are interested in selecting a training set that matches a given test set, we use the set of n-grams that occur both in the training set and in the development/test data (for target features, only development set features are used). I.e., $U^{\text{src}} = (U^{\text{src}}_{\text{dev}} \cup U^{\text{src}}_{\text{test}}) \cap U^{\text{src}}_{\text{train}}$ and $U^{\text{tgt}} = U^{\text{tgt}}_{\text{dev}} \cap U^{\text{tgt}}_{\text{train}}$.

Relevance scores: A feature u within a sentence x should be valued based on how salient that feature is within the "document" in which it occurs; here, the "document" is the set of training sentences. This is a task well suited to TFIDF. As an alternative to raw feature counts we thus also consider scores of the form $m_u(x) \leftarrow \text{tfidf}(u,x) = \text{tf}(u,x) \times \text{idf}^{\text{trn}}(u)$, where $\text{tf}(u,x)$ and $\text{idf}^{\text{trn}}(u)$ are defined as usual.

Feature weights: We wish to select those training samples that contain features occurring frequently in the test data while avoiding the over-selection of features that are very frequent in the training data because those are likely to be translated correctly anyway. This is similar to the approach in (Moore and Lewis, 2010) (see Equation (5)), where a log-probability ratio of in-domain to out-of-domain language model is utilized. In the present case, we need a value that is specific to feature $u \in U$; a natural approach is to use the ratio of counts $c^{\text{tst}}(u)/c^{\text{trn}}(u)$ where $c^{\text{tst}}(u)$ is the raw count of u in the development/test data, and $c^{\text{trn}}(u)$ is its raw count in the training data (note that $c^{\text{trn}}(u)$ is never zero due to the way U is defined). As an additional factor we allow feature length to have an influence. In general, longer n-grams might be considered more valuable since they typically lead to better translations and are more relevant for BLEU. Thus, we include a reward term for longer n-grams in the form of $\beta^{|u|}$ where $\beta \geq 1$ and $|u|$ is the length of feature u. This gives greater weight to longer n-grams when $\beta > 1$.

Concave function: It is imperative to find the right form of concave function since, as described in Section 2, the concave shape determines the degree to which redundancy and diminishing returns are represented. Intuitively, when the shape of the concave function for a feature becomes "flat" rapidly, that feature quickly looses its ability to provide additional value to a candidate subset. Many different concave functions were tested for ϕ, including one of the two functions implicit in (Biçici and Yuret, 2011) and derived in Section 3, and a variety of roots of the form $\phi(a) = a^{\alpha}$ for $0 < \alpha < 1$. In Table 2, for example, we find evidence that the simple square root $\phi(a) = \sqrt{a}$ performs slightly better than the log function. The square root is much less curved and decays much more gradually than either of the two functions implicit in (Biçici and Yuret, 2011), of which one is a log form and the other is even more curved and quickly saturates (see §3). The square root function yields a less curved submodular function, in the sense of (Conforti and Cornuejols, 1984), resulting in better worst-case guarantees. Indeed, Table 1 in (Biçici and Yuret, 2011) corroborates by showing that the more curved saturating function does worse than the less curved log function.

Four Components Together: Different instantia-

tions of the four components discussed above will result in different submodular functions of the general class defined in Eqn. (4). Particular settings of these general parameters produce the methods considered in (Biçici and Yuret, 2011), thus making that approach easily accessible once the general submodular framework is set up. As a very special case, this is also true of the cross-entropy method (Moore and Lewis, 2010), where $|U| = 1$, $m_u(x) \leftarrow \exp(m_{\text{ce}}(x))$ of Equation (5) [3], $w_u \leftarrow 1$, and $\phi(a) = a$ is the identity function. In Section 6, we specify the parameter settings used in our experiments.

Task	Train	Dev	Test	LM

5 Data and Systems

We evaluate our approach on the NIST Arabic-English translation task, using the NIST 2006 set for development and the NIST 2009 set for evaluation. The training data consists of all Modern Standard Arabic-English parallel LDC corpora permitted in the NIST evaluations (minus the restricted time periods). Together these sets form a mixed-domain training set containing relevant in-domain data similar to the NIST data sets but also less relevant data (e.g., the UN parallel corpora); we thus expect data selection to work well on this task. Additional English language modeling data was drawn from several other LDC corpora (English Gigaword, AQUAINT, HARD, ANC/DCI and the American National Corpus). Preprocessing included conversion of the Arabic data to Buckwalter format, tokenization, spelling normalization, and morphological segmentation using MADA (Habash et al., 2009). Numbers and URLs were replaced with variables. The English data was tokenized and lowercased. Postprocessing involved recasing the translation output, replacing variable names with their original corresponding tokens, and normalizing spelling and stray punctuation marks. The recasing model is an SMT system without reordering, trained on parallel cased and lowercased versions of the training data. The recasing model remains fixed for all experiments and is not retrained for different sizes of the training data. Evaluation follows the NIST guidelines and was done by computing BLEU scores using the official NIST evaluation tool mteval-v13a.pl with the $-c$ flag for case-sensitive scoring. In addition to the NIST task we also applied our method to the Europarl German-English translation task. The training data comes from the Europarl-v7 collection[4]; the development set is the 2006 dev set, and the test set is the 2007 test set. The number of reference translations is 1. The German data was preprocessed by tokenization, lower-casing, splitting noun compounds and lemmatization to address morphological variation in German. The English side was tokenized and lowercased. Evaluation was done by computing BLEU on the lowercased versions of the data. Since test and training data for this task come from largely the same domain we expect the training data to be less redundant or irrelevant; nevertheless it will be interesting to see how much different data selection methods can contribute even to in-domain translation tasks. The sizes of the various data sets are shown in Table 1.

All translation systems were trained using the GIZA++/Moses infrastructure (Koehn et al., 2007). The translation model is a standard phrase-based model with a maximum phrase length of 7. Since a large number of experiments had to be run for this study, more complex hierarchical or syntax-based translation models were deliberately excluded in order to limit the experimental turn-around time needed for each experiment. The reordering model is a hierarchical model according to (Galley and Manning, 2008). The feature weights in the log-linear function were optimized on the development set BLEU score using minimum error-rate training. The language models for the NIST task (5-grams) were trained on three different data sources (Gigaword, GALE data, and all remaining corpora), which were then interpolated into a single model. The interpolation weights were optimized separately for the two different genres present in the NIST task (newswire and web text). All models used Witten-Bell discounting and interpolation of higher-order and lower-order models. Language models remain fixed for all experiments, i.e., the language model training data is not subselected since we were interested in the effect of data subset selection on the translation model only. The language model for the Europarl system was a 5-gram trained on Europarl data only.

[3] Due to modularity, any monotone increasing transformation from $m_{\text{ce}}(x)$ to $m_u(x)$ that ensures $m_u(x) \geq 0$ is equivalent.

Table 4: Different instantiations of the general submodular function in Eq. 4 ($\beta = 1.5$ in all cases).

We first trained a baseline system on 100% of the training data. Different data selection methods were then used to select subsets of 10%, 20%, 30% and 40% of the data. While not reported in the tables, above 40%, the performance slowly drops to the 100% performance.

The first baseline selection method utilizes random data selection, for which 3 different data sets of the specified size were drawn randomly from the training data. Individual systems were trained on all random subsets of the same size, and their scores were averaged. The second baseline is the cross-entropy method by (Moore and Lewis, 2010). In-domain language models were trained on the combined development and test data, and out-of-domain models were trained on an equivalent amount of data drawn randomly from the training set. Sentences were ranked by the function in Eq. 5, and the top k percent were chosen. The order of the n-gram models was optimized on the development set and was found to be 3. Larger model orders resulted in worse performance, possibly due to the

limited size of the data used for their training. Since this method also involves random data selection, we report the average BLEU score over 5 different trials. For the submodular selection method, Table 4 shows the different values that were tested for the four components listed in Section 4. The combination was optimized on the development set. The selection algorithm (Alg. 1) runs within a few minutes on our complete training set of 189M words.

Results on the NIST 2009 test set are shown in Table 2. The scores for the submodular systems are averages over 3 different runs of MERT tuning. Random data subset selection (Row 1) falls short of the baseline system using 100% of the training data. The cross-entropy method (Row 2) surpasses the performance of the baseline system at about 20% of the data, demonstrating that data subset selection is a suitable technique for such mixed-domain translation tasks. The following rows show results for the various submodular functions shown in Table 4. Out of these, SM-5 corresponds to the best approach in (Biçici and Yuret, 2011). SM-6 is our own best-performing function, beating the cross-entropy method by a statistically significant margin ($p \leq 0.05$) under all conditions.[5] SM-6 is also significantly better than SM-5 in two cases. Finally, it surpasses the performance of the all-data system at only 10% of the training data; possibly, even smaller training data sets could be used but this option was not investigated. While the bilingual submodular functions SM-2 and SM-7) yield an improvement of up to 0.015 BLEU points on the dev set (not shown in the table), they do not consistently outperform the monolingual functions on the test set. Since test set target features cannot be used in our scenario, bilingual features are only helpful to the extent that the development set closely matches the test set. However, target features should be quite helpful when selecting data from an out-of-domain set to match an in-domain training set (as in e.g. (Axelrod et al., 2011)). We found no gain from the length reward $\beta^{|u|}$.

The Europarl results (Table 3) show a similar pattern. Although the differences in BLEU scores are smaller overall (as expected on an in-domain translation task), data subset selection improves over the all-data baseline system in this case as well. The cross-entropy method again outperforms random data selection. On this task we only tested our submodular function that worked best on the NIST task; again we find that it outperforms the cross-entropy method. In two conditions (10% and 30%) these differences are statistically significant. 10% of the training data suffices to outperform the all-data system, and up to a full BLEU point can be gained on this task using 20-30% of the data and a submodular data selection method.

[5] Statistical significance was measured using the paired bootstrap resampling test of (Koehn, 2004), applied to the systems with the median BLEU scores.

7 Conclusions

We have introduced submodularity to SMT data subset selection, generalizing previous approaches to this problem. Our method has theoretical performance guarantees, comes with scalable algorithms, and significantly improves over current, widely-used data selection methods on two different translation tasks. There are many possible extensions to this work. One strategy would be to extend the feature set U with features representing different types of linguistic information - e.g., when using a syntax-based system it might be advantageous to select training data that covers the set of syntactic structures seen in the test data. Secondly, the selected data was test data specific. In some contexts, it is not possible to train test data specific systems dynamically; in that case, different submodular functions could be designed to select a representative "summary" of the training data. Finally, the use of submodular functions for subset selection is applicable to other data sets that can be represented as features or as a pairwise similarity graph. Submodularity thus can be applied to a wide range of problems in NLP beyond machine translation.

Abstract

We investigate how to improve *bilingual embedding* which has been successfully used as a feature in phrase-based *statistical machine translation* (SMT). Despite bilingual embedding's success, the *contextual information*, which is of critical importance to translation quality, was ignored in previous work. To employ the contextual information, we propose a simple and memory-efficient model for learning bilingual embedding, taking both the source phrase and context around the phrase into account. Bilingual translation scores generated from our proposed bilingual embedding model are used as features in our SMT system. Experimental results show that the proposed method achieves significant improvements on large-scale Chinese-English translation task.

1 Introduction

In Statistical Machine Translation (SMT) system, it is difficult to determine the translation of some phrases that have ambiguous meanings.For example, the phrase "结果 jieguo" can be translated to either "results", "eventually" or "fruit", depending on the context around it. There are two reasons for the problem: First, the length of phrase pairs is restricted due to the limitation of model size and training data. Another reason is that SMT systems often fail to use contextual information in source sentence, therefore, phrase sense disambiguation highly depends on the language model which is trained only on target corpus.

To solve this problem, we present to learn context-sensitive bilingual semantic embedding. Our methodology is to train a supervised model where labels are automatically generated from phrase-pairs. For each source phrase, the aligned target phrase is marked as the positive label whereas other phrases in our phrase table are treated as negative labels. Different from previous work in bilingual embedding learning(Zou et al., 2013; Gao et al., 2014), our framework is a supervised model that utilizes contextual information in source sentence as features and make use of phrase pairs as weak labels. Bilingual semantic embeddings are trained automatically from our supervised learning task.

Our learned bilingual semantic embedding model is used to measure the similarity of phrase pairs which is treated as a feature in decoding. We integrate our learned model into a phrase-based translation system and experimental results indicate that our system significantly outperform the baseline system. On the NIST08 Chinese-English translation task, we obtained 0.68 BLEU improvement. We also test our proposed method on much larger web dataset and obtain 0.49 BLEU improvement against the baseline.

2 Related Work

Using vectors to represent word meanings is the essence of vector space models (VSM). The representations capture words' semantic and syntactic information which can be used to measure semantic similarities by computing distance between the vectors. Although most VSMs represent one word with only one vector, they fail to capture homonymy and polysemy of word. Huang et al. (2012) introduced global document context and multiple word prototypes which distinguishes and uses both local and global context via a joint training objective. Much of the research focus on the task of inducing representations for single languages. Recently, a lot of progress has

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 142–146,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

been made at representation learning for bilingual words. Bilingual word representations have been presented by Peirsman and Padó (2010) and Sumita (2000). Also unsupervised algorithms such as LDA and LSA were used by Boyd-Graber and Resnik (2010), Tam et al. (2007) and Zhao and Xing (2006). Zou et al. (2013) learn bilingual embeddings utilizes word alignments and monolingual embeddings result, Le et al. (2012) and Gao et al. (2014) used continuous vector to represent the source language or target language of each phrase, and then computed translation probability using vector distance. Vulić and Moens (2013) learned bilingual vector spaces from non-parallel data induced by using a seed lexicon. However, none of these work considered the word sense disambiguation problem which Carpuat and Wu (2007) proved it is useful for SMT. In this paper, we learn bilingual semantic embeddings for source content and target phrase, and incorporate it into a phrase-based SMT system to improve translation quality.

3 Context-Sensitive Bilingual Semantic Embedding Model

We propose a simple and memory-efficient model which embeds both contextual information of source phrases and aligned phrases in target corpus into low dimension. Our assumption is that high frequent words are likely to have multiple word senses; therefore, top frequent words are selected in source corpus. We denote our selected words as focused phrase. Our goal is to learn a bilingual embedding model that can capture discriminative contextual information for each focused phrase. To learn an effective context sensitive bilingual embedding, we extract context features nearby a focused phrase that will discriminate focused phrase's target translation from other possible candidates. Our task can be viewed as a classification problem that each target phrase is treated as a class. Since target phrases are usually in very high dimensional space, traditional linear classification model is not suitable for our problem. Therefore, we treat our problem as a ranking problem that can handle large number of classes and optimize the objectives with scalable optimizer stochastic gradient descent.

3.1 Bilingual Word Embedding

We apply a linear embedding model for bilingual embedding learning. Cosine similarity between bilingual embedding representation is considered as score function. The score function should be discriminative between target phrases and other candidate phrases. Our score function is in the form:

$$f(\mathbf{x}, \mathbf{y}; \mathbf{W}, \mathbf{U}) = cos(\mathbf{W}^T\mathbf{x}, \mathbf{U}^T\mathbf{y}) \quad (1)$$

where $\mathbf{x}$ is contextual feature vector in source sentence, and $\mathbf{y}$ is the representation of target phrase, $\mathbf{W} \in R^{|\mathbf{X}|\times k}, \mathbf{U} \in R^{|\mathbf{Y}|\times k}$ are low rank matrix. In our model, we allow $\mathbf{y}$ to be bag-of-words representation. Our embedding model is memory-efficient in that dimensionality of $\mathbf{x}$ and $\mathbf{y}$ can be very large in practical setting. We use $|\mathbf{X}|$ and $|\mathbf{Y}|$ means dimensionality of random variable $\mathbf{x}$ and $\mathbf{y}$, then traditional linear model such as max-entropy model requires memory space of $O(|\mathbf{X}||\mathbf{Y}|)$. Our embedding model only requires $O(k(|\mathbf{X}| + |\mathbf{Y}|))$ memory space that can handle large scale vocabulary setting. To score a focused phrase and target phrase pair with $f(\mathbf{x}, \mathbf{y})$, context features are extracted from nearby window of the focused phrase. Target words are selected from phrase pairs. Given a source sentence, embedding of a focused phrase is estimated from $\mathbf{W}^T\mathbf{x}$ and target phrase embedding can be obtained through $\mathbf{U}^T\mathbf{y}$.

3.2 Context Sensitive Features

Context of a focused phrase is extracted from nearby window, and in our experiment we choose window size of 6 as a focused phrase's context. Features are then extracted from the focused phrase's context. We demonstrate our feature extraction and label generation process from the Chinese-to-English example in figure 1. Window size in this example is three. Position features and Part-Of-Speech Tagging features are extracted from the focused phrase's context. The word *fruit*

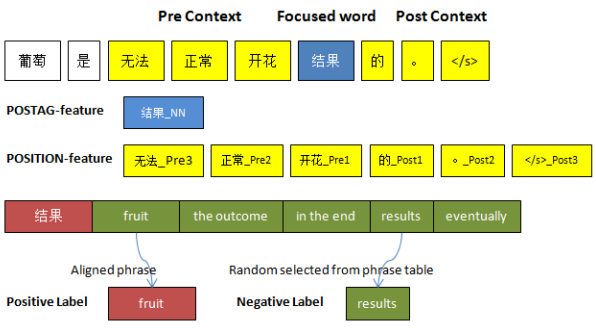

Figure 1: Feature extraction and label generation

is the aligned phrase of our focused phrase and is treated as positive label. The phrase *results* is a randomly selected phrase from phrase table results of 结果. Note that feature window is not well defined near the beginning or the end of a sentence. To conquer this problem, we add special padding word to the beginning and the end of a sentence to augment sentence.

3.3 Parameter Learning

To learn model parameter $\mathbf{W}$ and $\mathbf{U}$, we apply a ranking scheme on candidates selected from phrase table results of each focused phrase. In particular, given a focus phrase w, aligned phrase is treated as positive label whereas phrases extracted from other candidates in phrase table are treated as negative label. A max-margin loss is applied in this ranking setting.

$$I(\Theta) = \frac{1}{m}\sum_{i=1}^{m}(\delta - f(x_i, y_i; \Theta) - f(x_i, y_i'; \Theta))+ \quad (2)$$

Where $f(\mathbf{x_i}, \mathbf{y_i})$ is previously defined, $\Theta = \{W, U\}$ and + means max-margin hinge loss. In our implementation, a margin of $\delta = 0.15$ is used during training. Objectives are minimized through stochastic gradient descent algorithm. For each randomly selected training example, parameters are updated through the following form:

$$\mathbf{\Theta} := \mathbf{\Theta} - \alpha\frac{\partial l(\mathbf{\Theta})}{\partial \mathbf{\Theta}} \quad (3)$$

where $\Theta = \{\mathbf{W}, \mathbf{U}\}$. Given an instance with positive and negative label pair $\{\mathbf{x}, \mathbf{y}, \mathbf{y}'\}$, gradients of parameter $\mathbf{W}$ and $\mathbf{U}$ are as follows:

$$\frac{\partial l(\mathbf{W}, \mathbf{U})}{\partial \mathbf{W}} = qs\mathbf{x}(\mathbf{W}^T\mathbf{x})^T - pqs^3\mathbf{x}(\mathbf{U}^T\mathbf{y}) \quad (4)$$

$$\frac{\partial l(\mathbf{W}, \mathbf{U})}{\partial \mathbf{U}} = qs\mathbf{y}(\mathbf{U}^T\mathbf{y})^T - pqs^3\mathbf{y}(\mathbf{W}^T\mathbf{x}) \quad (5)$$

Where we set $p = (\mathbf{W}^T\mathbf{x})^T(\mathbf{U}^T\mathbf{y})$, $q = \frac{1}{||\mathbf{W}^T\mathbf{x}||_2}$ and $s = \frac{1}{||\mathbf{U}^T\mathbf{y}||_2}$. To initialize our model parameters with strong semantic and syntactic information, word vectors are pre-trained independently on source and target corpus through word2vec (Mikolov et al., 2013). And the pre-trained word vectors are treated as initial parameters of our model. The learned scoring function $f(\mathbf{x}, \mathbf{y})$ will be used during decoding phase as a feature in log-linear model which we will describe in detail later.

4 Integrating Bilingual Semantic Embedding into Phrase-Based SMT Architectures

To incorporate the context-sensitive bilingual embedding model into the state-of-the-art Phrase-Based Translation model, we modify the decoding so that context information is available on every source phrase. For every phrase in a source sentence, the following tasks are done at every node in our decoder:

- Get the focused phrase as well as its context in the source sentence.
- Extract features from the focused phrase's context.
- Get translation candidate extracted from phrase pairs of the focused phrase.
- Compute scores for any pair of the focused phrase and a candidate phrase.

We get the target sub-phrase using word alignment of phrase, and we treat NULL as a common target word if there is no alignment for the focused phrase. Finally we compute the matching score for source content and target word using bilingual semantic embedding model. If there are more than one word in the focus phrase, then we add all score together. A penalty value will be given if target is not in translation candidate list. For each phrase in a given SMT input sentence, the Bilingual Semantic score can be used as an additional feature in log-linear translation model, in combination with other typical context-independent SMT bilexicon probabilities.

5 Experiment

Our experiments are performed using an in-house phrase-based system with a log-linear framework. Our system includes a phrase translation model, an n-gram language model, a lexicalized reordering model, a word penalty model and a phrase penalty model, which is similar to Moses (Koehn et al., 2007). The evaluation metric is BLEU (Papineni et al., 2002).

5.1 Data set

We test our approach on LDC corpus first. We just use a subset of the data available for NIST OpenMT08 task[1] . The parallel training corpus

[1]LDC2002E18, LDC2002L27, LDC2002T01, LDC2003E07, LDC2003E14, LDC2004T07, LDC2005E83, LDC2005T06, LDC2005T10, LDC2005T34, LDC2006E24, LDC2006E26, LDC2006E34, LDC2006E86, LDC2006E92, LDC2006E93, LDC2004T08(HK_News, HK_Hansards)

Method	OpenMT08	WebData
	BLEU	BLEU
Our Baseline	26.24	29.32
LOC	26.78**	29.62*
LOC+POS	26.82**	29.81*

Table 1: Results of lowercase BLEU on NIST08 task. LOC is the location feature and POS is the Part-of-Speech feature * or ** equals to significantly better than our baseline($\rho < 0.05$ or $\rho < 0.01$, respectively)

contains 1.5M sentence pairs after we filter with some simple heuristic rules, such as sentence being too long or containing messy codes. As monolingual corpus, we use the XinHua portion of the English GigaWord. In monolingual corpus we filter sentence if it contain more than 100 words or contain messy codes, Finally, we get monolingual corpus containing 369M words. In order to test our approach on a more realistic scenario, we train our models with web data. Sentence pairs obtained from bilingual website and comparable webpage. Monolingual corpus is gained from some large website such as WiKi. There are 50M sentence pairs and 10B words monolingual corpus.

5.2 Results and Analysis

For word alignment, we align all of the training data with GIZA++ (Och and Ney, 2003), using the grow-diag-final heuristic to improve recall. For language model, we train a 5-gram modified Kneser-Ney language model and use Minimum Error Rate Training (Och, 2003) to tune the SMT. For both OpenMT08 task and WebData task, we use NIST06 as the tuning set, and use NIST08 as the testing set. Our baseline system is a standard phrase-based SMT system, and a language model is trained with the target side of bilingual corpus. Results on Chinese-English translation task are reported in Table 1. Word position features and part-of-speech tagging features are both useful for our bilingual semantic embedding learning. Based on our trained bilingual embedding model, we can easily compute a translation score between any bilingual phrase pair. We list some cases in table 2 to show that our bilingual embedding is context sensitive.

Contextual features extracted from source sentence are strong enough to discriminate different word senses. And we also observe from the word “结果 jieguo” that Part-Of-Speech Tagging features are effective in discriminating target phrases.

Table 2: Top ranked focused phrases based on bilingual semantic embedding

6 Conlusion

In this paper, we proposed a context-sensitive bilingual semantic embedding model to improve statistical machine translation. Contextual information is used in our model for bilingual word sense disambiguation. We integrated the bilingual semantic model into the phrase-based SMT system. Experimental results show that our method achieves significant improvements over the baseline on large scale Chinese-English translation task. Our model is memory-efficient and practical for industrial usage that training can be done on large scale data set with large number of classes. Prediction time is also negligible with regard to SMT decoding phase. In the future, we will explore more features to refine the model and try to utilize contextual information in target sentences.

Abstract

We present a novel approach to improve word alignment for statistical machine translation (SMT). Conventional word alignment methods allow discontinuous alignment, meaning that a source (or target) word links to several target (or source) words whose positions are discontinuous. However, we cannot extract phrase pairs from this kind of alignments as they break the alignment consistency constraint. In this paper, we use a weighted vote method to transform discontinuous word alignment to continuous alignment, which enables SMT systems extract more phrase pairs. We carry out experiments on large scale Chinese-to-English and German-to-English translation tasks. Experimental results show statistically significant improvements of BLEU score in both cases over the baseline systems. Our method produces a gain of +1.68 BLEU on NIST OpenMT04 for the phrase-based system, and a gain of +1.28 BLEU on NIST OpenMT06 for the hierarchical phrase-based system.

1 Introduction

Word alignment, indicating the correspondence between the source and target words in bilingual sentences, plays an important role in statistical machine translation (SMT). Almost all of the SMT models, not only phrase-based (Koehn et al., 2003), but also syntax-based (Chiang, 2005; Liu et al., 2006; Huang et al., 2006), derive translation knowledge from large amount bilingual text annotated with word alignment. Therefore, the quality of the word alignment has big impact on the quality of translation output.

Word alignments are usually automatically obtained from a large amount of bilingual training corpus. The most widely used toolkit for word alignment in SMT community is GIZA++ (Och and Ney, 2004), which implements the well known IBM models (Brown et al., 1993) and the HMM model (Vogel and Ney, 1996). Koehn et al. (2003) proposed some heuristic methods (e.g. the "*grow-diag-final"* method) to refine word alignments trained by GIZA++. Another group of word alignment methods (Liu et al., 2005; Moore et al., 2006; Riesa and Marcu, 2010) define feature functions to describe word alignment. They need manually aligned bilingual texts to train the model. However, the manually annotated data is too expensive to be available for all languages. Although these models reported high accuracy, the GIZA++ and "grow-diag-final" method are dominant in practice.

However, automatic word alignments are usually very noisy. The example in Figure 1 shows a Chinese and English sentence pair, with word alignment automatically trained by GIZA++ and the "grow-diag-final" method. We find many errors (dashed links) are caused by discontinuous alignment (formal definition is described in Section 2), a source (or target) word linking to several discontinuous target (or source) words. This kind of errors will result in the loss of many useful phrase pairs that are learned based on bilingual word alignment. Actually, according to the definition of phrases in a standard phrase-based model, we cannot extract phrases from the discontinuous alignment. The reason is that this kind of alignment break the alignment consistency constraint (Koehn et al., 2003). For example, the Chi-

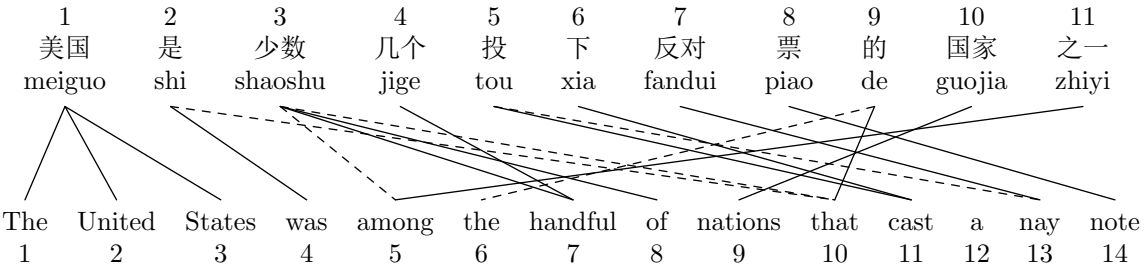

Figure 1: An example of word alignment between a Chinese and English sentence pair. The dashed links are incorrect alignments.

nese word "*shi*$_2$"[1] is aligned to the English words "*was*$_4$" and "*that*$_{10}$". However, these two English words are discontinuous, and we cannot extract the phrase pair "(*shi, was*)".

In this paper, we propose a simple *weighed vote* method to deal with the discontinuous word alignment. Firstly, we split the discontinuous alignment into several continuous alignment groups, and consider each continuous alignment group as a bucket. Secondly, we vote for each bucket with alignment score measured by word translation probabilities. Finally, we select the bucket with the highest score as the final alignment. The strength of our method is that we refine word alignment without using any external knowledge, as the word translation probabilities can be estimated from the bilingual corpus with the original word alignment.

We notice that the discontinuous alignment is helpful for hierarchical phrase-based model, as the model allows discontinuous phrases. Thus, for the hierarchical phrase-based model, our method may lost some discontinuous phrases. To solve the problem, we keep the original discontinuous alignment in the training corpus.

We carry out experiment with the state-of-the-art phrase-based and hierarchical phrase-based (Chiang, 2005) SMT systems implemented in Moses (Koehn et al., 2007). Experiments on large scale Chinese-to-English and German-to-English translation tasks demonstrate significant improvements in both cases over the baseline systems.

2 The Weighted Vote Method

To refine the discontinuous alignment, we propose a weighted vote method to transform discontinuous alignment to continuous alignment by discarding noisy links. We split discontinuous alignment into several continuous groups, and select the best group with the highest score computed by word translation probabilities as the final alignment.

For further understanding, we first describe some definitions. Given a word-aligned sentence pair (F_1^I, E_1^J, A), an **alignment set** $A_{set}(i)$ is the set of target word positions that aligned to the source word F_i^i:

$$A_{set}(i) = \{j|(i,j) \in A\} \quad (1)$$

For example, in Figure 1, the alignment set for the Chinese word "shaoshu$_3$" is $A_{set}(3) = \{5,7,8,10\}$. We define an **alignment span** $A_{span}(i)$ as $[min(A_{set}(i)), max(A_{set}(i))]$. Thus, the alignment span for the Chinese word "shaoshu$_3$" is $A_{span}(3) = [5,10]$.

The alignment for F_i^i is discontinuous if there exist some target words in $A_{span}(i)$ linking to another source word, i.e. $\exists(i',j') \in A$, where $i' \neq i$, $j' \in A_{span}(i)$. Otherwise, the alignment is continuous. According to the definition, the alignment for "shaoshu$_3$" is discontinuous. Because the target words "the$_6$" and "nations$_9$" in the alignment span link to another Chinese words "de$_9$" and "guojia$_{10}$", respectively. For a target word E_j^j, the definition is similar.

If the alignment for F_i^i is discontinuous, we can split the alignment span $A_{span}(i) = [j_1, j_2]$ into m continuous spans $\{[j_p^k, j_q^k]\}$, where $k = 1, 2, ..., m$, and $j_p^k, j_q^k \in [j_1, j_2]$. Our goal is to select the best continuous span for the word F_i^i. To do this, we score each continuous span with word translation probabilities:

$$S([j_p^k, j_q^k]) = \sum_{t=p}^{q} (Pr(E_{j_t^k}|F_i) + Pr(F_i|E_{j_t^k})) \quad (2)$$

where,

$$Pr(f|e) = \frac{count(f,e)}{\sum_{f'} count(f',e)} \quad (3)$$

[1]The subscript denotes the word position.

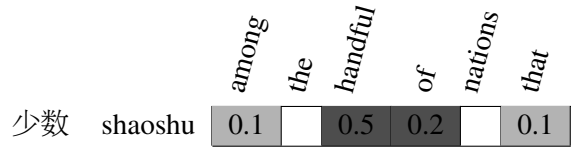

Figure 2: An example of weighted voted method for selecting the best continuous alignment from the discontinuous alignment. The heavy shading area is selected as the final alignment.

$$Pr(e|f) = \frac{count(e, f)}{\sum_{e'} count(f, e')} \quad (4)$$

The word translation probabilities can be computed from the bilingual corpus with the initial word alignment. Finally, we select the span with the highest score as the final alignment, and discard all other alignments.

We illustrate our method in Figure 2, which shows the source word "shaoshu" and its alignment in Figure 1. We split the alignments into three continuous alignment spans and compute score for each span. Finally, the span with highest score (heavy shading area) is selected as the final alignment.

We conduct the procedure for each source and target word, the improved alignment (solid links) is shown in Figure 1.

3 Experiment

To demonstrate the effect of the proposed method, we use the state-of-the-art phrase-based system and hierarchical phrase-based system implemented in Moses (Koehn et al., 2007). The phrase-based system uses continuous phrase pair as the main translation knowledge. While the hierarchical phrase-based system uses both continuous and discontinuous phrase pairs, which has an ability to capture long distance phrase reordering.

we carried out experiments on two translation tasks: the Chinese-to-English task comes from the NIST Open MT Evaluation, and the German-to-English task comes from the Workshop on Machine Translation (WMT) shared task.

3.1 Training

The training data we used are listed in Table 1. For the Chinese-English task, the bilingual data are selected from LDC. We used NIST MT03 as the development set and tested our system on NIST MT evaluation sets from 2004 to 2008. For the German-English task, the bilingual data are from the shared translation task 2013. We used WMT08 as the development set and tested our system on WMT test sets from 2010 to 2013.

Task	Src. Words	Tgt. Words

Refined	21.46	20.95	21.11	23.77

Table 3: German-to-English translation quality of the phrase-based system.

The baseline systems are trained on the training corpus with *initial* word alignment, which was obtained via GIZA++ and "grow-diag-final" method. Based on the initial word alignment, we computed word translation probabilities and used the proposed method to obtain a *refined* word alignment. Then we used the refined word alignment to train our SMT systems.

The translation results are evaluated by case-insensitive BLEU-4 (Papineni et al., 2002). The feature weights of the translation system are tuned with the standard minimum-error-rate-training (Och, 2003) to maximize the systems BLEU score on the development set.

3.2 Results

3.2.1 Phrase-based System

Table 2 shows Chinese-to-English translation quality of the phrase-based system. We observed that our refined method significantly outperformed the baseline word alignment on all test sets. The improvements are ranged from 0.97 to 1.68 BLEU%.

Table 3 shows German-to-English translation quality of the phrase-based system. The improvements are ranged from 0.51 to 0.75 BLEU%.

These results demonstrate that the proposed method improves the translation quality for

System	N04	N05	N06	N08

System	W10	W11	W12	W13
Baseline	21.22	19.77	20.53	23.51
Refined	21.34	20.64	20.88	23.82
Combined	21.65	20.87	21.16	24.04

Table 5: German-to-English translation quality of the hierarchical phrase-based system.

phrase-based system. The reason is that by discarding noisy word alignments from the discontinuous alignments, the phrase pairs constrained by the noisy alignments can be extracted. Thus the system utilized more phrase pairs than the baseline did.

3.2.2 Hierarchical Phrase-based System

The hierarchical phrase-based system utilizes discontinuous phrase pairs for long distance phrase reordering. Some of the discontinuous phrase pairs are extracted from the discontinuous alignments. By transforming the discontinuous alignments to continuous alignments, on the one hand, we may lost some discontinuous phrase pairs. On the other hand, we may extract additional continuous and discontinuous phrase pairs as the alignment restriction is loose.

See Figure 3 for illustration. From the initial alignment, we can extract a hierarchical phrase pair *"(dang X_1 shi, when X_1)"* from the discontinuous alignment of the English word "*when*". However, the hierarchical phrase pair cannot be extracted from our refined alignment, because our method discards the link between the Chinese word "*dang*" and the English word "*when*". Instead, we can extract another hierarchical phrase pair *"(X_1 shi, when X_1)"*.

Does our method still obtain improvements on the hierarchical phrase-based system? Table 4 and Table 5 shows Chinese-to-English and German-to-English translation quality of the hierarchical phrase-based system, respectively. For Chinese-to-English translation, the refined alignment obtained improvements ranged from 0.07 to 0.58

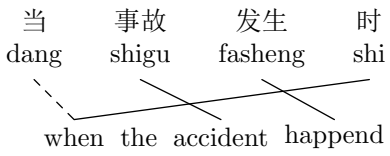

Figure 3: Example of word alignment between a Chinese and English sentence pair. The dashed initial link is discarded by our method.

BLEU% on the test set (the row "Refined"). While for German-to-English translation, the improvements ranged from 0.12 to 0.59 BLEU% on the test set (the row "Refined").

We find that the improvements are less than that of the phrase-based system. As discussed above, our method may lost some hierarchical phrase pairs that extracted from the discontinuous alignments. To solve the problem, we combine [2] the initial alignments and the refined alignments to train the SMT system. The results are shown in the row "Combined" in Table 4 and Table 5. For Chinese-to-English translation, we obtained an improvements of 1.28 BLEU% on NIST06 over the baseline. While for German-to-English translation, the greatest improvements is 1.10 BLEU% on WMT11.

4 Analyses

In order to further study the performance of the proposed method, we analyze the word alignment and the phrase table for Chinese-to-English translation. We find that our method improves the quality of word alignment. And as a result, more useful phrase pairs are extracted from the refined word alignment.

4.1 Word Alignment

The Chinese-to-English training corpus contains 4.5M sentence pairs. By applying GIZA++ and the "grow-diag-final" method, we obtained initial alignments. We find that 4.0M (accounting for 89%) sentence pairs contain discontinuous alignments. We then used the proposed method to discard noisy links. By doing this, the total links between words in the training corpus are reduced from 99.6M to 78.9M, indicating that 21% links are discarded.

[2] We do not perform combination for phrase-based system, because the phrase table extracted from the initial alignment is a subset of that extracted from the refined alignment.

Alignment	Precision	Recall	AER
Initial	62.94	89.55	26.07
Refined	73.43	87.82	20.01

Table 6: Precision, Recall and AER on Chinese-to-English alignment.

Alignment	StandPhr	HierPhr
Initial	29M	86M
Refined	104M	436M

Table 7: The phrase number extracted from the initial and refined alignment for the hierarchical phrase-based system on Chinese-to-English translation. StandPhr is standard phrase, HierPhr is hierarchical phrase.

We evaluated the alignment quality on 200 sentence pairs. Results are shown in Table 6. It is observed that our method improves the precision and decreases the AER, while keeping a high recall. This means that our method effectively discards noisy links in the initial word alignments.

4.2 Phrase Table

According to the standard definition of phrase in SMT, phrase pairs cannot be extracted from the discontinuous alignments. By transforming discontinuous alignments into continuous alignment, we can extract more phrase pairs. Table 7 shows the number of standard phrases and hierarchical phrases extracted from the initial and refined word alignments. We find that the number of both phrases and hierarchical phrases grows heavily. This is because that the word alignment constraint for phrase extraction is loosed by removing noisy links. Although the phrase table becomes larger, fortunately, there are some methods (Johnson et al., 2007; He et al., 2009) to prune phrase table without hurting translation quality.

For further illustration, we compare the phrase pairs extracted from the initial alignment and refined alignment in Figure 1. From the initial alignments, we extracted only 3 standard phrase pairs and no hierarchical phrase pairs (Table 8). After discarding noisy alignments (dashed links) by using the proposed method, we extracted 21 standard phrase pairs and 36 hierarchical phrases. Table 9 and Table 10 show selected phrase pairs and hierarchical phrase pairs, respectively.

5 Conclusion and Future Work

In this paper, we proposed a novel method to improve word alignment for SMT. The method refines initial word alignments by transforming discontinuous alignment to continuous alignment. As a result, more useful phrase pairs are extracted from the refined word alignment. Our method is simple and efficient, since it uses only the word translation probabilities obtained from the initial alignments to discard noisy links. Our method is independent of languages and can be applied to most SMT models. Experimental results show significantly improvements for the state-of-the-art phrase-based and hierarchical phrase-based systems on all Chinese-to-English and German-to-English translation tasks.

In the future, we will refine the method by considering neighbor words and alignments when discarding noisy links.

Abstract

Generative word alignment models, such as IBM Models, are restricted to one-to-many alignment, and cannot explicitly represent many-to-many relationships in a bilingual text. The problem is partially solved either by introducing heuristics or by agreement constraints such that two directional word alignments agree with each other. In this paper, we focus on the posterior regularization framework (Ganchev et al., 2010) that can force two directional word alignment models to agree with each other during training, and propose new constraints that can take into account the difference between function words and content words. Experimental results on French-to-English and Japanese-to-English alignment tasks show statistically significant gains over the previous posterior regularization baseline. We also observed gains in Japanese-to-English translation tasks, which prove the effectiveness of our methods under grammatically different language pairs.

1 Introduction

Word alignment is an important component in statistical machine translation (SMT). For instance phrase-based SMT (Koehn et al., 2003) is based on the concept of phrase pairs that are automatically extracted from bilingual data and rely on word alignment annotation. Similarly, the model for hierarchical phrase-based SMT is built from exhaustively extracted phrases that are, in turn, heavily reliant on word alignment.

The Generative word alignment models, such as the IBM Models (Brown et al., 1993) and HMM (Vogel et al., 1996), are popular methods for automatically aligning bilingual texts, but are restricted to represent one-to-many correspondence of each word. To resolve this weakness, various symmetrization methods are proposed. Och and Ney (2003) and Koehn et al. (2003) propose various heuristic methods to combine two directional models to represent many-to-many relationships. As an alternative to heuristic methods, filtering methods employ a threshold to control the trade-off between precision and recall based on a score estimated from the posterior probabilities from two directional models. Matusov et al. (2004) proposed arithmetic means of two models as a score for the filtering, whereas Liang et al. (2006) reported better results using geometric means. The joint training method (Liang et al., 2006) enforces agreement between two directional models. Posterior regularization (Ganchev et al., 2010) is an alternative agreement method which directly encodes agreement during training. DeNero and Macherey (2011) and Chang et al. (2014) also enforce agreement during decoding.

However, these agreement models do not take into account the difference in language pairs, which is crucial for linguistically different language pairs, such as Japanese and English: although content words may be aligned with each other by introducing some agreement constraints, function words are difficult to align.

We focus on the posterior regularization framework and improve upon the previous work by proposing new constraint functions that take into account the difference in languages in terms of content words and function words. In particular, we differentiate between content words and function words by frequency in bilingual data, following Setiawan et al. (2007).

Experimental results show that the proposed methods achieved better alignment qualities on the French-English Hansard data and the Japanese-English Kyoto free translation task (KFTT) measured by AER and F-measure. In translation evaluations, we achieved statistically significant gains

in BLEU scores in the NTCIR10.

2 Statistical word alignment with posterior regularization framework

Given a bilingual sentence $\boldsymbol{x} = (\boldsymbol{x}^s, \boldsymbol{x}^t)$ where $\boldsymbol{x}^s$ and $\boldsymbol{x}^t$ denote a source and target sentence, respectively, the bilingual sentence is aligned by a many-to-many alignment of $\boldsymbol{y}$. We represent posterior probabilities from two directional word alignment models as $\overrightarrow{p}_\theta(\overrightarrow{\boldsymbol{y}}|\boldsymbol{x})$ and $\overleftarrow{p}_\theta(\overleftarrow{\boldsymbol{y}}|\boldsymbol{x})$ with each arrow indicating a particular direction, and use θ to denote the parameters of the models. For instance, $\overrightarrow{y}$ is a subset of $\boldsymbol{y}$ for the alignment from $\boldsymbol{x}^s$ to $\boldsymbol{x}^t$ under the model of $p(\boldsymbol{x}^t, \overrightarrow{\boldsymbol{y}}|\boldsymbol{x}^s)$. In the case of IBM Model 1, the model is represented as follows:

$$p(\boldsymbol{x}^t, \overrightarrow{\boldsymbol{y}}|\boldsymbol{x}^s) = \prod_i \frac{1}{|\boldsymbol{x}^s|+1} p_t(x_i^t|\boldsymbol{x}^s_{\overrightarrow{y}_i}). \quad (1)$$

where we define the index of $\boldsymbol{x}^t$, $\boldsymbol{x}^s$ as $i, j (1 \leq i \leq |\boldsymbol{x}^t|, 1 \leq j \leq |\boldsymbol{x}^s|)$ and the posterior probability for the word pair (x_i^t, x_j^s) is defined as follows:

$$\overrightarrow{p}(i, j|\boldsymbol{x}) = \frac{p_t(x_i^t|x_j^s)}{\sum_{j'} p_t(x_i^t|x_{j'}^s)}. \quad (2)$$

Herein, we assume that the posterior probability for wrong directional alignment is zero (i.e., $\overrightarrow{p}(\overleftarrow{\boldsymbol{y}}|\boldsymbol{x}) = 0$).[1] Given the two directional models, Ganchev et al. defined a symmetric feature for each target/source position pair, i, j as follows:

$$\phi_{i,j}(\boldsymbol{x}, \boldsymbol{y}) = \begin{cases} +1 & (\overrightarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overrightarrow{y}_i = j), \\ -1 & (\overleftarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overleftarrow{y}_j = i), \\ 0 & otherwise. \end{cases} \quad (3)$$

The feature assigns 1 for the subset of word alignment for $\overrightarrow{\boldsymbol{y}}$, but assigns -1 for $\overleftarrow{\boldsymbol{y}}$. As a result, if a word pair i, j is aligned with equal posterior probabilities in two directions, the expectation of the feature value will be zero. Ganchev et al. defined a joint model that combines two directional models using arithmetic means:

$$p_\theta(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{2}\overrightarrow{p}_\theta(\boldsymbol{y}|\boldsymbol{x}) + \frac{1}{2}\overleftarrow{p}_\theta(\boldsymbol{y}|\boldsymbol{x}). \quad (4)$$

Under the posterior regularization framework, we instead use q that is derived by maximizing the following posterior probability parametrized by $\boldsymbol{\lambda}$ for each bilingual data $\boldsymbol{x}$ as follows (Ganchev et al., 2010):

$$q_{\boldsymbol{\lambda}}(\boldsymbol{y}|\boldsymbol{x}) = \frac{\overrightarrow{p}_\theta(\overrightarrow{\boldsymbol{y}}|\boldsymbol{x}) + \overleftarrow{p}_\theta(\overleftarrow{\boldsymbol{y}}|\boldsymbol{x})}{2} \cdot \frac{exp\{-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\}}{Z} \quad (5)$$

$$= \frac{\overrightarrow{q}(\overrightarrow{\boldsymbol{y}}|\boldsymbol{x})\frac{Z_{\overrightarrow{q}}}{\overrightarrow{p}_\theta(\boldsymbol{x})} + \overleftarrow{q}(\overleftarrow{\boldsymbol{y}}|\boldsymbol{x})\frac{Z_{\overleftarrow{q}}}{\overleftarrow{p}_\theta(\boldsymbol{x})}}{2Z},$$

$$Z = \frac{1}{2}\left(\frac{Z_{\overrightarrow{q}}}{\overrightarrow{p}_\theta} + \frac{Z_{\overleftarrow{q}}}{\overleftarrow{p_\theta}}\right),$$

$$\overrightarrow{q}(\overrightarrow{\boldsymbol{y}}|\boldsymbol{x}) = \frac{1}{Z_{\overrightarrow{q}}}\overrightarrow{p}_\theta(\overrightarrow{\boldsymbol{y}}, \boldsymbol{x}) exp\{-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\},$$

$$Z_{\overrightarrow{q}} = \sum_{\overrightarrow{y}} \overrightarrow{p}_\theta(\overrightarrow{\boldsymbol{y}}, \boldsymbol{x}) exp\{-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\},$$

$$\overleftarrow{q}(\overleftarrow{\boldsymbol{y}}|\boldsymbol{x}) = \frac{1}{Z_{\overleftarrow{q}}}\overleftarrow{p}_\theta(\overleftarrow{\boldsymbol{y}}, \boldsymbol{x}) exp\{-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\},$$

$$Z_{\overleftarrow{q}} = \sum_{\overleftarrow{y}} \overleftarrow{p}_\theta(\overleftarrow{\boldsymbol{y}}, \boldsymbol{x}) exp\{-\boldsymbol{\lambda}\cdot\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\},$$

such that $\mathbb{E}_{q_{\boldsymbol{\lambda}}}[\phi_{i,j}(\boldsymbol{x}, \boldsymbol{y})] = 0$. In the E-step of EM-algorithm, we employ $q_{\boldsymbol{\lambda}}$ instead of p_θ to accumulate fractional counts for its use in the M-step. $\boldsymbol{\lambda}$ is efficiently estimated by the gradient ascent for each bilingual sentence $\boldsymbol{x}$. Note that posterior regularization is performed during parameter estimation, and not during testing.

3 Posterior Regularization with Frequency Constraint

The symmetric constraint method represented in Equation (3) assumes a strong one-to-one relation for any word, and does not take into account the divergence in language pairs. For linguistically different language pairs, such as Japanese-English, content words may be easily aligned one-to-one, but function words are not always aligned together. In addition, Japanese is a pro-drop language which can easily violate the symmetric constraint when proper nouns in the English side have to be aligned with a "null" word. In addition, low frequency words may cause unreliable estimates for adjusting the weighing parameters $\boldsymbol{\lambda}$.

In order to solve the problem, we improve Ganchev's symmetric constraint so that it can consider the difference between content words and function words in each language. In particular, we follow the frequency-based idea of Setiawan et al. (2007) that discriminates content words and function words by their frequencies. We propose constraint features that take into account the difference between content words and function words, determined by a frequency threshold.

3.1 Mismatching constraint

First, we propose a mismatching constraint that penalizes word alignment between content words and function words by decreasing the corresponding posterior probabilities.

[1] No alignment is represented by alignment into a special token "null".

The constraint is represented as *f2c* (*function to content*) constraint:

$$\phi^{\text{f2c}}_{i,j}(\boldsymbol{x},\boldsymbol{y}) = \tag{6}$$
$$\begin{cases} +1 & (\overrightarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overrightarrow{y}_i = j) \cap ((x^t_i \in \mathcal{C}^t \cap x^s_j \in \mathcal{F}^s) \\ & \cup (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{C}^s)) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) > 0), \\ 0 & (\overleftarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overleftarrow{y}_j = i) \cap ((x^t_i \in \mathcal{C}^t \cap x^s_j \in \mathcal{F}^s) \\ & \cup (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{C}^s)) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) > 0), \\ 0 & (\overrightarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overrightarrow{y}_i = j) \cap ((x^t_i \in \mathcal{C}^t \cap x^s_j \in \mathcal{F}^s) \\ & \cup (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{C}^s)) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) < 0), \\ -1 & (\overleftarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overleftarrow{y}_j = i) \cap ((x^t_i \in \mathcal{C}^t \cap x^s_j \in \mathcal{F}^s) \\ & \cup (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{C}^s)) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) < 0). \end{cases}$$

where $\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) = \overrightarrow{p}_\theta(i,j|\boldsymbol{x}) - \overleftarrow{p}_\theta(i,j|\boldsymbol{x})$ is the difference in the posterior probabilities between the source-to-target and the target-to-source alignment. $\mathcal{C}^s$ and $\mathcal{C}^t$ represent content words in the source sentence and target sentence, respectively. Similarly, $\mathcal{F}^s$ and $\mathcal{F}^t$ are function words in the source and target sentence, respectively. Intuitively, when there exists a mismatch in content word and function word for a word pair (i,j), the constraint function returns a non-zero value for the model with the highest posterior probability. When coupled with the constraint such that the expectation of the feature value is zero, the constraint function decreases the posterior probability of the highest direction and discourages agreement with each other.

Note that when this constraint is not fired, we fall back to the constraint function in Equation (3) for each word pair.

3.2 Matching constraint

In contrast to the mismatching constraint, our second constraint function rewards alignment for *function to function* word matching, namely *f2f*. The f2f constraint function is defined as follows:

$$\phi^{\text{f2f}}_{i,j}(\boldsymbol{x},\boldsymbol{y}) = \tag{7}$$
$$\begin{cases} +1 & (\overrightarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overrightarrow{y}_i = j) \cap \\ & (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{F}^s) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) > 0), \\ 0 & (\overleftarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overleftarrow{y}_j = i) \cap \\ & (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{F}^s) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) > 0), \\ 0 & (\overrightarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overrightarrow{y}_i = j) \cap \\ & (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{F}^s) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) < 0), \\ -1 & (\overleftarrow{\boldsymbol{y}} \subset \boldsymbol{y}) \cap (\overleftarrow{y}_j = i) \cap \\ & (x^t_i \in \mathcal{F}^t \cap x^s_j \in \mathcal{F}^s) \cap (\delta_{i,j}(\boldsymbol{x},\boldsymbol{y}) < 0). \end{cases}$$

This constraint function returns a non-zero value for a word pair (i,j) when they are function words. As a result, the pair of function words are encouraged to agree with each other, but not other pairs. The *content to content* word matching function *c2c* can be defined similarly by replacing F^s and F^t by C^s and C^t, respectively. Likewise, the *function to content* word matching function *f2c* is defined by considering the matching of content words and function words in two languages. As noted in the mismatch function, when no constraint is fired, we fall back to Eq (3) for each word pair.

4 Experiment

4.1 Experimental Setup

The data sets used in our experiments are the French-English Hansard Corpus, and two data sets for Japanese-English tasks: the Kyoto free translation task (KFTT) and NTCIR10. The Hansard Corpus consists of parallel texts drawn from official records of the proceedings of the Canadian Parliament. The KFTT (Neubig, 2011) is derived from Japanese Wikipedia articles related to Kyoto, which is professionally translated into English. NTCIR10 comes from patent data employed in a machine translation shared task (Goto et al., 2013). The statistics of these data are presented in Table 1.

Sentences of over 40 words on both source and target sides are removed for training alignment models. We used a word alignment toolkit cicada [2] for training the IBM Model 4 with our proposed methods. Training is bootstrapped from IBM Model 1, followed by HMM and IBM Model 4. When generating the final bidirectional word alignment, we use a grow-diag-final heuristic for the Japanese-English tasks and an intersection heuristic in the French-English task, judged by preliminary studies.

Following Bisazza and Federico (2012), we automatically decide the threshold for word frequency to discriminate between content words and function words. Specifically, the threshold is determined by the ratio of highly frequent words. The threshold th is the maximum frequency that satisfies the following equation:

$$\frac{\sum_{w \in (freq(w) > th)} freq(w)}{\sum_{w \in all} freq(w)} > r. \tag{8}$$

Here, we empirically set $r = 0.5$ by preliminary studies. This method is based on the intuition that content words and function words exist in a document at a constant rate.

4.2 Word alignment evaluation

We measure the impact of our proposed methods on the quality of word alignment measured

Table 2: Results of word alignment evaluation with the heuristics-based method (GDF)

	KFTT				Hansard (French-English)			
method	precision	recall	AER	F	precision	recall	AER	F
symmetric	0.4595	0.5942	48.18	0.5182	0.7029	0.8816	*7.29*	0.7822
f2f	**0.4633**	*0.5997*	**47.73**	**0.5227**	**0.7042**	*0.8851*	*7.29*	*0.7844*
c2c	0.4606	0.5964	48.02	0.5198	0.7001	0.8816	7.34	0.7804
f2c	*0.4630*	**0.5998**	*47.74*	*0.5226*	*0.7037*	**0.8871**	**7.10**	**0.7848**

by AER and F-measure (Och and Ney, 2003). Since there exists no distinction for sure-possible alignments in the KFTT data, we use only sure alignment for our evaluation, both for the French-English and the Japanese-English tasks. Table 2 summarizes our results.

The baseline method is symmetric constraint (Ganchev et al., 2010) shown in Table 2. The numbers in bold and in italics indicate the best score and the second best score, respectively. The differences between f2f,f2c and baseline in KFTT are statistically significant at $p < 0.05$ using the sign-test, but in hansard corpus, there exist no significant differences between the baseline and the proposed methods. In terms of F-measure, it is clear that the f2f method is the most effective method in KFTT, and both f2f and f2c methods exceed the original posterior regularized model of Ganchev et al. (2010).

We also compared these methods with filtering methods (Liang et al., 2006), in addition to heuristic methods. We plot precision/recall curves and AER by varying the threshold between 0.1 and 0.9 with 0.1 increments. From Figures, it can be seen that our proposed methods are superior to the baseline in terms of both precision-recall and AER.

4.3 Translation evaluation

Next, we performed a translation evaluation, measured by BLEU (Papineni et al., 2002). We compared the grow-diag-final and filtering method (Liang et al., 2006) for creating phrase tables. The threshold for the filtering factor was set to 0.1 which was the best setting in the word alignment experiment in section 4.2 under KFTT. From the English side of the training data, we trained a word using the 5-gram model with SRILM (Stolcke and others, 2002). "Moses" toolkit was used as a decoder (Koehn et al., 2007) and the model parameters were tuned by k-best MIRA (Cherry and Foster, 2012). In order to avoid tuning instability, we evaluated the average of five runs (Hopkins and May, 2011). The results are summarized in Table 3. Our proposed methods achieved large gains in NTCIR10 task with the filtered method, but observed no gain in the KFTT with the filtered method. In NTCIR10 task with GDF, the gain in BLEU was smaller than that of KFTT. We calculate p-values and the difference between symmetric and c2c (the most effective proposed constraint) are lower than 0.05 in kftt with GDF and NTCIR10 with filtered method. There seems to be no clear tendency in the improved alignment qualities and the translation qualities, as shown in numerous previous studies (Ganchev et al., 2008).

Table 3: Results of translation evaluation

	KFTT		NTCIR10	
	GDF	Filtered	GDF	Filtered
symmetric	19.06	**19.28**	*28.3*	29.71
f2f	*19.15*	19.17	**28.36**	*29.74*
c2c	**19.26**	19.02	**28.36**	**29.92**
f2c	18.91	*19.20*	**28.36**	29.67

5 Conclusion

In this paper, we proposed new constraint functions under the posterior regularization framework. Our constraint functions introduce a fine-grained agreement constraint considering the frequency of words, a assuming that the high frequency words correspond to function words whereas the less frequent words may be treated as content words, based on the previous work of Setiawan et al. (2007). Experiments on word alignment tasks showed better alignment qualities measured by F-measure and AER on both the Hansard task and KFTT. We also observed large gain in BLEU, 0.2 on average, when compared with the previous posterior regularization method under NTCIR10 task.

As our future work, we will investigate more precise methods for deciding function words and content words for better alignment and translation qualities.

Abstract

Distinct properties of translated text have been the subject of research in linguistics for many year (Baker, 1993). In recent years computational methods have been developed to empirically verify the linguistic theories about translated text (Baroni and Bernardini, 2006). While many characteristics of translated text are more apparent in comparison to the original text, most of the prior research has focused on monolingual features of translated and original text. The contribution of this work is introducing bilingual features that are capable of explaining differences in translation direction using localized linguistic phenomena at the phrase or sentence level, rather than using monolingual statistics at the document level. We show that these bilingual features outperform the monolingual features used in prior work (Kurokawa et al., 2009) for the task of classifying translation direction.

1 Introduction

It has been known for many years in linguistics that translated text has distinct patterns compared to original or authored text (Baker, 1993). The term "Translationese" is often used to refer to the characteristics of translated text. Patterns of Translationese can be categorized as follows (Volansky et al., 2013):

1. **Simplification**: The process of translation is often coupled with a simplification process at several levels. For example, there tends to be less lexical variety in translated text and rare words are often avoided.
2. **Explicitation**: Translators often have to be more explicit in their translations due to lack of the cultural context that speakers of the source language have. Another manifestation of this pattern is making arguments more explicit which can be observed in the heavy use of cohesive markers like "therefore" and "moreover" in translated text (Koppel and Ordan, 2011).
3. **Normalization**: Translated text often contains more formal and repeating language.
4. **Interference**: A translator is likely to produce a translation that is structurally and grammatically closer to the source text or their native language.

In Figure 1 the size of a word in the "Translated" section is proportional to the difference between the frequency of the word in original and in the translated text (Fellows, 2013). For example, it is apparent that the word "the" is over-represented in translated English as noted by other research (Volansky et al., 2013). In addition, cohesive markers are clearly more common in translated text.

In the past few years there has been work on machine learning techniques for identifying Translationese. Standard machine learning algorithms like SVMs (Baroni and Bernardini, 2006) and Bayesian Logistic Regression (Koppel and Ordan, 2011) have been employed to train classifiers for one of the following tasks:

i. Given a chunk of text in a specific language, classify it as "Original" or "Translated".
ii. Given a chunk of translated text, predict the source language of the translation.
iii. Given a text chunk pair and their languages, predict the direction of translation.

There are two stated motivations for the tasks above: first, empirical validation of linguistic theories about Translationese (Volansky et al., 2013), and second, improving statistical machine translation by leveraging the knowledge of the translation direction in training and test data (Lember-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 159–164,

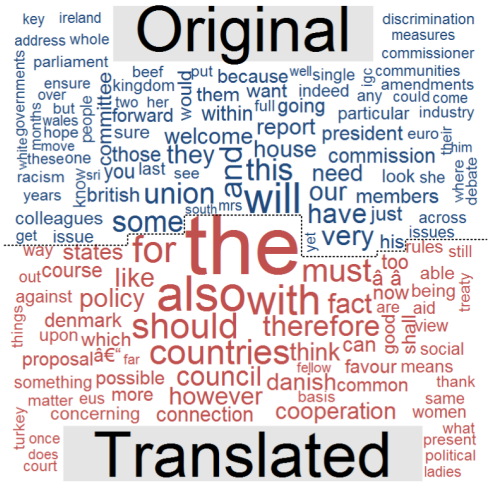

Figure 1: EuroParl Word Cloud Data Visualization (Translated vs Original) [1]

sky et al., 2012a; Lembersky et al., 2013; Lembersky et al., 2012b). Few parallel corpora including a customized version of EuroParl (Islam and Mehler, 2012) and a processed version of Hansard (Kurokawa et al., 2009) are labeled for translated versus original text. Using these limited resources, it has been shown that taking the translation direction into account when training a statistical machine translation system can improve translation quality (Lembersky et al., 2013). However, improving statistical machine translation using translation direction information has been limited by several factors.

1. **Limited Labeled Data**: The amount of labeled data is limited by language and domain and therefore by itself is not enough to make a significant improvement in statistical machine translation.
2. **Cross-Domain Scalability**: Current methods of Translationese detection do not scale across different corpora. For example, a classifier trained on EuroParl corpus (Koehn, 2005) had in-domain accuracy of 92.7% but out-of-domain accuracy of 64.8% (Koppel and Ordan, 2011).
3. **Text Chunk Size**: The reported high accuracy of Translationese detection is based on relatively large (approximately 1500 tokens) text chunks (Koppel and Ordan, 2011). When similar tasks are performed at the sentence level the accuracy drops by 15 percentage points or more (Kurokawa et al., 2009). Figure 2 shows how detection accuracy drops with the reduction of the input text chunk size. Since parallel data are often available at the sentence level or small chunks of text, existing detection methods aren't suitable for this type of data.

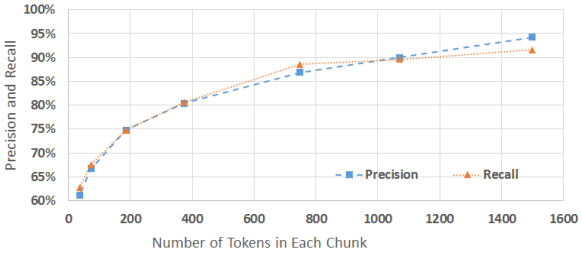

Figure 2: Effects of Chunk Size on Translationese Detection Accuracy[2]

Motivated by these limitations, in this work we focus on improving sentence-level classification accuracy by using non-domain-specific bilingual features at the sentence level. In addition to improving accuracy, these fine-grained features may be better able to confirm existing theories or discover new linguistic phenomena that occur in the translation process. We use a fast linear classifier trained with online learning, Vowpal Wabbit (Langford et al., 2007). The Hansard French-English dataset (Kurokawa et al., 2009) is used for training and test data in all experiments.

2 Related Work

While distinct patterns of Translationese have been studied widely in the past, the work of Baroni and Bernardini (2006) is the first to introduce a computational method for detecting Translationese with high accuracy. Prior work has shown in-domain accuracy can be very high at the chunk-level if fully lexicalized features are used (Volansky et al., 2013), but then the phenomena learned are clearly not generalizable across domains. For example, in Figure 1, it can be observed that content words like "commission", "council" or "union" can be used effectively for classification while they do not capture any general linguistic phenomena and are unlikely to scale

[1]This word cloud was created using the *wordcloud* and *tm* **R** packages (Fellows, 2013) from EuroParl parallel data annotated for translation direction (Islam and Mehler, 2012) obtained from http://www.hucompute.org/ressourcen/corpora/56.

[2]This is a reproduction of the results of Koppel and Ordan (2011) using function word frequencies as features for a logistic regression classifier. Based on the description of how text chunks were created, the results of the paper (92.7% accuracy) are based on text chunk sizes of approximately 1500 tokens.

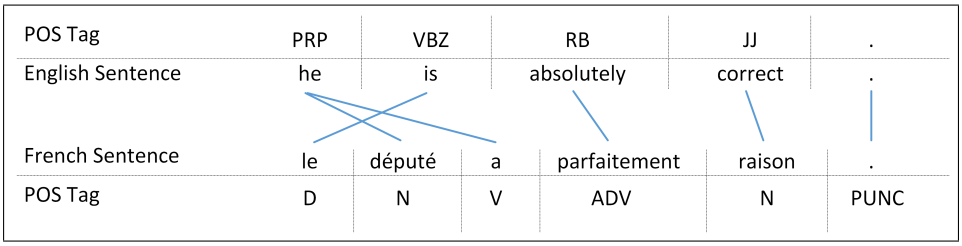

Figure 3: POS Tagged Aligned Sentence Pairs

to other corpora. This is also confirmed by an average human performance of 72.7% precision with 82.1% recall on a similar task where the test subjects were not familiar with the domain and were not able to use domain-specific lexical features (Baroni and Bernardini, 2006). A more general feature set still with high in-domain accuracy is POS tags with lexicalization of function words (Baroni and Bernardini, 2006; Kurokawa et al., 2009). We build on this feature set and explore bilingual features.

The only work to consider features of the two parallel chunks (one original, one translated) is the work of Kurokawa et al. (2009). They simply used the union of the n-gram mixed-POS[3] features of the two sides; these are monolingual features of the original and translated text and do not look at translation phenomena directly. Their work is also the only work to look at sentence level detection accuracy and report 15 percentage points drop in accuracy when going from chunk level to sentence level classification.

3 Bilingual Features for Translation Direction Classification

We are interested in learning common localized linguistic phenomena that occur during the translation process when translating in one direction but not the other.

3.1 POS Tag MTUs

Minimal translation units (MTUs) for a sentence pair are defined as pairs of source and target word sets that satisfy the following conditions (Quirk and Menezes, 2006).

1. No alignment links between distinct MTUs.
2. MTUs are not decomposable into smaller MTUs without violating the previous rule.

We use POS tags to capture linguistic structures and MTUs to map linguistic structures of the two languages. To obtain POS MTUs from a parallel corpus, first, the parallel corpus is word aligned. Next, the source and target side of the corpus are tagged independently. Finally, words are replaced with their corresponding POS tag in word-aligned sentence pairs. MTUs were extracted from the POS tagged word-aligned sentence pairs from left to right and listed in source order. Unigram, bi-gram, and higher order n-gram features were built over this sequence of POS MTUs. For example, for the sentence pair in Figure 3, the following POS MTUs will be extracted: `VBZ⇒D, PRP⇒(N,V), RB⇒ADV, JJ⇒N, .⇒PUNC`.

3.2 Distortion

In addition to the mapping of linguistic structures, another interesting phenomenon is the reordering of linguistic structures during translation. One hypothesis is that when translating from a fixed-order to a free-order language, the order of the target will be very influenced by the source (almost monotone translation), but when translating into a fixed order language, more re-ordering is required to ensure grammaticality of the target. To capture this pattern we add distortion to POS Tag MTU features. We experiment with absolute distortion (word position difference between source and target of a link) as well as HMM distortion (word position difference between the target of a link and the target of the previous link). We bin the distortions into three bins: "$= 0$", "> 0" and "< 0", to reduce sparsity.

4 Experimental Setup

For the translation direction detection task explained in section 1, we use a fast linear classifier trained with online learning, Vowpal Wabbit (Langford et al., 2007). Training data and classification features are explained in section 4.1 and 4.2.

[3]Only replacing content words with their POS tags while leaving function words as is.

	English-POS	French-POS	English-POS + French-POS	POS-MTU	POS-MTU + Absolute Distortion	POS-MTU + HMM Distorition
1-gram	56.59%	51.20%	59.46%	64.37%	64.58%	65.01%
2-gram	61.48%	54.27%	64.43%	69.60%	69.47%	69.29%
3-gram	63.93%	56.04%	67.43%	70.95%	69.45%	69.57%
4-gram	65.28%	57.72%	69.01%	70.29%	68.91%	68.58%
5-gram	65.71%	58.61%	69.32%	69.63%	68.36%	67.55%

Figure 4: Sentence level translation direction detection precision using different features with n-gram lengths of 1 through 5.

4.1 Data

For this task we require a parallel corpus with sentence pairs available in both directions (sentences authored in language A and then translated to language B and vice versa). While the customized version of EuroParl (Islam and Mehler, 2012) contains sentence pairs for many language pairs, none of the language pairs have sentence pairs available in both directions (e.g., it does contain sentences authored in English and translated into French but not vice versa). The Canadian Hansard corpus on the other hand fits the requirement as it has 742,408 sentence pairs translated from French to English and 2,203,504 sentences pairs that were translated from English to French (Kurokawa et al., 2009). We use the Hansard data for training classifiers. For training the HMM word alignment model used to define features, we use a larger set of ten billion words of parallel text from the WMT English-French corpus.

4.2 Preprocessing and Feature Extraction

We used a language filter[4], deduplication filter[5] and length ratio filter to clean the data. After filtering we were left with 1,890,603 English-French sentence pairs and 640,117 French-English sentence pairs. The Stanford POS tagger (Toutanova and Manning, 2000) was used to tag the English and the French sides of the corpus. The HMM alignment model (Vogel et al., 1996) trained on WMT data was used to word-align the Hansard corpus while replacing words with their corresponding POS tags. Due to differences in word breaking between the POS tagger tool and our word alignment tool there were some mismatches. For simplicity we dropped the entire sentence pair whenever a token mismatch occurred. This left us with 401,569 POS tag aligned sentence pairs in the French to English direction and 1,184,702 pairs in the other direction. We chose to create a balanced dataset and reduced the number of English-French sentences to 401,679 with 20,000 sentence pairs held out for testing in each direction.

5 Results

The results of our experiments on the translation direction detection task are listed in Table 4. We would like to point out several results from the table. First, when using only unigram features, the highest accuracy is achieved by the "POS-MTU + HMM Distortion" feature, which uses POS minimal translation units together with distortion. The highest accuracy overall if obtained by a "POS-MTU" trigram model, showing the advantage of bilingual features over prior work using only a union of monolingual features (reproduced by the "English-POS + French-POS" configuration). While higher order features generally show better in-domain accuracy, the advantage of low-order bilingual features might be even higher in cross-domain classification.

[4]A character n-gram language model is used to detect the language of source and target side text and filter them out if they do not match their annotated language.

[5]Duplicate sentences pairs are filtered out.

[6]For description of English POS tags see (Marcus et al., 1993) and (Abeillé et al., 2003) for French

	POS MTU (E⇒F)	FE#	EF#	Example
1	NNPS⇒(N,C)	336	12	quebecers(NNPS) ⇒ québécoises(N) et(C) des québécois
2	IN⇒(CL,V)	69	1027	a few days ago(IN) ⇒ il y(CL) a(V) quelques
3	PRP⇒(N,V)	18	663	he(PRP) is ⇒ le député(N) à(V)
4	(NNP,POS)⇒A	155	28	quebec(NNP) 's(POS) history ⇒ histoire québécoises(A)
5	(FW,FW)⇒ADV	7	195	pro(FW) bono(FW) work ⇒ bénévolement(ADV) travailler
6	(RB,MD)⇒V	2	112	money alone(RB) could(MD) solve ⇒ argent suffirait(V) à résoudre

Table 1: POS MTU features with highest weight. FE# indicates the number of times this feature appeared when translating from French to English.[6]

6 Analysis

An interesting aspect of this work is that it is able to extract features that can be linguistically interpreted. Although linguistic analysis of these features is outside the scope of this work, we list POS MTU features with highest positive or negative weights in Table 1. Although the top feature, NNPS⇒(N,C)[7], in this context is originating from a common phrase used by French speaking members of the Canadian Parliament, québécoises et des québécois, it does highlight an underlying linguistic phenomenon that is not specific to the Canadian Parliament. When translating a plural noun from English to French it is likely that only the masculine form of the noun appears, while if it was authored in French with both forms of the nouns, a single plural noun would appear in English as English doesn't have masculine and feminine forms of the word. A more complete form of this feature would have been NNPS⇒(N,C,N), but since word alignment models, in general, discourage one-to-many alignments, the extracted MTU only covers the first noun and conjunction.

7 Conclusion and Future Work

In this work we introduce new features for translation direction detection that leverage word alignment, source POS and target POS in the form of POS MTUs. POS MTUs are a powerful tool for capturing linguistic interactions between languages during the translation process. Since POS MTUs are not lexical features they are more likely to scale across corpora and domains compared to lexicalized features. Although most of the high weight POS MTU features used in classification (Table 1) are not corpus specific, unfortunately, due to lack of training data in multiple domains, experiments were not run to validate this claim. In future work, we intend to obtain training data from multiple domains that enables us to verify cross-domain scalability of POS-MTUs. In addition, observing linguistic phenomena that occur in one translation direction but not the other can be very informative in improving statistical machine translation quality. Another future direction for this work is leveraging sentence level translation direction detection to improve statistical machine translation output quality. Finally, further investigation of the linguistic interpretation of individual feature that are most discriminating between opposite translation directions can lead to discovery of new linguistic phenomena that occur during the translation process.

Syntax-Augmented Machine Translation using Syntax-Label Clustering

Abstract

Recently, syntactic information has helped significantly to improve statistical machine translation. However, the use of syntactic information may have a negative impact on the speed of translation because of the large number of rules, especially when syntax labels are projected from a parser in syntax-augmented machine translation. In this paper, we propose a syntax-label clustering method that uses an exchange algorithm in which syntax labels are clustered together to reduce the number of rules. The proposed method achieves clustering by directly maximizing the likelihood of synchronous rules, whereas previous work considered only the similarity of probabilistic distributions of labels. We tested the proposed method on Japanese-English and Chinese-English translation tasks and found order-of-magnitude higher clustering speeds for reducing labels and gains in translation quality compared with previous clustering method.

1 Introduction

In recent years, statistical machine translation (SMT) models that use syntactic information have received significant research attention. These models use syntactic information on the source side (Liu et al., 2006; Mylonakis and Sima'an, 2011), the target side (Galley et al., 2006; Huang and Knight, 2006) or both sides (Chiang, 2010; Hanneman and Lavie, 2013) produce syntactically correct translations. Zollmann and Venugopal (2006) proposed syntax-augmented MT (SAMT), which is a MT system that uses syntax labels of a parser. The SAMT grammar directly encodes syntactic information into the synchronous context-free grammar (SCFG) of Hiero (Chiang, 2007), which relies on two nonterminal labels. One problem in adding syntax labels to Hiero-style rules is that only partial phrases are assigned labels. It is common practice to extend labels by using the idea of combinatory categorial grammar (CCG) (Steedman, 2000) on the problem. Although this extended syntactical information may improve the coverage of rules and syntactic correctness in translation, the increased grammar size causes serious speed and data-sparseness problems. To address these problems, Hanneman and Lavie (2013) coarsen syntactic labels using the similarity of the probabilistic distributions of labels in synchronous rules and showed that performance improved.

In the present work, we follow the idea of label-set coarsening and propose a new method to group syntax labels. First, as an optimization criterion, we use the logarithm of the likelihood of synchronous rules instead of the similarity of probabilistic distributions of syntax labels. Second, we use exchange clustering (Uszkoreit and Brants, 2008), which is faster than the agglomerative-clustering algorithm used in the previous work. We tested our proposed method on Japanese-English and Chinese-English translation tasks and observed gains comparable to those of previous work with similar reductions in grammar size.

2 Syntax-Augmented Machine Translation

SAMT is an instance of SCFG $\mathcal{G}$, which can be formally defined as

$$\mathcal{G} = (\mathcal{N}, S, \mathcal{T}_\sigma, \mathcal{T}_\tau, \mathcal{R})$$

where $\mathcal{N}$ is a set of nonterminals, $S \in \mathcal{N}$ is a start label, $\mathcal{T}_\sigma$ and $\mathcal{T}_\tau$ are the source- and target-side terminals, and $\mathcal{R}$ is a set of synchronous rules. Each synchronous rule in $\mathcal{R}$ takes the form

$$X \rightarrow \langle \alpha, \beta, \sim \rangle$$

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 165–171,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

where $X \in \mathcal{N}$ is a nonterminal, $\alpha \in (\mathcal{N} \cup \mathcal{T}_\sigma)*$ is a sequence of nonterminals or source-side terminals, and $\beta \in (\mathcal{N} \cup \mathcal{T}_\tau)*$ is a sequence of nonterminals or target-side terminals. The number $\#NT(\alpha)$ of nonterminals in α is equal to the number $\#NT(\beta)$ of nonterminals in β, and $\sim$: $\{1, ..., \#NT(\alpha)\} \rightarrow \{1, ..., \#NT(\beta)\}$ is a one-to-one mapping from nonterminals in α to nonterminals in β. For each synchronous rule, a nonnegative real-value weight $w(X \rightarrow \langle \alpha, \beta, \sim \rangle)$ is assigned and the sum of the weights of all rules sharing the same left-hand side in a grammar is unity.

Hierarchical phrase-based SMT (Hiero) (Chiang, 2007) translates by using synchronous rules that only have two nonterminal labels X and S but have no linguistic information. SAMT augments the Hiero-style rules with syntax labels from a parser and extends these labels based on CCG. Although the use of extended syntax labels may increase the coverage of rules and improve the potential for syntactically correct translations, the growth of the nonterminal symbols significantly affects the speed of decoding and causes a serious data-sparseness problem.

To address these problems, Hanneman and Lavie (2013) proposed a label-collapsing algorithm, in which syntax labels are clustered by using the similarity of the probabilistic distributions of clustered labels in synchronous rules. First, Hanneman and Lavie defined the label-alignment distribution as

$$P(s|t) = \frac{\#(s,t)}{\#(t)} \tag{1}$$

where $\mathcal{N}_\sigma$ and $\mathcal{N}_\tau$ are the source- and target-side nonterminals in synchronous rules, $s \in \mathcal{N}_\sigma$ and $t \in \mathcal{N}_\tau$ are syntax labels from the source and target sides, $\#(s,t)$ denotes the number of left-hand-side label pairs, and $\#(t)$ denotes the number of target-side labels. Second, for each target-side label pair (t_i, t_j), we calculate the total distance d of the absolute differences in the likelihood of labels that are aligned to a source-side label s:

$$d(t_i, t_j) = \sum_{s \in \mathcal{N}_\sigma} |P(s|t_i) - P(s|t_j)| \tag{2}$$

Next, the closest syntax-label pair of $\hat{t}$ and $\hat{t}'$ is combined into a new single label. The agglomerative clustering is applied iteratively until the number of the syntax labels reaches a given value.

The clustering of Hanneman and Lavie proved successful in decreasing the grammar size and providing a statistically significant improvement in translation quality. However, their method relies on an agglomerative clustering with a worst-case time complexity of $O(|\mathcal{N}|^2 \log |\mathcal{N}|)$. Also, clustering based on label distributions does not always imply higher-quality rules, because it does not consider the interactions of the nonterminals on the left-hand side and the right-hand side in each synchronous rule.

3 Syntax-Label Clustering

As an alternative to using the similarity of probabilistic distributions as a criterion for syntax-label clustering, we propose a clustering method based on the maximum likelihood of the synchronous rules in a training data $\mathcal{D}$. We uses the idea of maximizing the Bayesian posterior probability $P(M|\mathcal{D})$ of the overall model structure M given data $\mathcal{D}$ (Stolcke and Omohundro, 1994). While their goal is to maximize the posterior

$$P(M|\mathcal{D}) \propto P(M)P(\mathcal{D}|M) \tag{3}$$

we omit the prior term $P(M)$ and directly maximize the $P(\mathcal{D}|M)$. A model M is a clustering structure[1] . The synchronous rule in the data $\mathcal{D}$ for SAMT with target-side syntax labels is represented as

$$X \rightarrow \langle a_1 Y^{(1)} a_2 Z^{(2)} a_3, b_1 Y^{(1)} b_2 Z^{(2)} b_3 \rangle \tag{4}$$

where a_1, a_2, a_3 and b_1, b_2, b_3 are the source- and target-side terminals, respectively X, Y, Z are nonterminal syntax labels, and the superscript number indicates alignment between the source- and target-side nonterminals. Using Equation (4) we maximize the posterior probability $P(\mathcal{D}|M)$ which we define as the probability of right-hand side given the syntax label X of the left-hand side rule in the training data as follows:

$$\sum_{X \rightarrow \langle \alpha, \beta, \sim \rangle \in \mathcal{D}} \log Pr(\langle \alpha, \beta, \sim \rangle | X) \tag{5}$$

For the sake of simplicity, we assume that the generative probability for each rule does not depend on the existence of terminal symbols and that the reordering in the target side may be ignored. Therefore, Equation (5) simplifies to

$$\sum_{X \rightarrow \langle a_1 Y^{(1)} a_2 Z^{(2)} a_3, b_1 Y^{(1)} b_2 Z^{(2)} b_3 \rangle} \log p(Y, Z|X) \tag{6}$$

[1] $P(M)$ is reflected by the number of clusters.

3.1 Optimization Criterion

The generative probability in each rule of the form of Equation (6) can be approximated by clustering nonterminal symbols as follows:

$$p(Y,Z|X) \approx p(Y|c(Y)) \cdot p(Z|c(Z)) \cdot p(c(Y),c(Z)|c(X)) \quad (7)$$

where we map a syntax label X to its equivalence cluster $c(X)$. This can be regarded as the clustering criterion usually used in a class-based n-gram language model (Brown et al., 1992). If each label on the right-hand side of a synchronous rule (4) is independent of each other, we can factor the joint model as follows:

$$p(Y,Z|X) \approx p(Y|c(Y)) \cdot p(Z|c(Z)) \cdot p(c(Y)|c(X)) p(c(Z)|c(X)) \quad (8)$$

We introduce the predictive idea of Uszkoreit and Brants (2008) to Equation (8), which doesn't condition on the clustered label $c(X)$, but directly on the syntax label X:

$$p(Y,Z|X) \approx p(Y|c(Y)) \cdot p(Z|c(Z)) \cdot p(c(Y)|X) \cdot p(c(Z)|X) \quad (9)$$

The objective in Equation (9) is represented using the frequency in the training data as

$$\frac{N(Y)}{N(c(Y))} \cdot \frac{N(X,c(Y))}{N(X)} \cdot \frac{N(Z)}{N(c(Z))} \cdot \frac{N(X,c(Z))}{N(X)} \quad (10)$$

where $N(X)$ and $N(c(X))$ denote the frequency[2] of X and $c(X)$, and $N(X,K)$ denotes the frequency of cluster K in the right-hand side of a synchronous rule whose left-hand side syntax label is X. By replacing the rule probabilities in Equation (9) with Equation (10) and plugging the result into Equation (6), our objective becomes

$$\begin{aligned} F(\mathcal{C}) &= \sum_{Y \in \mathcal{N}} N(Y) \cdot \log \frac{N(Y)}{N(c(Y))} + \sum_{X \in \mathcal{N}, K \in \mathcal{C}} N(X,K) \cdot \log \frac{N(X,K)}{N(X)} \\ &= \sum_{Y \in \mathcal{N}} N(Y) \cdot \log N(Y) - \sum_{Y \in \mathcal{N}} N(Y) \cdot \log N(c(Y)) + \sum_{X \in \mathcal{N}, K \in \mathcal{C}} N(X,K) \cdot \log N(X,K) - \sum_{X \in \mathcal{N}, K \in \mathcal{C}} N(X,K) \cdot \log N(X) \end{aligned} \quad (11)$$

[2] We use a fractional count (Chiang, 2007) which adds up to one as a frequency.

start with the initial mapping (label $X \rightarrow c(X)$)
compute objective function $F(\mathcal{C})$
for each label X do
remove label X from $c(X)$
for each cluster K do
move label X tentatively to cluster K
compute $F(\mathcal{C})$ for this exchange
move label X to cluster with maximum $F(\mathcal{C})$
do until the cluster mapping does not change

Table 1: Outline of syntax-label clustering method

where $\mathcal{C}$ denotes all clusters and $\mathcal{N}$ denotes all syntax labels. For Equation (11), the last summation is equivalent to the sum of the occurrences of all syntax labels, and canceled out by the first summation. K in the third summation considers clusters in a synchronous rule whose left-hand side label is X, and we let $ch(X)$ denote a set of those clusters. The second summation equals $\sum_{K \in C} N(K) \cdot \log N(K)$. As a result, Equation (11) simplifies to

$$F(\mathcal{C}) = \sum_{X \in \mathcal{N}, K \in ch(X)} N(X,K) \cdot \log N(X,K) - \sum_{K \in \mathcal{C}} N(K) \cdot \log N(K) \quad (12)$$

3.2 Exchange Clustering

We used an exchange clustering algorithm (Uszkoreit and Brants, 2008) which was proven to be very efficient in word clustering with a vocabulary of over 1 million words. The exchange clustering for words begins with the initial clustering of words and greedily exchanges words from one cluster to another such that an optimization criterion is maximized after the move. While agglomerative clustering requires recalculation for all pair-wise distances between words, exchange clustering only demands computing the difference of the objective for the word pair involved in a particular movement. We applied this exchange clustering to syntax-label clustering. Table 1 shows the outline. For initial clustering, we partitioned all the syntax labels into clusters according to the frequency of syntax labels in synchronous rules. If `remove` and `move` are as computationally intensive as computing the change in $F(\mathcal{C})$ in Equation (12), then the time complexity of `remove` and `move` is $O(K)$ (Martin et al., 1998), where K is the number of clusters. Since the `remove` procedure is called once for each label and, for a given label, the `move` procedure is called $K-1$ times

Data	Lang	Training			Development		Test	
		sent	src-tokens	tgt-tokens	sent	tgt-tokens	sent	tgt-tokens
IWSLT07	J to E	40 K	483 K	369 K	500	7.4 K	489	3.7 K
FBIS	C to E	302 K	2.7 M	3.4 M	1,664	47 K	919	30 K
NIST08		1 M	15 M	17 M				

Table 2: Data sets: The "sent" column indicates the number of sentences. The "src-tokens" and "tgt-tokens" columns indicate the number of words in the source- and the target-side sentences.

to find the maximum $F(\mathcal{C})$, the worst-time complexity for one iteration of the syntax-label clustering is $O(|\mathcal{N}|K^2)$. The exchange procedure is continued until the cluster mapping is stable or the number of iterations reaches a threshold value of 100.

4 Experiments

4.1 Data

We conducted experiments on Japanese-English (ja-en) and Chinese-English (zh-en) translation tasks. The ja-en data comes from IWSLT07 (Fordyce, 2007) in a spoken travel domain. The tuning set has seven English references and the test set has six English references. For zh-en data we prepared two kind of data. The one is extracted from FBIS[3], which is a collection of news articles. The other is 1 M sentences extracted rondomly from NIST Open MT 2008 task (NIST08). We use the NIST Open MT 2006 for tuning and the MT 2003 for testing. The tuning and test sets have four English references. Table 2 shows the details for each corpus. Each corpus is tokenized, put in lower-case, and sentences with over 40 tokens on either side are removed from the training data. We use KyTea (Neubig et al., 2011) to tokenize the Japanese data and Stanford Word Segmenter (Tseng et al., 2005) to tokenize the Chinese data. We parse the English data with the Berkeley parser (Petrov and Klein, 2007).

4.2 Experiment design

We did experiments with the SAMT (Zollmann and Venugopal, 2006) model with the Moses (Koehn et al., 2007). For the SAMT model, we conducted experiments with two label sets. One is extracted from the phrase structure parses and the other is extended with CCG[4]. We applied the proposed method (+*clustering*) and the baseline method (+*coarsening*), which uses the Hanneman label-collapsing algorithm described in Section 2, for syntax-label clustering to the SAMT models with *CCG*. The number of clusters for each clustering was set to 80. The language models were built using SRILM Toolkits (Stolcke, 2002). The language model with the IWSLT07 is a 5-gram model trained on the training data, and the language model with the FBIS and NIST08 is a 5-gram model trained on the Xinhua portion of English GigaWord. For word alignments, we used MGIZA++ (Gao and Vogel, 2008). To tune the weights for BLEU (Papineni et al., 2002), we used the n-best batch MIRA (Cherry and Foster, 2012).

5 Results and analysis

Tables 3 and 4 present the details of SAMT grammars with each label set learned by the experiments using the IWSLT07 (ja-en), FBIS and NIST08 (zh-en), which include the number of syntax labels and synchronous rules, the values of the objective ($F(\mathcal{C})$), and the standard deviation (SD) of the number of labels assigned to each cluster. For NIST08 we applied only the + *clustering* because the + *coarsening* needs a huge amount of computation time. Table 5 shows the differences between the BLEU score and the rule number for

each cluster number when using the IWSLT07 dataset.

Since the +*clustering* maximizes the likelihood of synchronous rules, it can introduce appropriate rules adapted to training data given a fixed number of clusters. For each experiment, SAMT grammars with the +*clustering* have a greater number of rules than with the +*coarsening* and, as shown in Table 5, the number of synchronous rules with +*clustering* increase with the number of clusters. For +*clustering* with eight clusters and +*coarsening* with 80 clusters, which have almost $2.4M$ rules, the BLEU score of +*clustering* with eight clusters is higher. Also, the SD of the number of labels, which indicates the balance of the number of labels among clusters, with +*clustering* is smaller than with +*coarsening*. These results suggest that +*clustering* maintain a large-scale variation of synchronous rules for high performance by balancing the number of labels in each cluster.

The number of synchronous rules grows as you progress from +*coarsening* to +*clustering* and finally to raw label with *CCG*. To confirm the effect of the number of rules, we measured the decoding time per sentence for translating the test set by taking the average of ten runs with FBIS corpus. +*coarsening* takes 0.14 s and +*clustering* takes 0.16 s while raw label with CCG takes 0.37s. Thus the increase in the number of synchronous rules adversely affects the decoding speed.

Table 6 presents the results for the experiments[5] using ja-en and zh-en with the BLEU metric. SAMT with *parse* have the lowest BLEU scores. It appears that the linguistic information of the raw syntax labels of the phrase structure parses is not enough to improve the translation performance. Hiero has the higher BLEU score than SAMT with *CCG* on zh-en. This is likely due to the low accuracy of the parses, on which SAMT relies while Hiero doesn't. SAMT with + *clustering* have the higher BLEU score than raw label with *CCG*. For SAMT with *CCG* using IWSLT07 and FBIS, though the statistical significance tests were not significant when $p < 0.05$, +*clustering* have the higher BLEU scores than +*coarsening*. For these results, the performance of +*clustering* is comparable to that of +*coarsening*. For the complexity of both clustering algorithm, though it is difficult to evaluate directly because the speed

[5]As another baseline, we also used Phrase-based SMT (Koehn et al., 2003) and Hiero (Chiang, 2007).

depends on how each algorithm is implemented, +*clustering* is an order of magnitude faster than +*coarsening*. For the clustering experiment that groups 5460 raw labels with *CCG* into 80 clusters using FBIS corpus, +*coarsening* takes about 1 week whereas +*clustering* takes about 10 minutes.

6 Conclusion

In this paper, we propose syntax-label clustering for SAMT, which uses syntax-label information to generate syntactically correct translations. One of the problems of SAMT is the large grammar size when a CCG-style extended label set is used in the grammar, which make decoding slower. We cluster syntax labels with a very fast exchange algorithm in which the generative probabilities of synchronous rules are maximized. We demonstrate the effectiveness of the proposed method by using it to translate Japanese-English and Chinese-English tasks and measuring the decoding speed, the accuracy and the clustering speed. Future work involves improving the optimization criterion. We expect to make a new objective that includes the terminal symbols and the reordering of nonterminal symbols that were ignored in this work. Another interesting direction is to determine the appropriate number of clusters for each corpus and the initialization method for clustering.

Testing for Significance of Increased Correlation with Human Judgment

Abstract

Automatic metrics are widely used in machine translation as a substitute for human assessment. With the introduction of any new metric comes the question of just how well that metric mimics human assessment of translation quality. This is often measured by correlation with human judgment. Significance tests are generally not used to establish whether improvements over existing methods such as BLEU are statistically significant or have occurred simply by chance, however. In this paper, we introduce a significance test for comparing correlations of two metrics, along with an open-source implementation of the test. When applied to a range of metrics across seven language pairs, tests show that for a high proportion of metrics, there is insufficient evidence to conclude significant improvement over BLEU.

1 Introduction

Within machine translation (MT), efforts are ongoing to improve evaluation metrics and find better ways to automatically assess translation quality. The process of validating a new metric involves demonstration that it correlates better with human judgment than a standard metric such as BLEU (Papineni et al., 2001). However, although it is standard practice in MT evaluation to measure increases in automatic metric scores with significance tests (Germann, 2003; Och, 2003; Kumar and Byrne, 2004; Koehn, 2004; Riezler and Maxwell, 2005; Graham et al., 2014), this has not been the case in papers proposing new metrics. Thus it is possible that some reported improvements in correlation with human judgment are attributable to chance rather than a systematic improvement.

In this paper, we motivate and introduce a novel significance test to assess the statistical significance of differences in correlation with human judgment for pairs of automatic metrics. We apply tests to the WMT-12 shared metrics task to compare each of the participating methods, and find that for a high proportion of metrics, there is not enough evidence to conclude that they significantly outperform BLEU.

2 Correlation with Human Judgment

A common means of assessing automatic MT evaluation metrics is Spearman's rank correlation with human judgments (Melamed et al., 2003), which measures the relative degree of monotonicity between the metric and human scores in the range $[-1, 1]$. The standard justification for calculating correlations over ranks rather than raw scores is to: (a) reduce anomalies due to absolute score differences; and (b) focus evaluation on what is generally the primary area of interest, namely the ranking of systems/translations.

An alternative means of evaluation is Pearson's correlation, which measures the linear correlation between a metric and human scores (Leusch et al., 2003). Debate on the relative merits of Spearman's and Pearson's correlation for the evaluation of automatic metrics is ongoing, but there is an increasing trend towards Pearson's correlation, e.g. in the recent WMT-14 shared metrics task.

Figure 1 presents the system-level results for two evaluation metrics – AMBER (Chen et al., 2012) and TERRORCAT (Fishel et al., 2012) – over the WMT-12 Spanish-to-English metrics task. These two metrics achieved the joint-highest rank correlation ($\rho = 0.965$) for the task, but differ greatly in terms of Pearson's correlation ($r = 0.881$ vs. 0.971, resp.). The largest contributor to this artifact is the system with the lowest human score, represented by the leftmost point in both plots.

(a) AMBER (b) TERRORCAT

Figure 1: Scatter plot of human and automatic scores of WMT-12 Spanish-to-English systems for two MT evaluation metrics (AMBER and TERRORCAT)

Consistent with the WMT-14 metrics shared task, we argue that Pearson's correlation is more sensitive than Spearman's correlation. There is still the question, however, of whether an observed difference in Pearson's r is statistically significant, which we address in the next section.

3 Significance Testing

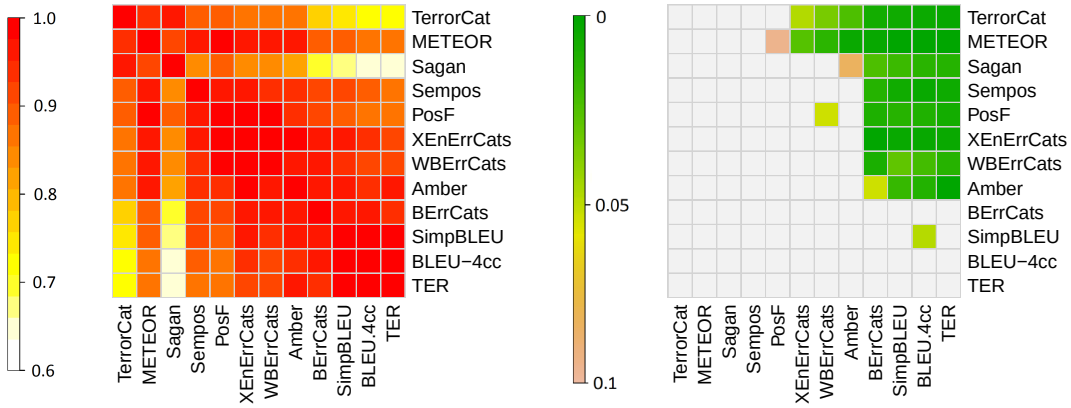
Evaluation of a new automatic metric, M_{new}, commonly takes the form of quantifying the correlation between the new metric and human judgment, $r(M_{new}, H)$, and contrasting it with the correlation for some baseline metric, $r(M_{base}, H)$. It is very rare in the MT literature for significance testing to be performed in such cases, however. We introduce a statistical test which can be used for this purpose, and apply the test to the evaluation of metrics participating in the WMT-12 metric evaluation task.

At first gloss, it might seem reasonable to perform significance testing in the following manner when an increase in correlation with human assessment is observed: apply a significance test separately to the correlation of each metric with human judgment, with the hope that the newly proposed metric will achieve a significant correlation where the baseline metric does not. However, besides the fact that the correlation between almost any document-level metric and human judgment will generally be significantly greater than zero, the logic here is flawed: the fact that one correlation is significantly higher than zero ($r(M_{new}, H)$) and that of another is not, does not necessarily mean that the *difference* between the two correlations is significant. Instead, a specific test should be applied to the difference in correlations on the data. For this same reason, confidence intervals for individual correlations with human judgment are also not particularly meaningful.

In psychological studies, it is often the case that samples that data are drawn from are independent, and differences in correlations are computed on independent data sets. In such cases, the Fisher r to z transformation is applied to test for significant differences in correlations. In the case of automatic metric evaluation, however, the data sets used are almost never independent. This means that if $r(M_{base}, H)$ and $r(M_{new}, H)$ are both > 0, the correlation between the metric scores themselves, $r(M_{base}, M_{new})$, must also be > 0. The strength of this correlation, directly between pairs of metrics, should be taken into account using a significance test of the difference in correlation between $r(M_{base}, H)$ and $r(M_{new}, H)$.

3.1 Correlated Correlations

Correlations computed for two separate automatic metrics on the same data set are not independent, and for this reason in order to test the difference in correlation between them, the degree to which the pair of metrics correlate with each other should be taken into account. The Williams test (Williams,



(a) Pearson's correlation (b) Statistical significance

Figure 2: (a) Pearson's correlation between pairs of automatic metrics; and (b) p-value of Williams significance tests, where a colored cell in row i (named on y-axis), col j indicates that metric i (named on x-axis) correlates significantly higher with human judgment than metric j; all results are based on the WMT-12 Spanish-to-English data set.

1959)[1] evaluates significance in a difference in dependent correlations (Steiger, 1980). It is formulated as follows, as a test of whether the population correlation between X_1 and X_3 equals the population correlation between X_2 and X_3:

$$t(n-3) = \frac{(r_{13} - r_{23})\sqrt{(n-1)(1+r_{12})}}{\sqrt{2K\frac{(n-1)}{(n-3)} + \frac{(r_{23}+r_{13})^2}{4}(1-r_{12})^3}},$$

where r_{ij} is the Pearson correlation between X_i and X_j, n is the size of the population, and:

$$K = 1 - {r_{12}}^2 - {r_{13}}^2 - {r_{23}}^2 + 2r_{12}r_{13}r_{23}$$

The Williams test is more powerful than the equivalent for independent samples (Fisher r to z), as it takes the correlations between X_1 and X_2 (metric scores) into account. All else being equal, the higher the correlation between the metric scores, the greater the statistical power of the test.

4 Evaluation and Discussion

Figure 2a is a heatmap of the degree to which automatic metrics correlate with one another when computed on the same data set, in the form of the Pearson's correlation between each pair of metrics that participated in the WMT-12 metrics task for Spanish-to-English evaluation. Metrics are ordered in all tables from highest to lowest *correlation with human assessment*. In addition, for the purposes of significance testing, we take the absolute value of all correlations, in order to compare error-based metrics with non-error based ones.

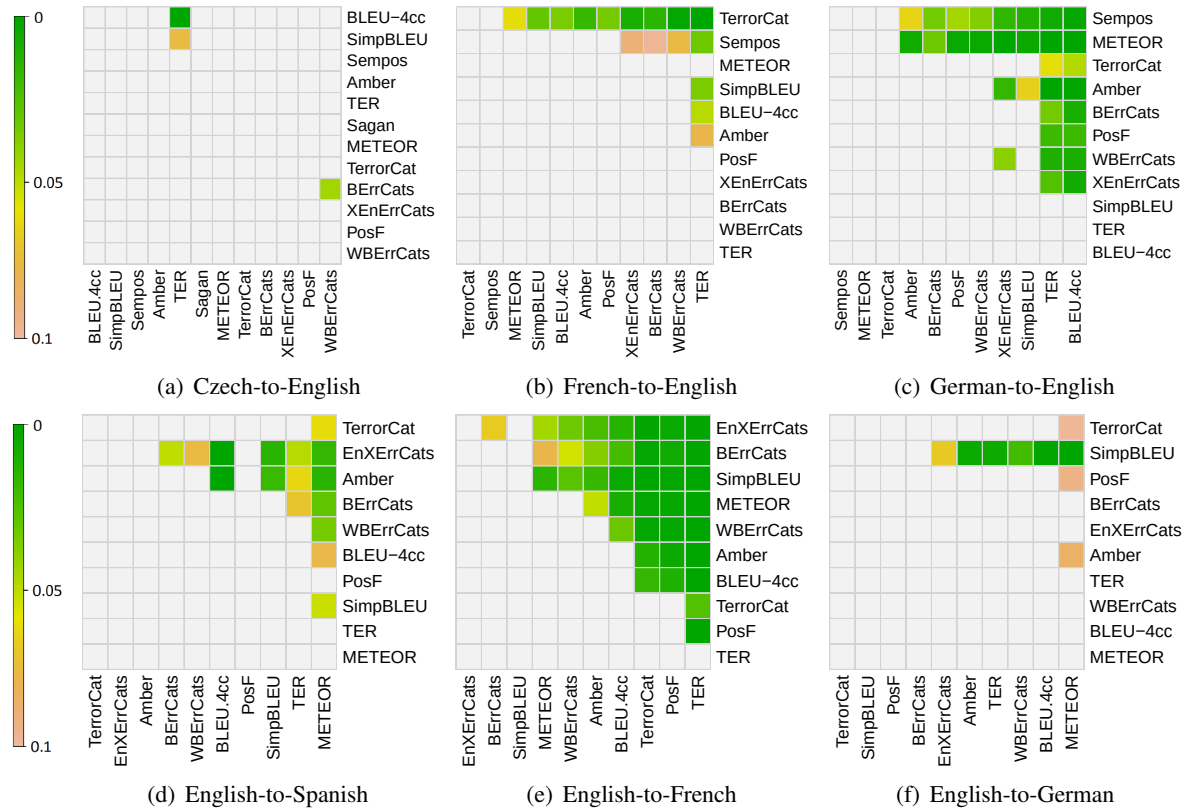
In general, the correlation is high amongst all pairs of metrics, with a high proportion of paired metrics achieving a correlation in excess of $r = 0.9$. Two exceptions to this are TERRORCAT (Fishel et al., 2012) and SAGAN (Castillo and Estrella, 2012), as seen in the regions of yellow and white.

Figure 2b shows the results of Williams significance tests for all pairs of metrics. Since we are interested in not only identifying significant differences in correlations, but ultimately ranking competing metrics, we use a one-sided test. Here again, the metrics are ordered from highest to lowest (absolute) correlation with human judgment.

For the Spanish-to-English systems, approximately 60% of WMT-12 metric pairs show a significant difference in correlation with human judgment at $p < 0.05$ (for one of the two metric directions).[2] As expected, the higher the correlation with human judgment, the more metrics a given method is superior to at a level of statistical significance. Although TERRORCAT (Fishel et al., 2012) achieves the highest absolute correlation with human judgment, it is not significantly better ($p \geq 0.05$) than the four next-best metrics (METEOR (Denkowski and Lavie, 2011), SAGAN (Castillo and Estrella, 2012), SEMPOS (Macháček and Bo-

[1] Also sometimes referred to as the Hotelling–Williams test.

[2] Correlation matrices (red) are maximally filled, in contrast to one-sided significance test matrices (green), where, at a maximum, fewer than half of the cells can be filled.



(a) Czech-to-English (b) French-to-English (c) German-to-English

Figure 3: Significance results for pairs of automatic metrics for each WMT-12 language pair.

jar, 2011) and POSF (Popovic, 2012)). There is not enough evidence to conclude, therefore, that this metric is any better at evaluating Spanish-to-English MT system quality than the next four metrics.

Figure 3 shows the results of significance tests for the six other language pairs used in the WMT-12 metrics shared task.[3] For no language pair is there an outright winner amongst the metrics, with proportions of significant differences between metrics for a given language pair ranging from 3% for Czech-to-English to 82% for English-to-French ($p < 0.05$). The number of metrics that significantly outperform BLEU for a given language pair is only 34% ($p < 0.05$), and no method significantly outperforms BLEU over all language pairs – indeed, even the best methods achieve statistical significance over BLEU for only a small minority of language pairs. This underlines the dangers of assessing metrics based solely on correlation numbers, and emphasizes the importance of statistical testing.

It is important to note that the number of competing metrics a metric significantly outperforms should not be used as the criterion for ranking competing metrics. This is due to the fact that the power of the Williams test to identify significant differences between correlations changes depending on the degree to which the pair of metrics correlate with each other. Therefore, a metric that happens to correlate strongly with many other metrics would be at an unfair advantage, were numbers of significant wins to be used to rank metrics. For this reason, it is best to interpret pairwise metric tests in isolation.

As part of this research, we have made available an open-source implementation of statistical tests tailored to the assessment of MT metrics available at `https://github.com/ygraham/significance-williams`.

5 Conclusions

We have provided an analysis of current methodologies for evaluating automatic metrics in machine translation, and identified an issue with respect to the lack of significance testing. We introduced the Williams test as a means of calculating the statistical significance of differences

[3] We omit English-to-Czech due to some metric scores being omitted from the WMT-12 data set.

in correlations for dependent samples. Analysis of statistical significance in the WMT-12 metrics shared task showed there is currently insufficient evidence for a high proportion of metrics to conclude that they outperform BLEU.

Abstract

We study a novel architecture for syntactic SMT. In contrast to the dominant approach in the literature, the system does not rely on translation rules, but treat translation as an unconstrained target sentence generation task, using soft features to capture lexical and syntactic correspondences between the source and target languages. Target syntax features and bilingual translation features are trained consistently in a discriminative model. Experiments using the IWSLT 2010 dataset show that the system achieves BLEU comparable to the state-of-the-art syntactic SMT systems.

1 Introduction

Translation rules have been central to hierarchical phrase-based and syntactic statistical machine translation (SMT) (Galley et al., 2004; Chiang, 2005; Liu et al., 2006; Quirk et al., 2005; Marcu et al., 2006; Shen and Joshi, 2008; Xie et al., 2011). They are attractive by capturing the recursiveness of languages and syntactic correspondences between them. One important advantage of translation rules is that they allow efficient decoding by treating MT as a statistical **parsing** task, transforming a source sentence to its translation via recursive rule application.

The efficiency takes root in the fact that target word orders are encoded in translation rules. This fact, however, also leads to rule explosion, noise and coverage problems (Auli et al., 2009), which can hurt translation quality. Flexibility of function word usage, rich morphology and paraphrasing all add to the difficulty of rule extraction. In addition, restricting target word orders by hard translation rules can also hurt output fluency.

* Work done while visiting Singapore University of Technology and Design (SUTD)

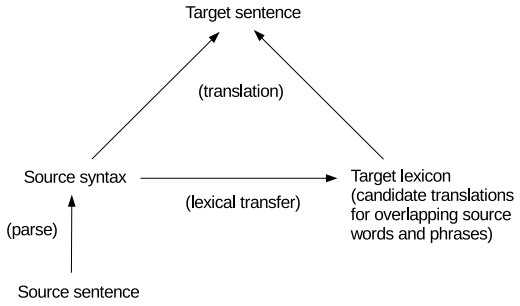

Figure 1: Overall system architecture.

A potential solution to the problems above is to treat translation as a **generation** task, representing syntactic correspondences using *soft* features. Both adequacy and fluency can potentially be improved by giving full flexibility to target synthesis, and leaving all options to the statistical model. The main challenge to this method is a significant increase in the search space (Knight, 1999). To this end, recent advances in tackling complex search tasks for text generation offer some solutions (White and Rajkumar, 2009; Zhang and Clark, 2011).

In this short paper, we present a preliminary investigation on the possibility of building a syntactic SMT system that does not use hard translation rules, by utilizing recent advances in statistical natural language generation (NLG). The overall architecture is shown in Figure 1. Translation is performed by first parsing the source sentence, then transferring source words and phrases to their target equivalences, and finally synthesizing the target output.

We choose dependency grammar for both the source and the target syntax, and adapt the syntactic text synthesis system of Zhang (2013), which performs dependency-based linearization. The linearization task for MT is different from the monolingual task in that not all translation options are used to build the output, and that bilingual correspondences need to be taken into account dur-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 177–182,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ing synthesis. The algorithms of Zhang (2013) are modified to perform word selection as well as ordering, using two sets of features to control translation adequacy and fluency, respectively.

Preliminary experiments on the IWSLT[1] 2010 data show that the system gives BLEU comparable to traditional tree-to-string and string-to-tree translation systems. It demonstrates the feasibility of leveraging statistical NLG techniques for SMT, and the possibility of building a statistical transfer-based MT system.

2 Approach

The main goal being proof of concept, we keep the system simple by utilizing existing methods for the main components, minimizing engineering efforts. Shown in Figure 1, the end-to-end system consists of two main components: *lexical transfer* and *synthesis*. The former provides candidate translations for (overlapping) source words and phrases. Although lexicons and rules can be used for this step, we take a simple statistical alignment-based approach. The latter searches for a target translation by constructing dependency trees bottom-up. The process can be viewed as a syntax-based generation process from a bag of overlapping translation options.

2.1 Lexical transfer

We perform word alignment using IBM model 4 (Brown et al., 1993), and then extract phrase pairs according to the alignment and automatically-annotated target syntax. In particular, consistent (Och et al., 1999) and cohesive (Fox, 2002) phrase pairs are extracted from intersected alignments in both directions: the target side must form a projective span, with a single root, and the source side must be contiguous. A resulting phrase pair consists of the source phrase, its target translation, as well as the head position and head part-of-speech (POS) of the target span, which are useful for target synthesis. We further restrict that neither the source nor the target side of a valid phrase pair contains over s words.

Given an input source sentence, the lexical transfer unit finds all valid target translation options for overlapping source phrases up to size s, and feeds them as inputs to the target synthesis decoder. The translation options with a probability below $\lambda \cdot P_{max}$ are filtered out, where P_{max} is the probability of the most probable translation. Here the probability of a target translation is calculated as the count of the translation divided by the count of all translations of the source phrase.

2.2 Synthesis

The synthesis module is based on the monolingual text synthesis algorithm of Zhang (2013), which constructs an ordered dependency tree given a bag of words. In the bilingual setting, inputs to the algorithm are translation options, which can be overlapping and mutually exclusive, and not necessarily all of which are included in the output. As a result, the decoder needs to perform word selection in addition to word ordering. Another difference between the bilingual and monolingual settings is that the former requires translation adequacy in addition to output fluency.

We largely rely on the monolingual system for MT decoding. To deal with overlapping translation options, a source coverage vector is used to impose mutual exclusiveness on input words and phrases. Each element in the coverage vector is a binary value that indicates whether a particular source word has been translated in the corresponding target hypothesis. For translation adequacy, we use a set of bilingual features on top of the set of monolingual features for text synthesis.

2.2.1 Search

The search algorithm is the best-first algorithm of Zhang (2013). Each search hypothesis is a partial or full target-language dependency tree, and hypotheses are constructed bottom-up from leaf nodes, which are translation options. An *agenda* is used to maintain a list of search hypothesis to be expanded, and a *chart* is used to record a set of accepted hypotheses. Initially empty, the chart is a beam of size $k \cdot n$, where n is the number of source words and k is a positive integer. The agenda is a priority queue, initialized with all leaf hypotheses (i.e. translation options). At each step, the highest-scored hypothesis e is popped off the agenda, and expanded by combination with all hypotheses on the chart in all possible ways, with the set of newly generated hypotheses $e_1, e_2, ...e_N$ being put onto the agenda, and e being put onto the chart. When two hypotheses are combined, they can be put in two different orders, and in each case different dependencies can be constructed between their head words, leading to different new

hypotheses. The decoder expands a fixed number L hypotheses, and then takes the highest-scored chart hypothesis that contains over $\beta \cdot n$ words as the output, where β is a real number near 1.0.

2.2.2 Model and training

A scaled linear model is used by the decoder to score search hypotheses:

$$Score(e) = \frac{\vec{\theta} \cdot \Phi(e)}{|e|},$$

where $\Phi(e)$ is the global feature vector of the hypothesis e, $\vec{\theta}$ is the parameter vector of the model, and $|e|$ is the number of leaf nodes in e. The scaling factor $|e|$ is necessary because hypotheses with different numbers of words are compared with each other in the search process to capture translation equivalence.

While the monolingual features of Zhang (2013) are applied (example feature templates from the system are shown in Table 1), an additional set of bilingual features is defined, shown

Table 2: Bilingual feature templates.

in Table 2. In the tables, s and t represent the source and target, respectively; h and m represent the head and modifier in a dependency arc, respectively; h_l and h_r represent the neighboring words on the left and right of h, respectively; m_l and m_r represent the neighboring words on the left and right of m, respectively; m_1 and m_2 represent the closest and second closest sibling of m on the side of h, respectively. dir represents the arc direction (i.e. left or right); PHRASE represents a lexical phrase; P($trans$) represents the source-to-target translation probability from the phrase-table, used as a real-valued feature; $path$ represents the shortest path in the source dependency tree between the two nodes that correspond to the target head and modifier, respectively; LEN($path$) represents the number of arcs on *path*, normalized to bins of [5, 10, 20, 40+]; LABELS($path$) represents the array of dependency arc labels on *path*; LABELSPOS($path$) represents the array of dependency arc labels and source POS on *path*. In addition, a real-valued four-gram language model feature is also used, with four-grams extracted from the surface boundary when two hypothesis are combined.

We apply the discriminative learning algorithm of Zhang (2013) to train the parameters $\vec{\theta}$. The algorithm requires training examples that consist of full target derivations, with leaf nodes being *input translation options*. However, the readily available

training examples are automatically-parsed target derivations, with leaf nodes being *the reference translation*. As a result, we apply a search procedure to find a derivation process, through which the target dependency tree is constructed from a subset of input translation options. The search procedure can be treated as a constrained decoding process, where only the oracle tree and its sub trees can be constructed. In case the set of translation options cannot lead to the oracle tree, we ignore the training instance.[2] Although the ignored training sentence pairs cannot be utilized for training the discriminative synthesizer, they are nevertheless used for building the phrase table and training the language model.

3 Experiments

We perform experiments on the IWSLT 2010 Chinese-English dataset, which consists of training sentence pairs from the dialog task (dialog) and Basic Travel and Expression Corpus (BTEC). The union of dialog and BTEC are taken as our training set, which contains 30,033 sentence pairs. For system tuning, we use the IWSLT 2004 test set (also released as the second development test set of IWSLT 2010), which contains 500 sentences. For final test, we use the IWSLT 2003 test set (also released as the first development test set of IWSLT 2010), which contains 506 sentences.

The Chinese sentences in the datasets are segmented using NiuTrans[3] (Xiao et al., 2012), while POS-tagging of both English and Chinese is performed using ZPar[4] version 0.5 (Zhang and Clark, 2011). We train the English POS-tagger using the WSJ sections of the Penn Treebank (Marcus et al., 1993), turned into lower-case. For syntactic parsing of both English and Chinese, we use the default models of ZPar 0.5.

We choose three baseline systems: a string-to-tree (S2T) system, a tree-to-string (T2S) system and a tree-to-tree (T2T) system (Koehn, 2010). The Moses release 1.0 implementations of all three systems are used, with default parameter settings. IRSTLM[5] release 5.80.03 (Federico et al., 2008) is used to train a four-gram language models over the English training data, which is applied to the baseline systems and our system. Kneser-Ney smoothing is used to train the language model.

[2]This led to the ignoring of over 40% of the training sentence pairs. For future work, we will consider substitute oracles from reachable target derivations by using maximum sentence level BLEU approximation (Nakov et al., 2012) or METEOR (Denkowski and Lavie, 2011) as selection criteria.

Table 4: Sample output sentences.

We use the tuning set to determine the optimal number of training iterations. The translation option filter λ is set to 0.1; the phrase size limit s is set to 5 in order to verify the effectiveness of synthesis; the number of expanded nodes L is set to 200; the chart factor k is set to 16 for a balance between efficiency and accuracy; the goal parameter β is set to 0.8.

The final scores of our system and the baselines are shown in Table 3. Our system gives a BLEU of 34.24, which is comparable to the baseline systems. Some example outputs are shown in Table 4. Manual comparison does not show significant differences in overall translation adequacy or fluency between the outputs of the four systems. However, an observation is that, while our system can produce more fluent outputs, the choice of translation options can be more frequently incorrect. This suggests that while the target synthesis component is effective under the bilingual setting, a stronger lexical selection component may be necessary for better translation quality.

4 Related work

As discussed in the introduction, our work is closely related to previous studies on syntactic MT, with the salient difference that we do not rely on hard translation rules, but allow free target synthesis. The contrast can be summarized as "translation by parsing" vs "translation by generation".

There has been a line of research on generation for translation. Soricut and Marcu (2006) use a form of weighted IDL-expressions (Nederhof and Satta, 2004) for generation. Bangalore et al. (2007) treats MT as a combination of global lexical transfer and word ordering; their generation component does not perform lexical selection, relying on an n-gram language model to order target words. Goto et al. (2012) use a monotonic phrase-based system to perform target word selection, and treats target ordering as a post-processing step. More recently, Chen et al. (2014) translate source dependencies arc-by-arc to generate pseudo target dependencies, and generate the translation by reordering of arcs. In contrast with these systems, our system relies more heavily on a syntax-based synthesis component, in order to study the usefulness of statistical NLG on SMT.

With respect to syntax-based word ordering, Chang and Toutanova (2007) and He et al. (2009) study a simplified word ordering problem by assuming that the un-ordered target dependency tree is given. Wan et al. (2009) and Zhang and Clark (2011) study the ordering of a bag of words, without input syntax. Zhang et al. (2012), Zhang (2013) and Song et al. (2014) further extended this line of research by adding input syntax and allowing joint inflection and ordering. de Gispert et al. (2014) use a phrase-structure grammer for word ordering. Our generation system is based on the work of Zhang (2013), but further allows lexical selection.

Our work is also in line with the work of Liang et al. (2006), Blunsom et al. (2008), Flanigan et al. (2013) and Yu et al. (2013) in that we build a discriminative model for SMT.

5 Conclusion

We investigated a novel system for syntactic machine translation, treating MT as an unconstrained generation task, solved by using a single discriminative model with both monolingual syntax and bilingual translation features. Syntactic correspondence is captured by using soft features rather than hard translation rules, which are used by most syntax-based statistical methods in the literature.

Our results are preliminary in the sense that the experiments were performed using a relatively small dataset, and little engineering effort was made on fine-tuning of parameters for the baseline and proposed models. Our Python implementation gives the same level of BLEU scores compared with baseline syntactic SMT systems, but is an order of magnitude slower than Moses. However, the results demonstrate the feasibility of leveraging text generation techniques for machine translation, directly connecting the two currently rather separated research fields. The system is not strongly dependent on the specific generation algorithm, and one potential of the SMT architecture is that it can directly benefit from advances in statistical NLG technology.

Abstract

We propose a simple and effective approach to learn translation spans for the hierarchical phrase-based translation model. Our model evaluates if a source span should be covered by translation rules during decoding, which is integrated into the translation system as soft constraints. Compared to syntactic constraints, our model is directly acquired from an aligned parallel corpus and does not require parsers. Rich source side contextual features and advanced machine learning methods were utilized for this learning task. The proposed approach was evaluated on NTCIR-9 Chinese-English and Japanese-English translation tasks and showed significant improvement over the baseline system.

1 Introduction

The hierarchical phrase-based (HPB) translation model (Chiang, 2005) has been widely adopted in statistical machine translation (SMT) tasks. The HPB translation rules based on the synchronous context free grammar (SCFG) are simple and powerful.

One drawback of the HPB model is the applications of translation rules to the input sentence are highly ambiguous. For example, a rule whose English side is "X1 by X2" can be applied to any word sequence that has "*by*" in them. In Figure 1, this rule can be applied to the whole sentence as well as to "*experiment by tomorrow*".

In order to tackle rule application ambiguities, a few previous works used syntax trees. Chiang (2005) utilized a syntactic feature in the HPB model, which represents if the source span covered by a translation rule is a syntactic constituent. However, the experimental results showed this feature gave no significant improvement. Instead of using the undifferentiated constituency feature, (Marton and Resnik, 2008) defined different soft syntactic features for different constituent types and obtained substantial performance improvement. Later, (Mylonakis and Sima'an, 2011) introduced joint probability synchronous grammars to integrate flexible linguistic information. (Liu et al., 2011) proposed the soft syntactic constraint model based on discriminative classifiers for each constituent type and integrated all of them into the translation model. (Cui et al., 2010) focused on hierarchical rule selection using many features including syntax constituents.

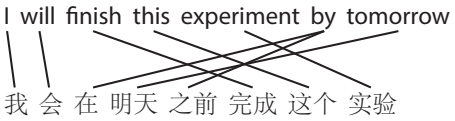

Figure 1: A translation example.

These works have demonstrated the benefits of using syntactic features in the HPB model. However, high quality syntax parsers are not always easily obtained for many languages. Without this problem, word alignment constraints can also be used to guide the application of the rules.

Suppose that we want to translate the English sentence into the Chinese sentence in Figure 1, a translation rule can be applied to the source span "*finish this experiment by tomorrow*". Nonetheless, if a rule is applied to "*experiment by*", then the Chinese translation can not be correctly obtained, because the target span projected from "*ex-*

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 183–188,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

periment by" contains words projected from the source words outside "*experiment by*".

In general, a translation rule projects one continuous source word sequence (source span) into one continuous target word sequence. Meanwhile, the word alignment links between the source and target sentence define the source spans where translation rules are applicable. In this paper, we call a source span that can be covered by a translation rule without violating word alignment links a *translation span*.

Translation spans that have been correctly identified can guide translation rules to function properly, thus (Xiong et al., 2010) attempted to use extra machine learning approaches to determine boundaries of translation spans. They used two separate classifiers to learn the beginning and ending boundaries of translation spans, respectively. A source word is marked as beginning (ending) boundary if it is the first (last) word of a translation span. However, a source span whose first and last words are both boundaries is not always a translation span. In Figure 1, "*I*" is a beginning boundary since it is the first word of translation span "*I will*" and "*experiment*" is an ending boundary since it is the last word of translation span "*finish this experiment*" , but "*I will finish this experiment*" is not a translation span. This happens because the translation spans are nested or hierarchical. Note that (He et al., 2010) also learned phrase boundaries to constrain decoding, but their approach identified boundaries only for monotone translation.

In this paper, taking fully into account that translation spans being nested, we propose an approach to learn hierarchical translation spans directly from an aligned parallel corpus that makes more accurate identification over translation spans.

The rest of the paper is structured as follows: In Section 2, we briefly review the HPB translation model. Section 3 describes our approach. We describe experiments in Section 4 and conclude in Section 5.

2 Hierarchical Phrase-based Translation

Chiang's HPB model is based on a weighted SCFG. A translation rule is like: $X \rightarrow \langle \gamma, \alpha, \sim \rangle$, where X is a nonterminal, γ and α are source and target strings of terminals and nonterminals, and $\sim$ is a one-to-one correspondence between nonterminals in γ and α. The weight of each rule is:

$$w\left(X \rightarrow \langle \gamma, \alpha, \sim \rangle\right) = \prod_t h_t(X \rightarrow \langle \gamma, \alpha, \sim \rangle)^{\lambda_t} \quad (1)$$

where h_t are the features defined on the rules.

Rewriting begins with a pair of linked start symbols and ends when there is no nonterminal left. Let D be a derivation of the grammar, $f\left(D\right)$ and $e\left(D\right)$ be the source and target strings generated by D. D consists of a set of triples $\langle r, i, j \rangle$, each of which stands for applying a rule r on a span $f\left(D\right)_i^j$. The weight of D is calculated as:

$$w\left(D\right) = \prod_{\langle r,i,j \rangle \in D} w\left(r\right) \times P_{lm}(e)^{\lambda_{lm}} \times \exp\left(-\lambda_{wp}\left|e\right|\right) \quad (2)$$

where $w\left(r\right)$ is the weight of rule r, the last two terms represent the language model and word penalty, respectively.

3 Learning Translation Spans

We will describe how to learn translation spans in this section.

3.1 Our Model

We make a series of binary classifiers $\{C_1, C_2, C_3, ...\}$ to learn if a source span $f\left(D\right)_i^j$ should be covered by translation rules during translation. C_k is trained and tested on source spans whose lengths are k, i.e., $k = j - i + 1$.[1]

C_k learns the probability

$$P_k\left(v | f\left(D\right), i, j\right) \quad (3)$$

where $v \in \{0, 1\}$, $v = 1$ represents a rule is applied on $f\left(D\right)_i^j$, otherwise $v = 0$.

Training instances for these classifiers are extracted from an aligned parallel corpus according to Algorithm 1. For example, "*I will*" and "*will finish*" are respectively extracted as positive and negative instances in Figure 1.

Note that our model in Equation 3 only uses the source sentence $f\left(D\right)$ in the condition. This means that the probabilities can be calculated before translation. Therefore, the predicted probabilities can be integrated into the decoder conveniently as soft constraints and no extra time is added during decoding. This enables us to use rich source contextual features and various machine learning methods for this learning task.

[1] We indeed can utilize just one classifier for all source spans. However, it will be difficult to design features for such a classifier unless only boundary word features are adopted. On the contrary, we can fully take advantage of rich information about inside words as we turn to the fixed span length approach.

3.2 Integration into the decoder

It is straightforward to integrate our model into Equation 2. It is extended as

$$w(D) = \prod_{\langle r,i,j\rangle \in D} w(r) \times P_{lm}(e)^{\lambda_{lm}} \times \exp(-\lambda_{wp}|e|) \times P_k(v=1|f(D),i,j)^{\lambda_k} \quad (4)$$

where λ_k is the weight for C_k.

During decoding, the decoder looks up the probabilities P_k calculated and stored before decoding.

Algorithm 1 Extract training instances.

Input: A pair of parallel sentence f_1^n and e_1^m with word alignments A.

Output: Training examples for $\{C_1, C_2, C_3, ...\}$.

```
for i = 1 to n do
  for j = i to n do
    if ∃e_p^q, 1 ≤ p ≤ q ≤ m
    & ∃(k,t) ∈ A, i ≤ k ≤ j, p ≤ t ≤ q
    & ∀(k,t) ∈ A, i ≤ k ≤ j ↔ p ≤ t ≤ q
    then
      f_i^j is a positive instance for C_{j-i+1}
    else
      f_i^j is a negative instance for C_{j-i+1}
    end if
  end for
end for
```

3.3 Classifiers

We compare two machine learning methods for learning a series of binary classifiers.

For the first method, each C_k is individually learned using the maximum entropy (ME) approach (Berger et al., 1996):

$$P_k(v|f(D),i,j) = \frac{\exp\left(\sum_t \mu_t h_t(v, f(D), i, j)\right)}{\sum_{v'} \exp\left(\sum_t \mu_t h_t(v', f(D), i, j)\right)} \quad (5)$$

where h_t is a feature function and μ_t is weight of h_t. We use rich source contextual features: unigram, bigram and trigram of the phrase $[f_{i-3}, ..., f_{j+3}]$.

As the second method, these classification tasks are learned in the continuous space using feed-forward neural networks (NNs). Each C_k has the similar structure with the NN language model (Vaswani et al., 2013). The inputs to the NN are indices of the words: $[f_{i-3}, ..., f_{j+3}]$. Each source word is projected into an N dimensional vector. The output layer has two output neurons, whose values correspond to $P_k(v=0|f(D),i,j)$ and $P_k(v=1|f(D),i,j)$.

For both ME and NN approaches, words that occur only once or never occur in the training corpus are treated as a special word "UNK" (unknown) during classifier training and predicting, which can reduce training time and make the classifier training more smooth.

4 Experiment

We evaluated the effectiveness of the proposed approach for Chinese-to-English (CE) and Japanese-to-English (JE) translation tasks. The datasets officially provided for the patent machine translation task at NTCIR-9 (Goto et al., 2011) were used in our experiments. The detailed training set statistics are given in Table 1. The development and test

		SOURCE	TARGET
CE	#Sents	954k	
	#Words	37.2M	40.4M
	#Vocab	288k	504k
JE	#Sents	3.14M	
	#Words	118M	104M
	#Vocab	150k	273k

Table 1: Data sets.

sets were both provided for CE task while only the test set was provided for JE task. Therefore, we used the sentences from the NTCIR-8 JE test set as the development set. Word segmentation was done by BaseSeg (Zhao et al., 2006; Zhao and Kit, 2008; Zhao et al., 2010; Zhao and Kit, 2011; Zhao et al., 2013) for Chinese and Mecab [2] for Japanese.

To learn the classifiers for each translation task, the training set and development set were put together to obtain symmetric word alignment using GIZA++ (Och and Ney, 2003) and the *grow-diag-final-and* heuristic (Koehn et al., 2003). The source span instances extracted from the aligned training and development sets were used as the training and validation data for the classifiers.

The toolkit Wapiti (Lavergne et al., 2010) was adopted to train ME classifiers using the classical quasi-newton optimization algorithm with limited memory. The NNs are trained by the toolkit NPLM (Vaswani et al., 2013). We chose "rectifier" as the activation function and the logarithmic loss function for NNs. The number of epochs was set to 20. Other parameters were set to default

10	0.15	0.21	0.97	0.28	0.97	0.08	0	1	0.23	0.99

Table 2: Classification accuracies. The Rate column represents ratio of positive instances to negative instances; the P and N columns give classification accuracies for positive and negative instances.

values. The training time of one classifier on a 12-core 3.47GHz Xeon X5690 machine was 0.5h (2.5h) using ME (NN) approach for CE task; 1h (4h) using ME (NN) approach for JE task .

The classification results are shown in Table 2. Instead of the undifferentiated classification accuracy, we present separate classification accuracies for positive and negative instances. The big difference between classification accuracies for positive and negative instances was caused by the unbalanced rate of positive and negative instances in the training corpus. For example, if there are more positive training instances, then the classifier will tend to classify new instances as positive and the classification accuracy for positive instances will be higher. In our classification tasks, there are less positive instances for longer span lengths.

Since the word order difference of JE task is much more significant than that of CE task, there are more negative Japanese translation span instances than Chinese. In JE tasks, the ME classifiers C_8, C_9 and C_{10} predicted all new instances to be negative due to the heavily unbalanced instance distribution.

As shown in Table 2, NN outperformed ME approach for our classification tasks. As the span length growing, the advantage of NN became more significant. Since the classification accuracies deceased to be quite low for source spans with more than 10 words, only $\{C_1, ..., C_{10}\}$ were integrated into the HPB translation system.

For each translation task, the recent version of Moses HPB decoder (Koehn et al., 2007) with the training scripts was used as the baseline (Base). We used the default parameters for Moses, and a 5-gram language model was trained on the target side of the training corpus by IRST LM Toolkit [3] with improved Kneser-Ney smoothing. $\{C_1, ..., C_{10}\}$ were integrated into the baseline with different weights, which were tuned by MERT (Och, 2003) together with other feature weights (language model, word penalty,...) under the log-linear framework (Och and Ney, 2002).

	Method	TER	BLEU-n 4	n-gram precisions 1 2 3 4
CE	Base	49.39- -	33.07- -	69.9/40.7/25.8/16.9
	BLM	48.60	33.93	70.0/41.4/26.6/17.6
	ME	49.02-	33.63-	70.0/41.2/26.3/17.4
	NN	48.09++	34.35++	70.1/41.9/27.0/18.0
JE	Base	57.39- -	30.13- -	67.1/38.3/23.0/14.0
	BLM	56.79	30.81	67.7/38.9/23.6/14.5
	ME	56.48	31.01	67.6/39.0/23.8/14.7
	NN	55.96++	31.77++	67.8/39.7/24.6/15.4

Table 3: Translation results. The symbol ++ (- -) represents a significant difference at the $p < 0.01$ level and - represents a significant difference at the $p < 0.05$ level against the BLM.

We compare our method with the baseline and the boundary learning method (BLM) (Xiong et al., 2010) based on Maximum Entropy Markov Models with Markov order 2. Table 3 reports BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores. Significance tests are conducted using bootstrap sampling (Koehn, 2004). Our ME classifiers achieve comparable translation improvement with the BLM and NN classifiers enhance translation system significantly compared to others. Table 3 also shows that the relative gain was higher for higher n-grams, which is reasonable since the higher n-grams have higher ambiguities in the translation rule application.

It is true that because of multiple parallel sentences, a source span can be applied with transla-

[3] http://hlt.fbk.eu/en/irstlm

tion rules in one sentence pair but not in another sentence pair. So we used the probability score as a feature in the decoding. That is, we did not use classification results directly but use the probability score for softly constraining the decoding process.

5 Conclusion

We have proposed a simple and effective translation span learning model for HPB translation. Our model is learned from aligned parallel corpora and predicts translation spans for source sentence before translating, which is integrated into the translation system conveniently as soft constraints. We compared ME and NN approaches for this learning task. The results showed that NN classifiers on the continuous space model achieved both higher classification accuracies and better translation performance with acceptable training times.

Abstract

Since larger n-gram Language Model (LM) usually performs better in Statistical Machine Translation (SMT), how to construct efficient large LM is an important topic in SMT. However, most of the existing LM growing methods need an extra monolingual corpus, where additional LM adaption technology is necessary. In this paper, we propose a novel neural network based bilingual LM growing method, only using the bilingual parallel corpus in SMT. The results show that our method can improve both the perplexity score for LM evaluation and BLEU score for SMT, and significantly outperforms the existing LM growing methods without extra corpus.

1 Introduction

'*Language Model (LM) Growing*' refers to adding n-grams outside the corpus together with their probabilities into the original LM. This operation is useful as it can make LM perform better through letting it become larger and larger, by only using a small training corpus.

There are various methods for adding n-grams selected by different criteria from a monolingual corpus (Ristad and Thomas, 1995; Niesler and Woodland, 1996; Siu and Ostendorf, 2000; Siivola et al., 2007). However, all of these approaches need additional corpora. Meanwhile the extra corpora from different domains will not result in better LMs (Clarkson and Robinson, 1997; Iyer et al., 1997; Bellegarda, 2004; Koehn and Schroeder, 2007). In addition, it is very difficult or even impossible to collect an extra large corpus for some special domains such as the TED corpus (Cettolo et al., 2012) or for some rare languages. Therefore, to improve the performance of LMs, without assistance of extra corpus, is one of important research topics in SMT.

Recently, Continues Space Language Model (CSLM), especially Neural Network based Language Model (NNLM) (Bengio et al., 2003; Schwenk, 2007; Mikolov et al., 2010; Le et al., 2011), is being actively used in SMT (Schwenk et al., 2006; Son et al., 2010; Schwenk, 2010; Schwenk et al., 2012; Son et al., 2012; Niehues and Waibel, 2012). One of the main advantages of CSLM is that it can more accurately predict the probabilities of the n-grams, which are not in the training corpus. However, in practice, CSLMs have not been widely used in the current SMT systems, due to their too high computational cost.

Vaswani and colleagues (2013) propose a method for reducing the training cost of CSLM and apply it to SMT decoder. However, they do not show their improvement for decoding speed, and their method is still slower than the n-gram LM. There are several other methods for attempting to implement neural network based LM or translation model for SMT (Devlin et al., 2014; Liu et al., 2014; Auli et al., 2013). However, the decoding speed using n-gram LM is still state-of-the-art one. Some approaches calculate the probabilities of the n-grams n-grams before decoding, and store them in the n-gram format (Wang et al., 2013a; Arsoy et al., 2013; Arsoy et al., 2014). The '*converted CSLM*' can be directly used in SMT. Though more n-grams which are not in the train-

ing corpus can be generated by using some of these '*converting*' methods, these methods only consider the monolingual information, and do not take the bilingual information into account.

We observe that the translation output of a phrase-based SMT system is concatenation of phrases from the phrase table, whose probabilities can be calculated by CSLM. Based on this observation, a novel neural network based bilingual LM growing method is proposed using the '*connecting phrases*'. The remainder of this paper is organized as follows: In Section 2, we will review the existing CSLM converting methods. The new neural network based bilingual LM growing method will be proposed in Section 3. In Section 4, the experiments will be conducted and the results will be analyzed. We will conclude our work in Section 5.

2 Existing CSLM Converting Methods

Traditional Backoff N-gram LMs (BNLMs) have been widely used in many NLP tasks (Zhang and Zhao, 2013; Jia and Zhao, 2014; Zhao et al., 2013; Zhang et al., 2012; Xu and Zhao, 2012; Wang et al., 2013b; Jia and Zhao, 2013; Wang et al., 2014). Recently, CSLMs become popular because they can obtain more accurate probability estimation.

2.1 Continues Space Language Model

A CSLM implemented in a multi-layer neural network contains four layers: the input layer projects (first layer) all words in the context h_i onto the projection layer (second layer); the hidden layer (third layer) and the output layer (fourth layer) achieve the non-liner probability estimation and calculate the LM probability $P(w_i|h_i)$ for the given context (Schwenk, 2007).

CSLM is able to calculate the probabilities of all words in the vocabulary of the corpus given the context. However, due to too high computational complexity, CSLM is mainly used to calculate the probabilities of a subset of the whole vocabulary (Schwenk, 2007). This subset is called a *short-list*, which consists of the most frequent words in the vocabulary. CSLM also calculates the sum of the probabilities of all words not included in the short-list by assigning a neuron with the help of BNLM. The probabilities of other words not in the short-list are obtained from an BNLM (Schwenk, 2007; Schwenk, 2010; Wang et al., 2013a).

Let w_i and h_i be the current word and history, respectively. CSLM with a BNLM calculates the probability $P(w_i|h_i)$ of w_i given h_i, as follows:

$$P(w_i|h_i) = \begin{cases} \frac{P_c(w_i|h_i)}{\sum_{w \in V_0} P_c(w|h_i)} P_s(h_i) & \text{if } w_i \in V_0 \\ P_b(w_i|h_i) & \text{otherwise} \end{cases} \quad (1)$$

where V_0 is the short-list, $P_c(\cdot)$ is the probability calculated by CSLM, $\sum_{w \in V_0} P_c(w|h_i)$ is the summary of probabilities of the neuron for all the words in the short-list, $P_b(\cdot)$ is the probability calculated by the BNLM, and

$$P_s(h_i) = \sum_{v \in V_0} P_b(v|h_i). \quad (2)$$

We may regard that CSLM redistributes the probability mass of all words in the short-list, which is calculated by using the n-gram LM.

2.2 Existing Converting Methods

As baseline systems, our approach proposed in (Wang et al., 2013a) only re-writes the probabilities from CSLM into the BNLM, so it can only conduct a convert LM with the same size as the original one. The main difference between our proposed method in this paper and our previous approach is that n-grams outside the corpus are generated firstly and the probabilities using CSLM are calculated by using the same method as our previous approach. That is, the proposed new method is the same as our previous one when no grown n-grams are generated.

The method developed by Arsoy and colleagues (Arsoy et al., 2013; Arsoy et al., 2014) adds all the words in the short-list after the tail word of the i-grams to construct the (i+1)-grams. For example, if the i-gram is "*I want*", then the (i+1)-grams will be "*I want* *", where "*" stands for any word in the short list. Then the probabilities of the (i+1)-grams are calculated using (i+1)-CSLM. So a very large intermediate (i+1)-grams will have to be grown[1], and then be pruned into smaller suitable size using an entropy-based LM pruning method modified from (Stolcke, 1998). The (i+2)-grams are grown using (i+1)-grams, recursively.

[1]In practice, the probabilities of all the target/tail words in the short list for the history i-grams can be calculated by the neurons in the output layer at the same time, which will save some time. According to our experiments, the time cost for Arsoy's growing method is around 4 times more than our proposed method, if the LMs which are 10 times larger than the original one are grown with other settings all the same.

3 Bilingual LM Growing

The translation output of a phrase-based SMT system can be regarded as a concatenation of phrases in the phrase table (except unknown words). This leads to the following procedure:

Step 1. All the n-grams included in the phrase table should be maintained at first.

Step 2. The connecting phrases are defined in the following way.

The w_a^b is a target language phrase starting from the a-th word ending with the b-th word, and $\beta w_a^b \gamma$ is a phrase including w_a^b as a part of it, where β and γ represent any word sequence or none. An i-gram phrase $w_1^k w_{k+1}^i$ $(1 \leq k \leq i-1)$ is a connecting phrase[2], if :

(1) w_1^k is the right (rear) part of one phrase βw_1^k in the phrase table, or

(2) w_{k+1}^i is the left (front) part of one phrase $w_{k+1}^i \gamma$ in the phrase table.

After the probabilities are calculated using C-SLM (Eqs.1 and 2), we combine the n-grams in the phrase table from Step 1 and the connecting phrases from Step 2.

3.1 Ranking the Connecting Phrases

Since the size of connecting phrases is too huge (usually more than one Terabyte), it is necessary to decide the usefulness of connecting phrases for SMT. The more useful connecting phrases can be selected, by ranking the appearing probabilities of the connecting phrases in SMT decoding.

Each line of a phrase table can be simplified (without considering other unrelated scores in the phrase table) as

$$f \;|||\; e \;|||\; P(e|f), \tag{3}$$

where the $P(e|f)$ means the translation probability from $f(source\ phrase)$ to $e(target\ phrase)$, which can be calculated using bilingual parallel training data. In decoding, the probability of a target phrase e appearing in SMT should be

$$P_t(e) = \sum_f P_s(f) \times P(e|f), \tag{4}$$

where the $P_s(f)$ means the appearing probability of a source phrase, which can be calculated using source language part in the bilingual training data.

Using $P_t(e)$[3], we can select the connecting phrases e with high appearing probabilities as the n-grams to be added to the original n-grams. These n-grams are called '*grown n-grams*'. Namely, we build all the connecting phrases at first, and then we use the appearing probabilities of the connecting phrases to decide which connecting phrases should be selected. For an i-gram connecting phrase $w_1^k w_{k+1}^i$, where w_1^k is part of βw_1^k and w_{k+1}^i is part of $w_{k+1}^i \gamma$ (the βw_1^k and $w_{k+1}^i \gamma$ are from the phrase table), the probability of the connecting phrases can be roughly estimated as

$$P_{\text{con}}(w_1^k w_{k+1}^i) = \sum_{k=1}^{i-1} \Big(\sum_{\beta} P_t(\beta w_1^k) \times \sum_{\gamma} P_t(w_{k+1}^i \gamma) \Big). \tag{5}$$

A threshold for $P_{\text{con}}(w_1^k w_{k+1}^i)$ is set, and only the connecting phrases whose appearing probabilities are higher than the threshold will be selected as the grown n-grams.

3.2 Calculating the Probabilities of Grown N-grams Using CSLM

To our bilingual LM growing method, a 5-gram LM and n-gram (n=2,3,4,5) CSLMs are built by using the target language of the parallel corpus, and the phrase table is learned from the parallel corpus.

The probabilities of unigram in the original n-gram LM will be maintained as they are. The n-grams from the bilingual phrase table will be grown by using the '*connecting phrases*' method. As the whole connecting phrases are too huge, we use the ranking method to select the more useful connecting phrases. The distribution of different n-grams (n=2,3,4,5) of the grown LMs are set as the same as the original LM.

The probabilities of the grown n-grams (n=2,3,4,5) are calculated using the 2,3,4,5-CSLM, respectively. If the tail (target) words of the grown n-grams are not in the short-list of C-SLM, the $P_b(\cdot)$ in Eq. 1 will be applied to calculate their probabilities.

[2] We are aware that connecting phrases can be applied to not only two phrases, but also three or more. However the appearing probabilities (which will be discussed in Eq. 5 of next subsection) of connecting phrases are approximately estimated. To estimate and compare probabilities of longer phrases in different lengths will lead to serious bias, and the experiments also showed using more than two connecting phrases did not perform well (not shown for limited space), so only two connecting phrases are applied in this paper.

[3] This $P_t(e)$ hence provides more bilingual information, in comparison with using monolingual target LMs only.

We combine the n-grams (n=1,2,3,4,5) together and re-normalize the probabilities and backoff weights of the grown LM. Finally the original BNLM and the grown LM are interpolated. The entire process is illustrated in Figure 1.

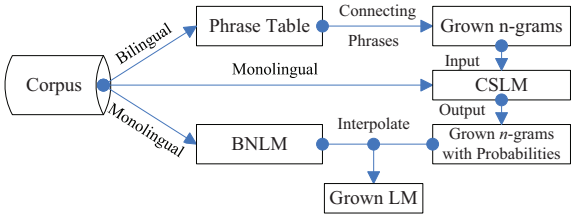

Figure 1: NN based bilingual LM growing.

4 Experiments and Results

4.1 Experiment Setting up

The same setting up of the NTCIR-9 Chinese to English translation baseline system (Goto et al., 2011) was followed, only with various LMs to compare them. The Moses phrase-based SMT system was applied (Koehn et al., 2007), together with GIZA++ (Och and Ney, 2003) for alignment and MERT (Och, 2003) for tuning on the development data. Fourteen standard SMT features were used: five translation model scores, one word penalty score, seven distortion scores, and one LM score. The translation performance was measured by the case-insensitive BLEU on the tokenized test data.

We used the patent data for the Chinese to English patent translation subtask from the NTCIR-9 patent translation task (Goto et al., 2011). The parallel training, development, and test data sets consist of 1 million (M), 2,000, and 2,000 sentences, respectively.

Using SRILM (Stolcke, 2002; Stolcke et al., 2011), we trained a 5-gram LM with the interpolated Kneser-Ney smoothing method using the 1M English training sentences containing 42M words without cutoff. The 2,3,4,5-CSLMs were trained on the same 1M training sentences using CSLM toolkit (Schwenk, 2007; Schwenk, 2010). The settings for CSLMs were: input layer of the same dimension as vocabulary size (456K), projection layer of dimension 256 for each word, hidden layer of dimension 384 and output layer (short-list) of dimension 8192, which were recommended in the CSLM toolkit and (Wang et al., 2013a)[4].

[4]Arsoy used around 55 M words as the corpus, including 84K words as vocabulary, and 20K words as short-list. In this paper, we used the same setting as our previous work, which covers 92.89% of the frequency of words in the training corpus, for all the baselines and our method for fair comparison.

4.2 Results

The experiment results were divided into four groups: the original BNLMs (BN), the CSLM Re-ranking (RE), our previous converting (WA), the Arsoy's growing, and our growing methods. For our bilingual LM growing method, 5 bilingual grown LMs (BI-1 to 5) were conducted in increasing sizes. For the method of Arsoy, 5 grown LMs (AR-1 to 5) with similar size of BI-1 to 5 were also conducted, respectively.

For the CSLM re-ranking, we used CSLM to re-rank the 100-best lists of SMT. Our previous converted LM, Arsoy's grown LMs and bilingual grown LMs were interpolated with the original BNLMs, using default setting of SRILM[5]. To reduce the randomness of MERT, we used two methods for tuning the weights of different SMT features, and two BLEU scores are corresponding to these two methods. The **BLEU-s** indicated that the **same** weights of the BNLM (BN) features were used for all the SMT systems. The **BLEU-i** indicated that the MERT was run **independently** by three times and the average BLEU scores were taken.

We also performed the paired bootstrap resampling test (Koehn, 2004)[6]. Two thousands samples were sampled for each significance test. The marks at the right of the BLEU score indicated whether the LMs were significantly better/worse than the Arsoy's grown LMs with the same IDs for SMT ("++/−−": significantly better/worse at $\alpha = 0.01$, "+/−": $\alpha = 0.05$, no mark: not significantly better/worse at $\alpha = 0.05$).

From the results shown in Table 1, we can get the following observations:

(1) Nearly all the bilingual grown LMs outperformed both BNLM and our previous converted LM on PPL and BLEU. As the size of grown LMs is increased, the PPL always decreased and the BLEU scores trended to increase. These indicated that our proposed method can give better probability estimation for LM and better performance for SMT.

(2) In comparison with the grown LMs in Ar-

[5]In our previous work, we used the development data to tune the weights of interpolation. In this paper, we used the default 0.5 as the interpolation weights for fair comparison.

[6]We used the code available at `http://www.ark.cs.cmu.edu/MT`

Table 1: Performance of the Grown LMs

LMs	n-grams	PPL	BLEU-s	BLEU-i	ALH
BN	73.9M	108.8	32.19	32.19	3.03
RE	N/A	**97.5**	32.34	32.42	N/A
WA	73.9M	104.4	32.60	32.62	3.03
AR-1	217.6M	103.3	32.55	32.75	3.14
AR-2	323.8M	103.1	32.61	32.64	3.18
AR-3	458.5M	103.0	32.39	32.71	3.20
AR-4	565.6M	102.8	32.67	32.51	3.21
AR-5	712.2M	102.5	32.49	32.60	3.22
BI-1	223.5M	101.9	32.81+	33.02+	3.20
BI-2	343.6M	101.0	32.92+	33.11++	3.24
BI-3	464.5M	100.6	33.08++	**33.25**++	3.26
BI-4	571.0M	100.3	**33.15**++	33.12++	3.28
BI-5	705.5M	100.1	33.11++	33.24++	3.31

soy's method, our grown LMs obtained better PPL and significantly better BLEU with the similar size. Furthermore, the improvement of PPL and BLEU of the existing methods became saturated much more quickly than ours did, as the LMs grew.

(3) The last column was the Average Length of the n-grams Hit (ALH) in SMT decoding for different LMs using the following function

$$ALH = \sum_{i=1}^{5} P_{i-gram} \times i, \tag{6}$$

where the P_{i-gram} means the ratio of the i-grams hit in SMT decoding. There were also positive correlations between ALH, PPL and BLEUs. The ALH of bilingual grown LM was longer than that of the Arsoy's grown LM of the similar size. In another word, less back-off was used for our proposed grown LMs in SMT decoding.

4.3 Experiments on TED Corpus

The TED corpus is in special domain as discussed in the introduction, where large extra monolingual corpora are hard to find. In this subsection, we conducted the SMT experiments on TED corpora using our proposed LM growing method, to evaluate whether our method was adaptable to some special domains.

We mainly followed the baselines of the IWSLT 2014 evaluation campaign[7], only with a few modifications such as the LM toolkits and n-gram order for constructing LMs. The Chinese (CN) to English (EN) language pair was chosen, using dev2010 as development data and test2010 as evaluation data. The same LM growing method was applied on TED corpora as on NTCIR corpora. The results were shown in Table 2.

[7] https://wit3.fbk.eu/

Table 2: CN-EN TED Experiments

LMs	n-grams	PPL	BLEU-s
BN	7.8M	87.1	12.41
WA	7.8M	85.3	12.73
BI-1	23.1M	79.2	12.92
BI-2	49.7M	78.3	13.16
BI-3	73.4M	**77.6**	**13.24**

Table 2 indicated that our proposed LM growing method improved both PPL and BLEU in comparison with both BNLM and our previous CSLM converting method, so it was suitable for domain adaptation, which is one of focuses of the current SMT research.

5 Conclusion

In this paper, we have proposed a neural network based bilingual LM growing method by using the bilingual parallel corpus only for SMT. The results show that our proposed method can improve both LM and SMT performance, and outperforms the existing LM growing methods significantly without extra corpus. The connecting phrase-based method can also be applied to LM adaptation.

Better Statistical Machine Translation through Linguistic Treatment of Phrasal Verbs

Kostadin Cholakov and Valia Kordoni
Humboldt-Universität zu Berlin, Germany
{kostadin.cholakov,kordonieva}@anglistik.hu-berlin.de

Abstract

This article describes a linguistically informed method for integrating phrasal verbs into statistical machine translation (SMT) systems. In a case study involving English to Bulgarian SMT, we show that our method does not only improve translation quality but also outperforms similar methods previously applied to the same task. We attribute this to the fact that, in contrast to previous work on the subject, we employ detailed linguistic information. We found out that features which describe phrasal verbs as idiomatic or compositional contribute most to the better translation quality achieved by our method.

1 Introduction

Phrasal verbs are a type of multiword expressions (MWEs) and as such, their meaning is not derivable, or is only partially derivable, from the semantics of their lexemes. This, together with the high frequency of MWEs in every day communication (see Jackendoff (1997)), calls for a special treatment of such expressions in natural language processing (NLP) applications. Here, we concentrate on statistical machine translation (SMT) where the word-to-word translation of MWEs often results in wrong translations (Piao et al., 2005).

Previous work has shown that the application of dedicated methods to identify MWEs and then integrate them in some way into the SMT process often improves translation quality. Generally, automatically extracted lexicons of MWEs are employed in the identification step. Further, various integration strategies have been proposed. The so called *static* strategy suggests training the SMT system on corpora in which each MWE is treated as a single unit, e.g. *call_off*. This improves SMT indirectly by improving the alignment between source and target sentences in the training data. Various versions of this strategy are applied in Lambert and Banchs (2005), Carpuat and Diab (2010), and Simova and Kordoni (2013). In all cases there is some improvement in translation quality, caused mainly by the better treatment of separable PVs, such as in *turn the light on*.

Another strategy, which is referred to as *dynamic*, is to modify directly the SMT system. Ren et al. (2009), for example, treat bilingual MWEs pairs as parallel sentences which are then added to training data and subsequently aligned with GIZA++ (Och and Ney, 2003). Other approaches perform feature mining and modify directly the automatically extracted translation table. Ren et al. (2009) and Simova and Kordoni (2013) employ Moses[1] to build and train phrase-based SMT systems and then, in addition to the standard phrasal translational probabilities, they add a binary feature which indicates whether an MWE is present in a given source phrase or not. Carpuat and Diab (2010) employ the same approach but the additional feature indicates the number of MWEs in each phrase. All studies report improvements over a baseline system with no MWE knowledge but these improvements are comparable to those achieved by static methods.

In this article, we further improve the dynamic strategy by adding features which, unlike all previous work, also encode some of the linguistic properties of MWEs. Since it is their peculiar linguistic nature that makes those expressions problematic for SMT, it is our thesis that providing more linguistic information to the translation process will improve it. In particular, we concentrate on a specific type of MWEs, namely phrasal verbs (PVs). We add 4 binary features to the translation table which indicate not only the presence of a PV but also its *transitivity*, *separability*, and *idiomaticity*. We found that PVs are very suitable for this study since we can easily extract the necessary informa-

tion from various language resources.

To prove our claim, we perform a case study with an English to Bulgarian SMT system. Bulgarian lacks PVs in the same form they appear in English. It is often the case that an English PV is translated to a single Bulgarian verb. Such many-to-one mappings cause the so called *translation asymmetries* which make the translation of PVs very problematic.

We perform automated and manual evaluations with a number of feature combinations which show that the addition of all 4 features proposed above improves translation quality significantly. Moreover, our method outperforms static and dynamic methods previously applied to the same test data. A notable increase in performance is observed for separable PVs where the verb and the particle(s) were not adjacent in the input English sentence as well as for idiomatic PVs. This clearly demonstrates the importance of linguistic information for the proper treatment of PVs in SMT.

We would like to point out that we view the work presented here as a preliminary study towards a more general linguistically informed method for handling similar types of translation asymmetries. The experiments with a single phenomenon, namely PVs, serve as a case study the purpose of which is to demonstrate the validity of our approach and the crucial role of properly integrated linguistic information into SMT. Our work, however, can be immediately extended to other phenomena, such as collocations and noun compounds.

The remainder of the paper is organised as follows. Section 2 describes the asymmetries caused by PVs in English to Bulgarian translation. Section 3 provides details about the resources involved in the experiments. Section 4 describes our method and the experimental setup. Section 5 presents the results and discusses the improvements in translation quality achieved by the method. Sections 6 concludes the paper.

2 Translation Asymmetries

We will first illustrate the main issues which arise when translating English PVs into Bulgarian. For more convenience, the Bulgarian phrases are transcribed with Latin letters.

An English PV is usually mapped to a single Bulgarian verb:

(1) Toj *otmeni* sreshtata.
he cancelled meeting-the
'He *called off* the meeting.'

In the example above the PV *called off* has to be mapped to the single Bulgarian verb *otmeni*, i.e. there is many-to-one mapping. Other cases require a many-to-many type of mapping. One such case is the mapping of an English PV to a 'da'-construction in Bulgarian. Such constructions are very frequent in Bulgarian every day communication since they denote complex verb tenses, modal verb constructions, and subordinating conjunctions:

(2) Toj trjabva da skasa s neja.
he should break off with her
'He should *break off* with her.'

Here, *da skasa* should be mapped to the PV *break off*. Other such cases include Bulgarian reflexive verb constructions.

Note that such many-to-many mappings in the case of Bulgarian pose an additional challenge for the SMT system because, for a good translation, it needs to guess whether to add a 'da' particle or not which further complicates the treatment of PVs. Also, Bulgarian is a language with rich morphology and often translations with very good semantic quality lack the proper morphological inflection. This affects negatively both automated and manual evaluation of translation quality.

3 Language Resources

We employ the data used in the studies reported in Simova and Kordoni (2013). The authors experimented with both static and dynamic methods for handling PVs in an English to Bulgarian SMT system. This allows us to compare the performance of our linguistically informed approach to that of methods which do not make use of the linguistic properties of PVs.

The data for the experiments are derived from the SeTimes news corpus[2] which contains parallel news articles in English and 9 Balkan languages. The training data consist of approximately 151,000 sentences. Another 2,000 sentences are used for the tuning. The test set consists of 800 sentences, 400 of which contain one or more in-

[2] http://www.setimes.com

stances of PVs. There are 138 unique PVs with a total of 403 instances in the test data. Further, a language model for the target language is created based on a 50 million words subset of the Bulgarian National Reference Corpus.[3] All English data are POS tagged and lemmatised using the TreeTagger (Schmid, 1994). For Bulgarian, these tasks were performed with the BTB-LPP tagger (Savkov et al., 2011).

Simova and Kordoni (2013) create automatically a lexicon containing English PVs. It is employed for the identification of such verbs in the data used in the experiments. The lexicon is constructed from a number of resources: the English Phrasal Verbs section of Wiktionary,[4] the Phrasal Verb Demon dictionary,[5] the CELEX Lexical Database (Baayen et al., 1995), WordNet (Fellbaum, 1998), the COMLEX Syntax dictionary (Macleod et al., 1998), and the gold standard data used for the experiments in McCarthy et al. (2003) and Baldwin (2008). English PVs are identified in the data using the jMWE library (Kulkarni and Finlayson, 2011) as well as a post-processing module implemented in the form of a constrained grammar (Karlsson et al., 1995) which filters out spurious PV candidates. For the identification of PVs, Simova and Kordoni (2013) report 91% precision (375 correct instances found) and a recall score of 93% for the 800 test sentences.

The Moses toolkit is employed to build a factored phrase-based translation model which operates on lemmas and POS tags. Given the rich Bulgarian morphology, the use of lemma information instead of surface word forms allows for a better mapping between source and target translation equivalents. The parallel data are aligned with GIZA++. Further, 2 5-gram language models are built using the SRILM toolkit[6] on the monolingual Bulgarian data to model lemma and POS n-gram information. Note that the Bulgarian POS tags are quite complex, so they can account for a variety of morphological phenomena. Automated translation is performed by mapping English lemmas and POS tags to their Bulgarian equivalents and then generating the proper Bulgarian word form by using lemma and POS tag information.

feature 1	PV present	no PV
feature 2	transitive	intransitive
feature 3	separable	inseparable
feature 4	idiomatic	(semi-)comp.

Table 1: Values for the 4 new features.

4 Addition of Linguistic Features

The resources from which the PV lexicon is constructed also contain various types of linguistic information. Wiktionary provides the most details since the entries there contain information about the valency of the verb (transitive vs intransitive) and whether a particle can be separated from the PV in particle verb constructions. Consider *fell off his bike* and **fell his bike off* vs *turn the engine on* and *turn on the engine*.

Further, Wiktionary indicates whether a given PV is compositional or idiomatic in nature. The meaning of (semi-)compositional PVs can be (partially) derived from the meaning of their lexemes, e.g. *carry in*. The degree of compositionality affects the productivity with which verbs and particles combine. Verbs with similar semantics often combine with the same particle, e.g. *bring/carry in*. This is not the case for fully idiomatic PVs, e.g. *get/*obtain over*. Therefore, the notion of compositionality plays a very important role in the treatment of PVs and MWEs in general. The dataset described in McCarthy et al. (2003) also indicates whether a PV is idiomatic or not.

We were able to acquire the PV lexicon and we augmented it with the information obtained from the various resources. Then, once the system is trained, we add 4 binary features to each entry in the automatically created translation table. The values those features take are shown in Table 1. If a given property is not specified for some PV in the lexicon, the value of the corresponding feature is 0. Naturally, if no PV is identified in a source phrase, the value of all 4 features is 0. This is different from previous work where only one feature is added, indicating the presence of a PV. By adding those new features, we want to bias the SMT system towards using phrases that do not "split" PVs during decoding.

	with PVs		no PVs		all	
	bleu	nist	bleu	nist	bleu	nist
baseline	0.244	5.97	0.228	5.73	0.237	6.14
static	0.246	**6.02**	0.230	**5.76**	0.239	**6.18**
dynamic-1	0.250	5.92	0.226	5.54	0.244	6.02
dynamic-4	**0.267**	6.01	**0.232**	5.74	**0.256**	6.16

dynamic-1	0.24	0.51	0.25
dynamic-4	**0.3**	0.5	0.2

Table 3: Manual evaluation of translation quality.

5 Results and Discussion

Automatic Evaluation. Table 2 presents the results from the automatic evaluation, in terms of BLEU (Papineni et al., 2002) and NIST (Doddington, 2002) scores, of 4 system setups. The baseline has no MWE knowledge, while the static and the dynamic-1 system setups are reproduced from the experiments described in Simova and Kordoni (2013). Dynamic-1 includes only a single binary feature which indicates the presence of a PV while our method, dynamic-4, includes the 4 features described in Table 1.

Our method outperforms all other setups in terms of BLEU score, thus proving our point that adding features describing the linguistic properties of PVs improves SMT even further. Also, the results for the 400 sentences without PVs show that the 4 new features do not have a negative impact for PV-free contexts.

In terms of NIST the static strategy consistently performs best, followed closely by our method. NIST is a measure which weights the translated n-grams according to their informativeness. Due to the nature of this measure, less frequent correctly translated n-grams are given more weight in the evaluation process because NIST considers them "more informative". Such less frequent n-grams, or in our case PVs, are likely to be captured better by the static setup. Therefore, this setup achieves the highest NIST scores. This fact also suggests that dynamic and static strategies influence the SMT process in different ways, with our method tending to capture more frequent (and thus less informative) n-grams. Interestingly, the other dynamic method, dynamic-1, has the worst performance of all setups in terms of NIST.

Manual evaluation. To get a better insight on how the different setups deal with the translation of PVs, we also performed a manual evaluation. A native speaker of Bulgarian was asked to judge the translations of PVs for the 375 test sentences in which such verbs were correctly identified during the identification step. The human subject takes into account the target PV and a limited context around it and judges the translation as:

- *good* - correct translation of the PV, correct verb inflection
- *acceptable* - correct translation of the PV but wrong inflection, or wrongly built *da-* or reflexive construction
- *incorrect* - wrong translation which changes the meaning of the sentence

Table 3 shows the results. Our method dynamic-4 produces more good translations and less incorrect ones than all other setups. This illustrates further the benefits of adding linguistic features to the translation model. The results achieved by the static approach are attributed to the better handling of separable PVs in sentences where the particle was not adjacent to the verb. The dynamic-1 approach and the baseline often interpret the particle literally in such cases which leads to almost twice the amount of wrong translations. Our method, on the other hand, performs slightly lower than the static approach in this respect but still much better than the other 2 setups.

Compared to dynamic-1 and the baseline, the static approach also handles better idiomatic PVs but performs slightly worse for sentences with compositional PVs. However, the addition of a specific feature to encode idiomaticity in the translation model enables our method dynamic-4 to achieve the best performance for idiomatic PVs while still handling successfully many compositional PVs. To summarise, the improved results of our method in comparison to previous work are attributed to the better handling of separable PVs which occur in a split form and even more to the improved ability to differentiate between compositional and idiomatic PVs.

Feature combinations. Our method performs best when all 3 linguistic features described above

are taken into account by the SMT system. However, we also experimented with different combinations of those features in order to get some insight of the way each feature influences the translation quality. Adding only the feature denoting verb transitiveness did not lead to any significant improvement compared to the dynamic-1 setup. Also, the combination which leaves out this feature and uses the remaining ones ranks second, achieving only a slightly worse performance than dynamic-4, the setup in which all features are employed. It seems that the transitiveness feature does not contribute much to the task at hand. Adding only the feature denoting separable vs inseparable PVs and adding only the one denoting idiomaticity led to results slightly higher than those of the dynamic-1 and static setups but still, those results were significantly lower than the ones presented in Tables 2 and 3.

6 Conclusion and Outlook

In this article, we showed that the addition of linguistically informative features to a phrase-based SMT model improves the translation quality of a particular type of MWEs, namely phrasal verbs. In a case study involving SMT from English to Bulgarian, we showed that adding features which encode not only the presence of a PV in a given phrase but also its transitiveness, separability, and idiomaticity led to better translation quality compared to previous work which employs both static and dynamic strategies.

In future research, we will extend our method to other language pairs which exhibit the same type of translation asymmetries when it comes to PVs. Such language pairs include, among others, English-Spanish and English-Portuguese.

Further, we will apply our linguistically informed method to other phenomena which cause similar issues for SMT. Immediate candidate phenomena include other types of MWEs, collocations, and noun compounds. When it comes to MWEs, we will pay special attention to the compositionality aspect since it seems to have contributed most to the good performance achieve by our method in the study presented here.

Abstract

Sentence level evaluation in MT has turned out far more difficult than corpus level evaluation. Existing sentence level metrics employ a limited set of features, most of which are rather sparse at the sentence level, and their intricate models are rarely trained for ranking. This paper presents a simple linear model exploiting 33 relatively dense features, some of which are novel while others are known but seldom used, and train it under the *learning-to-rank* framework. We evaluate our metric on the standard WMT12 data showing that it outperforms the strong baseline METEOR. We also analyze the contribution of individual features and the choice of training data, language-pair vs. target-language data, providing new insights into this task.

1 Introduction

Evaluating machine translation (MT) output at the *sentence/ segment level* has turned out far more challenging than corpus/ system level. Yet, sentence level evaluation can be useful because it allows fast, fine-grained analysis of system performance on individual sentences.

It is instructive to contrast two widely used metrics, METEOR (Michael Denkowski and Alon Lavie, 2014) and BLEU (Papineni et al., 2002), on sentence level evaluation. METEOR constantly shows better correlation with human ranking than BLEU (Papineni et al., 2002). Arguably, this shows that sentence level evaluation demands finer grained and trainable models over *less sparse features*. Ngrams, the core of BLEU, are sparse at the sentence level, and a mismatch for longer ngrams implies that BLEU falls back on shorter ngrams. In contrast, METEOR has a trainable model and incorporates a small, yet wider set of features that are less sparse than ngrams. We think that METEOR's features and its training approach *only suggest* that sentence level evaluation should be treated as a modelling challenge. This calls for questions such as what model, what features and what training objective are better suited for modelling sentence level evaluation.

We start out by explicitly formulating sentence level evaluation as the problem of *ranking* a set of competing hypothesis. Given data consisting of human ranked system outputs, the problem then is to formulate an easy to train model for ranking. One particular existing approach (Ye et al., 2007) looks especially attractive because we think it meshes well with a range of effective techniques for *learning-to-rank* (Li, 2011).

We deliberately select a linear modelling approach inspired by *RankSVM* (Herbrich et al., 1999), which is easily trainable for ranking and allows analysis of the individual contributions of features. Besides presenting a new metric and a set of known, but also a set of novel features, we target three questions of interest to the MT community:

- What kind of features are more helpful for sentence level evaluation?
- How does a simple linear model trained for ranking compare to the well-developed metric METEOR on sentence level evaluation?
- Should we train the model for each language pair separately or for a target language?

Our new metric dubbed BEER[1] outperforms METEOR on WMT12 data showing the effectiveness of dense features in a learning-to-rank framework. The metric and the code are available as free software[2].

2 Model

Our model is a linear combination of features trained for ranking similar to RankSVM (Herbrich et al., 1999) or, to readers familiar with SMT system tuning, to PRO tuning (Hopkins and May, 2011):

$$score(sys) = \vec{w} \cdot \vec{x}_{sys}$$

where $\vec{w}$ represents a weight vector and $\vec{x}_{sys}$ a vector of feature values for system output sys. Looking at evaluation as a ranking problem, we contrast (at least) two system translations $good$ and bad for the same source sentence. Assuming that $humanRank(good) > humanRank(bad)$ as ranked

[1] BEER participated on WMT14 evaluation metrics task where it was the highest scoring sentence level evaluation metric on average over all language pairs (Stanojević and Sima'an, 2014)

[2] https://github.com/stanojevic/beer

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 202–206,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

by human judgement, we expect metric $score(\cdot)$ to fulfill $score(good) > score(bad)$:

$$\begin{aligned} \vec{\boldsymbol{w}} \cdot \vec{\boldsymbol{x}}_{good} &> \vec{\boldsymbol{w}} \cdot \vec{\boldsymbol{x}}_{bad} \quad \Leftrightarrow \\ \vec{\boldsymbol{w}} \cdot \vec{\boldsymbol{x}}_{good} - \vec{\boldsymbol{w}} \cdot \vec{\boldsymbol{x}}_{bad} &> 0 \quad \Leftrightarrow \\ \vec{\boldsymbol{w}} \cdot (\vec{\boldsymbol{x}}_{good} - \vec{\boldsymbol{x}}_{bad}) &> 0 \quad \wedge \\ \vec{\boldsymbol{w}} \cdot (\vec{\boldsymbol{x}}_{bad} - \vec{\boldsymbol{x}}_{good}) &< 0 \end{aligned}$$

The two feature vectors $(\vec{\boldsymbol{x}}_{good} - \vec{\boldsymbol{x}}_{bad})$ and $(\vec{\boldsymbol{x}}_{bad} - \vec{\boldsymbol{x}}_{good})$ can be considered as positive and negative instances for training our linear classifier. For training this model, we use Logistic Regression from the Weka toolkit (Hall et al., 2009).

3 Features

Generally speaking we identify *adequacy* and *fluency* features. For both types we devise far less sparse features than word ngrams.

Adequacy features We use precision P, recall R and F1-score F as follows:

P_{func}, R_{func}, F_{func} on matched function words

P_{cont}, R_{cont}, F_{cont} on matched content words

P_{all}, R_{all}, F_{all} on matched words of any type

P_{char}, R_{char}, F_{char} matching of the char ngrams

By differentiating between function and non-function words, our metric weighs each kind of words according to importance for evaluation. Matching character ngrams, originally proposed in (Yang et al., 2013), rewards certain translations even if they did not get the morphology completely right. Existing metrics use stemmers for this, but using character ngrams is independent of the availability of a good quality stemmer. Higher-order character ngrams have less risk of sparse counts than word ngrams. In our experiments we used char ngrams for n up to 6, which makes the total number of adequacy features 27.

Fluency features To evaluate word order we follow (Isozaki et al., 2010; Birch and Osborne, 2010) in representing reordering as a permutation π over $[1..n]$ and then measuring the distance to the ideal monotone permutation $\langle 1, 2, \cdots, n \rangle$. We present a novel approach based on factorization into *permutation trees (PETs)* (Zhang and Gildea, 2007), and contrast it with Kendall τ (Birch and Osborne, 2010; Isozaki et al., 2010). PETs are factorizations of permutations, which allows for an abstract and *less sparse* view of word order as exemplified next. Kendall score was regularly shown to have high correlation with human judgment on distant language pairs (Isozaki et al., 2010; Birch and Osborne, 2010).

Features based on PETs We informally review PETs in order to exploit them for novel ordering features. We refer the reader to (Zhang and Gildea, 2007) and (Maillette de Buy Wenniger and Sima'an, 2011) for a formal treatment of PETs and efficient factorization algorithms.

A PET of permutation π is a tree organization of π's *unique, atomic building blocks*, called *operators*. Every operator on a PET node is an *atomic permutation* (not factorizing any further),[3] and it stands for the permutation of the direct children of that node. Figure 1a shows an example PET that has one 4-branching node with operator $\langle 2, 4, 1, 3 \rangle$, two binary branching nodes of which one decorated with the inverted operator $\langle 2, 1 \rangle$ and another with the monotone $\langle 1, 2 \rangle$.

PETs have two important properties making them attractive for measuring order difference: firstly, order difference is measured on the operators – the *atomic reordering building blocks* of the permutation, and secondly, the operators on higher level nodes capture *hidden ordering patterns* that cannot be observed without factorization. Statistics over ordering patterns in PETs are far less sparse than word or character ngram statistics.

Intuitively, among the atomic permutations, the binary monotone operator $\langle 1, 2 \rangle$ signifies no ordering difference at all, whereas the binary inverted $\langle 2, 1 \rangle$ signifies the shortest unit of order difference. Operators of length four like $\langle 2, 4, 1, 3 \rangle$ (Wu, 1997) are presumably more complex than $\langle 2, 1 \rangle$, whereas operators longer than four signify even more complex order difference. Therefore, we devise possible branching feature functions over the operator length for the nodes in PETs:

- factor 2 - with two features: $\Delta_{[\,]}$ and $\Delta_{<>}$ (there are no nodes with factor 3 (Wu, 1997))
- factor 4 - feature $\Delta_{=4}$
- factor bigger than 4 - feature $\Delta_{>4}$

Consider permutations $\langle 2, 1, 4, 3 \rangle$ and $\langle 4, 3, 2, 1 \rangle$, none of which has exactly matching ngrams beyond unigrams. Their PETs are in Figures 1b and 1c. Intuitively, $\langle 2, 1, 4, 3 \rangle$ is somewhat less scrambled than $\langle 4, 3, 2, 1 \rangle$ because it has at least some position in correct order. These "abstract ngrams" pertaining to correct ordering of full phrases could be counted using $\Delta_{[\,]}$ which would recognize that on top of the PET in 1b there is a binary monotone node, unlike the PET in Figure 1c which has no monotone nodes at all.

Even though the set of operators that describe a permutation is unique for the given permutation, the ways in which operators are combined (the derivation tree) is not unique. For example, for the fully monotone

[3] For example $\langle 2, 4, 1, 3 \rangle$ is atomic whereas $\langle 4, 3, 2, 1 \rangle$ is not. The former does not contain any contiguous sub-ranges of integers whereas the latter contains sub-range $\{2, 3, 4\}$ in reverse order $\langle 4, 3, 2 \rangle$, which factorizes into two binary inverting nodes cf. Fig. 1c.

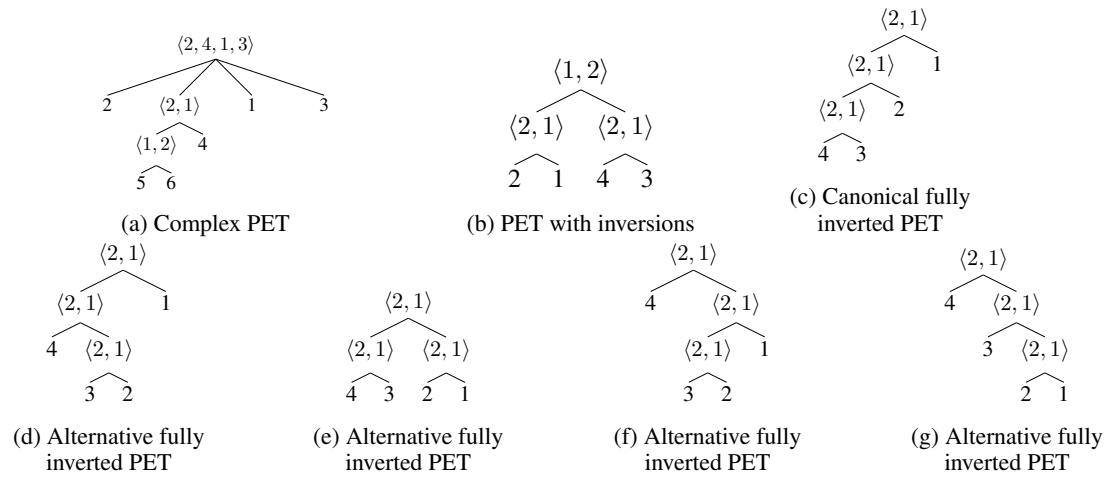

Figure 1: Examples of PETs

permutation $\langle 4, 3, 2, 1\rangle$ there are 5 possible derivations (PETs) presented in Figures 1c, 1d, 1e, 1f and 1g. The features on PETs that we described so far look at the operators independently (they treat a derivation as a set of operators) so differenct derivations do not influence the score–whichever derviation we use we will get the same feature score. However, the number of derivations might say something about the *goodness* of the permutation. Similar property of permutations was found to be helpful earlier in (Mylonakis and Sima'an, 2008) as an ITG prior for learning translation rule probabilities.

Permutations like $\langle 3, 2, 1, 4\rangle$ and $\langle 2, 4, 3, 1\rangle$ have the same set of operators, but the former factorizes into more PETs than the latter because $\langle 4, 3\rangle$ must group first before grouping it with 2 and then 1 in $\langle 2, 4, 3, 1\rangle$. The "freedom to bracket" in different ways could be a signal of better grouping of words (even if they have inverted word order). Hence we exploit one more feature:

Δ_{count} the ratio between the number of alternative PETs for the given permutation, to the number of PETs that could be built if permutation was perfectly grouped (fully monotone or fully inverted).

Finding the number of PETs that could be built does not require building all PETs or encoding them in the chart. The number can be computed directly from the canonical left-branching PET. Since multiple different PETs appear only in cases when there is a sequence of more than one node that is either $\langle 1, 2\rangle$ or $\langle 2, 1\rangle$ (Zhang et al., 2008), we can use these sequences to predict the number of PETs that could be built. Let X represent a set of sequences of the canonical derivation. The number of PETs is computed in the following way:

$$\#PETs = \prod_{x \in X} Cat(|x|) \quad (1)$$

$$Cat(n) = \frac{1}{n+1}\binom{2n}{n} \quad (2)$$

where $Cat(\cdot)$ is a Catalan number. The proof for this formula is beyond the scope of this paper. The reader can consider the example of the PET in Figure 1c. That derivation has one sequence of monotone operators of length 3. So the number of PETs that could be built is $Cat(3) = 5$.

4 Experiments

We use human judgments from the WMT tasks: WMT13 is used for training whereas WMT12 for testing. The baseline is METEOR's latest version (Michael Denkowski and Alon Lavie, 2014), one of the best metrics on sentence level. To avoid contaminating the results with differences with METEOR due to resources, we use the same alignment, tokenization and lowercasing (*-norm* in METEOR) algorithms, and the same tables of function words, synonyms, paraphrases and stemmers.

Kendall τ correlation is borrowed from WMT12 (Callison-Burch et al., 2012):

$$\tau = \frac{\#concordant - \#discordant - \#ties}{\#concordant + \#discordant + \#ties}$$

$\#concordant$ represents the number of pairs ordered in the same way by metric and by human, $\#discordant$ the number of opposite orderings and $\#ties$ the number of tied rankings by metric.

Beside testing our full metric BEER, we perform experiments where we remove one kind of the following features at a time:

1. char n-gram features (P, R and F-score)
2. all word features (P, R and F-score for all, function and content words),
3. all function and content words features
4. all F-scores (all words, function words, content words, char ngrams)

metric	en-cs	en-fr	en-de	en-es	cs-en	fr-en	de-en	es-en	avg τ
BEER without char features	0.124	0.178	0.168	0.149	0.121	0.17	0.179	0.078	0.146

6. Kendall τ features
7. all fluency features (PET and Kendall τ)

Table 1 shows the results sorted by their average Kendall τ correlation with human judgment.

5 Analysis

Given these experimental results, we are coming back to the questions we asked in the introduction.

5.1 What kind of features are more helpful for sentence level evaluation?

Fluency vs. Adequacy The fluency features play a smaller role than adequacy features. Apparently, many SMT systems participating in this task have rather similar reordering models, trained on similar data, which makes the fluency features not that discriminative relative to adequacy features. Perhaps in a different application, for example MT system tuning, the reordering features would be far more relevant because ignoring them would basically imply disregarding the importance of the reordering model in MT.

Character vs. Word features We observe that, precision, recall and F-score on *character ngrams* are crucial. We think that this shows that less sparse features are important for sentence level evaluation. The second best features are *word features*. Without word features, BEER scores just below METEOR, which suggests that word boundaries play a role as well. In contrast, differentiating between *function and content words* does not seem to be important.

PETs vs. Kendall τ Despite the smaller role for reordering features we can make a few observations. Firstly, while PETs and Kendall seem to have similar effect on English-Foreign cases, in all four cases of Foreign-English PETs give better scores. We hypothesize that the quality of the permutations (induced between system output and reference) is better for English than for the other target languages. Discarding PET features has far larger impact than discarding Kendall. Most interestingly, for de-en it makes the difference in outperforming METEOR. In many cases discarding Kendall τ improves the BEER score, likely because it conflicts with the PET features that are found more effective.

5.2 Is a linear model sufficient?

A further insight, from our perspective, is that *F-score* features constitute a crucial set of features, *even when the corresponding precision and recall features are included*. Because our model merely allows for linear interpolation, whereas F-score is a non-linear function of precision and recall, we think this suggests that a non-linear interpolation of precision and recall is useful.[4] By formulating the evaluation as a ranking problem it is relatively easy to "upgrade" for using non-linear models while using the same (or larger) set of features.

5.3 Train for the language pair or only for the target language?

All our models were trained for each language pair. This is not the case with many other metrics which train their models for each target language instead of language pair. We contrast these two settings in Table 2. Training for each language pair separately does not give significant improvement over training for the target language only. A possible reason could be that by training for the target language we have more training data (in this case four times more).

Train for	cs-en	fr-en	de-en	es-en	avg τ
target lang	0.199	0.257	0.273	0.248	0.244
lang pair	0.198	0.263	0.283	0.245	0.247

Table 2: Kendall τ scores on WMT12 for different training data

5.4 BEER vs. METEOR

The results across individual language pairs are mostly consistent with the averages with a few exceptions. BEER outperforms METEOR in five out of eight language pairs, ties at one (the difference is only 0.001 on es-en) and loses in two (en-fr and cs-en). In some cases BEER is better than METEOR by a large margin (see, e.g., en-cs, en-de).

[4] Interestingly, METEOR tunes β in F_β.

6 Conclusion

In this work we show that combining less sparse features at the sentence level into a linear model that is trained on ranking we can obtain state-of-the-art results. The analysis of the results shows that features on character ngrams are crucial, besides the standard word level features. The reordering features, while rather important, are less effective within this WMT task, albeit the more abstract PET features have larger impact than the often used Kendall. Good performance of F-score features leads to the conclusion that linear models might not be sufficient for modeling human sentence level ranking and to learn the right relation between precision and recall it could be worthwhile exploring non-linear models.

Abstract

We present a human judgments dataset and an adapted metric for evaluation of Arabic machine translation. Our medium-scale dataset is the first of its kind for Arabic with high annotation quality. We use the dataset to adapt the BLEU score for Arabic. Our score (AL-BLEU) provides partial credits for stem and morphological matchings of hypothesis and reference words. We evaluate BLEU, METEOR and AL-BLEU on our human judgments corpus and show that AL-BLEU has the highest correlation with human judgments. We are releasing the dataset and software to the research community.

1 Introduction

Evaluation of Machine Translation (MT) continues to be a challenging research problem. There is an ongoing effort in finding simple and scalable metrics with rich linguistic analysis. A wide range of metrics have been proposed and evaluated mostly for European target languages (Callison-Burch et al., 2011; Macháček and Bojar, 2013). These metrics are usually evaluated based on their correlation with human judgments on a set of MT output. While there has been growing interest in building systems for translating into Arabic, the evaluation of Arabic MT is still an under-studied problem. Standard MT metrics such as BLEU (Papineni et al., 2002) or TER (Snover et al., 2006) have been widely used for evaluating Arabic MT (El Kholy and Habash, 2012). These metrics use strict word and phrase matching between the MT output and reference translations. For morphologically rich target languages such as Arabic, such criteria are too simplistic and inadequate. In this paper, we present: (a) the first human judgment dataset for Arabic MT (b) the Arabic Language BLEU (AL-BLEU), an extension of the BLEU score for Arabic MT evaluation.

Our annotated dataset is composed of the output of six MT systems with texts from a diverse set of topics. A group of ten native Arabic speakers annotated this corpus with high-levels of inter- and intra-annotator agreements. Our AL-BLEU metric uses a rich set of morphological, syntactic and lexical features to extend the evaluation beyond the exact matching. We conduct different experiments on the newly built dataset and demonstrate that AL-BLEU shows a stronger average correlation with human judgments than the BLEU and METEOR scores. Our dataset and our AL-BLEU metric provide useful testbeds for further research on Arabic MT and its evaluation.[1]

2 Related Work

Several studies on MT evaluation have pointed out the inadequacy of the standard n-gram based evaluation metrics for various languages (Callison-Burch et al., 2006). For morphologically complex languages and those without word delimiters, several studies have attempted to improve upon them and suggest more reliable metrics that correlate better with human judgments (Denoual and Lepage, 2005; Homola et al., 2009).

A common approach to the problem of morphologically complex words is to integrate some linguistic knowledge in the metric. METEOR (Denkowski and Lavie, 2011), TER-Plus (Snover et al., 2010) incorporate limited linguistic resources. Popović and Ney (2009) showed that n-gram based evaluation metrics calculated on POS sequences correlate well with human judgments, and recently designed and evaluated MPF, a BLEU-style metric based on morphemes and POS tags (Popović, 2011). In the same direc-

[1] The dataset and the software are available at: http://nlp.qatar.cmu.edu/resources/AL-BLEU

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 207–213,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

tion, Chen and Kuhn (2011) proposed AMBER, a modified version of BLEU incorporating recall, extra penalties, and light linguistic knowledge about English morphology. Liu et al. (2010) propose TESLA-M, a variant of a metric based on n-gram matching that utilizes light-weight linguistic analysis including lemmatization, POS tagging, and WordNet synonym relations. This metric was then extended to TESLA-B to model phrase synonyms by exploiting bilingual phrase tables (Dahlmeier et al., 2011). Tantug et al. (2008) presented BLEU+, a tool that implements various extension to BLEU computation to allow for a better evaluation of the translation performance for Turkish.

To the best of our knowledge the only human judgment dataset for Arabic MT is the small corpus which was used to tune parameters of the METEOR metric for Arabic (Denkowski and Lavie, 2011). Due to the shortage of Arabic human judgment dataset, studies on the performance of evaluation metrics have been constrained and limited. A relevant effort in this area is the upper-bound estimation of BLEU and METEOR scores for Arabic MT output (El Kholy and Habash, 2011). As part of its extensive functionality, the AMEANA system provides the upper-bound estimate by an exhaustive matching of morphological and lexical features between the hypothesis and the reference translations. Our use of morphological and lexical features overlaps with the AMEANA framework. However, we extend our partial matching to a supervised tuning framework for estimating the value of partial credits. Moreover, our human judgment dataset allows us to validate our framework with a large-scale gold-standard data.

3 Human judgment dataset

We describe here our procedure for compiling a diverse Arabic MT dataset and annotating it with human judgments.

3.1 Data and systems

We annotate a corpus composed of three datasets: (1) the standard English-Arabic NIST 2005 corpus, commonly used for MT evaluations and composed of news stories. We use the first English translation as the source and the single corresponding Arabic sentence as the reference. (2) the MEDAR corpus (Maegaard et al., 2010) that consists of texts related to the climate change with four Arabic reference translations. We only use the first reference in this study. (3) a small dataset of Wikipedia articles (WIKI) to extend our corpus and metric evaluation to topics beyond the commonly-used news topics. This sub-corpus consists of our in-house Arabic translations of seven English Wikipedia articles. The articles are: *Earl Francis Lloyd*, *Western Europe*, *Citizenship*, *Marcus Garvey*, *Middle Age translation*, *Acadian*, *NBA*. The English articles which do not exist in the Arabic Wikipedia were manually translated by a bilingual linguist.

Table 1 gives an overview of these sub-corpora characteristics.

	NIST	**MEDAR**	**WIKI**
# of Documents	100	4	7
# of Sentences	1056	509	327

Table 1: Statistics on the datasets.

We use six state-of-the-art English-to-Arabic MT systems. These include four research-oriented phrase-based systems with various morphological and syntactic features and different Arabic tokenization schemes and also two commercial off-the-shelf systems.

3.2 Annotation of human judgments

In order conduct a manual evaluation of the six MT systems, we formulated it as a ranking problem. We adapt the framework used in the WMT 2011 shared task for evaluating MT metrics on European language pairs (Callison-Burch et al., 2011) for Arabic MT. We gather human ranking judgments by asking ten annotators (each native speaker of Arabic with English as a second language) to assess the quality of the English-Arabic systems, by ranking sentences relative to each other, from the best to the worst (ties are allowed).

We use the Appraise toolkit (Federmann, 2012) designed for manual MT evaluation. The tool displays to the annotator, the source sentence and translations produced by various MT systems. The annotators received initial training on the tool and the task with ten sentences. They were presented with a brief guideline indicating the purpose of the task and the main criteria of MT output evaluation.

Each annotator was assigned to 22 ranking tasks. Each task included ten screens. Each screen involveed ranking translations of ten sentences. In total, we collected $22,000$ rankings for 1892 sen-

tences (22 tasks×10 screens×10 judges). In each annotation screen, the annotator was shown the source-language (English) sentences, as well as five translations to be ranked. We did not provide annotators with the reference to avoid any bias in the annotation process. Each source sentence was presented with its direct context. Rather than attempting to get a complete ordering over the systems, we instead relied on random selection and a reasonably large sample size to make the comparisons fair (Callison-Burch et al., 2011).

An example of a source sentence and its five translations to be ranked is given in Table 2.

3.3 Annotation quality and analysis

In order to ensure the validity of any evaluation setup, a reasonable of *inter-* and *intra*-annotator agreement rates in ranking should exist. To measure these agreements, we deliberately reassigned 10% of the tasks to second annotators. Moreover, we ensured that 10% of the screens are redisplayed to the same annotator within the same task. This procedure allowed us to collect reliable quality control measure for our dataset.

	κ_{inter}	κ_{intra}
EN-AR	0.57	0.62
Average EN-EU	0.41	0.57
EN-CZ	0.40	0.54

Table 3: Inter- and intra-annotator agreement scores for our annotation compared to the average scores for five English to five European languages and also English-Czech (Callison-Burch et al., 2011).

We measured head-to-head pairwise agreement among annotators using Cohen's kappa (κ) (Cohen, 1968), defined as follows:

$$\kappa = \frac{P(A) - P(E)}{1 - P(E)}$$

where P(A) is the proportion of times annotators agree and P(E) is the proportion of agreement by chance.

Table 3 gives average values obtained for inter-annotator and intra-annotator agreement and compare our results to similar annotation efforts in WMT-13 on different European languages. Here we compare against the average agreement for English to five languages and also from English to one morphologically rich language (Czech).[4]

Based on Landis and Koch (1977) κ interpretation, the κ_{inter} value (57%) and also comparing our agreement scores with WMT-13 annotations, we believe that we have reached a reliable and consistent annotation quality.

4 AL-BLEU

Despite its well-known shortcomings (Callison-Burch et al., 2006), BLEU continues to be the de-facto MT evaluation metric. BLEU uses an exact n-gram matching criterion that is too strict for a morphologically rich language like Arabic. The system outputs in Table 2 are examples of how BLEU heavily penalizes Arabic. Based on BLEU, the best hypothesis is from Sys_5 which has three unigram and one bigram exact matches with the reference. However, the sentence is the 4$^{\text{th}}$ ranked by annotators. In contrast, the output of Sys_3 (ranked 1$^{\text{st}}$ by annotators) has only one exact match, but several partial matches when morphological and lexical information are taken into consideration.

We propose the Arabic Language BLEU (AL-BLEU) metric which extends BLEU to deal with Arabic rich morphology. We extend the matching to morphological, syntactic and lexical levels with an optimized partial credit. AL-BLEU starts with the exact matching of hypothesis tokens against the reference tokens. Furthermore, it considers the following: (a) morphological and syntactic feature matching, (b) stem matching. Based on Arabic linguistic intuition, we check the matching of a subset of 5 morphological features: (i) POS tag, (ii) gender (iii) number (iv) person (v) definiteness. We use the MADA package (Habash et al., 2009) to collect the stem and the morphological features of the hypothesis and reference translation.

Figure 1 summarizes the function in which we consider partial matching ($m(t_h, t_r)$) of a hypothesis token (t_h) and its associated reference token (t_r). Starting with the BLEU criterion, we first check if the hypothesis token is same as the reference one and provide the full credit for it. If the exact matching fails, we provide partial credit for matching at the stem and morphological level. The value of the partial credits are the sum of the stem weight (w_s) and the morphological fea-

[4]We compare against the agreement score for annotations performed by WMT researchers which are higher than the WMT annotations on Mechanical Turk.

Table 2: Example of ranked MT outputs in our gold-standard dataset. The first two rows specify the English input and the Arabic reference, respectively. The third row of the table lists the different MT system as ranked by annotators, using BLEU scores (column 4) and AL-BLEU (column 6). The different translation candidates are given here along with their associated Bucklwalter transliteration.[3] This example, shows clearly that AL-BLEU correlates better with human decision.

$$m(t_h, t_r) = \begin{cases} 1, & \textbf{if } t_h = t_r \\ w_s + \sum_{i=1}^{5} w_{fi} & \textbf{otherwise} \end{cases}$$

Figure 1: Formulation of our partial matching.

ture weights (w_{fi}). Each weight is included in the partial score, if such matching exist (e.g., stem match). In order to avoid over-crediting, we limit the range of weights with a set of constraints. Moreover, we use a development set to optimize the weights towards improvement of correlation with human judgments, using a hill-climbing algorithm (Russell and Norvig, 2009). Figure 2 illustrates these various samples of partial matching highlighted in different colors.

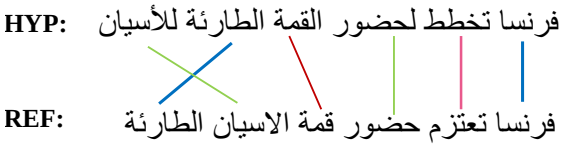

Figure 2: An MT example with exact matchings (blue), stem and morphological matching (green), stem only matching (red) and morphological-only matching (pink).

Following the BLEU-style exact matching and scoring of different n-grams, AL-BLEU updates the n-gram scores with the partial credits from non-exact matches. We use a minimum partial credit for n-grams which have tokens with different matching score. The contribution of a partially-matched n-gram is not 1 (as counted in BLEU), but the minimum value that individual tokens within the bigram are credited. For example, if a bigram is composed of a token with exact matching and a token with stem matching, this bigram receives a credit equal to a unigram with the stem matching (a value less than 1). While partial credits are added for various n-grams, the final computation of the AL-BLEU is similar to the original BLEU based on the geometric mean of the different matched n-grams. We follow BLEU in using a very small smoothing value to avoid zero n-gram counts and zero score.

5 Experiments and results

An automatic evaluation metric is said to be successful if it is shown to have high agreement with human-performed evaluations (Soricut and Brill, 2004). We use Kendall's tau τ (Kendall, 1938), a coefficient to measure the correlation between the system rankings and the human judgments at the sentence level. Kendall's tau τ is calculated as follows:

$$\tau = \frac{\text{\# of concordant pairs - \# of discordant pairs}}{\text{total pairs}}$$

where a *concordant pair* indicates two translations of the same sentence for which the ranks obtained from the manual ranking task and from the corresponding metric scores agree (they disagree in a *discordant pair*). The possible values of τ range from -1 (all pairs are discordant) to 1 (all pairs

	Dev	Test
BLEU	0.3361	0.3162
METEOR	0.3331	0.3426
AL-BLEU$_{Morph}$	**0.3746**	0.3535
AL-BLEU$_{Lex}$	0.3732	**0.3564**
AL-BLEU	**0.3759**	**0.3521**

Table 4: Comparison of the average Kendall's τ correlation.

are concordant). Thus, an automatic evaluation metric with a higher τ value is making predictions that are more similar to the human judgments than an automatic evaluation metric with a lower τ. We calculate the τ score for each sentence and average the scores to reach the corpus-level correlation. We conducted a set of experiments to compare the correlation of AL-BLEU against the state-of-the art MT evaluation metrics. For this we use a subset of 900 sentences extracted from the dataset described in Section 3.1. As mentioned above, the stem and morphological features in AL-BLEU are parameterized each by weights which are used to calculate the partial credits. We optimize the value of each weight towards correlation with human judgment by hill climbing with 100 random restarts using a development set of 600 sentences. The 300 remaining sentences (100 from each corpus) are kept for testing. The development and test sets are composed of equal portions of sentences from the three sub-corpora (NIST, MEDAR, WIKI).

As baselines, we measured the correlation of BLEU and METEOR with human judgments collected for each sentence. We did not observe a strong correlation with the Arabic-tuned METEOR. We conducted our experiments on the standard METEOR which was a stronger baseline than its Arabic version. In order to avoid the zero n-gram counts and artificially low BLEU scores, we use a smoothed version of BLEU. We follow Liu and Gildea (2005) to add a small value to both the matched n-grams and the total number of n-grams (epsilon value of 10^{-3}). In order to reach an optimal ordering of partial matches, we conducted a set of experiments in which we compared different orders between the morphological and lexical matchings to settle with the final order which was presented in Figure 1.

Table 4 shows a comparison of the average correlation with human judgments for BLEU, METEOR and AL-BLEU. AL-BLEU shows a strong improvement against BLEU and a competitive improvement against METEOR both on the test and development sets. The example in Table 2 shows a sample case of such improvement. In the example, the sentence ranked the highest by the annotator has only two exact matching with the reference translation (which results in a low BLEU score). The stem and morphological matching of AL-BLEU, gives a score and ranking much closer to human judgments.

6 Conclusion

We presented AL-BLEU, our adaptation of BLEU for the evaluation of machine translation into Arabic. The metric uses morphological, syntactic and lexical matching to go beyond exact token matching. We also presented our annotated corpus of human ranking judgments for evaluation of Arabic MT. The size and diversity of the topics in the corpus, along with its relatively high annotation quality (measured by IAA scores) makes it a useful resource for future research on Arabic MT. Moreover, the strong performance of our AL-BLEU metric is a positive indicator for future exploration of richer linguistic information in evaluation of Arabic MT.

Abstract

We present a pairwise learning-to-rank approach to machine translation evaluation that learns to differentiate *better* from *worse* translations in the context of a given reference. We integrate several layers of linguistic information encapsulated in tree-based structures, making use of both the reference and the system output simultaneously, thus bringing our ranking closer to how humans evaluate translations. Most importantly, instead of deciding upfront which types of features are important, we use the learning framework of preference re-ranking kernels to learn the features automatically. The evaluation results show that learning in the proposed framework yields better correlation with humans than computing the direct similarity over the same type of structures. Also, we show our structural kernel learning (SKL) can be a general framework for MT evaluation, in which syntactic and semantic information can be naturally incorporated.

1 Introduction

We have seen in recent years fast improvement in the overall quality of machine translation (MT) systems. This was only possible because of the use of automatic metrics for MT evaluation, such as BLEU (Papineni et al., 2002), which is the de-facto standard; and more recently: TER (Snover et al., 2006) and METEOR (Lavie and Denkowski, 2009), among other emerging MT evaluation metrics. These automatic metrics provide fast and inexpensive means to compare the output of different MT systems, without the need to ask for human judgments each time the MT system has been changed.

As a result, this has enabled rapid development in the field of statistical machine translation (SMT), by allowing to train and tune systems as well as to track progress in a way that highly correlates with human judgments.

Today, MT evaluation is an active field of research, and modern metrics perform analysis at various levels, e.g., lexical (Papineni et al., 2002; Snover et al., 2006), including synonymy and paraphrasing (Lavie and Denkowski, 2009); syntactic (Giménez and Màrquez, 2007; Popović and Ney, 2007; Liu and Gildea, 2005); semantic (Giménez and Màrquez, 2007; Lo et al., 2012); and discourse (Comelles et al., 2010; Wong and Kit, 2012; Guzmán et al., 2014; Joty et al., 2014).

Automatic MT evaluation metrics compare the output of a system to one or more human references in order to produce a *similarity* score. The quality of such a metric is typically judged in terms of correlation of the scores it produces with scores given by human judges. As a result, some evaluation metrics have been trained to reproduce the scores assigned by humans as closely as possible (Albrecht and Hwa, 2008). Unfortunately, humans have a hard time assigning an absolute score to a translation. Hence, direct human evaluation scores such as *adequacy* and *fluency*, which were widely used in the past, are now discontinued in favor of ranking-based evaluations, where judges are asked to rank the output of 2 to 5 systems instead. It has been shown that using such ranking-based assessments yields much higher inter-annotator agreement (Callison-Burch et al., 2007).

While evaluation metrics still produce numerical scores, in part because MT evaluation shared tasks at NIST and WMT ask for it, there has also been work on a ranking formulation of the MT evaluation task for a given set of outputs. This was shown to yield higher correlation with human judgments (Duh, 2008; Song and Cohn, 2011).

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 214–220,

Learning automatic metrics in a pairwise setting, i.e., learning to distinguish between two alternative translations and to decide which of the two is better (which is arguably one of the easiest ways to produce a ranking), emulates closely how human judges perform evaluation assessments in reality. Instead of learning a similarity function between a translation and the reference, they learn how to differentiate a better from a worse translation given a corresponding reference. While the pairwise setting does not provide an absolute quality scoring metric, it is useful for most evaluation and MT development scenarios.

In this paper, we propose a pairwise learning setting similar to that of Duh (2008), but we extend it to a new level, both in terms of feature representation and learning framework. First, we integrate several layers of linguistic information encapsulated in tree-based structures; Duh (2008) only used lexical and POS matches as features. Second, we use information about both the reference and two alternative translations *simultaneously*, thus bringing our ranking closer to how humans rank translations. Finally, instead of deciding upfront which types of features between hypotheses and references are important, we use a our structural kernel learning (SKL) framework to generate and select them automatically.

The structural kernel learning (SKL) framework we propose consists in: (*i*) designing a structural representation, e.g., using syntactic and discourse trees of translation hypotheses and a references; and (*ii*) applying structural kernels (Moschitti, 2006; Moschitti, 2008), to such representations in order to automatically inject structural features in the preference re-ranking algorithm. We use this method with translation-reference pairs to directly learn the features themselves, instead of learning the importance of a predetermined set of features. A similar learning framework has been proven to be effective for question answering (Moschitti et al., 2007), and textual entailment recognition (Zanzotto and Moschitti, 2006).

Our goals are twofold: (*i*) in the short term, to demonstrate that structural kernel learning is suitable for this task, and can effectively learn to rank hypotheses at the segment-level; and (*ii*) in the long term, to show that this approach provides a unified framework that allows to integrate several layers of linguistic analysis and information and to improve over the state-of-the-art.

Below we report the results of some initial experiments using syntactic and discourse structures. We show that learning in the proposed framework yields better correlation with humans than applying the traditional translation–reference similarity metrics using the same type of structures. We also show that the contributions of syntax and discourse information are cumulative. Finally, despite the limited information we use, we achieve correlation at the segment level that outperforms BLEU and other metrics at WMT12, e.g., our metric would have been ranked higher in terms of correlation with human judgments compared to TER, NIST, and BLEU in the WMT12 Metrics shared task (Callison-Burch et al., 2012).

2 Kernel-based Learning from Linguistic Structures

In our pairwise setting, each sentence s in the source language is represented by a tuple $\langle t_1, t_2, r\rangle$, where t_1 and t_2 are two alternative translations and r is a reference translation. Our goal is to develop a classifier of such tuples that decides whether t_1 is a better translation than t_2 given the reference r.

Engineering features for deciding whether t_1 is a better translation than t_2 is a difficult task. Thus, we rely on the automatic feature extraction enabled by the SKL framework, and our task is reduced to choosing: (*i*) a meaningful structural representation for $\langle t_1, t_2, r\rangle$, and (*ii*) a feature function ϕ_{mt} that maps such structures to substructures, i.e., our feature space. Since the design of ϕ_{mt} is complex, we use tree kernels applied to two simpler structural mappings $\phi_M(t_1, r)$ and $\phi_M(t_2, r)$. The latter generate the tree representations for the translation-reference pairs (t_1, r) and (t_2, r). The next section shows such mappings.

2.1 Representations

To represent a translation-reference pair (t, r), we adopt shallow syntactic trees combined with RST-style discourse trees. Shallow trees have been successfully used for question answering (Severyn and Moschitti, 2012) and semantic textual similarity (Severyn et al., 2013b); while discourse information has proved useful in MT evaluation (Guzmán et al., 2014; Joty et al., 2014). Combined shallow syntax and discourse trees worked well for concept segmentation and labeling (Saleh et al., 2014a).

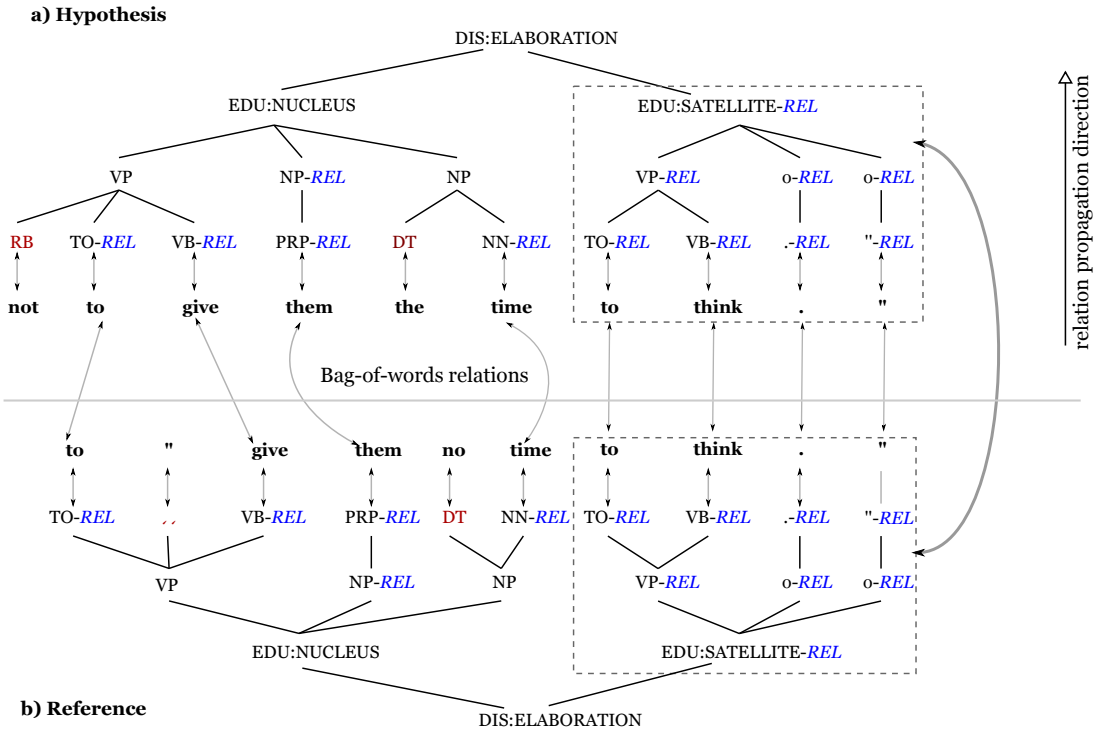

Figure 1: Hypothesis and reference trees combining discourse, shallow syntax and POS.

Figure 1 shows two example trees combining discourse, shallow syntax and POS: one for a translation hypothesis (top) and the other one for the reference (bottom). To build such structures, we used the Stanford POS tagger (Toutanova et al., 2003), the Illinois chunker (Punyakanok and Roth, 2001), and the discourse parser[1] of (Joty et al., 2012; Joty et al., 2013).

The lexical items constitute the leaves of the tree. The words are connected to their respective POS tags, which are in turn grouped into chunks. Then, the chunks are grouped into elementary discourse units (EDU), to which the nuclearity status is attached (i.e., NUCLEUS or SATELLITE). Finally, EDUs and higher-order discourse units are connected by discourse relations (e.g., DIS:ELABORATION).

2.2 Kernels-based modeling

In the SKL framework, the *learning objects* are pairs of translations $\langle t_1, t_2 \rangle$. Our objective is to automatically learn which pair features are important, independently of the source sentence. We achieve this by using kernel machines (KMs) over two learning objects $\langle t_1, t_2 \rangle, \langle t_1^{'}, t_2^{'} \rangle$, along with an explicit and structural representation of the pairs (see Fig. 1).

[1]The discourse parser can be downloaded from `http://alt.qcri.org/tools/`

More specifically, KMs carry out learning using the scalar product

$$K_{mt}(\langle t_1, t_2 \rangle, \langle t_1', t_2' \rangle) = \phi_{mt}(t_1, t_2) \cdot \phi_{mt}(t_1', t_2'),$$

where ϕ_{mt} maps pairs into the feature space.

Considering that our task is to decide whether t_1 is better than t_2, we can conveniently represent the vector for the pair in terms of the difference between the two translation vectors, i.e., $\phi_{mt}(t_1, t_2) = \phi_K(t_1) - \phi_K(t_2)$. We can approximate K_{mt} with a preference kernel PK to compute this difference in the kernel space K:

$$\begin{aligned} & PK(\langle t_1, t_2 \rangle, \langle t_1', t_2' \rangle) \qquad (1) \\ & = K(t_1) - \phi_K(t_2)) \cdot (\phi_K(t_1') - \phi_K(t_2')) \\ & = K(t_1, t_1') + K(t_2, t_2') - K(t_1, t_2') - K(t_2, t_1') \end{aligned}$$

The advantage of this is that now $K(t_i, t_j') = \phi_K(t_i) \cdot \phi_K(t_j')$ is defined between two translations only, and not between two pairs of translations. This simplification enables us to map translations into simple trees, e.g., those in Figure 1, and then to apply them tree kernels, e.g., the Partial Tree Kernel (Moschitti, 2006), which carry out a scalar product in the subtree space.

We can further enrich the representation ϕ_K, if we consider all the information available to the human judges when they are ranking translations. That is, the two alternative translations along with their corresponding reference.

In particular, let r and r' be the references for the pairs $\langle t_1, t_2 \rangle$ and $\langle t'_1, t'_2 \rangle$, we can redefine all the members of Eq. 1, e.g., $K(t_1, t'_1)$ becomes

$K(\langle t_1, r \rangle, \langle t'_1, r' \rangle) = \text{PTK}(\phi_M(t_1, r), \phi_M(t'_1, r'))$
$+ \quad \text{PTK}(\phi_M(r, t_1), \phi_M(r', t'_1))$,

where ϕ_M maps a pair of texts to a single tree.

There are several options to produce the bitext-to-tree mapping for ϕ_M. A simple approach is to only use the tree corresponding to the first argument of ϕ_M. This leads to the basic model $K(\langle t_1, r \rangle, \langle t'_1, r' \rangle) = \text{PTK}(\phi_M(t_1), \phi_M(t'_1)) + \text{PTK}(\phi_M(r), \phi_M(r'))$, i.e., the sum of two tree kernels applied to the trees constructed by ϕ_M (we previously informally mentioned it).

However, this simple mapping may be ineffective since the trees within a pair, e.g., (t_1, r), are treated independently, and no meaningful features connecting t_1 and r can be derived from their tree fragments. Therefore, we model $\phi_M(r, t_1)$ by using word-matching *relations* between t_1 and r, such that connections between words and constituents of the two trees are established using position-independent word matching. For example, in Figure 1, the thin dashed arrows show the links connecting the matching words between t_1 and r. The propagation of these relations works from the bottom up. Thus, if all children in a constituent have a link, their parent is also linked.

The use of such connections is essential as it enables the comparison of the structural properties and relations between two translation-reference pairs. For example, the tree fragment [ELABORATION [SATELLITE]] from the translation is connected to [ELABORATION [SATELLITE]] in the reference, indicating a link between two entire discourse units (drawn with a thicker arrow), and providing some reliability to the translation[2].

Note that the use of connections yields a graph representation instead of a tree. This is problematic as effective models for graph kernels, which would be a natural fit to this problem, are not currently available for exploiting linguistic information. Thus, we simply use K, as defined above, where the mapping $\phi_M(t_1, r)$ only produces a tree for t_1 annotated with the marker REL representing the connections to r. This marker is placed on all node labels of the tree generated from t_1 that match labels from the tree generated from r.

In other words, we only consider the trees enriched by markers separately, and ignore the edges connecting both trees.

3 Experiments and Discussion

We experimented with datasets of segment-level human rankings of system outputs from the WMT11 and the WMT12 Metrics shared tasks (Callison-Burch et al., 2011; Callison-Burch et al., 2012): we used the WMT11 dataset for training and the WMT12 dataset for testing. We focused on translating into English only, for which the datasets can be split by source language: Czech (cs), German (de), Spanish (es), and French (fr). There were about 10,000 non-tied human judgments per language pair per dataset. We scored our pairwise system predictions with respect to the WMT12 human judgments using the Kendall's Tau (τ), which was official at WMT12.

Table 1 presents the τ scores for all metric variants introduced in this paper: for the individual language pairs and overall. The left-hand side of the table shows the results when using as similarity the direct kernel calculation between the corresponding structures of the candidate translation and the reference[3], e.g., as in (Guzmán et al., 2014; Joty et al., 2014). The right-hand side contains the results for structured kernel learning.

We can make the following observations:
(*i*) The overall results for all SKL-trained metrics are higher than the ones when applying direct similarity, showing that learning tree structures is better than just calculating similarity.
(*ii*) Regarding the linguistic representation, we see that, when learning tree structures, syntactic and discourse-based trees yield similar improvements with a slight advantage for the former. More interestingly, when both structures are put together in a combined tree, the improvement is cumulative and yields the best results by a sizable margin. This provides positive evidence towards our goal of a unified tree-based representation with multiple layers of linguistic information.
(*iii*) Comparing to the best evaluation metrics that participated in the WMT12 Metrics shared task, we find that our approach is competitive and would have been ranked among the top 3 participants.

[2]Note that a non-pairwise model, i.e., $K(t_1, r)$, could also be used to match the structural information above, but it would not learn to compare it to a second pair (t_2, r).

[3]Applying tree kernels between the members of a pair to generate one feature (for each different kernel function) has become a standard practice in text similarity tasks (Severyn et al., 2013b) and in question answering (Severyn et al., 2013a).

		Similarity					Structured Kernel Learning				
	Structure	*cs*-en	*de*-en	*es*-en	*fr*-en	all	*cs*-en	*de*-en	*es*-en	*fr*-en	all
1	SYN	0.169	0.188	0.203	0.222	0.195	0.190	0.244	0.198	0.158	0.198
2	DIS	0.130	0.174	0.188	0.169	0.165	0.176	0.235	0.166	0.160	0.184
3	DIS+POS	0.135	0.186	0.190	0.178	0.172	0.167	0.232	0.202	0.133	0.183
4	DIS+SYN	0.156	0.205	0.206	0.203	0.192	**0.210**	**0.251**	**0.240**	**0.223**	**0.231**

Table 1: Kendall's (τ) correlation with human judgements on WMT12 for each language pair.

Furthermore, our result (0.237) is ahead of the correlation obtained by popular metrics such as TER (0.217), NIST (0.214) and BLEU (0.185) at WMT12. This is very encouraging and shows the potential of our new proposal.

In this paper, we have presented only the first exploratory results. Our approach can be easily extended with richer linguistic structures and further combined with some of the already existing strong evaluation metrics.

		Testing				
	Train	*cs*-en	*de*-en	*es*-en	*fr*-en	all
1	*cs*-en	0.210	0.204	0.217	0.204	0.209
2	*de*-en	0.196	0.251	0.203	0.202	0.213
3	*es*-en	0.218	0.204	**0.240**	0.223	0.221
4	*fr*-en	0.203	0.218	0.224	0.223	0.217
5	all	**0.231**	**0.258**	0.226	**0.232**	**0.237**

Table 2: Kendall's (τ) on WMT12 for cross-language training with DIS+SYN.

Note that the results in Table 1 were for training on WMT11 and testing on WMT12 for each language pair in isolation. Next, we study the impact of the choice of training language pair. Table 2 shows cross-language evaluation results for DIS+SYN: lines 1-4 show results when training on WMT11 for one language pair, and then testing for each language pair of WMT12.

We can see that the overall differences in performance (see the last column: *all*) when training on different source languages are rather small, ranging from 0.209 to 0.221, which suggests that our approach is quite independent of the source language used for training. Still, looking at individual test languages, we can see that for de-en and es-en, it is best to train on the same language; this also holds for fr-en, but there it is equally good to train on es-en. Interestingly, training on es-en improves a bit for cs-en.

These somewhat mixed results have motivated us to try tuning on the full WMT11 dataset; as line 5 shows, this yielded improvements for all language pairs except for es-en. Comparing to line 4 in Table 1, we see that the overall Tau improved from 0.231 to 0.237.

4 Conclusions and Future Work

We have presented a pairwise learning-to-rank approach to MT evaluation, which learns to differentiate good from bad translations in the context of a given reference. We have integrated several layers of linguistic information (lexical, syntactic and discourse) in tree-based structures, and we have used the structured kernel learning to identify relevant features and learn pairwise rankers.

The evaluation results have shown that learning in the proposed SKL framework is possible, yielding better correlation (Kendall's τ) with human judgments than computing the direct kernel similarity between translation and reference, over the same type of structures. We have also shown that the contributions of syntax and discourse information are cumulative, indicating that this learning framework can be appropriate for the combination of different sources of information. Finally, despite the limited information we used, we achieved better correlation at the segment level than BLEU and other metrics in the WMT12 Metrics task.

In the future, we plan to work towards our long-term goal, i.e., including more linguistic information in the SKL framework and showing that this can help. This would also include more semantic information, e.g., in the form of Brown clusters or using semantic similarity between the words composing the structure calculated with latent semantic analysis (Saleh et al., 2014b).

We further want to show that the proposed framework is flexible and can include information in the form of quality scores predicted by other evaluation metrics, for which a vector of features would be combined with the structured kernel.

Two Improvements to Left-to-Right Decoding for Hierarchical Phrase-based Machine Translation

Maryam Siahbani and **Anoop Sarkar**
School of Computing Science
Simon Fraser University

msiahban,anoop@cs.sfu.ca

Abstract

Left-to-right (LR) decoding (Watanabe et al., 2006) is promising decoding algorithm for hierarchical phrase-based translation (Hiero) that visits input spans in arbitrary order producing the output translation in left to right order. This leads to far fewer language model calls, but while LR decoding is more efficient than CKY decoding, it is unable to capture some hierarchical phrase alignments reachable using CKY decoding and suffers from lower translation quality as a result. This paper introduces two improvements to LR decoding that make it comparable in translation quality to CKY-based Hiero.

1 Introduction

Hierarchical phrase-based translation (Hiero) (Chiang, 2007) uses a lexicalized synchronous context-free grammar (SCFG) extracted from word and phrase alignments of a bitext. Decoding for Hiero is typically done with CKY-style decoding with time complexity $O(n^3)$ for source input with n words. Computing the language model score for each hypothesis within CKY decoding requires two histories, the left and the right edge of each span, due to the fact that the target side is built inside-out from sub-spans (Heafield et al., 2011; Heafield et al., 2013).

LR-decoding algorithms exist for phrase-based (Koehn, 2004; Galley and Manning, 2010) and syntax-based (Huang and Mi, 2010; Feng et al., 2012) models and also for hierarchical phrase-based models (Watanabe et al., 2006; Siahbani et al., 2013), which is our focus in this paper.

Watanabe et al. (2006) first proposed left-to-right (LR) decoding for Hiero (LR-Hiero henceforth) which uses beam search and runs in $O(n^2b)$ in practice where n is the length of source sentence and b is the size of beam (Huang and Mi, 2010). To simplify target generation, SCFG rules are constrained to be prefix-lexicalized on target side aka Griebach Normal Form (GNF). Throughout this paper we abuse the notation for simplicity and use the term GNF grammars for such SCFGs. This constraint drastically reduces the size of grammar for LR-Hiero in comparison to Hiero grammar (Siahbani et al., 2013). However, the original LR-Hiero decoding algorithm does not perform well in comparison to current state-of-the-art Hiero and phrase-based translation systems. Siahbani et al. (2013) propose an augmented version of LR decoding to address some limitations in the original LR-Hiero algorithm in terms of translation quality and time efficiency.

Although, LR-Hiero performs much faster than Hiero in decoding and obtains BLEU scores comparable to phrase-based translation system on some language pairs, there is still a notable gap between CKY-Hiero and LR-Hiero (Siahbani et al., 2013). We show in this paper using instructive examples that CKY-Hiero can capture some complex phrasal re-orderings that are observed in language pairs such as Chinese-English that LR-Hiero cannot (c.f. Sec.3).

We introduce two improvements to LR decoding of GNF grammars: (1) We add *queue diversity* to the cube pruning algorithm for LR-Hiero, and (2) We extend the LR-Hiero decoder to capture all the hierarchical phrasal alignments that are reachable in CKY-Hiero (restricted to using GNF grammars). We evaluate our modifications on three language pairs and show that LR-Hiero can reach the translation scores comparable to CKY-Hiero in two language pairs, and reduce the gap between Hiero and LR-Hiero on the third one.

2 LR Decoding with Queue Diversity

LR-Hiero uses a constrained lexicalized SCFG which we call a GNF grammar: $X \rightarrow \langle \gamma, \bar{b}\, \beta \rangle$ where γ is a string of non-terminal and terminal symbols, $\bar{b}$ is a string of terminal symbols and β is a possibly empty sequence of non-terminals. This ensures that as each rule is used in a derivation,

Algorithm 1: LR-Hiero Decoding

1: Input sentence: $\mathbf{f} = f_0 f_1 \dots f_n$
2: $\mathcal{F}$ = FutureCost($\mathbf{f}$) (Precompute future cost[1] for spans)
3: $S_0 = \{\}$ (Create empty initial stack)
4: $h_0 = (\langle s \rangle, [[0, n]], \emptyset, \mathcal{F}_{[0,n]})$ (Initial hypothesis 4-tuple)
5: Add h_0 to S_0 (Push initial hyp into first Stack)
6: **for** $i = 1, \dots, n$ **do**
7: $cubeList = \{\}$ (MRL is max rule length)
8: **for** $p = max(i - \text{MRL}, 0), \dots, i - 1$ **do**
9: $\{G\}$ = Grouped(S_p) (based on the first uncovered span)
10: **for** $g \in \{G\}$ **do**
11: $[u, v] = g_{span}$
12: R = GetSpanRules($[u, v]$)
13: **for** $R_s \in R$ **do**
14: $cube = [g_{hyps}, R_s]$
15: Add $cube$ to $cubeList$
16: S_i = Merge($cubeList, \mathcal{F}$) (Create stack S_i and add new hypotheses to it, see Figure 1)
17: **return** $\arg\max(S_n)$

18: **Merge**($CubeList, \mathcal{F}$)
19: $heapQ = \{\}$
20: **for** each (H, R) in $cubeList$ **do**
21: $hypList$ = getBestHypotheses($(H, R), \mathcal{F}, d$) (d best hypotheses of each cube)
22: **for** each h' in $hypList$ **do**
23: push($heapQ, (h'_c, h', [H, R])$ (Push new hyp in queue)
24: $hypList = \{\}$
25: **while** $|heapQ| > 0$ and $|hypList| < K$ **do**
26: $(h'_c, h', [H, R])$ = pop($heapQ$) (pop the best hypothesis)
27: push($heapQ, GetNeighbours([H, R])$ (Push neighbours to queue)
28: Add h' to $hypList$
29: **return** $hypList$

the target string is generated from left to right. The rules are obtained from a word and phrase aligned bitext using the rule extraction algorithm in (Watanabe et al., 2006).

LR-Hiero decoding uses a top-down depth-first search, which strictly grows the hypotheses in target surface ordering. Search on the source side follows an Earley-style search (Earley, 1970), the dot jumps around on the source side of the rules based on the order of nonterminals on the target side. This search is integrated with beam search or cube pruning to find the k-best translations.

Algorithm 1 shows the pseudocode for LR-Hiero decoding with cube pruning (Chiang, 2007) (CP). LR-Hiero with CP was introduced in (Siahbani et al., 2013). In this pseudocode, we have introduced the notion of *queue diversity* (explained below). However to understand our change we need to understand the algorithm in more detail.

[1]The future cost is precomputed in a way similar to the phrase-based models (Koehn et al., 2007) using only the terminal rules of the grammar.

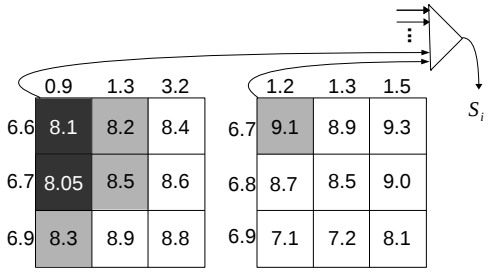

Figure 1: Cubes (grids) are fed to a priority queue (triangle) and generated hypotheses are iteratively popped from the queue and added to stack S_i. Lower scores are better. Scores of rules and hypotheses appear on the top and left side of the grids respectively. Shaded entries are hypotheses in the queue and black ones are popped from the queue and added to S_i.

Each source side non-terminal is instantiated with the legal spans given the input source string, e.g. if there is a Hiero rule $\langle aX_1, a'X_1 \rangle$ and if a only occurs at position 3 in the input then this rule can be applied to span $[3, i]$ for all i, $4 < i \leq n$ for input of length n and source side X_1 is instantiated to span $[4, i]$. A worked out example of how the decoder works is shown in Figure 2. Each partial hypothesis h is a 4-tuple (h_t, h_s, h_{cov}, h_c): consisting of a translation prefix h_t, a (LIFO-ordered) *list* h_s of uncovered spans, source words coverage set h_{cov} and the hypothesis cost h_c. The initial hypothesis is a null string with just a sentence-initial marker $\langle s \rangle$ and the list h_s containing a span of the whole sentence, $[0, n]$. The hypotheses are stored in stacks $S_0, \dots, S_n$, where S_p contains hypotheses covering p source words just like in stack decoding for phrase-based SMT (Koehn et al., 2003).

To fill stack S_i we consider hypotheses in each stack S_p[2], which are first partitioned into a set of groups $\{G\}$, based on their first uncovered span (line 9). Each group g is a 2-tuple (g_{span}, g_{hyps}), where g_{hyps} is a list of hypotheses which share the same first uncovered span g_{span}. Rules matching the span g_{span} are obtained from routine *GetSpanRules*. Each g_{hyps} and possible R_s create a cube which is added to $cubeList$.

The *Merge* routine gets the best hypotheses from all cubes (see Fig.1). Hypotheses (rows) and columns (rules) are sorted based on their scores. $GetBestHypotheses((H, R), \mathcal{F}, d)$ uses current hypothesis H and rule R to produce new hypotheses. The first best hypothesis, h' along with its score h'_c and corresponding cube (H, R) is placed in a priority queue $heapQ$ (triangle in Figure 1 and line 23 in Algorithm 1). Iteratively the K best

[2]As the length of rules are limited (at most MRL), we can ignore stacks with index less than $i - \text{MRL}$

rules	hypotheses

Figure 2: The process of translating the Chinese sentence in Figure 3(b) in LR-Hiero. Left side shows the rules used in the derivation (G indicates glue rules as defined in (Watanabe et al., 2006)). The hypotheses column shows the translation prefix and the ordered list of yet-to-be-covered spans.

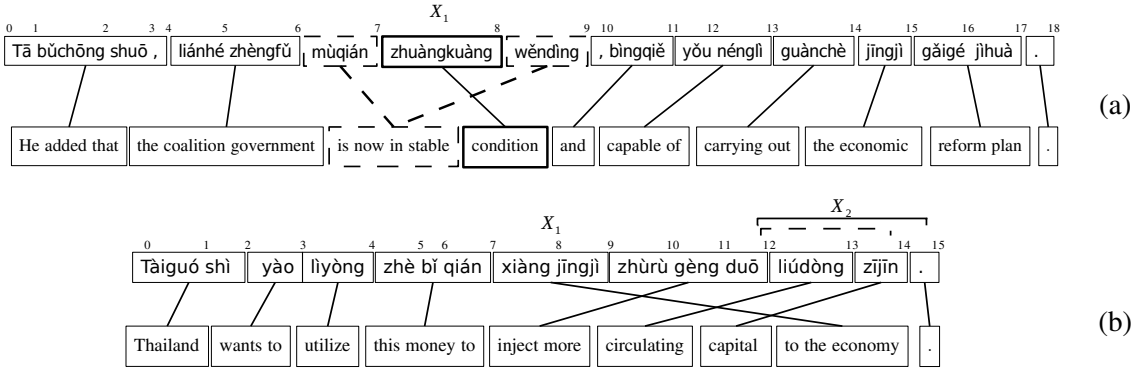

Figure 3: Two Chinese-English sentence pairs from devset data in experiments. (a) Correct rule cannot be matched to [6,18], our modifications match the rule to the first subspan [6,9] (b) LR-Hiero detects a wrong span for X_2 [12,15], we modify the rule matching match X_2 to all subspans [12,13], [12,14] and [12,15], corresponding to 3 hypotheses.

hypotheses in the queue are popped (line 26) and for each hypothesis its neighbours in the cube are added to the priority queue (line 27). Decoding finishes when stack S_n has been filled.

The language model (LM) score violates the hypotheses generation assumption of CP and can cause search errors. In Figure 1, the topmost and leftmost entry of the right cube has a score worse than many hypotheses in the left cube due to the LM score. This means the right cube has hypotheses that are ignored. This type of search error hurts LR-Hiero more than CKY-Hiero, due to the fact that hypotheses scores in LR-Hiero rely on a future cost, while CKY-Hiero uses the inside score for each hypothesis. To solve this issue for LR-Hiero we introduce the notion of *queue diversity* which is the parameter d in $GetBestHypotheses((H, R), \mathcal{F}, d)$. This parameter guarantees that each cube will produce at least d candidate hypotheses for the priority queue. d=1 in standard cube pruning for LR-Hiero (Siahbani et al., 2013). We apply the idea of diversity at queue level, before generating K best hypothesis, such that the *GetBestHypotheses* routine generates d best hypotheses from each cube and all these hypotheses are pushed to the priority queue (line 22-23). We fill each stack differently from CKY-Hiero and so queue diversity is different from lazy cube pruning (Pust and Knight, 2009) or cube growing (Huang and Chiang, 2007; Vilar and Ney, 2009; Xu and Koehn, 2012).

3 Capturing Missing Alignments

Figure 3(a) and Figure 3(b) show two examples of a common problem in LR-Hiero decoding. The decoder steps for Figure 3(b) are shown in Figure 2. The problem occurs in Step 5 of Figure 2 where rule #5 is matched to span $[7, 15]$. During decoding LR-Hiero maintains a stack (*last-in-first-out*) of yet-to-be-covered spans and tries to translate the first uncovered span (span $[7, 15]$ in Step 5). LR-Hiero should match rule #5 to span $[7, 15]$, therefore X_2 is forced to match span $[12, 15]$ which leads to the translation of span $[7, 9]$ (corresponding to X_1) being reordered around it

causing the incorrect translation in Step 9. If we use the same set of rules for translation in Hiero (CKY-based decoder), the decoder is able to generate the correct translation for span $[7, 14]$ (it works bottom-up and generate best translation for each source span). Then it combines translation of $[7, 14]$ with translation of spans $[0, 7]$ and $[14, 15]$ using glue rules (monotonic combination).

In Figure 3(a) monotonic translations after span $[6, 9]$ are out of reach of the LR-Hiero decoder which has to use the non-terminals to support the reordering within span $[6, 9]$. In this example the first few phrases are translated monotonically, then for span $[6, 18]$ we have to apply rule $\langle$muqian X_1 wending, is now in stable $X_1\rangle$ to obtain the correct translation. But this rule cannot be matched to span $[6, 18]$ and the decoder fails to generate the correct translation. While CKY-Hiero can apply this rule to span $[6, 9]$, generate correct translation for this span and monotonically combine it with translation of other spans ($[0, 6]$, $[9, 18]$).

In both these cases, CKY-Hiero has no difficulty in reaching the target sentence *with the same GNF rules*. The fact that we have to process spans as they appear in the stack in LR-Hiero means that we cannot combine arbitrary adjacent spans to deal with such cases. So purely bottom-up decoders such as CKY-Hiero can capture the alignments in Figure 3 but LR-Hiero cannot.

We extend the LR-Hiero decoder to handle such cases by making the GNF grammar more expressive. Rules are partitioned to three types based on the right boundary in the source and target side. The rhs after the $\Rightarrow$ shows the new rules we create within the decoder using a new non-terminal X_r to match the right boundary.

$$\begin{aligned} &\text{(a)}\ \langle \gamma\bar{a}, \bar{b}\beta\rangle \Rightarrow \langle \gamma\bar{a}X_r, \bar{b}\beta X_r\rangle \\ &\text{(b)}\ \langle \gamma X_n, \bar{b}\beta X_n\rangle \Rightarrow \langle \gamma X_n X_r, \bar{b}\beta X_n X_r\rangle \\ &\text{(c)}\ \langle \gamma X_n, \bar{b}\beta X_m\rangle \Rightarrow \langle \gamma X_n X_r, \bar{b}\beta X_m X_r\rangle \end{aligned} \quad (1)$$

where γ is a string of terminals and non-terminals, $\bar{a}$ and $\bar{b}$ are terminal sequences of source and target respectively, β is a possibly empty sequence of non-terminals and X_n and X_m are different non-terminals distinct from X_r[3]. The extra non-terminal X_r lets us add a new yet-to-be-covered span to the bottom of the stack at each rule application which lets us match any two adjacent spans just as in CKY-Hiero. This captures the missing alignments that could not be previously captured in the LR-Hiero decoder[4].

In Table 4 we translated devset sentences using forced decoding to show that our modifications to LR-Hiero in this section improves the alignment coverage when compared to CKY-Hiero.

4 Experiments

We evaluate our modifications to LR-Hiero decoder on three language pairs (Table 1): German-English (De-En), Czech-English (Cs-En) and Chinese-English (Zh-En).

[3]In rule type (c) X_n will be in β and X_m will be in γ.

[4]For the sake of simplicity, in rule type (b) we can merge X_n and X_r as they are in the same order on both source and target side.

We use a 5-gram LM trained on the Gigaword corpus and use KenLM (Heafield, 2011). We tune weights by minimizing BLEU loss on the dev set through MERT (Och, 2003) and report BLEU scores on the test set. Pop limit for Hiero and LR-Hiero+CP is 500 and beam size LR-Hiero is 500. Other extraction and decoder settings such as maximum phrase length, etc. were identical across settings. To make the results comparable we use the same feature set for all baselines, Hiero as well (including new features proposed by (Siahbani et al., 2013)).

We use 3 baselines: (i) our implementation of (Watanabe et al., 2006): LR-Hiero with beam search (LR-Hiero) and (ii) LR-Hiero with cube pruning (Siahbani et al., 2013): (LR-Hiero+CP); and (iii) Kriya, an open-source implementation of Hiero in Python, which performs comparably to other open-source Hiero systems (Sankaran et al., 2012).

Table 3 shows model sizes for LR-Hiero (GNF) and Hiero (SCFG). Typical Hiero rule extraction excludes phrase-pairs with unaligned words on boundaries (loose phrases). We use similar rule extraction as Hiero, except that exclude non-GNF rules and include loose phrase-pairs as terminal rules.

Table 2a shows the translation quality of different systems in terms of BLEU score. Row 3 is from (Siahbani et al., 2013)[5]. As we discussed in Section 2, LR-Hiero+CP suffers from severe search errors on Zh-En (1.5 BLEU) but using queue diversity (QD=15) we fill this gap. We use the same QD(=15) in next rows for Zh-en. For Cs-En and De-En we use regular cube pruning (QD=1), as it works as well as beam search (compare rows 4 and 2).

We measure the benefit of the new modified rules from Section 3: (*ab*): adding modifications for rules type (a) and (b); (*abc*): modification of all rules. We can see that for all language pairs (ab) constantly improves performance of LR-Hiero, significantly better than LR-Hiero+CP and LR-Hiero (p-value$<$0.05) on Cs-En and Zh-En, evaluated by MultEval (Clark et al., 2011). But modifying rule type (c) does not show any improvement due to spurious ambiguity created by type (c) rules.

[5]We report results on Cs-En and De-En in (Siahbani et al., 2013). Row 4 is the same translation system as row 3 (LR-Hiero+CP). We achieve better results than our previous work (Siahbani et al., 2013) (row 4 vs. row 3) due to bug corrections and adding loose phrases as terminal rules.

Model	**Cs-En**	**De-En**	**Zh-En**
Hiero	1,961.6	858.5	471.9
LR-Hiero	266.5	116.0	100.9

Table 3: Model sizes (millions of rules).

Model	Cs-En	De-En	Zh-En
Hiero	318	351	187
LR-Hiero	278	300	132
LR-Hiero+(abc)	338	361	174

Table 4: No. of sentence covered in forced decoding of a sample of sentences from the devset. We improve the coverage by 31% for Chinese-English and more than 20% for the other two language pairs.

Figure 2b shows the results in terms of average number of language model queries on a sample set of 50 sentences from test sets. All of the baselines use the same wrapper to KenLM (Heafield, 2011) to query the language model, and we have instrumented the wrapper to count the statistics. In (Siahbani et al., 2013) we discuss that LR-Hiero with beam search (Watanabe et al., 2006) does not perform at the same level of state-of-the-art Hiero (more LM calls and less translation quality). As we can see in this figure, adding new modified rules slightly increases the number of language model queries on Cs-En and De-En so that LR-Hiero+CP still works 2 to 3 times faster than Hiero. On Zh-En, LR-Hiero+CP applies queue diversity (QD=15) which reduces search errors and improves translation quality but increases the number of hypothesis generation as well. LR-Hiero+CP with our modifications works substantially faster than LR-Hiero while obtain significantly better translation quality on Zh-En.

Comparing Table 2a with Figure 2b we can see that overall our modifications to LR-Hiero decoder significantly improves the BLEU scores compared to previous LR decoders for Hiero. We obtain comparable results to CKY-Hiero for Cs-En and De-En and remarkably improve results on Zh-En, while at the same time making 2 to 3 times less LM calls on Cs-En and De-En compared to CKY-Hiero.

Reordering Model for Forest-to-String Machine Translation

Martin Čmejrek

Prague, Czech Republic
martin.cmejrek@us.ibm.com

Abstract

In this paper, we present a novel extension of a forest-to-string machine translation system with a reordering model. We predict reordering probabilities for every pair of source words with a model using features observed from the input parse forest. Our approach naturally deals with the ambiguity present in the input parse forest, but, at the same time, takes into account only the parts of the input forest used by the current translation hypothesis. The method provides improvement from 0.6 up to 1.0 point measured by (T − B)/2 metric.

1 Introduction

Various commonly adopted statistical machine translation (SMT) approaches differ in the amount of linguistic knowledge present in the rules they employ.

Phrase-based (Koehn et al., 2003) models are strong in lexical coverage in local contexts, and use external models to score reordering options (Tillman, 2004; Koehn et al., 2005).

Hierarchical models (Chiang, 2005) use lexicalized synchronous context-free grammar rules to produce local reorderings. The grammaticality of their output can be improved by additional reordering models scoring permutations of the source words. Reordering model can be either used for source pre-ordering (Tromble and Eisner,), integrated into decoding via translation rules extension (Hayashi et al., 2010), additional lexical features (He et al.,), or using external sources of information, such as source syntactic features observed from a parse tree (Huang et al., 2013).

Tree-to-string (T2S) models (Liu et al., 2006; Galley et al., 2006) use rules with syntactic structures, aiming at even more grammatically appropriate reorderings.

Forest-to-string (F2S) systems (Mi et al., 2008; Mi and Huang, 2008) use source syntactic forest as the input to overcome parsing errors, and to alleviate sparseness of translation rules.

The parse forest may often represent several meanings for an ambiguous input that may need to be transtated differently using different word orderings. The following example of an ambiguous Chinese sentence with ambiguous part-of-speech labeling motivates our interest in the reordering model for the F2S translation.

tǎolùn (0)	hùi (1)	zěnmeyàng (2)
discussion/NN discuss/VV	meeting/NN will/VV	how/VV

There are several possible meanings based on the different POS tagging sequences. We present translations for two of them, together with the indices to their original source words:

(a) NN NN VV:
How$_2$ *was*$_2$ *the*$_0$ *discussion*$_0$ *meeting*$_1$*?*

(b) VV VV VV:
Discuss$_0$ *what*$_2$ *will*$_1$ *happen*$_1$.

A T2S system starts from a single parse corresponding to one of the possible POS sequences, the same tree can be used to predict word reorderings. On the other hand, a F2S system deals with the ambiguity through exploring translation hypotheses for all competing parses representing the different meanings. As our example suggests, different meanings also tend to reorder differently

during translation. First, the reordering model suitable for F2S translation should allow for translation of all meanings present in the input. Second, as the process of deriving a partial translation hypothesis rules out some of the meanings, the reordering model should restrict itself to features originating in the relevant parts of the input forest. Our work presents a novel technique satisfying both these requirements, while leaving the disambuiguation decision up to the model using global features.

The paper is organized as follows: We briefly overview the F2S and Hiero translation models in Section 2, present the proposed forest reordering model in Section 3, describe our experiment and present results in Section 4.

2 Translation Models

Forest-to-string translation (Mi et al., 2008) is an extension of the tree-to-string model (Liu et al., 2006; Huang et al., 2006) allowing it to use a packed parse forest as the input instead of a single parse tree.

Figure 1 shows a tree-to-string **translation rule** (Huang et al., 2006), which is a tuple $\langle lhs(r), rhs(r), \psi(r)\rangle$, where $lhs(r)$ is the source-side tree fragment, whose internal nodes are labeled by nonterminal symbols (like NP), and whose frontier nodes are labeled by source-language words (like "zěnmeyàng") or variables from a finite set $\mathcal{X} = \{x_1, x_2, \ldots\}$; $rhs(r)$ is the target-side string expressed in target-language words (like "how was") and variables; and $\psi(r)$ is a mapping from $\mathcal{X}$ to nonterminals. Each variable $x_i \in \mathcal{X}$ occurs *exactly once* in $lhs(r)$ and *exactly once* in $rhs(r)$.

The Table 1 lists all rules necessary to derive translations (a) and (b), with their internal structure removed for simplicity.

Typically, an F2S system translates in two steps (shown in Figure 2): parsing and decoding. In the parsing step, the source language input is converted into a *parse forest* (A). In the decoding step, we first convert the parse forest into a *translation forest* F^t in (B) by using the fast pattern-matching technique (Zhang et al., 2009). Then the decoder uses dynamic programing with beam search and cube pruning to find the approximation to the best scoring derivation in the translation forest, and outputs the target string.

3 Forest Reordering Model

In this section, we describe the process of applying the reordering model scores. We score pairwise translation reorderings for every pair of source words similarly as described by Huang et al. (2013). In their approach, an external model of ordering distributions of *sibling* constituent pairs predicts the reordering of word pairs. Our approach deals with parse forests rather than with single trees, thus we have to model the scores differently. We model ordering distributions for every pair of *close relatives*–nodes in the parse forest that may occur together as frontier nodes of a single matching rule. We further condition the distribution on a third node–a common ancestor of the node pair that corresponds to the root node of the matching rule. This way our external model takes into acount the syntactic context of the hypothesis. For example, nodes $\mathrm{NP}_{0,1}$ and $\mathrm{NP}_{1,2}$ are close relatives, $\mathrm{NP}_{0,2}$ and $\mathrm{IP}_{0,3}$ are their common ancestors; $\mathrm{NP}_{0,1}$ and $\mathrm{VV}_{2,3}$ are close relatives, $\mathrm{IP}_{0,3}$ is their common ancestor; $\mathrm{NP}_{0,1}$ and $\mathrm{VV}_{1,2}$ are not close relatives.

More formally, let us have an input sentence $(w_0, ..., w_n)$ and its translation hypothesis h. For every i and j such that $0 \leq i < j \leq n$ we assume that the translations of w_i and w_j are in the hypothesis h either in the same or inverted ordering $o_{ij} \in \{Inorder, Reorder\}$, with a probability $P_{order}(o_{ij}|h)$. Conditioning on h signifies that the probabilistic model takes the current hypothesis as a parameter. The reordering score of the entire hy-

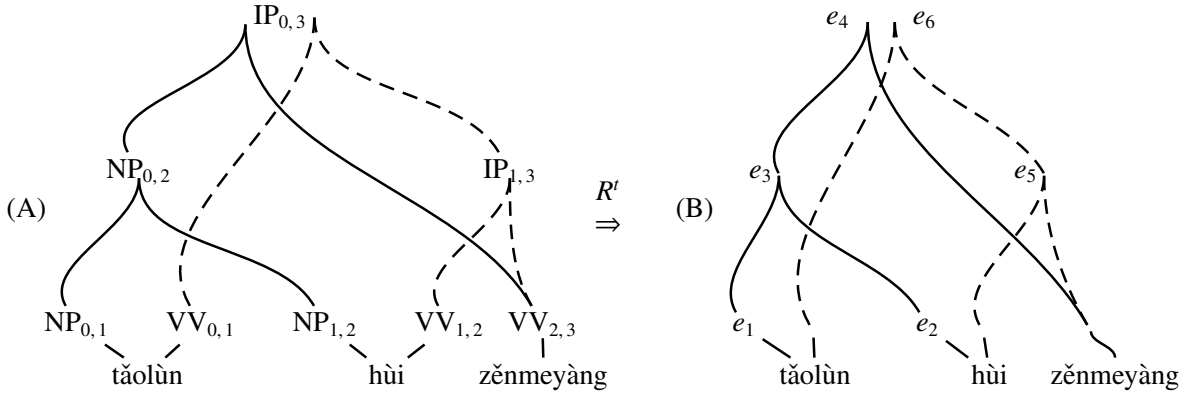

Figure 2: Parse and translation hypergraphs. (A) The parse forest of the example sentence. Solid hyperedges denote the best parse, dashed hyperedges denote the second best parse. Unary edges were collapsed. (B) The corresponding translation forest F^t after applying the tree-to-string translation rule set R^t. Each translation hyperedge (e.g. e_4) has the same index as the corresponding rule (r_4). The forest-to-string system can produce the example translation (a) (solid derivation: r_1, r_2, r_3, and r_4) and (b) (dashed derivation: r_5, r_6).

pothesis $f_{order}(h)$ is then computed as

$$f_{order} = \sum_{0 \le i < j \le n} -\log P_{order}(o_{ij} = o^h_{ij} \mid h), \quad (1)$$

where o^h_{ij} denotes the actual ordering used in h.

The score f_{order} can be computed recursively by dynamic programing during the decoding. As an example, we show in Table 2 reordering probabilities retrieved in decoding of our sample sentence.

(a) If h is a hypothesis formed by a single translation rule r with no frontier nonterminals, we evaluate all word pairs w_i and w_j covered by h such that $i < j$. For each such pair we find the frontier nodes x and y matched by r such that x spans exactly w_i and y spans exactly w_j. (In this case, x and y match preterminal nodes, each spanning one position). We also find the node z matching the root of r. Then we directly use the Equation 1 to compute the score using an external model $P_{order}(o_{ij}|xyz)$ to estimate the probability of reordering the relative nodes. For example, when applying rule r_5, we use the ordering distribution $P_{order}(o_{1,2}|\mathrm{VV}_{1,2}, \mathrm{VV}_{2,3}, \mathrm{IP}_{1,3})$ to score reorderings of hùi and zěnmeyàng.

(b) If h is a hypothesis formed by a T2S rule with one or more frontier nonterminals, we evaluate all word pairs as follows: If both w_i and w_j are spanned by the same frontier nonterminal (e.g., tǎolùn and hùi when applying the rule r_4), the score f_{order} had been already computed for the underlying subhypothesis, and therefore was already included in the total score. Otherwise, we compute the word pair ordering cost. We find the close relatives x and y representing each w_i and w_j. If w_i is matched by a terminal in r, we select x as the node matching r and spanning exactly w_i. If w_i is spanned by a frontier nonterminal in r (meaning that it was translated in a subhypothesis), we select x as the node matching that nonterminal. We proceed identically for w_j and y. For example, when applying the rule r_4, the word zěnmeyàng will be represented by the node $\mathrm{VV}_{2,3}$, while tǎolùn and hùi will be represented by the node $\mathrm{NP}_{0,2}$.

Note that the ordering o^h_{ij} cannot be determined in some cases, sometimes a source word does not produce any translation, or the translation of one word is entirely surrounded by the translations of another word. A weight corresponding to the binary discount feature $f_{o_{unknown}}$ is added to the score for each such case.

The external model $P_{order}(o_{ij}|xyz)$ is implemented as a maximum entropy model. Features of the model are observed from paths connecting node z with nodes x and y as follows: First, we pick paths $z \to x$ and $z \to y$. Let z' be the last node shared by both paths (the closest common ancestor of x and y). Then we distinguish three types of path: (1) The *common prefix* $z \to z'$ (it may have zero length), the *left path* $z \to x$, and the *right path* $z \to y$. We observe the following features on each path: the syntactic labels of the nodes, the production rules, the spans of nodes, a list of stop words immediately preceding and following the span of the node. We merge the features observed from different paths $z \to x$ and $z \to y$. This approach

ignores the internal structure of each rule[1], relying on frontier node annotation. On the other hand it is still feasible to precompute the reordering probabilities for all combinations of *xyz*.

4 Experiment

In this section we describe the setup of the experiment, and present results. Finally, we propose future directions of research.

4.1 Setup

Our baseline is a strong F2S system (Čmejrek et al., 2013) built on large data with the full set of model features including rule translation probabilities, general lexical and provenance translation probabilities, language model, and a variety of sparse features. We build it as follows. The training corpus consists of 16 million sentence pairs available within the DARPA BOLT Chinese-English task. The corpus includes a mix of newswire, broadcast news, webblog data coming from various sources such as LDC, HK Law, HK Hansard and UN data. The Chinese text is segmented with a segmenter trained on CTB data using conditional random fields (CRF).

Bilingual word alignments are trained and combined from two sources: GIZA (Och, 2003) and maximum entropy word aligner (Ittycheriah and Roukos, 2005).

Language models are trained on the English side of the parallel corpus, and on monolingual corpora, such as Gigaword (LDC2011T07) and Google News, altogether comprising around 10 billion words.

We parse the Chinese part of the training data with a modified version of the Berkeley parser (Petrov and Klein, 2007), then prune the obtained parse forests for each training sentence with the marginal probability-based inside-outside algorithm to contain only $3n$ CFG nodes, where n is the sentence length.

We extract tree-to-string translation rules from forest-string sentence pairs using the forest-based GHKM algorithm (Mi and Huang, 2008; Galley et al., 2004).

In the decoding step, we use larger input parse forests than in training, we prune them to contain $10n$ nodes. Then we use fast pattern-matching (Zhang et al., 2009) to convert the parse forest into the translation forest.

The proposed reordering model is trained on 100,000 automatically aligned forest-string sentence pairs from the parallel training data. These sentences provide 110M reordering events that are used by `megam` (Daumé III, 2004) to train the maximum entropy model.

The current implementation of the reordering model requires offline preprocessing of the input hypergraphs to precompute reordering probabilities for applicable triples of nodes (x, y, z). Since the number of levels in the syntactic trees in T2S rules is limited to 4, we only need to consider such triples, where z is up to 4 levels above x or y.

We tune on 1275 sentences, each with 4 references, from the LDC2010E30 corpus, initially released under the DARPA GALE program.

We combine two evaluation metrics for tuning and testing: B (Papineni et al., 2002) and T (Snover et al., 2006). Both the baseline and the reordering experiments are optimized with MIRA (Crammer et al., 2006) to maximize (T - B)/2.

We test on three different test sets: GALE Web test set from LDC2010E30 corpus (1239 sentences, 4 references), NIST MT08 Newswire

[1]Only to some extent, the rule still has to match the input forest, but the reordering model decides based on the sum of paths observed between the root and frontier nodes.

System	GALE Web			MT08 Newswire			MT08 Web		
	$\frac{T-B}{2}$	B	T	$\frac{T-B}{2}$	B	T	$\frac{T-B}{2}$	B	T
F2S	8.8	36.1	53.7	5.6	40.6	51.8	12.0	31.3	55.3
+Reordering	8.2	36.4	52.7	4.8	41.7	50.5	11.0	31.7	53.7
Δ	*-0.6*	*+0.3*	*-1.0*	*-0.8*	*+1.1*	*-1.3*	*-1.0*	*+0.4*	*-1.6*

Table 3: Results.

portion (691 sentences, 4 references), and NIST MT08 Web portion (666 sentences, 4 references).

4.2 Results

Table 3 shows all results of the baseline and the system extended with the forest reordering model. The (T − B)/2 score of the baseline system is 12.0 on MT08 Newswire, showing that it is a strong baseline. The system with the proposed reordering model significantly improves the baseline by 0.6, 0.8, and 1.0 (T − B)/2 points on GALE Web, MT08 Newswire, and MT08 Web.

The current approach relies on frontier node annotations, ignoring to some extent the internal structure of the T2S rules. As part of future research, we would like to compare this approach with the one that takes into accout the internal structure as well.

5 Conclusion

We have presented a novel reordering model for the forest-to-string MT system. The model deals with the ambiguity of the input forests, but also predicts specifically to the current parse followed by the translation hypothesis. The reordering probabilities can be precomputed by an offline process, allowing for efficient scoring in runtime. The method provides improvement from 0.6 up to 1.0 point measured by (T − B)/2 metrics.

Abstract

Many statistical models for natural language processing exist, including context-based neural networks that (1) model the previously seen context as a latent feature vector, (2) integrate successive words into the context using some learned representation (embedding), and (3) compute output probabilities for incoming words given the context. On the other hand, brain imaging studies have suggested that during reading, the brain (a) continuously builds a context from the successive words and every time it encounters a word it (b) fetches its properties from memory and (c) integrates it with the previous context with a degree of effort that is inversely proportional to how probable the word is. This hints to a parallelism between the neural networks and the brain in modeling context (1 and a), representing the incoming words (2 and b) and integrating it (3 and c). We explore this parallelism to better understand the brain processes and the neural networks representations. We study the alignment between the latent vectors used by neural networks and brain activity observed via Magnetoencephalography (MEG) when subjects read a story. For that purpose we apply the neural network to the same text the subjects are reading, and explore the ability of these three vector representations to predict the observed word-by-word brain activity.

Our novel results show that: before a new word i is read, brain activity is well predicted by the neural network latent representation of context and the predictability decreases as the brain integrates the word and changes its own representation of context. Secondly, the neural network embedding of word i can predict the MEG activity when word i is presented to the subject, revealing that it is correlated with the brain's own representation of word i. Moreover, we obtain that the activity is predicted in different regions of the brain with varying delay. The delay is consistent with the placement of each region on the processing pathway that starts in the visual cortex and moves to higher level regions. Finally, we show that the output probability computed by the neural networks agrees with the brain's own assessment of the probability of word i, as it can be used to predict the brain activity after the word i's properties have been fetched from memory and the brain is in the process of integrating it into the context.

1 Introduction

Natural language processing has recently seen a surge in increasingly complex models that achieve impressive goals. Models like deep neural networks and vector space models have become popular to solve diverse tasks like sentiment analysis and machine translation. Because of the complexity of these models, it is not always clear how to assess and compare their performances as they might be useful for one task and not the other. It is also not easy to interpret their very high-dimensional and mostly unsupervised representations. The brain is another computational system that processes language. Since we can record brain activity using neuroimaging, we propose a new direction that promises to improve our understanding of both how the brain is processing language and of what the neural networks are modeling by aligning the brain data with the neural networks representations.

In this paper we study the representations of two kinds of neural networks that are built to predict the incoming word: recurrent and finite context models. The first model is the Recurrent Neural Network Language Model (Mikolov et al., 2011) which uses the entire history of words to model context. The second is the Neural Probabilistic Language Model (NPLM) which uses limited context constrained to the recent words (3 grams or 5 grams). We trained these models on a large Harry Potter fan fiction corpus and we then used them to predict the words of chapter 9 of *Harry Potter and the Sorcerer's Stone* (Rowling, 2012). In parallel, we ran an MEG experiment in which 3 subject read the words of chapter 9 one by one while their brain activity was recorded. We then looked for the alignment between the word-by-word vectors produced by the neural networks and the word-by-word neural activity recorded by MEG.

Our neural networks have 3 key constituents: a hidden layer that summarizes the history of the previous words ; an embeddings vector that summarizes the (constant) properties of a given word and finally the output probability of a word given

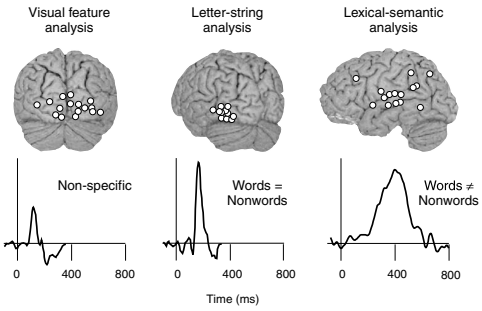

Figure 1: Cortical dynamics of silent reading. This figure is adapted from (Salmelin, 2007). Dots represent projected sources of activity in the visual cortex (left brain sketch) and the temporal cortex (right brain sketch). The curves display the mean time course of activation in the depicted source areas for different conditions. The initial visual feature analysis in the visual cortex at $\sim$100 ms is non-specific to language. Comparing responses to letter strings and other visual stimuli reveals that letter string analysis occurs around 150 ms. Finally comparing the responses to words and nonwords (made-up words) reveals lexical-semantic analysis in the temporal cortex at $\sim$200-500ms.

the context. We set out to find the brain analogs of these model constituents using an MEG decoding task. We compare the different models and their representations in terms of how well they can be used to decode the word being read from MEG data. We obtain correspondences between the models and the brain data that are consistent with a model of language processing in which brain activity encodes story context, and where each new word generates additional brain activity, flowing generally from visual processing areas to more high level areas, culminating in an updated story context, and reflecting an overall magnitude of neural effort influenced by the probability of that new word given the previous context.

1.1 Neural processes involved in reading

Humans read with an average speed of 3 words per second. Reading requires us to perceive incoming words and gradually integrate them into a representation of the meaning. As words are read, it takes 100ms for the visual input to reach the visual cortex. 50ms later, the visual input is processed as letter strings in a specialized region of the left visual cortex (Salmelin, 2007). Between 200-500ms, the word's semantic properties are processed (see Fig. 1). Less is understood about the cortical dynamics of word integration, as multiple theories exist (Friederici, 2002; Hagoort, 2003).

Magnetoencephalography (MEG) is a brain-imaging tool that is well suited for studying language. MEG records the change in the magnetic field on the surface of the head that is caused by a large set of aligned neurons that are changing their firing patterns in synchrony in response to a stimulus. Because of the nature of the signal, MEG recordings are directly related to neural activity and have no latency. They are sampled at a high frequency (typically 1kHz) that is ideal for tracking the fast dynamics of language processing.

In this work, we are interested in the mechanism of human text understanding as the meaning of incoming words is fetched from memory and integrated with the context. Interestingly, this is analogous to neural network models of language that are used to predict the incoming word. The mental representation of the previous context is analogous to the latent layer of the neural network which summarizes the relevant context before seeing the word. The representation of the meaning of a word is analogous to the embedding that the neural network learns in training and then uses. Finally, one common hypotheses is that the brain integrates the word with inversely proportional effort to how predictable the word is (Frank et al., 2013). There is a well studied response known as the N400 that is an increase of the activity in the temporal cortex that has been recently shown to be graded by the amount of surprisal of the incoming word given the context (Frank et al., 2013). This is analogous to the output probability of the incoming word from the neural network.

Fig. 2 shows a hypothetical activity in an MEG sensor as a subject reads a story in our experiment, in which words are presented one at a time for 500ms each. We conjecture that the activity in time window a, i.e. before word i is understood, is mostly related to the previous context before seeing word i. We also conjecture that the activity in time window b is related to understanding word i and integrating it into the context, leading to a new representation of context in window c.

Using three types of features from neural networks (hidden layer context representation, output probabilities and word embeddings) from three different models of language (one recurrent model and two finite context models), we therefore set to predict the activity in the brain in different time windows. We want to align the brain data with the various model constituents to understand where and when different types of processes are computed in the brain, and simultaneously, we want to

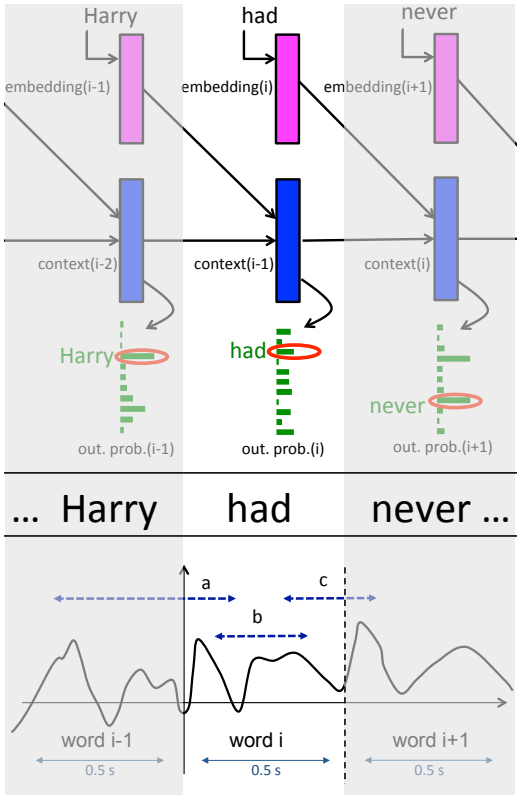

Figure 2: [Top] Sketch of the updates of a neural network reading chapter 9 after it has been trained. Every word corresponds to a fixed embedding vector (magenta). A context vector (blue) is computed before the word is seen given the previous words. Given the context vector, the probability of every word can be computed (symbolized by the histogram in green). We only use the output probability of the actual word (red circle). [Bottom] Hypothetical activity in an MEG sensor when the subject reads the corresponding words. The time periods approximated as a, b and c can be tested for information content relating to: the context of the story before seeing word i (modeled by the context vector at i), the representation of the properties of word i (the embedding of word i) and the integration of word i into the context (the output probability of word i). The periods drawn here are only a conjecture on the timings of such cognitive events.

use the brain data to shed light on what the neural network vectors are representing.

Related work

Decoding cognitive states from brain data is a recent field that has been growing in popularity. Most decoding studies that study language use functional Magnetic Resonance Imaging (fMRI), while some studies use MEG. MEG's high temporal resolution makes it invaluable for looking at the dynamics of language understanding. (Sudre et al., 2012) decode from MEG the word a subject is reading. The authors estimate from the MEG data the semantic features of the word and use these as an intermediate step to decode what the word is. This is in principle similar to the classification approach we follow, as we will also use the feature vectors as an intermediate step for word classification. However the experimental paradigm in (Sudre et al., 2012) is to present to the subjects single isolated words and to find how the brain represents their semantic features; whereas we have a much more complex and "naturalistic" experiment in which the subjects read a non-artificial passage of text, and we look at processes that exceed individual word processing: the construction of the meanings of the successive words and the prediction/integration of incoming words.

In (Frank et al., 2013), the amount of surprisal that a word has given its context is used to predict the intensity of the N400 response described previously. This is the closest study we could find to our approach. This study was concerned with analyzing the brain processes related only to surprisal while we propose a more integral account of the processes in the brain. The study also didn't address the major contribution we propose here, which is to shed light on the inner constituents of language models using brain imaging.

1.2 Recurrent and finite context neural networks

Similar to standard language models, neural language models also learn probability distributions over words given their previous context. However, unlike standard language models, words are represented as real-valued vectors in a high dimensional space. These word vectors, referred to as *word embeddings*, can be different for input and output words, and are learned from training data. Thus, although at training and test time, the input and output to the neural language models are *one-hot* representation of words, it is their embeddings that are used to compute word probability distributions. After training the embedding vectors are fixed and it is these vectors that we will use later on to predict MEG data. To predict MEG data, we will also use the latent vector representations of context that these neural networks produce, as well as the probability of the current word given the context. In this section, we will describe how recurrent neural network language models and feedforward neural probabilistic language models compute word probabilities. In the interest of space, we keep this description brief, and for details, the reader is requested to refer to the original papers describing these models.

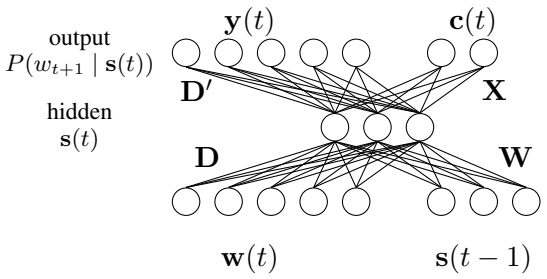

Figure 3: Recurrent neural network language model.

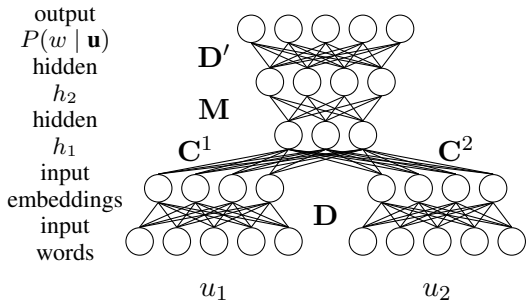

Figure 4: Neural probabilistic language model

Recurrent Neural Network Language Model

Unlike standard feedforward neural language models that only look at a fixed number of past words, recurrent neural network language models use all the previous history from position 1 to $t-1$ to predict the next word. This is typically achieved by *feedback* connections, where the hidden layer activations used for predicting the word in position $t-1$ are fed back into the network to compute the hidden layer activations for predicting the next word. The hidden layer thus stores the history of all previous words. We use the RNNLM architecture as described in Mikolov (2012), shown in Figure 3. The input to the RNNLM at position t are the one-hot representation of the current word, $\mathbf{w}(t)$, and the activations from the hidden layer at position $t-1$, $\mathbf{s}(t-1)$. The output of the hidden layer at position $t-1$ is

$$\mathbf{s}(t) = \phi\left(\mathbf{D}\mathbf{w}(t) + \mathbf{W}\mathbf{s}(t-1)\right),$$

where $\mathbf{D}$ is the matrix of input word embeddings, $\mathbf{W}$ is a matrix that transforms the activations from the hidden layer in position $t-1$, and ϕ is a sigmoid function, defined as $\phi(x) = \frac{1}{1+\exp(-x)}$, that is applied elementwise. We need to compute the probability of the next word $\mathbf{w}(t+1)$ given the hidden state $\mathbf{s}(t)$. For fast estimation of output word probabilities, Mikolov (2012) divides the computation into two stages: First, the probability distribution over *word classes* is computed, after which the probability distribution over the subset of words belonging to the class are computed. The class probability of a particular class with index m at position t is computed as:

$$P(\mathbf{c}_m(t) \mid \mathbf{s}(t)) = \frac{\exp\left(\mathbf{s}(t)\mathbf{X}\mathbf{v}_m\right)}{\sum_{c=1}^{C}\left(\exp\left(\mathbf{s}(t)\mathbf{X}\mathbf{v}_c\right)\right)},$$

where $\mathbf{X}$ is a matrix of class embeddings and $\mathbf{v_m}$ is a one-hot vector representing the class with index m. The normalization constant is computed over all classes C. Each class specifies a subset V' of words, potentially smaller than the entire vocabulary V. The probability of an output word l at position $t+1$ given that its class is m is defined as:

$$P(\mathbf{y}_l(t+1) \mid \mathbf{c}_m(t), \mathbf{s}(t)) = \frac{\exp\left(\mathbf{s}(t)\mathbf{D}'\mathbf{v}_l\right)}{\sum_{k=1}^{V'}\left(\exp\left(\mathbf{s}(t)\mathbf{D}'\mathbf{v}_k\right)\right)},$$

where $\mathbf{D}'$ is a matrix of output word embeddings and $\mathbf{v}_l$ is a one hot vector representing the word with index l. The probability of the word $\mathbf{w}(t+1)$ given its class c_i can now be computed as:

$$P(\mathbf{w}(t+1) \mid \mathbf{s}(t)) = P(\mathbf{w}(t+1) \mid c_i, \mathbf{s}(t))\, P(c_i \mid \mathbf{s}(t)).$$

Neural Probabilistic Language Model

We use the feedforward neural probabilistic language model architecture of Vaswani et al. (2013), as shown in Figure 4. Each context $\mathbf{u}$ comprises a sequence of words $\mathbf{u}_j$ ($1 \le j \le n-1$) represented as one-hot vectors, which are fed as input to the neural network. At the output layer, the neural network computes the probability $P(w \mid \mathbf{u})$ for each word w, as follows.

The output of the first hidden layer h_1 is

$$h_1 = \phi\left(\sum_{j=1}^{n-1}\mathbf{C}^j\mathbf{D}\mathbf{u}_j + \mathbf{b}_1\right),$$

where $\mathbf{D}$ is a matrix of input word embeddings which is shared across all positions, the $\mathbf{C}^j$ are the context matrices for each word in $\mathbf{u}$, $\mathbf{b}_1$ is a vector of biases with the same dimension as h_1, and ϕ is applied elementwise. Vaswani et al. (2013) use rectified linear units (Nair and Hinton, 2010) for

the hidden layers h_1 and h_2, which use the activation function $\phi(x) = \max(0, x)$.

The output of the second layer h_2 is

$$h_2 = \phi\left(\mathbf{M}h_1 + \mathbf{b}_2\right),$$

where $\mathbf{M}$ is a weight matrix between h_1 and h_2 and $\mathbf{b}_2$ is a vector of biases for h_2. The probability of the output word is computed at the output softmax layer as:

$$P(w \mid \mathbf{u}) = \frac{\exp\left(\mathbf{v}_w \mathbf{D}' h_2 + \mathbf{b}^T \mathbf{v}_w\right)}{\sum_{w'=1}^{V} \exp\left(\mathbf{v}_{w'} \mathbf{D}' h_2 + \mathbf{b}^T \mathbf{v}_{w'}\right)},$$

where $\mathbf{D}'$ is the matrix of output word embeddings, $\mathbf{b}$ is a vector of biases for every output word and $\mathbf{v}_w$ its the one hot representation of the word w in the vocabulary.

2 Methods

We describe in this section our approach. In summary, we trained the neural network models on a Harry Potter fan fiction database. We then ran these models on chapter 9 of *Harry Potter and the Sorcerer's Stone* (Rowling, 2012) and computed the context and embedding vectors and the output probability for each word. In parallel, 3 subjects read the same chapter in an MEG scanner. We build models that predict the MEG data for each word as a function of the different neural network constituents. We then test these models with a classification task that we explain below. We detect correspondences between the neural network components and the brain processes that underlie reading in the following fashion. If using a neural network vector (e.g. the RNNLM embedding vector) allows us to classify significantly better than chance in a given region of the brain at a given time (e.g. the visual cortex at time 100-200ms), then we can hypothesize a relationship between that neural network constituent and the time/location of the analogous brain process.

2.1 Training the Neural Networks

We used the freely available training tools provided by Mikolov (2012)[1] and Vaswani et al. (2013)[2] to train our RNNLM and NPLM models used in our brain data classification experiments. Our training data comprised around 67.5 million words for training and 100 thousand words for validation from the Harry Potter fan fiction database (http://harrypotterfanfiction.com). We restricted the vocabulary to the top 100 thousand words which covered all but 4 words from Chapter 9 of *Harry Potter and the Sorcerer's Stone*.

For the RNNLM, we trained models with different hidden layers and learning rates and found the RNNLM with 250 hidden units to perform best on the validation set. We extracted our word embeddings from the input matrix $\mathbf{D}$ (Figure 3). We used the default settings for all other hyper parameters.

We trained 3-gram and 5-gram NPLMs with 150 dimensional word embeddings and experimented with different number of units for the first hidden layer (h_1 in Figure 4), and different learning rates. For both the 3-gram and 5-gram models, we found 750 hidden units to perform the best on the validation set and chose those models for our final experiments. We used the output word embeddings $\mathbf{D}'$ in our experiments. We visually inspected the nearest neighbors in the 150 dimensional word embedding space for some words and didn't find the neighbors from $\mathbf{D}'$ or $\mathbf{D}$ to be distinctly better than each other. We leave the comparison of input and output embeddings on brain activity prediction for future work.

2.2 MEG paradigm

We recorded MEG data for three subjects (2 females and one male) while they read chapter 9 of *Harry Potter and the Sorcerer's Stone* (Rowling, 2012). The participants were native English speakers and right handed. They were chosen to be familiar with the material: we made sure they had read the Harry Potter books or seen the movies series and were familiar with the characters and the story. All the participants signed the consent form, which was approved by the University of Pittsburgh Institutional Review Board, and were compensated for their participation.

The words of the story were presented in rapid serial visual format (Buchweitz et al., 2009): words were presented one by one at the center of the screen for 0.5 seconds each. The text was shown in 4 experimental blocks of ∼11 minutes. In total, 5176 words were presented. Chapter 9 was presented in its entirety without modifications and each subject read the chapter only once.

One can think of an MEG machine as a large helmet, with sensors located on the helmet that

[1] http://rnnlm.org/

[2] http://nlg.isi.edu/software/nplm

record the magnetic activity. Our MEG recordings were acquired on an Elekta Neuromag device at the University of Pittsburgh Medical Center Presbyterian Hospital. This machine has 306 sensors distributed into 102 locations on the surface of the subject's head. Each location groups 3 sensors or two types: one magnometer that records the intensity of the magnetic field and two planar gradiometers that record the change in the magnetic field along two orthogonal planes[3].

Our sampling frequency was 1kHz. For preprocessing, we used Signal Space Separation method (SSS, (Taulu et al., 2004)), followed by its temporal extension (tSSS, (Taulu and Simola, 2006)).

For each subject, the experiment data consists therefore of a 306 dimensional time series of length ∼45 minutes. We averaged the signal in every sensor into 100ms non-overlapping time bins. Since words were presented for 500ms each, we therefore obtain for every word $p = 306 \times 5$ values corresponding to 306 vectors of 5 points.

2.3 Decoding experiment

To find which parts of brain activity are related to the neural network constituents (e.g. the RNNLM context vector), we run a prediction and classification experiment in a 10-fold cross validated fashion. At every fold, we train a linear model to predict MEG data as a function of one of the feature sets, using 90% of the data. On the remaining 10% of the data, we run a classification experiment.

MEG data is very noisy. Therefore, classifying single word waveforms yields a low accuracy, peaking at 60%, which might lead to false negatives when looking for correspondences between neural network features and brain data. To reveal informative features, one can boost signal by either having several repetitions of the stimuli in the experiment and then averaging (Sudre et al., 2012) or by combining the words into larger chunks (Wehbe et al., 2014). We chose the latter because the former sacrifices word and feature diversity.

At testing, we therefore repeat the following 300 times. Two sets of words are chosen randomly from the test fold. To form the first set, 20 words are sampled without replacement from the test sample (unseen by the classifier). To form the second set, the k^{th} word is chosen randomly from all words in the test fold having the same length as the k^{th} word of the first set. Since every fold of the data was used 9 times in the training phase and once in the testing phase, and since we use a high number of randomized comparisons, this averages out biases in the accuracy estimation. Classifying sets of 20 words improves the classification accuracy greatly while lowering its variance and makes it dissociable from chance performance. We compare only between words of equal length, to minimize the effect of the low level visual features on the classification accuracy.

After averaging out the results of multiple folds, we end up with average accuracies that reveal how related one of the models' constituents (e.g. the RNNLM context vector) is to brain data.

2.3.1 Annotation of the stimulus text

We have 9 sets of annotations for the words of the experiment. Each set j can be described as a matrix $\mathbf{F}_j$ in which each row i corresponds to the vector of annotations of word i. Our annotations correspond to the 3 model constituents for each of the 3 models: the hidden layer representation before word i, the output probability of word i and the learned embeddings for word i.

2.3.2 Classification

In order to align the brain processes and the different constituents of the different models, we use a classification task. The task is to classify the word a subject is reading out of two possible choices from its MEG recording. The classifier uses one type of feature in an intermediate classification step. For example, the classifier learns to predict the MEG activity for any setting of the RNNLM hidden layer. Given an unseen MEG recording for an unknown word i and two possible story words i' and i'' (one of which being the true word i), the classifier predicts the MEG activity when reading i' and i'' from their hidden layer vectors. It then assigns the label i' or i'' to the word recording i depending on which prediction is the closest to the recording. The following are the detailed steps of this complex classification task. However, for the rest of the paper the most useful point to keep in mind is that the main purpose of the classification is to find a correspondence between the brain data and a given feature set j.

1. Normalize the columns of $\mathbf{M}$ (zero mean, standard deviation = 1). Pick feature set $\mathbf{F}_j$ and normalize its columns to a minimum of 0 and a maximum of 1.

[3] In this paper, we treat these three different sensors as three different dimensions without further exploiting their physical properties.

2. Divide the data into 10 folds, for each fold b:

   (a) Isolate $\mathbf{M}^b$ and $\mathbf{F}_j^b$ as test data. The remainder $\mathbf{M}^{-b}$ and $\mathbf{F}_j^{-b}$ will be used for training[4].

   (b) Subtract the mean of the columns of $\mathbf{M}^{-b}$ from $\mathbf{M}^b$ and $\mathbf{M}^{-b}$ and the mean of the columns of $\mathbf{F}_j^{-b}$ from $\mathbf{F}_j^b$ and $\mathbf{F}_j^{-b}$

   (c) Use ridge regression to solve
   $$\mathbf{M}^{-b} = \mathbf{F}_j^{-b} \times \boldsymbol{\beta}_j^t$$
   by tuning the λ parameter to every one of the p output dimensions independently. λ is chosen via generalized cross validation (Golub et al., 1979).

   (d) Perform a binary classification. Sample from the set of words in b a set c of 20 words. Then sample from b another set of 20 words such that the k^{th} word in c and d have the same number of letters. For every sample (c,d):

      i. predict the MEG data for c and d as: $\mathbf{P}^c = \mathbf{F}_j^c \times \mathbf{\Gamma}_j^b$ and $\mathbf{P}^d = \mathbf{F}_j^d \times \mathbf{\Gamma}_j^b$

      ii. assign to $\mathbf{M}^c$ the label c or d depending on which of $\mathbf{P}^c$ or $\mathbf{P}^d$ is closest (Euclidean distance).

      iii. assign to $\mathbf{M}^d$ the label c or d depending on which of $\mathbf{P}^c$ or $\mathbf{P}^d$ is closest (Euclidean distance).

3. Compute the average accuracy.

2.3.3 Restricting the analysis spatially: a searchlight equivalent

We adapt the searchlight method (Kriegeskorte et al., 2006) to MEG. The searchlight is a discovery procedure used in fMRI in which a cube is slid over the brain and an analysis is performed in each location separately. It allows to find regions in the brain where a specific phenomenon is occurring. In the MEG sensor space, for every one of the 102 sensor locations ℓ, we assign a group of sensors g_ℓ. For every location ℓ, we identify the locations that immediately surround it in any direction (Anterior, Right Anterior, Right etc...) when looking at the 2D flat representation of the location of the sensors in the MEG helmet (see Fig. 9 for an illustration of the 2D helmet). g_ℓ therefore contains the 3 sensors at location ℓ and at the neighboring locations. The maximum number of sensors in a group is 3×9. The locations at the edge of the helmet have fewer sensors because of the missing neighbor locations.

[4]The rows from $\mathbf{M}^{-b}$ and $\mathbf{F}_j^{-b}$ that correspond to the five words before or after the test set are ignored in order to make the test set independent.

2.3.4 Restricting the analysis temporally

Instead of using the entire time course of the word, we can use only one of the corresponding 100ms time windows. Obtaining a high classification accuracy using one of the time windows and feature set j means that the analogous type of information is encoded at that time.

2.3.5 Classification accuracy by time and region

The above steps compute whole brain accuracy using all the time series. In order to perform a more precise spatio-temporal analysis, one can use only one time window m and one location ℓ for the classification. This can answer the question of when and where different information is represented by brain activity. For every location, we will use only the columns corresponding to the time point m for the sensors belonging to the group g_ℓ. Step (d) of the classification procedure is changed as such:

(d) Perform a binary classification. Sample from the set of words in b a set c of 20 words. Then sample from b another set of 20 words such that the k^{th} word in c and d have the same number of letters. For every sample (c,d), and for every setting of $\{m, \ell\}$:

   i. predict the MEG data for c and d as: $\mathbf{P}^c_{\{m,\ell\}} = \mathbf{F}_j^c \times \mathbf{\Gamma}^b_{j,\{m,\ell\}}$ and $\mathbf{P}^d_{\{m,\ell\}} = \mathbf{F}_j^d \times \mathbf{\Gamma}^b_{j,\{m,\ell\}}$

   ii. assign to $\mathbf{M}^c_{\{m,\ell\}}$ the label c or d depending on which of $\mathbf{P}^c_{\{m,\ell\}}$ or $\mathbf{P}^d_{\{m,\ell\}}$ is closest (Euclidean distance).

   iii. assign to $\mathbf{M}^d_{\{m,\ell\}}$ the label c or d depending on which of $\mathbf{P}^c_{\{m,\ell\}}$ or $\mathbf{P}^d_{\{m,\ell\}}$ is closest (Euclidean distance).

2.3.6 Statistical significance testing

We determine the distribution for chance performance empirically. Because the successive word samples in our MEG and feature matrices are not independent and identically distributed, we break the relationship between the MEG and feature matrices by shifting the feature matrices by large delays (e.g. 2000 to 2500 words) and we repeat the classification using the delayed matrices. This simulates chance performance more fairly than a permutation test because it keeps the time structure of the matrices. It was used in (Wehbe et al.,

2014) and inspired by (Chwialkowski and Gretton, 2014). For every $\{m, \ell\}$ setting we can therefore compute a standardized z-value by subtracting the mean of the shifted classifications and dividing by the standard deviation. We then compute the p-value for the true classification accuracy being due to chance. Since the three p-values for the three subjects for a given $\{m, \ell\}$ are independent, we combine them using Fisher's method for independent test statistics (Fisher, 1925). The statistics we obtain for every $\{m, \ell\}$ are dependent because they comprise nearby time and space windows. We control the false discovery rate using (Benjamini and Yekutieli, 2001) to adjust for the testing at multiple locations and time windows. This method doesn't assume any kind of independence or positive dependence.

3 Results

We present in Fig. 5 the accuracy using all the time windows and sensors. In Fig. 6 we present the classification accuracy when running the classification at every time window exclusively. In Fig. 9 we present the accuracy when running the classification using different time windows and groups of sensors centered at every one of the 102 locations.

It is important to lay down some conventions to understand the complex results in these plots. To recap, we are trying to find parallels between model constituents and brain processes. We use:

- a subset of the data (for example the time window 0-100ms and all the sensors)
- one type of feature (for example the hidden context layer from the NPLM 3g model)

and we obtain a classification accuracy A. If A is low, there is probably no relationship between the feature set and the subset of data. If A is high, it hints to an association between the subset of data and the mental process that is analogous to the feature set. For example, when using all the sensors and time window 0-100ms, along with the NPLM 3g hidden layer, we obtain an accuracy of 0.70 (higher than chance with p $< 10^{-14}$, see Fig. 6). Since the NPLM 3g hidden layer summarizes the context of the story before seeing word i, this suggests that the brain is still processing the context of the story before word i between 0-100ms.

Fig. 6 shows the accuracy for different types of features when using all of the time points and all the sensors to classify a word. We can see

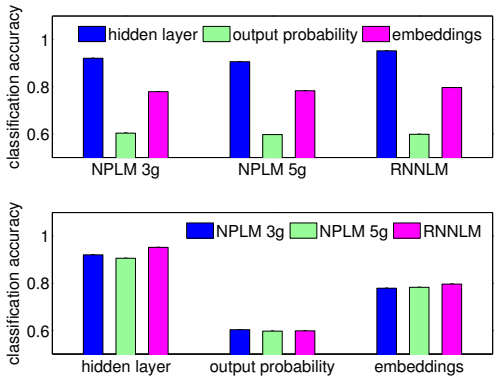

Figure 5: Average accuracy using all time windows and sensors, grouped by model (top) and type of feature (bottom). All accuracies are significantly higher than chance ($p < 10^{-8}$).

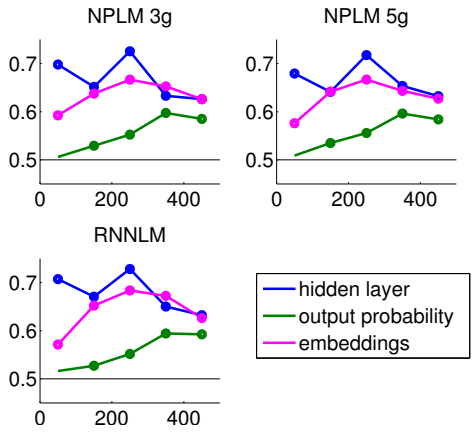

Figure 6: Average accuracy in different time windows when using different types of features as input to the classifier, for different models. Accuracy is plotted in the center of the respective time window. Points marked with a circle are significantly higher than chance accuracy for the given feature set and time window after correction.

similar classification accuracies for the three types of models, with RNNLM ahead for the hidden layer and embeddings and behind for the output probability features. The hidden layer features are the most powerful for classification. Between the three types of features, the hidden layer features are the best at capturing the information contained in the brain data, suggesting that most of the brain activity is encoding the previous context. The embedding features are the second best. Finally the output probability have the smallest accuracies. This makes sense considering that they capture much less information than the other two high dimensional descriptive vectors, as they do not represent the complex properties of the words, only a numerical assessment of their likelihood.

Fig. 6 shows the accuracy when using different windows of time exclusively, for the 100ms time

windows starting at $0, 100 \ldots 400$ms after word presentation. We can see that using the embedding vector becomes increasingly more useful for classification until 300-400ms, and then its performance starts decreasing. This results aligns with the following hypothesis: the word is being perceived and understood by the brain gradually after its presentation, and therefore the brain representation of the word becomes gradually similar to the neural network representation of the word (i.e. the embedding vector). The output probability feature accuracy peaks at a later time than the embeddings accuracy. Obtaining a higher than chance accuracy at time window m using the output probability as input to the classifier suggests strongly that the brain is integrating the word at time window m, because it is responding differently for predictable and unpredictable words[5]. The integration step happens after the perception step, which is probably why the output probability curves peak later than the embeddings curves.

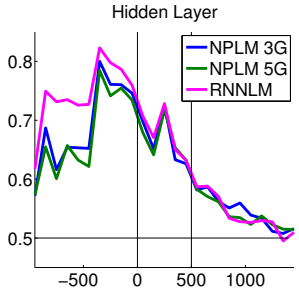

Figure 7: Average accuracy in time for the different hidden layers. The analysis is extended to the time windows before and after the word is presented, the input feature is restricted to be the hidden layer before the central word is seen. The first vertical bar indicates the onset of the word, the second one indicates the end of its presentation.

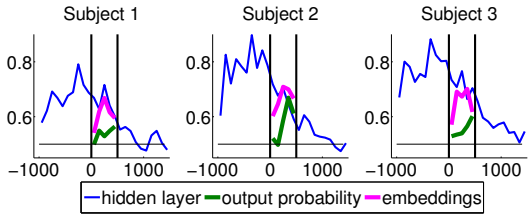

Figure 8: Accuracy in time when using the RNNLM features for each of the three subjects.

To understand the time dynamics of the hidden layer accuracy we need to see a larger time scale than the word itself. The hidden layer captures the context before word i is seen. Therefore it seems reasonable that the hidden layer is not only related to the activity when the word is on the screen, but also related to the activity before the word is presented, which is the time when the brain is integrating the previous words to build that context. On the other hand, as the word i and subsequent words are integrated, the context starts diverging from the context of word i (computed before seeing word i). We therefore ran the same analysis as before, but this time we also included the time windows before and after word i in the analysis, while maintaining the hidden layer vector to be the context before word i is seen. We see the behavior we predicted in the results: the context before seeing word i becomes gradually more useful for classification until word i is seen, and then it gradually decreases until it is no longer useful since the context has changed. We observe the RNNLM hidden layer has a higher classification accuracy than the finite context NPLMs. This might be due to the fact that the RNNLM has a more complete representation of context that captures more of the properties of the previous words.

To show the consistency of the results, we plot as illustration the three curves we obtain for each subject for the RNNLM (Fig. 8). The patterns seem very consistent indicating the phenomena we described can be detected at the subject level.

We now move on to the spatial decomposition of the analysis. When the visual input enters the brain, it first reaches the visual cortex at the back of the head, and then moves anteriorly towards the left and right temporal cortices and eventually the frontal cortex. As it flows through these areas, it is processed to higher levels of interpretations. In Fig. 9, we plot the accuracy for different regions of the brain and different time windows for the RNNLM features. To make the plots simpler we multiplied by zero the accuracies which were not significantly higher than chance. We expand a few characteristic plots. We see that in the back of the head the embedding features have an accuracy that seems to peak very early on. As we move forward in the brain towards the left and right temporal cortices, we see the embeddings accuracy peaking at a later time, reflecting the delay it takes for the information to reach this part of the brain. The output probability start being useful for classification after the embeddings, and specifically in the left temporal cortex which is the cite where the N400

[5]the fact that we can classify accurately during windows 300-400ms indicates that the classifier is taking advantage of the N400 response discussed in the introduction

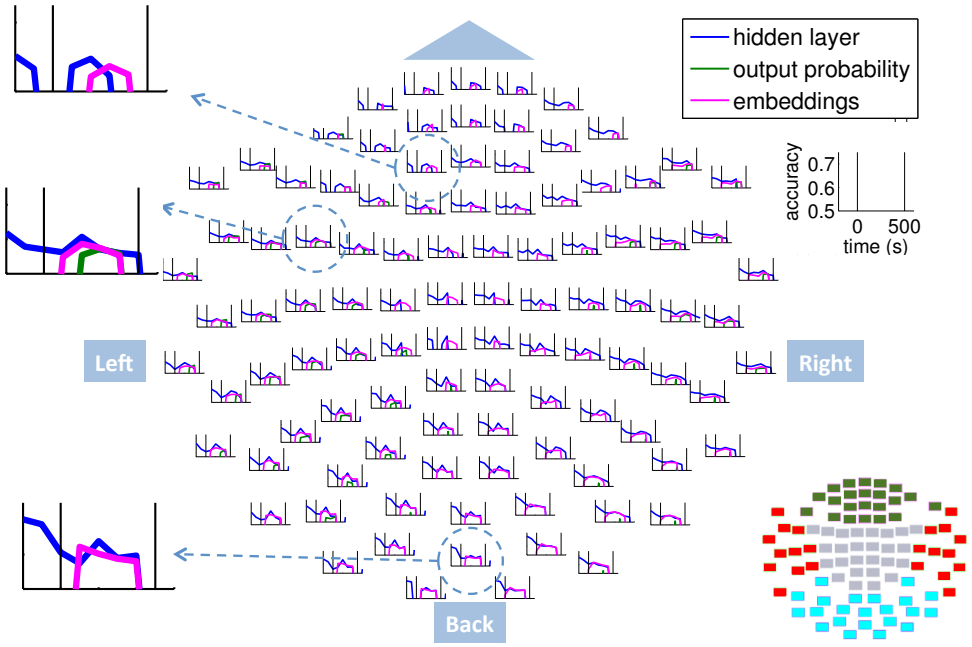

Figure 9: Average accuracy in time and space on the MEG helmet when using the RNNLM features. For each of the 102 locations the average accuracy for the group of sensors centered at that location is plotted versus time. The axes are defined in the rightmost, empty plot. Three plots have been magnified to show the increasing delay in high accuracy when using the embeddings feature, reflecting the delay in processing the incoming word as information travels through the brain. A sensor map is provided in the lower right corner: visual cortex = cyan, temporal = red, frontal = dark green.

is reported in the literature. Finally, as we reach the frontal cortex, we see that the embeddings features have an even later accuracy peak.

4 Conclusion and contributions

Novel brain data exploration We present here a novel and revealing approach to shed light on the brain processes involved in reading. This is a departure from the classical approach of controlling for a few variables in the text (e.g. showing a sentence with an expected target word versus an unexpected one). While we cannot make clear cut causal claims because we did not control for our variables, we are able to explore the data much more and offer a much richer interpretation than is possible with artificially constrained stimuli.

Comparing two models of language Adding brain data into the equation allowed us to compare the performance of the models and to identify a slight advantage for the RNNLM in capturing the text contents. Numerical comparison is however a secondary contribution of our approach. We showed that it might be possible to use brain data to understand, interpret and illustrate what exactly is being encoded by the obscure vectors that neural networks compute, by drawing parallels between the models constituents and brain processes.

Anecdotally, in the process of running the experiments, we noticed that the accuracy for the hidden layer of the RNNLM was peaking in the time window corresponding to word $i-2$, and that it was decreasing during word $i-1$. Since this was against our expectations, we went back and looked at the code and found that it was indeed returning a delayed value and corrected the features. We therefore used the brain data in order to correct a mis-specification in our neural network model. This hints if not proves the potential of our approach for assessing language models.

Future Work The work described here is our first attempt along the promising endeavor of matching complex computational models of language with brain processes using brain recordings. We plan to extend our efforts by (1) collecting data from more subjects and using various types of text and (2) make the brain data help us with training better statistical language models by using it to determine whether the models are expressive enough or have reached a sufficient degree of convergence.

A Cognitive Model of Semantic Network Learning

Aida Nematzadeh, Afsaneh Fazly, and Suzanne Stevenson

Abstract

Child semantic development includes learning the meaning of words as well as the semantic relations among words. A presumed outcome of semantic development is the formation of a semantic network that reflects this knowledge. We present an algorithm for simultaneously learning word meanings and gradually growing a semantic network, which adheres to the cognitive plausibility requirements of incrementality and limited computations. We demonstrate that the semantic connections among words in addition to their context is necessary in forming a semantic network that resembles an adult's semantic knowledge.

1 Introduction

Child semantic development includes the acquisition of word-to-concept mappings (part of word learning), and the formation of semantic connections among words/concepts. There is considerable evidence that understanding the semantic properties of words improves child vocabulary acquisition. In particular, children are sensitive to commonalities of semantic categories, and this abstract knowledge facilitates subsequent word learning (Jones et al., 1991; Colunga and Smith, 2005). Furthermore, representation of semantic knowledge is significant as it impacts how word meanings are stored in, searched for, and retrieved from memory (Steyvers and Tenenbaum, 2005; Griffiths et al., 2007).

Semantic knowledge is often represented as a graph (a *semantic network*) in which nodes correspond to words/concepts[1], and edges specify the semantic relations (Collins and Loftus, 1975; Steyvers and Tenenbaum, 2005). Steyvers and Tenenbaum (2005) demonstrated that a semantic network that encodes adult-level knowledge of words exhibits a *small-world* and *scale-free* structure. That is, it is an overall sparse network with highly-connected local sub-networks, where these sub-networks are connected through high-degree hubs (nodes with many neighbours).

Much experimental research has investigated the underlying mechanisms of vocabulary learning and characteristics of semantic knowledge (Quine, 1960; Bloom, 1973; Carey and Bartlett, 1978; Gleitman, 1990; Samuelson and Smith, 1999; Jones et al., 1991; Jones and Smith, 2005). However, existing computational models focus on certain aspects of semantic acquisition: Some researchers develop computational models of word learning without considering the acquisition of semantic connections that hold among words, or how this semantic knowledge is structured (Siskind, 1996; Regier, 2005; Yu and Ballard, 2007; Frank et al., 2009; Fazly et al., 2010). Another line of work is to model formation of semantic categories but this work does not take into account how word meanings/concepts are acquired (Anderson and Matessa, 1992; Griffiths et al., 2007; Fountain and Lapata, 2011).

Our goal in this work is to provide a cognitively-plausible and unified account for both acquiring and representing semantic knowledge. The requirements for cognitive plausibility enforce some constraints on a model to ensure that it is comparable with the cognitive process it is formulating (Poibeau et al., 2013). As we model semantic acquisition, the first requirement is incrementality, which means that the model learns gradually as it processes the input. Also, there is a limit on the number of computations the model performs at each step.

In this paper, we present an algorithm for si-

[1]Here we assume that the nodes of a semantic network are word forms and its edges are determined by the semantic features of those words.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 244–254,

multaneously learning word meanings and growing a semantic network, which adheres to the cognitive plausibility requirements of incrementality and limited computations. We examine networks created by our model under various conditions, and explore what is required to obtain a structure that has appropriate semantic connections and has a small-world and scale-free structure.

2 Related Work

Models of Word Learning. Given a word learning scenario, there are potentially many possible mappings between words in a sentence and their meanings (real-world referents), from which only some mappings are correct (the *mapping problem*). One of the most dominant mechanisms proposed for vocabulary acquisition is *cross-situational learning*: people learn word meanings by recognizing and tracking statistical regularities among the contexts of a word's usage across various situations, enabling them to narrow in on the meaning of a word that holds across its usages (Siskind, 1996; Yu and Smith, 2007; Smith and Yu, 2008). A number of computational models attempt to solve the mapping problem by implementing this mechanism, and have successfully replicated different patterns observed in child word learning (Siskind, 1996; Yu and Ballard, 2007; Fazly et al., 2010). These models have provided insight about underlying mechanisms of word learning, but none of them consider the semantic relations that hold among words, or how the semantic knowledge is structured. Recently, we have investigated properties of the semantic structure of the resulting (final) acquired knowledge of such a learner (Nematzadeh et al., 2014). However, that work did not address how such structural knowledge might develop and evolve incrementally within the learning model.

Models of Categorization. Computational models of categorization focus on the problem of forming semantic clusters given a defined set of features for words (Anderson and Matessa, 1992; Griffiths et al., 2007; Sanborn et al., 2010). Anderson and Matessa (1992) note that a cognitively plausible categorization algorithm needs to be incremental and only keep track of one potential partitioning; they propose a Bayesian framework (the Rational Model of Categorization or RMC) that specifies the joint distribution on features and category labels, and allows an unbounded number of clusters. Sanborn et al. (2010) examine different categorization models based on RMC. In particular, they compare the performance of the approximation algorithm of Anderson and Matessa (1992) (local MAP) with two other approximation algorithms (Gibbs Sampling and Particle Filters) in various human categorization paradigms. Sanborn et al. (2010) find that in most of the simulations the local MAP algorithm performs as well as the two other algorithms in matching human behavior.

The Representation of Semantic Knowledge. There is limited work on computational models of semantic acquisition that examine the representation of the semantic knowledge. Steyvers and Tenenbaum (2005) propose an algorithm for building a network with small-world and scale-free structure. The algorithm starts with a small complete graph, incrementally adds new nodes to the graph, and for each new node uses a probabilistic mechanism for selecting a subset of current nodes to connect to. However, their approach does not address the problem of learning word meanings or the semantic connections among them. Fountain and Lapata (2011) propose an algorithm for learning categories that also creates a semantic network by comparing all the possible word pairs. However, they too do not address the word learning problem, and do not investigate the structure of the learned semantic network to see whether it has the properties observed in adult knowledge.

3 The Incremental Network Model

We propose here a model that unifies the incremental acquisition of word meanings and formation of a semantic network structure that reflects the similarities among those meanings. We use an existing model to learn the meanings of words (Section 3.1), and use those incrementally developing meanings as the input to the algorithm proposed here for gradually growing a semantic network (Section 3.2).

3.1 The Word Learner

We use the model of Fazly et al. (2010); this learning algorithm is incremental and involves limited calculations, thus satisfying basic cognitive plausibility requirements. A naturalistic language learning scenario consists of linguistic data in the context of non-linguistic data, such as the objects,

Utterance: {*let*, *find*, *a*, *picture*, *to*, *color* }
Scene: {LET, PRONOUN, HAS_POSSESSION, CAUSE, ARTIFACT, WHOLE, CHANGE, ... }

Table 1: A sample utterance-scene pair.

events, and social interactions that a child perceives. This kind of input is modeled here as a pair of an *utterance* (the words a child hears) and a *scene* (the semantic features representing the meaning of those words), as shown in Table 1 (and described in more detail in Section 5.1). The word learner is an instance of cross-situational learning applied to a sequence of such input pairs: for each pair of a word w and a semantic feature f, the model incrementally learns $P(f|w)$ from co-occurrences of w and f across all the utterance-scene pairs.

For each word, the probability distribution over all semantic features, $P(.|w)$, represents the word's *meaning*. The estimation of $P(.|w)$ is made possible by introducing a set of latent variables, *alignments*, that correspond to the possible mappings between words and features in a given utterance–scene pair. The learning problem is then to find the mappings that best explain the data, which is solved by using an incremental version of the expectation–maximization (EM) algorithm (Neal and Hinton, 1998). We skip the details of the derivations and only report the resulting formulas.

The model processes one utterance-scene pair at a time. For the input pair processed at time t, first the probability of each possible alignment (alignment probability) is calculated as:[2]

$$P(a_{ij}|u, f_i) = \frac{P_{t-1}(f_i|w_j)}{\sum_{w' \in u} P_{t-1}(f_i|w')} \quad (1)$$

where u is the utterance, and a_{ij} is the alignment variable specifying the word w_j that is mapped to the feature f_i. $P_{t-1}(f_i|w_j)$ is taken from the model's current learned meaning of word w_j. Initially, $P_0(f_i|w_j)$ is uniformly distributed. After calculating the alignment probabilities, the learned meanings are updated as:

$$P_t(f_i|w_j) = \frac{\sum_{u \in U_t} P(a_{ij}|u, f_i)}{\sum_{f' \in \mathcal{M}} \sum_{u \in U_t} P(a_{ij}|u, f')} \quad (2)$$

where U_t is the set of utterances processed so far, and $\mathcal{M}$ is the set of features that the model has observed. Note that for each w–f pair, the value of the summations in this formula can be incrementally updated after processing any utterance that contains w; the summation does not have to be calculated at every step.

[2]This corresponds to the expectation step of EM.

3.2 Growing a Semantic Network

In our extended model, as we learn words incrementally (as above), we also structure those words into a semantic network based on the (partially) learned meanings. At any given point in time, the network will include as its nodes all the word types the word learner has been exposed to. Weighted edges (capturing semantic distance) will connect those pairs of word types whose learned meanings at that point are sufficiently semantically similar (according to a threshold). Since the probabilistic meaning of a word is adjusted each time it is observed, a word may either lose or gain connections in the network after each input is processed. Thus, to incrementally develop the network, at each time step, our algorithm must both examine existing connections (to see which edges should be removed) and consider potential new connections (to see which edges should be added).

A simple approach to achieve this is to examine the current semantic similarity between a word w in the input and all the current words in the network, and include edges between only those word pairs that are sufficiently similar. However, comparing w to all the words in the network each time it is observed is computationally intensive (and not cognitively plausible).

We present an approach for incrementally growing a semantic network that limits the computations when processing each input word w; see Algorithm 1. After the meaning of w is updated, we first check all the words that w is currently (directly) connected to, to see if any of those edges need to be removed, or have their weight adjusted. Next, to look for new connections for w, the idea is to select only a small subset of words, $\mathcal{S}$, to which w will be compared. The challenge then is to select $\mathcal{S}$ in a way that will yield a network whose semantic structure reasonably approximates the network that would result from full knowledge of comparing w to all the words.

Previous work has suggested picking "important" words (e.g., high-degree words) independently of the target word w — assuming these might be words for which a learner might need to understand their relationship to w in the future (Steyvers and Tenenbaum, 2005). Our proposal is instead to consider for $\mathcal{S}$ those words that are

Algorithm 1 Growing a network after each input u.

```
for all w in u do
  update P(.|w) using Eqn. (2)
  update current connections of w
  select S(w), a subset of words in the network
  for all w' in S(w) do
    if w and w' are sufficiently similar then
      connect w and w' with an edge
    end if
  end for
end for
```

likely to be similar to w. That is, since the network only needs to connect similar words to w, if we can guess what (some of) those words are, then we will do best at approximating the situation of comparing w to all words.

The question now is how to find semantically similar words to w that are not already connected to w in the network. To do so, we incrementally track semantic similarity among words usages as their meanings are developing. Specifically we cluster word tokens (not types) according to their current word meanings. Since the probabilistic meanings of words are continually evolving, incremental clusters of word tokens can capture developing similarities among the various usages of a word type, and be a clue to which words (types) w might be similar to. In the next section, we describe the Bayesian clustering process we use to identify potentially similar words.

3.3 Semantic Clustering of Word Tokens

We use the Bayesian framework of Anderson and Matessa (1992) to form semantic clusters.[3] Recall that for each word w, the model learns its meanings as a probability distribution over all semantic features, $P(.|w)$. We represent this probability distribution as a vector F whose length is the number of possible semantic features. Each element of the vector holds the value $P(f|w)$ (which is continuous). Given a word w and its vector F, we need to calculate the probability that w belongs to each existing cluster, and also allow for the possibility of it forming a new cluster. Using Bayes rule we have:

$$P(k|F) = \frac{P(k)P(F|k)}{\sum_{k'} P(k')P(F|k')} \quad (3)$$

[3]The distribution specified by this model is equivalent to that of a Dirichlet Process Mixture Model (Neal, 2000).

where k is a given cluster. We thus need to calculate the prior probability, $P(k)$, and the likelihood of each cluster, $P(F|k)$.

Calculation of Prior. The prior probability that word $n+1$ is assigned to cluster k is calculated as:

$$P(k) = \begin{cases} \frac{n_k}{n+\alpha} & n_k > 0 \\ \frac{\alpha}{n+\alpha} & n_k = 0 \text{ (new cluster)} \end{cases} \quad (4)$$

where n_k is the number of words in cluster k, n is the number of words observed so far, and α is a parameter that determines how likely the creation of a new cluster is. The prior favors larger clusters, and also discourages the creation of new clusters in later stages of learning.

Calculation of Likelihood. To calculate the likelihood $P(F|k)$ in Eqn. (3), we assume that the features are independent:

$$P(F|k) = \prod_{f_i \in F} P(f_i = v|k) \quad (5)$$

where $P(f_i = v|k)$ is the probability that the value of the feature in dimension i is equal to v given the cluster k. To derive $P(f_i|k)$, following Anderson and Matessa (1992), we assume that each feature given a cluster follows a Gaussian distribution with an unknown variance σ^2 and mean μ. (In the absence of any prior information about a variable, it is often assumed to have a Gaussian distribution.) The mean and variance of this distribution are inferred using Bayesian analysis: We assume the variance has an inverse χ^2 prior, where σ_0^2 is the prior variance and a_0 is the confidence in the prior variance:

$$\sigma^2 \sim \text{Inv-}\chi^2(a_0, \sigma_0^2) \quad (6)$$

The mean given the variance has a Gaussian distribution with μ_0 as the prior mean and λ_0 as the confidence in the prior mean.

$$\mu|\sigma \sim \text{N}(\mu_0, \frac{\sigma^2}{\lambda_0}) \quad (7)$$

Given the above conjugate priors, $P(f_i|k)$ can be calculated analytically and is a Student's t distribution with the following parameters:

$$P(f_i|k) \sim t_{a_i}(\mu_i, \sigma_i^2(1 + \frac{1}{\lambda_i})) \quad (8)$$

$$\lambda_i = \lambda_0 + n_k \quad (9)$$

$$a_i = a_0 + n_k \quad (10)$$

$$\mu_i = \frac{\lambda_0 \mu_0 + n_k \bar{f}}{\lambda_0 + n_k} \quad (11)$$

$$\sigma_i^2 = \frac{a_0 \sigma_0^2 + (n_k - 1)s^2 + \frac{\lambda_0 n_k}{\lambda_0 + n_k}(\mu_0 + \bar{f})^2}{a_0 + n_k} \quad (12)$$

where $\bar{f}$ and s^2 are the sample mean and variance of the values of f_i in k.

Note that in the above equations, the mean and variance of the distribution are simply derived by combining the sample mean and variance with the prior mean and variance while considering the confidence in the prior mean (λ_0) and variance (a_0). This means that the number of computations to calculate $P(F|K)$ is limited as w is only compared to the "prototype" of each cluster, which is represented by μ_i and σ_i of different features.

Adding a word w to a cluster. We add w to the cluster k with highest posterior probability, $P(k|F)$, as calculated in Eqn. (3).[4] The parameters of the selected cluster (k, μ_i, λ_i, σ_i, and a_i for each feature f_i) are then updated incrementally.

Using the Clusters to Select the Words in $\mathcal{S}(w)$. We can now form $S(w)$ in Algorithm 1 by selecting a given number of words n_s whose tokens are probabilistically chosen from the clusters according to how likely each cluster k is given w: the number of word tokens picked from each k is proportional to $P(k|F)$ and is equal to $P(k|F) \times n_s$.

4 Evaluation

We evaluate a semantic network in two regards: The semantic connectivity of the network – to what extent the semantically-related words are connected in the network; and the structure of the network – whether it exhibits a *small-world* and *scale-free* structure or not.

4.1 Evaluating Semantic Connectivity

The distance between the words in the network indicates their semantic similarity: the more similar a word pair, the smaller their distance. For word pairs that are connected via a path in the network, this distance is the weighted shortest path length between the two words. If there is no path between a word pair, their distance is considered to be ∞ (which is represented with a large number). We refer to this distance as the "learned" semantic similarity.

[4]This approach is referred to as local MAP (Sanborn et al., 2010); because of the incremental nature of the algorithm, it maximizes the current posterior distribution as opposed to the "global" posterior.

To evaluate the semantic connectivity of the learned network, we compare these learned similarity scores to "gold-standard" similarity scores that are calculated using the WordNet similarity measure of Wu and Palmer (1994) (also known as the WUP measure). We choose this measure since it captures the same type of similarity as in our model: words are considered similar if they belong to the same semantic category. Moreover, this measure does not incorporate information about other types of similarities, for example, words are not considered similar if they occur in similar contexts. Thus, the scores calculated with this measure are comparable with those of our learned network.

Given the gold-standard similarity scores for each word pair, we evaluate the semantic connectivity of the network based on two performance measures: coefficient of correlation and the median rank of the first five gold-standard associates. Correlation is a standard way to compare two lists of similarity scores (Budanitsky and Hirst, 2006). We create two lists, one containing the gold-standard similarity scores for all word pairs, and the other containing their corresponding learned similarity scores. We calculate the Spearman's rank correlation coefficient, ρ, between these two lists of similarity scores. Note that the learned similarity scores reflect the semantic distance among words whereas the WordNet scores reflect semantic closeness. Thus, a negative correlation is best in our evaluation, where the value of -1 corresponds to the maximum correlation.

Following Griffiths et al. (2007), we also calculate the median learned rank of the first five gold-standard associates for all words: For each word w, we first create a "gold-standard" associates list: we sort all other words based on their gold-standard similarity to w, and pick the five most similar words (associates) to w. Similarly, we create a "learned associate list" for w by sorting all words based on their learned semantic similarity to w. For all words, we find the ranks of their first five gold-standard associates in their learned associate list. For each associate, we calculate the median of these ranks for all words. We only report the results for the first three gold-standard associates since the pattern of results is similar for the fourth and fifth associates; we refer to the median rank of first three gold-standard associates as

1^{st}, 2^{nd}, and 3^{rd}.

4.2 Evaluating the Structure of the Network

A network exhibits a small-world structure when it is characterized by short path length between most nodes and highly-connected neighborhoods (Watts and Strogatz, 1998). We first explain how these properties are measured for a graph with N nodes and E edges. Then we discuss how these properties are used in assessing the small-world structure of a graph.[5].

Short path lengths. Most of the nodes of a small-world network are reachable from other nodes via relatively short paths. For a connected network (*i.e.*, all the node pairs are reachable from each other), this can be measured as the average distance between all node pairs (Watts and Strogatz, 1998). Since our networks are not connected, we instead measure this property using the median of the distances (d_{median}) between all node pairs (Robins et al., 2005), which is well-defined even when some node pairs have a distance of ∞.

Highly-connected neighborhoods. The neighborhood of a node n in a graph consists of n and all of the nodes that are connected to it. A neighborhood is maximally connected if it forms a complete graph —*i.e.*, there is an edge between all node pairs. Thus, the maximum number of edges in the neighborhood of n is $k_n(k_n-1)/2$, where k_n is the number of neighbors. A standard metric for measuring the connectedness of neighbors of a node n is called the *local clustering coefficient* (C) (Watts and Strogatz, 1998), which calculates the ratio of edges in the neighborhood of n (E_n) to the maximum number of edges possible for that neighborhood:

$$C = \frac{E_n}{k_n(k_n-1)/2} \tag{13}$$

The *local clustering coefficient* C ranges between 0 and 1. To estimate the connectedness of all neighborhoods in a network, we take the average of C over all nodes, *i.e.*, C_{avg}.

Small-world structure. A graph exhibits a small-world structure if d_{median} is relatively small and C_{avg} is relatively high. To assess this for a graph g, these values are typically compared to those of a random graph with the same number of nodes and edges as g (Watts and Strogatz, 1998; Humphries and Gurney, 2008). The random graph is generated by randomly rearranging the edges of the network under consideration (Erdos and Rényi, 1960). Because any pair of nodes is equally likely to be connected as any other, the median of distances between nodes is expected to be low for a random graph. In a small-world network, this value d_{median} is expected to be as small as that of a random graph: even though the random graph has edges more uniformly distributed, the small-world network has many locally-connected components which are connected via *hubs*. On the other hand, C_{avg} is expected to be much higher in a small-world network compared to its corresponding random graph, because the edges of a random graph typically do not fall into clusters forming highly connected neighborhoods.

Given these two properties, the "small-worldness" of a graph g is measured as follows (Humphries and Gurney, 2008):

$$\sigma_g = \frac{\frac{C_{avg}(g)}{C_{avg}(random)}}{\frac{d_{median}(g)}{d_{median}(random)}} \tag{14}$$

where $random$ is the random graph corresponding to g. In a small-world network, it is expected that $C_{avg}(g) \gg C_{avg}(random)$ and $d_{median}(g) \geq d_{median}(random)$, and thus $\sigma_g > 1$.

Note that Steyvers and Tenenbaum (2005) made the empirical observation that small-world networks of semantic knowledge had a single connected component that contained the majority of nodes in the network. Thus, in addition to σ_g, we also measure the relative size of a network's largest connected component having size N_{lcc}:

$$\text{size}_{\text{lcc}} = \frac{N_{lcc}}{N} \tag{15}$$

Scale-free structure. A scale-free network has a relatively small number of *high-degree* nodes that have a large number of connections to other nodes, while most of its nodes have a small degree, as they are only connected to a few nodes. Thus, if a network has a scale-free structure, its degree distribution (*i.e.*, the probability distribution of degrees over the whole network) will follow a power-law distribution (which is said to be "scale-free"). We evaluate this property of a network by plotting its degree distribution in the logarithmic scale, which (if a power-law distribution) should appear as a straight line. None of our networks ex-

[5]We take the description of these measures from Nematzadeh et al. (2014)

hibit a scale-free structure; thus, we do not report the results of this evaluation, and leave it to future work for further investigation.

5 Experimental Set-up

5.1 Input Representation

Recall that the input to the model consists of a sequence of utterance–scene pairs intended to reflect the linguistic data a child is exposed to, along with the associated meaning a child might grasp. As in much previous work (Yu and Ballard, 2007; Fazly et al., 2010), we take child-directed utterances from the CHILDES database (MacWhinney, 2000) in order to have naturalistic data. In particular, we use the Manchester corpus (Theakston et al., 2001), which consists of transcripts of conversations with 12 British children between the ages of $1;8$ and $3;0$. We represent each utterance as a bag of lemmatized words (see Utterance in Table 1).

For the scene representation, we have no large corpus to draw on that encodes the semantic portion of language acquisition data.[6] We thus automatically generate the semantics associated with an utterance, using a scheme first introduced in Fazly et al. (2010). The idea is to first create an input generation lexicon that provides a mapping between all the words in the input data and their associated *meanings*. A scene is then represented as a set that contains the meanings of all the words in the utterance. We use the input generation lexicon of Nematzadeh et al. (2012) because the word meanings reflect information about their semantic categories, which is crucial to forming the semantic clusters as in Section 3.3.

In this lexicon, the "true" meaning for each word w is a vector over a set of possible semantic features for each part of speech; in the vector, each feature is associated with a *score* for that word (see Figure 1). Depending on the word's part of speech, the features are extracted from various

[6] Yu and Ballard (2007) created a corpus by hand-coding the objects and cues that were present in the environment, but that corpus is very small. Frank et al. (2013) provide a larger manually annotated corpus (5000 utterances), but it is still very small for longitudinal simulations of word learning. (Our corpus contains more than 100,000 utterances.) Moreover, the corpus of Frank et al. (2013) is limited because a considerable number of words are not semantically coded. (Only a subset of concrete objects in the environment are coded.)

apple: { FOOD:1, SOLID:.72, $\cdots$, PLANT-PART:.22, PHYSICAL-ENTITY:.17, WHOLE:.06, $\cdots$ }

Figure 1: Sample true meaning features & their scores for *apple* from Nematzadeh et al. (2012).

lexical resources such as WordNet[7], VerbNet[8], and Harm (2002). The score for each feature is calculated using a measure similar to tf-idf that reflects the association of the feature with the word and with its semantic category: term frequency indicates the strength of association of the feature with the word, and inverse document frequency (where the documents are the categories) indicates how informative a feature is for that category. The semantic categories of nouns (which we focus on in our networks) are given by WordNet lex-names[9], a set of 25 general categories of entities. (We use only nouns in our semantic networks because the semantic similarity of words with different parts of speech cannot be compared, since their semantic features are drawn from different resources.)

The input generation lexicon is used to generate a scene representation for an utterance as follows: For each word w in the utterance, we probabilistically sample features, in proportion to their score, from the full set of features in its true meaning. The probabilistic sampling allows us to simulate the noise and uncertainty in the input a child perceives by omitting some meaning features from the scene. The scene representation is the union of all the features sampled for all the words in the utterance (see Scene in Table 1).

5.2 Methods

We experiment with our network-growth method that draws on the incremental clustering, and create "upper-bound" and baseline networks for comparison. Note that all the networks are created using our Algorithm 1 (page 4) to grow networks incrementally, drawing on the learned meanings of words and updating their connections on the basis of this evolving knowledge. The only difference in creating the networks resides in how the comparison set $\mathcal{S}(w)$ is chosen for each target word w that is being added to the growing network at each time step. We provide more details in the paragraphs below.

Upper-bound. Recall that one of our main goals is to substantially reduce the number of similarity comparisons needed to grow a semantic network, in contrast to the straightforward method of comparing each w to all current words. At the same time, we need to understand the impact of the increased efficiency on the quality of the resulting networks. We thus need to compare the target properties of our networks that are learned using a small comparison set $\mathcal{S}$, to those of an "upper-bound" network that takes into account all the pair-wise comparisons among words. We create this upper-bound network by setting $\mathcal{S}(w)$ to contain all words currently in the network.

Baselines. On the other hand, we need to evaluate the (potential) benefit of our cluster-driven selection process over a more simplistic approach to selecting $\mathcal{S}(w)$. To do so, we consider three baselines, each using a different criteria for choosing the comparison set $\mathcal{S}(w)$: The Random baseline chooses the members of this set randomly from the set of all observed words. The Context baseline can be seen as an "informed" baseline that attempts to incorporate some semantic knowledge: Here, we select words that are in the recent context prior to w in the input, assuming that such words are likely to be semantically related to w. We also include a third baseline, Random+Context, that picks half of the members of $\mathcal{S}$ randomly and half of them from the prior context.

Cluster-based Methods. We report results for three cluster-based networks that differ in their choice of $\mathcal{S}(w)$ as follows: The Clusters-only network chooses words in $\mathcal{S}(w)$ from the set of clusters, proportional to the probability of each cluster k given word w (as explained in Section 3.3). In order to incorporate different types of semantic information in selecting $\mathcal{S}$, we also create a Clusters+Context network that picks half of the members of $\mathcal{S}$ from clusters (as above), and half from the prior context. For completeness, we include a Clusters+Random network that similarly chooses half of words in $\mathcal{S}$ from clusters and half randomly from all observed words.

We have experimented with several other methods, but they all performed substantially worse than the baselines, and hence we do not report them here. E.g., we tried picking words in $\mathcal{S}$ from the best cluster. We also tried a few methods inspired by (Steyvers and Tenenbaum, 2005): E.g., we examined a method where if a member of $\mathcal{S}(w)$ was sufficiently similar to w, we added the direct neighbors of that word to $\mathcal{S}$. We also tried to grow networks by choosing the members of $\mathcal{S}$ according to the degree or frequency of nodes in the network.

5.3 Experimental Parameters

We use $20,000$ utterance–scene pairs as our training data. Recall that we use clustering to help guide our semantic network growth algorithm. Given the clustering algorithm in Section 3.3, we are interested to find the set of clusters that best explain the data. (Other clustering algorithms can be used instead of this algorithm.) We perform a search on the parameter space, and select the parameter values that result in the best clustering, based on the number of clusters and their average F-score. The value of the clustering parameters are as follows: $\alpha = 49$, $\lambda_0 = 1.0$, $a_0 = 2.0$, $\mu_0 = 0.0$, and $\sigma_0 = 0.05$. Two nouns with feature vectors F_1 and F_2 are connected in the network if $cosine(F1, F2)$ is greater than or equal to 0.6. (This threshold was selected following empirical examination of the similarity values we observe among the "true" meaning in our input generation lexicon.) The weight on the edge that connects these nouns specifies their semantic distance, which is calculated as $1 - cosine(F1, F2)$.

Because we aim for a network creation method that is cognitively plausible in performing a limited number of word-to-word comparisons, we need to ensure that all the different methods of selecting the comparison set $\mathcal{S}(w)$ yield roughly similar numbers of such comparisons. Keeping the size of $\mathcal{S}$ constant does not guarantee this, because each method can yield differing numbers of connections of the target word w to other words. We thus parameterize the size of $\mathcal{S}$ for each method to keep the number of computations similar, based on experiments on the development data. In development work we also found that having an increasing size of $\mathcal{S}$ over time improved the results, as more words were compared as the knowledge of learned meanings improved. To achieve this, we use a percentage of the words in the network as the size of $\mathcal{S}$. In practice, the setting of this parameter yields a number of comparisons across all methods that is about 8% of the maximum possible word-to-word comparisons that would be performed in the naive (computationally intensive) approach.

Note that all the Cluster-based, Random and Random+Context methods include a random selection mechanism; thus, we run each of these methods 50 times and report the average ρ, median ranks and size_{lcc} (see Section 4). For the networks (out of 50 runs) that exhibit a small-world structure (small-worldness greater than one), we report the average small-worldness. We also report the percentage of runs whose resulting network exhibit a small-world structure.

6 Experimental Results and Discussion

Table 2 presents our results, including the evaluation measures explained above, for the Upper-bound, Baseline, and Cluster-based networks created by the various methods described in Section 5.2.[10]

Recall that the Upper-bound network is formed from examining a word's similarity to all other (observed) words when it is added to the network. We can see that this network is highly connected (0.85) and has a small-world structure (5.5). There is a statistically significant correlation of the network's similarity measures with the gold standard ones (-0.38). For this Upper-bound structure, the median ranks of the first three associates are between 31 and 42. These latter two measures on the Upper-bound network give an indication of the difficulty of learning a semantic network whose knowledge matches gold-standard similarities.

Considering the baseline networks, we note that the Random network is actually somewhat better (in connectivity and median ranks) than the Context network that we thought would provide a more informed baseline. Interestingly, the correlation value for both networks is no worse than for the Upper-bound. The combination of Random+Context yields a slightly lower correlation, and no better ranks or connectivity than Random. Note that none of the baseline networks exhibit a small world structure ($\sigma_g \ll 1$ for all three, except for one out of 50 runs for the Random method).

Recall that the Random network is not a network resulting from randomly connecting word pairs, but one that incrementally compares each target word with a set of randomly chosen words when considering possible new connections. We suspect that this approach performs reasonably well because it enables the model to find a broad range of similar words to the target; this might be effective especially because the learned meanings of words are changing over time.

Turning to the Cluster-based methods, we see that indeed some diversity in the comparison set for a target word might be necessary to good performance. We find that the measures on the Clusters-only network are roughly the same as on the Random one, but when we combine the two in Clusters+Random we see an improvement in the ranks achieved. It is possible that the selection from clusters does not have sufficient diversity to find some of the valid new connections for a word.

We note that the best results overall occur with the Clusters+Context network, which combines two approaches to selecting words that have good potential to be similar to the target word. The correlation coefficient for this network is at a respectable 0.36, and the median ranks are the second best of all the network-growth methods. Importantly, this network shows the desired small-world structure in most of the runs (77%), with the highest connectivity and a small-world measure well over 1.

The fact that the Clusters+Context network is better overall than the networks of the Clusters-only and Context methods indicates that both clusters and context are important in making "informed guesses" about which words are likely to be similar to a target word. Given the small number of similarity comparisons used in our experiments (only around 8% of all possible word-to-word comparisons), these observations suggest that both the linguistic context and the evolving relations among word usages (captured by the incremental clustering of learned meanings) contain information crucial to the process of growing a semantic network in a cognitively plausible way.

7 Conclusions

We propose a unified model of word learning and semantic network formation, which creates a network of words in which connections reflect structured knowledge of semantic similarity between words. The model adheres to the cognitive plausibility requirements of incrementality and use of limited computations. That is, when incrementally adding or updating a word's connections in the network, the model only looks at a subset of words rather than comparing the target word to all the nodes in the network. We demonstrate that

[10] All the reported co-efficients of correlation (ρ) are statistically significant at $p < 0.01$.

Comparing all Pairs

Method	Semantic Connectivity				Small World	
	ρ	1^{st}	2^{nd}	3^{rd}	size_{lcc}	σ_g (%)

Table 2: Connectivity and small-worldness measures for the Upper-bound, Baseline, and Cluster-based network-growth methods; best performances across the Baseline and Cluster-based methods are shown in bold. ρ: co-efficient of correlation between similarities of word pairs in network and in gold-standard; 1^{st}, 2^{nd}, 3^{rd}: median ranks of corresponding gold-standard associates given network similarities; size_{lcc}: proportion of network in the largest connected component; σ_g: overall "small-worldness", should be greater than 1; %: the percentage of runs whose resulting networks exhibit a small-world structure. Note there are 1074 nouns in each network.

using the evolving knowledge of semantic connections among words as well as their context of usage enables the model to create a network that shows the properties of adult semantic knowledge. This suggests that the information in the semantic relations among words and their context can efficiently guide semantic network growth.

Abstract

Models that acquire semantic representations from both linguistic and perceptual input are of interest to researchers in NLP because of the obvious parallels with human language learning. Performance advantages of the multi-modal approach over language-only models have been clearly established when models are required to learn concrete noun concepts. However, such concepts are comparatively rare in everyday language. In this work, we present a new means of extending the scope of multi-modal models to more commonly-occurring abstract lexical concepts via an approach that learns multi-modal embeddings. Our architecture outperforms previous approaches in combining input from distinct modalities, and propagates perceptual information on concrete concepts to abstract concepts more effectively than alternatives. We discuss the implications of our results both for optimizing the performance of multi-modal models and for theories of abstract conceptual representation.

1 Introduction

Multi-modal models that learn semantic representations from both language and information about the perceptible properties of concepts were originally motivated by parallels with human word learning (Andrews et al., 2009) and evidence that many concepts are grounded in perception (Barsalou and Wiemer-Hastings, 2005). The perceptual information in such models is generally mined directly from images (Feng and Lapata, 2010; Bruni et al., 2012) or from data collected in psychological studies (Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013).

By exploiting the additional information encoded in perceptual input, multi-modal models can outperform language-only models on a range of semantic NLP tasks, including modelling similarity (Bruni et al., 2014; Kiela et al., 2014) and free association (Silberer and Lapata, 2012), predicting compositionality (Roller and Schulte im Walde, 2013) and concept categorization (Silberer and Lapata, 2014). However, to date, these previous approaches to multi-modal concept learning focus on concrete words such as *cat* or *dog*, rather than abstract concepts, such as *curiosity* or *loyalty*. However, differences between abstract and concrete processing and representation (Paivio, 1991; Hill et al., 2013; Kiela et al., 2014) suggest that conclusions about concrete concept learning may not necessarily hold in the general case. In this paper, we therefore focus on multi-modal models for learning both abstract and concrete concepts.

Although concrete concepts might seem more basic or fundamental, the vast majority of open-class, meaning-bearing words in everyday language are in fact abstract. 72% of the noun or verb tokens in the British National Corpus (Leech et al., 1994) are rated by human judges[1] as more abstract than the noun *war*, for instance, a concept many would already consider to be quite abstract. Moreover, abstract concepts by definition encode higher-level (more general) principles than concrete concepts, which typically reside naturally in a single semantic category or domain (Crutch and Warrington, 2005). It is therefore likely that abstract representations may prove highly applicable for multi-task, multi-domain or transfer learning models, which aim to acquire 'general-purpose' conceptual knowledge without reference to a specific objective or task (Collobert and Weston, 2008; Mesnil et al., 2012).

In a recent paper, Hill et al. (2014) investigate whether the multi-modal models cited above are

[1] Contributors to the USF dataset (Nelson et al., 2004).

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 255–265,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

effective for learning concepts other than concrete nouns. They observe that representations of certain abstract concepts can indeed be enhanced in multi-modal models by combining perceptual and linguistic input with an *information propagation* step. Hill et al. (2014) propose ridge regression as an alternative to the nearest-neighbour averaging proposed by Johns and Jones (2012) for such propagation, and show that it is more robust to changes in the type of concept to be learned. However, both methods are somewhat inelegant, in that they learn separate linguistic and 'pseudo-perceptual' representations, which must be combined via a separate *information combination* step. Moreover, for the majority of abstract concepts, the best performing multi-modal model employing these techniques remains less effective than conventional text-only representation learning model.

Motivated by these observations, we introduce an architecture for learning both abstract and concrete representations that generalizes the skipgram model of Mikolov et al. (2013) from text-based to multi-modal learning. Aspects of the model design are influenced by considering the process of human language learning. The model moderates the training input to include more perceptual information about commonly-occurring concrete concepts and less information about rarer concepts. Moreover, it integrates the processes of combining perceptual and linguistic input and propagating information from concrete to abstract concepts into a single representation update process based on back-propagation.

We train our model on running-text language and two sources of perceptual descriptors for concrete nouns: the ESPGame dataset of annotated images (Von Ahn and Dabbish, 2004) and the CSLB set of concept property norms (Devereux et al., 2013). We find that our model combines information from the different modalities more effectively than previous methods, resulting in an improved ability to model the USF free association gold standard (Nelson et al., 2004) for concrete nouns. In addition, the architecture propagates the extra-linguistic input for concrete nouns to improve representations of abstract concepts more effectively than alternative methods. While this propagation can effectively extend the advantage of the multi-modal approach to many more concepts than simple concrete nouns, we observe that the benefit of adding perceptual input appears to decrease as target concepts become more abstract. Indeed, for the most abstract concepts of all, language-only models still provide the most effective learning mechanism.

Finally, we investigate the optimum quantity and type of perceptual input for such models. Between the most concrete concepts, which can be effectively represented directly in the perceptual modality, and the most abstract concepts, which cannot, we identify a set of concepts that cannot be represented effectively directly in the perceptual modality, but still benefit from perceptual input propagated in the model via concrete concepts.

The motivation in designing our model and experiments is both practical and theoretical. Taken together, the empirical observations we present are potentially important for optimizing the learning of representations of concrete and abstract concepts in multi-modal models. In addition, they offer a degree of insight into the poorly understood issue of how abstract concepts may be encoded in human memory.

2 Model Design

Before describing how our multi-modal architecture encodes and integrates perceptual information, we first describe the underlying corpus-based representation learning model.

Language-only Model Our multi-modal architecture builds on the continuous log-linear skipgram language model proposed by Mikolov et al. (2013). This model learns lexical representations in a similar way to neural-probabilistic language models (NPLM) but without a non-linear hidden layer, a simplification that facilitates the efficient learning of large vocabularies of dense representations, generally referred to as *embeddings* (Turian et al., 2010). Embeddings learned by the model achieve state-of-the-art performance on several evaluations including sentence completion and analogy modelling (Mikolov et al., 2013).

For each word type w in the vocabulary V, the model learns both a 'target-embedding' $r_w \in \mathbb{R}^d$ and a 'context-embedding' $\hat{r}_w \in \mathbb{R}^d$ such that, given a target word, its ability to predict nearby context words is maximized. The probability of seeing context word c given target w is defined as:

$$p(c|w) = \frac{e^{\hat{r}_c \cdot r_w}}{\sum_{v \in V} e^{\hat{r}_v \cdot r_w}}$$

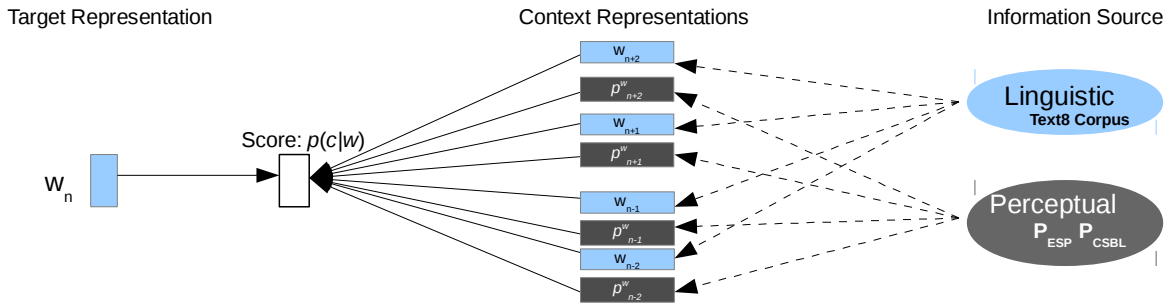

Figure 1: Our multi-modal model architecture. Light boxes are elements of the original Mikolov et al. (2013) model. For target words w_n in the domain of $\mathbf{P}$ (concrete concepts), the model updates its representations based on corpus context words $w_{n\pm i}$, then on words $p^w_{n\pm i}$ in perceptual pseudo-sentences. For w_n not in the domain of $\mathbf{P}$ (abstract concepts), updates are based solely on the $w_{n\pm i}$.

The model learns from a set of target-word, context-word pairs, extracted from a corpus of sentences as follows. In a given sentence S (of length N), for each position $n \leq N$, each word w_n is treated in turn as a target word. An integer $t(n)$ is then sampled from a uniform distribution on $\{1, \ldots k\}$, where $k > 0$ is a predefined maximum context-window parameter. The pair tokens $\{(w_n, w_{n+j}) : -t(n) \leq j \leq t(n), w_i \in S\}$ are then appended to the training data. Thus, target/context training pairs are such that (i) only words within a k-window of the target are selected as context words for that target, and (ii) words closer to the target are more likely to be selected than those further away.

The training objective is then to maximize the sum of the log probabilities T across of all such examples from S and across all sentences in the corpus, where T is defined as follows:

$$T = \frac{1}{N} \sum_{n=1}^{N} \sum_{-t(n) \leq j \leq t(n), j \neq 0} log(p(w_{n+j}|w_n))$$

The model free parameters (target-embeddings and context-embeddings of dimension d for each word in the corpus with frequency above a certain threshold f) are updated according to stochastic gradient descent and backpropation, with learning rate controlled by Adagrad (Duchi et al., 2011). For efficiency, the output layer is encoded as a hierarchical softmax function based on a binary Huffman tree (Morin and Bengio, 2005).

As with other distributional architectures, the model captures conceptual semantics by exploiting the fact that words appearing in similar linguistic contexts are likely to have similar meanings. Informally, the model adjusts its embeddings to increase the 'probability' of seeing the language in the training corpus. Since this probability increases with the $p(c|w)$, and the $p(c|w)$ increase with the dot product $\hat{r}_c \cdot r_w$, the updates have the effect of moving each target-embedding incrementally 'closer' to the context-embeddings of its collocates. In the target-embedding space, this results in embeddings of concept words that regularly occur in similar contexts moving closer together.

Multi-modal Extension We extend the Mikolov et al. (2013) architecture via a simple means of introducing perceptual information that aligns with human language learning. Based on the assumption that frequency in domain-general linguistic corpora correlates with the likelihood of 'experiencing' a concept in the world (Bybee and Hopper, 2001; Chater and Manning, 2006), perceptual information is introduced to the model whenever designated concrete concepts are encountered in the running-text linguistic input. This has the effect of introducing more perceptual input for commonly experienced concrete concepts and less input for rarer concrete concepts.

To implement this process, perceptual information is extracted from external sources and encoded in an associative array $\mathbf{P}$, which maps (typically concrete) words w to bags of perceptual features $\mathbf{b}(w)$. The construction of this array depends on the perceptual information source; the process for our chosen sources is detailed in Section 2.1.

Training our model begins as before on running-text. When a sentence S_m containing a word w in the domain of $\mathbf{P}$ is encountered, the model finishes training on S_m and begins learning from a perceptual pseudo-sentence $\hat{S_m}(w)$. $\hat{S_m}(w)$ is constructed by alternating the token w with a fea-

$\hat{S}(crocodile)$ = **Crocodile** legs **crocodile** teeth **crocodile** teeth **crocodile** scales **crocodile** green **crocodile**.

$\hat{S}(screwdriver)$ = **Screwdriver** handle **screwdriver** flat **screwdriver** long **screwdriver** handle **screwdriver** head.

Figure 2: Example pseudo-sentences generated by our model.

ture sampled at random from $\mathbf{b}(w)$ until $\hat{S_m}(w)$ is the same length as S_m (see Figure 2). Because we want the ensuing perceptual learning process to focus on how w relates to its perceptual properties (rather than how those properties relate to each other), we insert multiple instances of w into $\hat{S_m}(w)$. This ensures that the majority of training cases derived from $\hat{S_m}(w)$ are instances of (w, feature) rather than (feature, feature) pairs. Once training on $\hat{S_m}(w)$ is complete, the model reverts to the next 'genuine' (linguistic) sentence S_{m+1}, and the process continues. Thus, when a concrete concept is encountered in the corpus, its embedding is first updated based on language (moved incrementally closer to concepts appearing in similar linguistic contexts), and then on perception (moved incrementally closer to concepts with the same or similar perceptual features).

For greater flexibility, we introduce a parameter α reflecting the raw quantity of perceptual information relative to linguistic input. When $\alpha = 2$, two pseudo-sentences are generated and inserted for every corpus occurrence of a token from the domain of $\mathbf{P}$. For non-integral α, the number of sentences inserted is $\lfloor\alpha\rfloor$, and a further sentence is added with probability $\alpha - \lfloor\alpha\rfloor$.

In all experiments reported in the following sections we set the window size parameter $k = 5$ and the minimum frequency parameter $f = 3$, which guarantees that the model learns embeddings for all concepts in our evaluation sets. While the model learns both target and context-embeddings for each word in the vocabulary, we conduct our experiments with the target embeddings only. We set the dimension parameter $d = 300$ as this produces high quality embeddings in the language-only case (Mikolov et al., 2013).

2.1 Information Sources

We construct the associative array of perceptual information $\mathbf{P}$ from two sources typical of those used for multi-modal semantic models.

ESPGame Dataset The ESP-Game dataset (ESP) (Von Ahn and Dabbish, 2004) consists of 100,000 images, each annotated with a list of lexical concepts that appear in that image.

For any concept w identified in an ESP image, we construct a corresponding bag of features $\mathbf{b}(w)$. For each ESP image I that contains w, we append the other concept tokens identified in I to $\mathbf{b}(w)$. Thus, the more frequently a concept co-occurs with w in images, the more its corresponding lexical token occurs in $\mathbf{b}(w)$. The array $\mathbf{P_{ESP}}$ in this case then consists of the $(w, \mathbf{b}(w))$ pairs.

CSLB Property Norms The Centre for Speech, Language and the Brain norms (CSLB) (Devereux et al., 2013) is a recently-released dataset containing semantic properties for 638 concrete concepts produced by human annotators. The CSLB dataset was compiled in the same way as the McRae et al. (2005) property norms used widely in multi-modal models (Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013); we use CSLB because it contains more concepts. For each concept, the proportion of the 30 annotators that produced a given feature can also be employed as a measure of the strength of that feature.

When encoding the CSLB data in $\mathbf{P}$, we first map properties to lexical forms (e.g. *is_green* becomes *green*). By directly identifying perceptual features and linguistic forms in this way, we treat features observed in the perceptual data as (sub)concepts to be acquired via the same multi-modal input streams and stored in the same domain-general memory as the evaluation concepts. This design decision in fact corresponds to a view of cognition that is sometimes disputed (Fodor, 1983). In future studies we hope to compare the present approach to architectures with domain-specific conceptual memories.

For each concept w in CSLB, we then construct a feature bag $\mathbf{b}(w)$ by appending lexical forms to $\mathbf{b}(w)$ such that the count of each feature word is equal to the strength of that feature for w. Thus, when features are sampled from $\mathbf{b}(w)$ to create pseudo-sentences (as detailed previously) the probability of a feature word occurring in a sentence reflects feature strength. The array $\mathbf{P_{CSLB}}$ then consists of all $(w, \mathbf{b}(w))$ pairs.

Linguistic Input The linguistic input to all models is the 400m word Text8 Corpus[2] of

2.2 Evaluation

We evaluate the quality of representations by how well they reflect *free association* scores, an empirical measure of cognitive conceptual proximity. The University of South Florida Norms (USF) (Nelson et al., 2004) contain free association scores for over 40,000 concept pairs, and have been widely used in NLP to evaluate semantic representations (Andrews et al., 2009; Feng and Lapata, 2010; Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013). Each concept that we extract from the USF database has also been rated for conceptual concreteness on a Likert scale of 1-7 by at least 10 human annotators. Following previous studies (Huang et al., 2012; Silberer and Lapata, 2012), we measure the (Spearman ρ) correlation between association scores and the cosine similarity of vector representations.

We create separate abstract and concrete concept lists by ranking the USF concepts according to concreteness and sampling at random from the first and fourth quartiles respectively. We also introduce a complementary noun/verb dichotomy, on the intuition that information propagation may occur differently from noun to noun or from noun to verb (because of their distinct structural relationships in sentences). POS-tags are not assigned as part of the USF data, so we draw the noun/verb distinction based on the majority POS-tag of USF concepts in the lemmatized British National Corpus (Leech et al., 1994). The abstract/concrete and noun/verb dichotomies yield four distinct concept lists. For consistency, the concrete noun list is filtered so that each concrete noun concept w has a perceptual representation $\mathbf{b}(\mathrm{w})$ in both $\mathbf{P_{ESP}}$ and $\mathbf{P_{CSLB}}$. For the four resulting concept lists C (concrete/abstract, noun/verb), a corresponding set of evaluation pairs $\{(w_1, w_2) \in USF : w_1, w_2 \in C\}$ is extracted (see Table 3 for details).

Concept Type	List	Pairs	Examples
concrete nouns	541	1418	*yacht, cup*
abstract nouns	100	295	*fear, respect*
all nouns	666	1815	*fear, cup*
concrete verbs	50	66	*kiss, launch*
abstract verbs	50	127	*differ, obey*
all verbs	100	221	*kiss, obey*

Table 3: Details the subsets of USF data used in our evaluations, downloadable from our website.

3 Results and Discussion

Our experiments were designed to answer four questions, outlined in the following subsections: (1) Which model architectures perform best at *combining* information pertinent to multiple modalities when such information exists explicitly (as common for concrete concepts)? (2) Which model architectures best propagate perceptual information to concepts for which it does not exist explicitly (as is common for abstract concepts)? (3) Is it preferable to include all of the perceptual input that can be obtained from a given source, or to filter this input stream in some way? (4) How much perceptual vs. linguistic input is optimal for learning various concept types?

3.1 Combining information sources

To evaluate our approach as a method of information combination we compared its performance on the concrete noun evaluation set against three alternative methods. The first alternative is simple concatenation of these perceptual vectors with linguistic vectors embeddings learned

by the Mikolov et al. (2013) model on the Text8 Corpus. In the second alternative (proposed for multi-modal models by Silberer and Lapata (2012)), *canonical correlation analysis* (CCA) (Hardoon et al., 2004) was applied to the vectors of both modalities. CCA yields reduced-dimensionality representations that preserve underlying inter-modal correlations, which are then concatenated. The final alternative, proposed by Bruni et al. (2014) involves applying Singular Value Decomposition (SVD) to the matrix of concatenated multi-modal representations, yielding smoothed representations.[3]

When implementing the concatenation, CCA and SVD methods, we first encoded the perceptual input directly into sparse feature vectors, with coordinates for each of the 2726 features in CSLB and for each of the 100,000 images in ESP. This sparse encoding matches the approach taken by Silberer and Lapata (2012), for CCA and concatenation, and by Hill et al. (2014) for the ridge regression method of propagation (see below).

We compare these alternatives to our proposed model with $\alpha = 1$. In The CSLB and ESP models, all training pseudo-sentences are generated from the arrays $\mathbf{P_{CSLB}}$ and $\mathbf{P_{ESP}}$ respectively. In the models classed as *CSLB&ESP*, a random choice between $\mathbf{P_{CSLB}}$ and $\mathbf{P_{ESP}}$ is made every time perceptual input is included (so that the overall quantity of perceptual information is the same).

As shown in Figure 2 (left side), the embeddings learned by our model achieve a higher correlation with the USF data than simple concatenation, CCA and SVD regardless of perceptual input source. With the optimal perceptual source (ESP only), for instance, the correlation is 11% higher that the next best alternative method, CCA.

One possible factor behind this improvement is that, in our model, the learned representations fully integrate the two modalities, whereas for both CCA and the concatenation method each representation feature (whether of reduced dimension or not) corresponds to a particular modality. This deeper integration may help our architecture to overcome the challenges inherent in information combination such as inter-modality differences in information content and representation sparsity. It is also important to note that Bruni et al. (2014) applied their SVD method with comparatively dense perceptual representations extracted from images, whereas our dataset-based perceptual vectors were sparsely-encoded.

[3]CCA was implemented using the *CCA* package in R. SVD was implemented using *SVDLIBC* (`http://tedlab.mit.edu/~dr/SVDLIBC/`), with truncation factor $k = 1024$ as per (Bruni et al., 2014).

3.2 Propagating input to abstract concepts

To test the process of information propagation in our model, we evaluated the learned embeddings of more abstract concepts. We compared our approach with two recently-proposed alternative methods for inferring perceptual features when explicit perceptual information is unavailable.

Johns and Jones In the method of Johns and Jones (2012), pseudo-perceptual representations for target concepts without a perceptual representations (uni-modal concepts) are inferred as a weighted average of the perceptual representations of concepts that do have such a representation (bi-modal concepts).

In the first step of their two-step method, for each uni-modal concept $\mathbf{k}$, a quasi-perceptual representation is computed as an average of the perceptual representations of bi-modal concepts, weighted by the proximity between each of these concepts and $\mathbf{k}$

$$\mathbf{k}^p = \sum_{\mathbf{c} \in \bar{C}} S(\mathbf{k}^l, \mathbf{c}^l)^\lambda \cdot \mathbf{c}^p$$

where $\bar{C}$ is the set of bi-modal concepts, $\mathbf{c}^p$ and $\mathbf{k}^p$ are the perceptual representations for $\mathbf{c}$ and $\mathbf{k}$ respectively, and $\mathbf{c}^l$ and $\mathbf{k}^l$ the linguistic representations. The exponent parameter λ reflects the learning rate.

In step two, the initial quasi-perceptual representations are inferred for a second time, but with the weighted average calculated over the perceptual or initial quasi-perceptual representations of all other words, not just those that were originally bi-modal. As with Johns and Jones (2012), we set the learning rate parameter λ to be 3 in the first step and 13 in the second.

Ridge Regression An alternative, proposed for the present purpose by Hill et al. (2014), uses *ridge regression* (Myers, 1990). Ridge regression is a variant of least squares regression in which a regularization term is added to the training objective to favor solutions with certain properties.

For bi-modal concepts of dimension n_p, we apply ridge regression to learn n_p linear functions

$f_i : \mathbb{R}^{n_l} \rightarrow \mathbb{R}$ that map the linguistic representations (of dimension n_l) to a particular perceptual feature i. These functions are then applied together to map the linguistic representations of uni-modal concepts to full quasi-perceptual representations.

Following Hill et al. (2014), we take the Euclidian l_2 norm of the inferred parameter vector as the regularization term. This ensures that the regression favors lower coefficients and a smoother solution function, which should provide better generalization performance than simple linear regression. The objective for learning the f_i is then to minimize

$$\|\mathbf{a}X - Y_i\|_2^2 + \|\mathbf{a}\|_2^2$$

where $\mathbf{a}$ is the vector of regression coefficients, X is a matrix of linguistic representations and Y_i a vector of the perceptual feature i for the set of bi-modal concepts.

Comparisons We applied the Johns and Jones method and ridge regression starting from linguistic embeddings acquired by the Mikolov et al. (2013) model on the Text8 Corpus, and concatenated the resulting pseudo-perceptual and linguistic representations. As with the implementation of our model, the perceptual input for these alternative models was limited to concrete nouns (i.e. concrete nouns were the only bi-modal concepts in the models).

Figure 3 (right side) shows the propagation performance of the three models. While the correlations overall may seem somewhat low, this is a consequence of the difficulty of modelling the USF data. In fact, the performance of both the language-only model and our multi-modal extension across the concept types (from 0.18 to 0.36) is equal to or higher than previous models evaluated on the same data (Feng and Lapata, 2010; Silberer and Lapata, 2012; Silberer et al., 2013).

For learning representations of concrete verbs, our approach achieves a 69% increase in performance over the next best alternative. The performance of the model on abstract verbs is marginally inferior to Johns and Jones' method. Nevertheless, the clear advantage for concrete verbs makes our model the best choice for learning representations of verbs in general, as shown by performance on the set *all verbs*, which also includes mixed abstract-concrete pairs.

Our model is also marginally inferior to alternative approaches in learning representations of abstract nouns. However, in this case, no method improves on the linguistic-only baseline. It is possible that perceptual information is simply so removed from the core semantics of these concepts that they are best acquired via the linguistic medium alone, regardless of learning mechanism. The moderately inferior performance of our method in such cases is likely caused by its greater inherent inter-modal dependence compared with methods that simply concatenate uni-modal representations. When the perceptual signal is of low quality, this greater inter-modal dependence allows the linguistic signal to be obscured.

The trade-off, however, is generally higher-quality representations when the perceptual signal is stronger, exemplified by the fact that our proposed approach outperforms alternatives on pairs generated from both abstract and concrete nouns (*all nouns*). Indeed, the low performance of the Johns and Jones method on *all nouns* is striking given that: (a) It performs best on *abstract nouns* ($\rho = .282$), and (b) For concrete nouns it reverts to simple concatenation, which also performs comparatively well ($\rho = .249$). The poor performance of the Jobns and Jones method on *all nouns* must therefore derive its comparisons of mixed abstract-concrete or concrete-abstract pairs. This suggests that the pseudo-perceptual representations inferred by this method for abstract concepts method may not be compatible with the directly-encoded perceptual representations of concrete concepts, rendering the comparison computation between items of differing concreteness inaccurate.

3.3 Direct representation vs. propagation

Although property norm datasets such as the CSLB data typically consist of perceptual feature information for concrete nouns only, image-based datasets such as ESP do contain information on more abstract concepts, which was omitted from the previous experiments. Indeed, image banks such as Google Images contain millions of photographs portraying quite abstract concepts, such as *love* or *war*. On the other hand, encodings or descriptions of abstract concepts are generally more subjective and less reliable than those of concrete concepts (Wiemer-Hastings and Xu, 2005). We therefore investigated whether or not it is preferable to include this additional information as model input or to restrict perceptual input

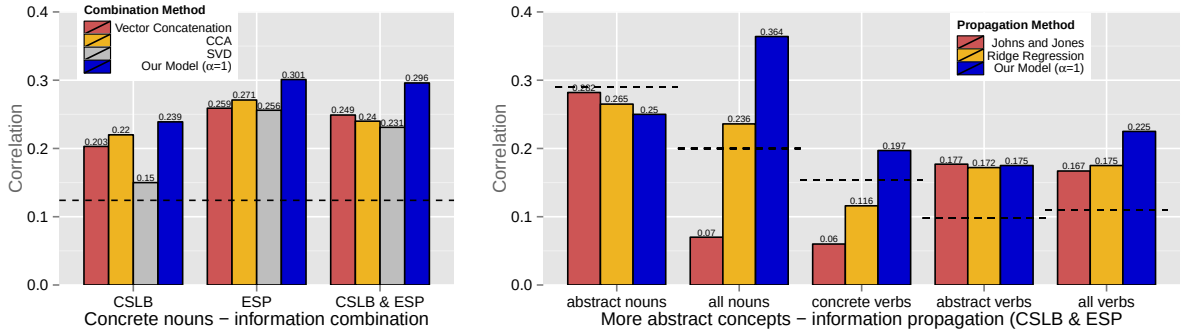

Figure 3: The proposed approach compared with other methods of information combination (left) and propagation. Dashed lines indicate language-only model baseline. For brevity we include both perceptual input sources ESP and CSLB when comparing means of propagation; results with individual information sources were similar.

to concrete nouns as previously.

Of our evaluation sets, it was possible to construct from ESP (and add to $\mathbf{P_{ESP}}$) representations for all of the concrete verbs, and for approximately half of the abstract verbs and abstract nouns. Figure 4 (top), shows the performance of a our model trained on all available perceptual input versus the model in which the perceptual input was restricted to concrete nouns.

The results reflect a clear manifestation of the abstract/concrete distinction. Concrete verbs behave similarly to concrete nouns, in that they can be effectively represented directly from perceptual information sources. The information encoded in these representations is beneficial to the model and increases performance. In contrast, constructing 'perceptual' representations of abstract verbs and abstract nouns directly from perceptual information sources is clearly counter-productive (to the extent that performance also degrades on the combined sets *all nouns* and *all verbs*). It appears in these cases that the perceptual input acts to obscure or contradict the otherwise useful signal inferred from the corpus.

As shown in the previous section, the inclusion of any form of perceptual input inhibits the learning of abstract nouns. However, this is not the case for abstract verbs. Our model learns higher quality representations of abstract verbs if perceptual input is restricted to concrete nouns than if no perceptual input is included at all *and* when perceptual input is included for both concrete nouns and abstract verbs. This supports the idea of a gradual scale of concreteness: The most concrete concepts can be effectively represented directly in the perceptual modality; somewhat more abstract concepts cannot be represented directly in the perceptual modality, but have representations that are improved by propagating perceptual input from concrete concepts via language; and the most abstract concepts are best acquired via language alone.

3.4 Source and quantity of perceptual input

For different concept types, we tested the effect of varying the proportion of perceptual to linguistic input (the parameter α). Perceptual input was restricted to concrete nouns as in Sections 3.1-3.2.

As shown in Figure 4, performance on concrete nouns improves (albeit to a decreasing degree) as α increases. When learning concrete noun representations, linguistic input is apparently redundant if perceptual input is of sufficient quality and quantity. For the other concept types, in each case there is an optimal value for α in the range .5–2, above which perceptual input obscures the linguistic signal and performance degrades. The proximity of these optima to 1 suggests that for optimal learning, when a concrete concept is experienced approximately equal weight should be given to available perceptual and linguistic information.

4 Conclusions

Motivated by the notable prevalence of abstract concepts in everyday language, and their likely importance to flexible, general-purpose representation learning, we have investigated how abstract and concrete representations can be acquired by multi-modal models. In doing so, we presented a simple and easy-to-implement architecture for acquiring semantic representations of both types of

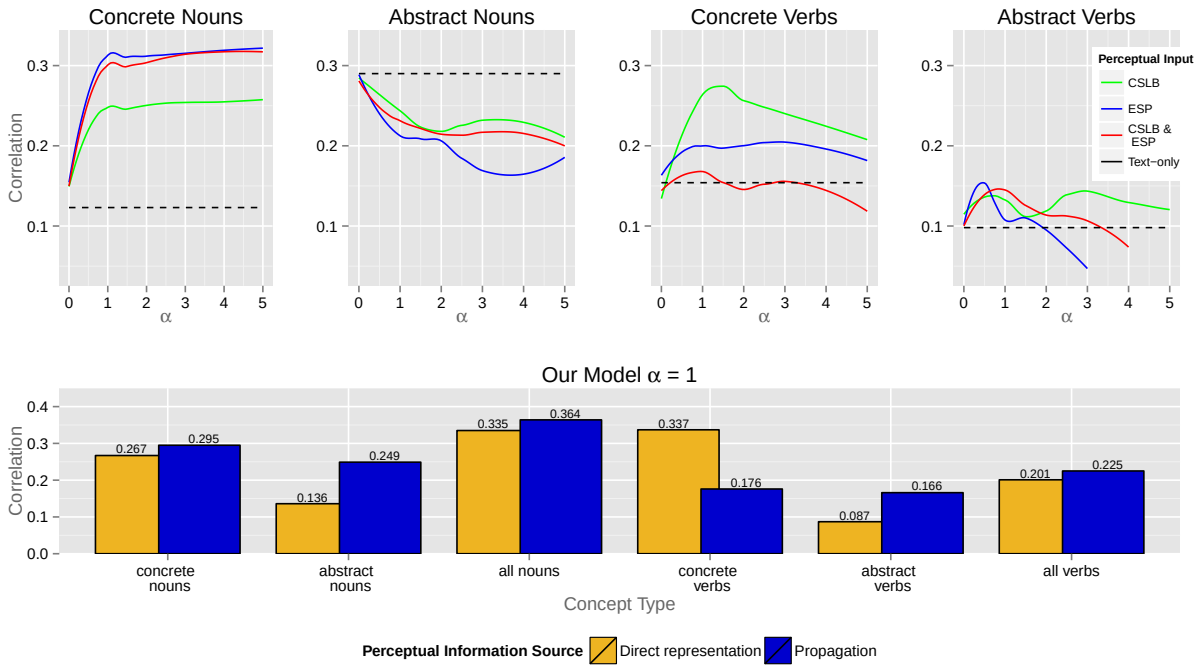

Figure 4: Top: Comparing the strategy of directly representing abstract concepts from perceptual information where available (yellow bars) vs. propagating via concrete concepts. Bottom: The effect of increasing α on correlation with USF pairs (Spearman ρ) for each concept type. Horizontal dashed lines indicate language-only model baseline.

concept from linguistic and perceptual input.

While neuro-probabilistic language models have been applied to the problem of multi-modal representation learning previously (Srivastava and Salakhutdinov, 2012; Wu et al., 2013; Silberer and Lapata, 2014) our model and experiments develop this work in several important ways. First, we address the problem of learning abstract concepts. By isolating concepts of different concreteness and part-of-speech in our evaluation sets, and separating the processes of information combination and propagation, we demonstrate that the multi-modal approach is indeed effective for some, but perhaps not all, abstract concepts. In addition, our model introduces a clear parallel with human language learning. Perceptual input is introduced precisely when concrete concepts are 'experienced' by the model in the corpus text, much like a language learner experiencing concrete entities via sensory perception.

Taken together, our findings indicate the utility of distinguishing three concept types when learning representations in the multi-modal setting.

Type I Concepts that can be effectively represented directly in the perceptual modality. For such concepts, generally concrete nouns or concrete verbs, our proposed approach provides a simple means of combining perceptual and linguistic input. The resulting multi-modal representations are of higher quality than those learned via other approaches, resulting in a performance improvement of over 10% in modelling free association.

Type II Concepts, including abstract verbs, that cannot be effectively represented directly in the perceptual modality, but whose representations can be improved by joint learning from linguistic input and perceptual information about related concepts. Our model can effectively propagate perceptual input (exploiting the relations inferred from the linguistic input) from Type I concepts to enhance the representations of Type II concepts above the language-only baseline. Because of the frequency of abstract concepts, such propagation extends the benefit of the multi-modal approach to a far wider range of language than models based solely in the concrete domain.

Type III Concepts that are more effectively learned via language-only models than multi-modal models, such as abstract nouns. Neither

our proposed approach nor alternative propagation methods achieve an improvement in representation quality for these concepts over the language-only baseline. Of course, it is an empirical question whether a multi-modal approach could ever enhance the representation learning of these concepts, one with potential implications for cognitive theories of grounding (a topic of much debate in psychology (Grafton, 2009; Barsalou, 2010)).

Additionally, we investigated the optimum type and quantity of perceptual input for learning concepts of different types. We showed that too much perceptual input can result in degraded representations. For concepts of type I and II, the optimal quantity resulted from setting $\alpha = 1$; i.e. whenever a concrete concept was encountered, the model learned from an equal number of language-based and perception-based examples. While we make no formal claims here, such observations may ultimately provide insight into human language learning and semantic memory.

In future we will address the question of whether Type III concepts can ever be enhanced via multi-modal learning, and investigate multi-modal models that optimally learn concepts of each type. This may involve filtering the perceptual input stream for concepts according to concreteness, and possibly more elaborate model architectures that facilitate distinct representational frameworks for abstract and concrete concepts.

Go Climb a Dependency Tree and Correct the Grammatical Errors

Longkai Zhang Houfeng Wang

Abstract

State-of-art systems for grammar error correction often correct errors based on word sequences or phrases. In this paper, we describe a grammar error correction system which corrects grammatical errors at tree level directly. We cluster all error into two groups and divide our system into two modules correspondingly: the general module and the special module. In the general module, we propose a TreeNode Language Model to correct errors related to verbs and nouns. The TreeNode Language Model is easy to train and the decoding is efficient. In the special module, two extra classification models are trained to correct errors related to determiners and prepositions. Experiments show that our system outperforms the state-of-art systems and improves the F_1 score.

1 Introduction

The task of grammar error correction is difficult yet important. An automatic grammar error correction system can help second language (L2) learners improve the quality of their writing. In recent years, there are various competitions devoted to grammar error correction, such as the HOO-2011(Dale and Kilgarriff, 2011), HOO-2012(Dale et al., 2012) and the CoNLL-2013 shared task (Ng et al., 2013). There has been a lot of work addressing errors made by L2 learners. A significant proportion of the systems for grammar error correction train individual statistical models to correct each special kind of error word by word and ignore error interactions. These methods assume no interactions between different kinds of grammatical errors. In real problem settings errors are correlated, which makes grammar error correction much more difficult.

Recent research begins to focus on the error interaction problem. For example, Wu and Ng (2013) decodes a global optimized result based on the individual correction confidence of each kind of errors. The individual correction confidence is still based on the noisy context. Rozovskaya and Roth (2013) uses a joint modeling approach, which considers corrections in phrase structures instead of words. For dependencies that are not covered by the joint learning model, Rozovskaya and Roth (2013) uses the results of Illinois system in the joint inference. These results are still at word level and are based on the noisy context. These systems can consider error interactions, however, the systems are complex and inefficient. In both Wu and Ng (2013) and Rozovskaya and Roth (2013), Integer Linear Programming (ILP) is used for decoding a global optimized result. In the worst case, the time complexity of ILP can be exponent.

In contrast, we think a better grammar error correction system should correct grammatical errors at sentence level directly and efficiently. The system should correct as many kinds of errors as possible in a generalized framework, while allowing special models for some kinds of errors that we need to take special care. We cluster all error into two groups and correspondingly divide our system into two modules: the general module and the special module. In the general module, our system views each parsed sentence as a dependency tree. The system generates correction candidates for each node on the dependency tree. The correction can be made on the dependency tree globally. In this module, nearly all replacement errors related to verb form, noun form and subject-verb agreement errors can be considered. In the special module, two extra classification models are used to correct the determiner errors and preposition errors . The classifiers are also trained at tree node level. We take special care of these two kinds

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 266–277,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

of errors because these errors not only include replacement errors, but also include insertion and deletion errors. A classification model is more suitable for handling insertion and deletion errors. Besides, they are the most common errors made by English as a Second Language (ESL) learners and are much easier to be incorporated into a classification framework.

We propose a TreeNode Language Model (TNLM) to efficiently measure the correctness of selecting a correction candidate of a node in the general module. Similar to the existing statistical language models which assign a probability to a linear chain of words, our TNLM assigns correctness scores directly on each node on the dependency tree. We select candidates for each node to maximize the global correctness score and use these candidates to form the corrected sentence. The global optimized inference can be tackled efficiently using dynamic programming. Because the decoding is based on the whole sentence, error interactions can be considered. Our TNLM only needs to use context words related to each node on the dependency tree. Training a TreeNode language model costs no more than training ordinary language models on the same corpus. Experiments show that our system can outperform the state-of-art systems.

The paper is structured as follows. Section 1 gives the introduction. In section 2 we describe the task and give an overview of the system. In section 3 we describe the general module and in section 4 we describe the special module. Experiments are described in section 5. In section 6 related works are introduced, and the paper is concluded in the last section.

2 Task and System Overview

2.1 Task Description

The task of grammar error correction aims to correct grammatical errors in sentences. There are various competitions devoted to the grammar error correction task for L2 learners. The CoNLL-2013 shared task is one of the most famous, which focuses on correcting five types of errors that are commonly made by non-native speakers of English, including determiner, preposition, noun number, subject-verb agreement and verb form errors. The training data released by the task organizers come from the NUCLE corpus(Dahlmeier et al., 2013). This corpus contains essays written by ESL learners, which are then corrected by English teachers. The test data are 50 student essays. Details of the corpus are described in Ng et al. (2013).

2.2 System Architecture

In our system, lists of correction candidates are first generated for each word. We generate candidates for nouns based on their plurality. We generate candidates for verbs based on their tenses. Then we select the correction candidates that maximize the overall correctness score. An example process of correcting figure 1(a) is shown in table 1.

Correcting grammatical errors using local statistical models on word sequence is insufficient. The local models can only consider the contexts in a fixed window. In the example of figure 1(a), the context of the verb "is" is "that boy is on the", which sounds reasonable at first glance but is incorrect when considering the whole sentence. The limitation of local classifiers is that long distance syntax information cannot be incorporated within the local context. In order to effectively use the syntax information to get a more accurate correcting result, we think a better way is to tackle the problem directly at tree level to view the sentence as a whole. From figure 1(a) we can see that the node "is" has two children on the dependency tree: "books" and "on". When we consider the node "is", its context is "books is on", which sounds incorrect. Therefore, we can make better corrections using such context information on nodes.

Therefore, our system corrects grammatical errors on dependency trees directly. Because the correlated of words are more linked on trees than in a word sequence, the errors are more easier to be corrected on the trees and the agreement of different error types is guaranteed by the edges. We follow the strategy of treating different kinds of errors differently, which is used by lots of grammar error correction systems. We cluster the five types of errors considered in CoNLL-2013 into two groups and divide our system into two modules correspondingly.

- **The general module**, which is responsible for the verb form errors, noun number errors and subject-verb agreement errors. These errors are all replacement errors, which can be corrected by replacing the wrongly used word with a reasonable candidate word.

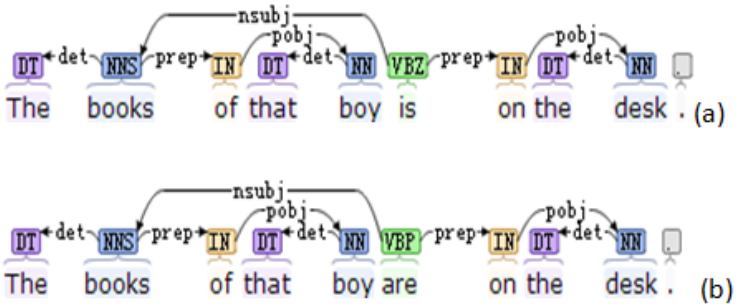

Figure 1: Dependency parsing results of (a) the original sentence "The books of that boy is on the desk ." (b) the corrected sentence.

Position	Original	Correction Candidates	Corrected
1	The	The	The
2	books	books, book	books
3	of	of	of
4	that	that	that
5	boy	boy, boys	boy
6	is	is,are,am,was,were,be,being,been	are
7	on	on	on
8	the	the	the
9	desk	desk, desks	desk
10	.	.	.

Table 1: An example of the "correction candidate generation and candidate selection" framework.

- **The special module**, where two classification models are used to correct the determiner errors and preposition errors at tree level. We take special care of these two kinds of errors because these errors include both replacement errors and insertion/deletion errors. Besides, they are the most common errors made by ESL learners and is much easier to be incorporated into a classification framework.

We should make it clear that we are not the first to use tree level correction models on ungrammatical sentences. Yoshimoto et al. (2013) uses a Treelet Language model (Pauls and Klein, 2012) to correct agreement errors. However, the performance of Treelet language model is not that good compared with the top-ranked system in CoNLL-2013. The reason is that the production rules in the Treelet language model are based on complex contexts, which will exacerbate the data sparseness problem. The "context" in Treelet language model also include words ahead of treelets, which are sometimes unrelated to the current node. In contrast, our TreeNode Language model only needs to consider useful context words related to each node on the dependency tree. To train a TreeNode language model costs no more than training ordinary language models on the same corpus.

2.3 Data Preparation

Our system corrects grammatical errors on dependency trees directly, therefore the sentences in training and testing data should have been parsed before being corrected. In our system, we use the Stanford parser[1] to parse the New York Times source of the Gigaword corpus[2], and use the parsed sentences as our training data. We use the original training data provided by CoNLL-2013 as the develop set to tune all parameters.

Some sentences in the news texts use a different writing style against the sentences written by ESL learners. For example, sentences written by ESL learners seldom include dialogues between people, while very often news texts include paragraphs such as "'I am frightened!' cried Tom". We use heuristic rules to eliminate the sentences in the Gigaword corpus that are less likely to appear in the ESL writing. The heuristic rules include delet-

[1]http://nlp.stanford.edu/software/lex-parser.shtml
[2]https://catalog.ldc.upenn.edu/LDC2003T05

ing sentences that are too short or too long[3], deleting sentences that contains certain punctuations such as quotation marks, or deleting sentences that are not ended with a period.

In total we select and parse 5 million sentences of the New York Times source of English newswire in the Gigaword corpus. We build the system and experiment based on these sentences.

3 The General Module

3.1 Overview

The general module aims to correct verb form errors, noun number errors and subject-verb agreement errors. Other replacement errors such as spelling errors can also be incorporated into the general module. Here we focus on verb form errors, noun number errors and subject-verb agreement errors only. Our general module views each sentence as a dependency tree. All words in the sentence form the nodes of the tree. Nodes are linked through directed edges, annotated with the dependency relations.

Before correcting the grammatical errors, the general module should generate correction candidates for each node first. For each node we use the word itself as its first candidate. Because the general module considers errors related to verbs and nouns, we generate extra correction candidates only for verbs and nouns. For verbs we use all its verb forms as its extra candidates. For example when considering the word "speaks", we use itself and {speak, spoke, spoken, speaking} as its correction candidates. For nouns we use its singular form and plural form as its extra correction candidates. For example when considering the word "dog", we use itself and "dogs" as its correction candidate. If the system selects the original word as the final correction, the sentence remains unchanged. But for convenience we still call the newly generated sentence "the corrected sentence".

In a dependency tree, the whole sentence s can be formulized as a list of production rules $r_1, ..., r_L$ of the form: $[r = head \rightarrow modifier_1, modifier_2 ...]$. An example of all production rules of figure 1(a) is shown in table 2. Because the production rules are made up of words, selecting a different correction candidate for only one node will result in a list of different production rules. For example, figure 1(b) selects the correction candidate "is" to replace the original "are". Therefore the production rules of figure 1(b) include [are → books, on], instead of [is → books, on] in figure 1(a).

books → The, of
of → boy
boy → that
is → books, on
on → desk
desk → the

Table 2: All the production rules in the example of figure 1(a)

The overall correctness score of s, which is $score(s)$, can be further decomposed into $\prod_{i=0}^{L} score(r_i)$. A reasonable score function should score the correct candidate higher than the incorrect one. Consider the node "is" in Figure 1(a), the production rule with head "is" is $[is \rightarrow books, on]$. Because the correction of "is" is "are", a reasonable scorer should have $score([is \rightarrow books, on]) < score([are \rightarrow books, on])$.

Given the formulation of sentence $s = [r_1, ..., r_L]$ and the candidates for each node, we are faced with two problems:

1. **Score Function**. Given a fixed selection of candidate for each node, how to compute the overall score of the dependency tree, i.e., $score(s)$. Because $score(s)$ is decomposed into $\prod_{i=0}^{L} score(r_i)$, the problem becomes finding a $score$ function to measure the correctness of each r given a fixed selection of candidates.

2. **Decoding**. Given each node a list of correction candidates and a reasonable score function $score(r)$ for the production rules, how to find the selection of candidates that maximize the overall score of the dependency tree.

For the first problem, we propose a TreeNode Language Model as the correctness measure of a fixed candidate selection. For the decoding problem, we use a dynamic programming method to efficiently find the correction candidates that maximize the overall score. We will describe the details in the following sections.

One concern is whether the automatically parsed trees are reliable for grammar error correction. We define "reliable" as follows. If we

[3] In our experiment, no less than 5 words and no more than 30 words.

change some words in original sentence into their reasonable correction candidates (e.g. change "is" to "are") but the structure of the dependency tree does not change (except the replaced word and its corresponding POS tag, which are definitely changed), then we say the dependency tree is reliable for this sentence. To verify this we randomly selected 1000 sentences parsed by the Stanford Parser. We randomly select the verbs and nouns and replace them with a wrong form. We parsed the modified sentences again and asked 2 annotators to examine whether the dependency trees are reliable for grammar error correction. We find that 99% of the dependency trees are reliable. Therefore we can see that the dependency tree can be used as the structure for grammar error correction directly.

3.2 TreeNode Language Model

In our system we use the score of TreeNode Language Model (TNLM) as the scoring function. Consider a node n on a dependency tree and assume n has K modifiers $C_1, ..., C_K$ as its child nodes. We define $Seq(n) = [C_1, ..., n, ..., C_K]$ as an ordered sub-sequence of nodes that includes the node n itself and all its child nodes. The order of the sub-sequence in $Seq(n)$ is sorted based on their position in the sentence. In this formulation, we can score the correctness of a production rule r by scoring the correctness of $Seq(n)$. Because $Seq(n)$ is a word sequence, we can use a language model to measure its correctness. The sub-sequences are not identical to the original text. Therefore instead of using ordinary language models, we should train special language models using the sub-sequences to measure the correctness of a production rule.

Take the sentence in figure 2 as an example. When considering the node "is" in the word sequence, it is likely to be corrected into "are" because it appear directly after the plural noun "parents". However, by the definition above, the subsequence corresponding to the node "damaged" is "car is damaged by ". In such context, the word "is" is less likely to be changed to "are". From the example we can see that the sub-sequence is suitable to be used to measure the correctness of a production rule. From this example we can also find that the sub-sequences are different with ordinary sentences, because ordinary sentences are less likely to end with "by".

Table 3 shows all the sub-sequences in the example of figure 2. If we collect all the subsequences in the corpus to form a new subsequence corpus, we can train a language model based on the new sub-sequence corpus. This is our TreeNode Language Model. One advantage of TLM is that once we have generated the subsequences, we can train the TLM in the same way as we train ordinary language models. Besides, the TLM is not limited to a fixed smoothing method. Any smoothing methods for ordinary language models are applicable for TLM.

Node	Sub-sentence
The	The
car	The car of
of	of parents
my	my
parents	my parents
is	is
damaged	car is damaged by
by	by storm
the	the
storm	the storm

Table 3: All the sub-sentences in the example of figure 2

In our system we train the TLM using the same way as training tri-gram language model. For a sub-sequence $S = w_0...w_L$, we calculate $P(S) = \prod_{i=0}^{L} P(w_i|w_{i-1}w_{i-2})$. The smoothing method we use is interpolation, which assumes the final $P'(w_i|w_{i-1}w_{i-2})$ of the tri-gram language model follows the following decomposition:

$$\begin{aligned} P'(w_i|w_{i-1}w_{i-2}) =& \lambda_1 P(w_i|w_{i-1}w_{i-2}) \\ &+ \lambda_2 P(w_i|w_{i-1}) \\ &+ \lambda_3 P(w_i) \end{aligned} \quad (1)$$

where λ_1, λ_2 and λ_3 are parameters sum to 1. The parameters λ_1, λ_2 and λ_3 are estimated through EM algorithm(Baum et al., 1970; Dempster et al., 1977; Jelinek, 1980).

3.3 Decoding

The decoding problem is to select one correction candidate for each node that maximizes the overall score of the corrected sentence. When the sentence is long and contains many verbs and nouns, enumerating all possible candidate selections is time-consuming. We use a bottom-up dynamic

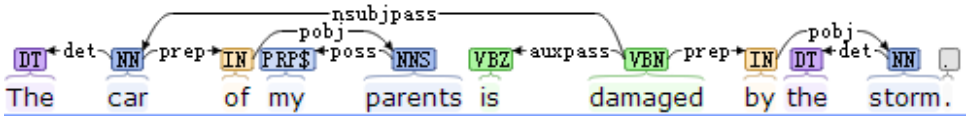

Figure 2: A illustrative sentence for TreeNode Language Model.

programming approach to find the maximized corrections within polynomial time complexity.

For a node n with L correction candidates $n_1, ...n_L$ and K child nodes $C_1, ..., C_K$, we define $n.scores[i]$ as the maximum score if we choose the ith candidate n_i for n. Because we decode from leaves to the root, $C_1.scores, ..., C_K.scores$ have already been calculated before we calculate $n.scores$.

We assume the sub-sequence $Seq(n_i) = [C_1, ..., C_M, n_i, C_{M+1}, ..., C_K]$ without loss of generality, where $C_1, .., C_M$ are the nodes before n_i and $C_{M+1}, ..., C_K$ are the nodes after n_i.

We define $c_{i,j}$ as the jth correction candidate of child node C_i. Given a selection of candidates for each child node $seq = [c_{1,j_1}, ..., c_{M,j_M}, n_i, c_{M+1,j_{M+1}}, ..., c_{K,j_K}]$, we can calculate $score(seq)$ as:

$$score(seq) = TNLM(seq) \prod_{i=1}^{K} C_i.scores[j_i] \quad (2)$$

where $TNLM(seq)$ is the TreeNode Language Model score of seq. Then, $n.scores[i]$ is calculated as:

$$n.scores[i] = \max_{\forall seq} score(seq) \quad (3)$$

Because seq is a word sequence, the maximization can be efficiently calculated using Viterbi algorithm (Forney Jr, 1973). To be specific, the Viterbi algorithm uses the transition scores and emission scores as its input. The transition scores in our model are the tri-gram probabilities from our tri-gram TNLM. The emission scores in our model are the candidate scores of each child: $C_1.scores, ..., C_K.scores$, which have already been calculated.

After the bottom-up calculation, we only need to look into the "ROOT" node to find the maximum score of the whole tree. Similar to the Viterbi algorithm, back pointers should be kept to find which candidate is selected for the final corrected sentence. Detailed decoding algorithm is shown in table 4.

```
Function decode(Node n)
  if n is leaf
    set n.scores uniformly
    return
  for each child c of n
    decode(c)
  calculating n.scores using Viterbi
End Function
BEGIN
  decode(ROOT)
  find the maximum score for the tree and backtrack all candidates
END
```

Table 4: The Decoding algorithm

In the real world implementations, we add a controlling parameter for the confidence of the correctness of the inputs. We multiply λ on $P(w_0|w_{-2}w_{-1})$ of the tri-gram TNLM if the correcting candidate w_0 is the same word in the original input. λ is larger than 1 to "emphasis" the confidence of the original word because the most of the words in the inputs are correct. The value of λ can be set using the development data.

3.4 The Special Module

The special module is designed for determiner errors and preposition errors. We take special care of these two kinds of errors because these errors include insertion and deletion errors, which cannot be corrected in the general module. Because there is a fixed number of prepositions and determiners, these two kinds of errors are much easier to be incorporated into a classification framework. Besides, they are the most common errors made by ESL learners and there are lots of previous works that leave valuable guidance for us to follow.

Similar to many previous state-of-art systems, we treat the correction of determiner errors and preposition errors as a classification problem. Although some previous works (e.g. Rozovskaya et al. (2013)) use NPs and the head of NPs as

features, they are basically local classifiers making predictions on word sequences. Difference to the local classifier approaches, we make predictions on the nodes of the dependency tree directly. In our system we correct determiner errors and preposition errors separately.

For the determiner errors, we consider the insertion, deletion and replacement of articles (i.e. 'a', 'an' and 'the'). Because the articles are used to modify nouns in the dependency trees, we can classify based on noun nodes. We give each noun node (node whose POS tag is noun) a label to indicate which article it should take. We use left position (LP) and right position (RP) to specify the position of the article. The article therefore locates between LP and RP. If a noun node already has an article as its modifier, then LP will be the position directly ahead of the article. In this case, $RP = LP + 2$. If an insertion is needed, the RP is the position of the first child node of the noun node. In this case $LP = RP - 1$. With this notation, detailed feature templates we use to correct determiner errors are listed in table 5. In our model we use 3 labels: 'a', 'the' and '$\emptyset$'. We use 'a', 'the' to represent a noun node should be modified with 'a' or ''the' correspondingly. We use ''$\emptyset$' to indicate that no article is needed for the noun node. We use rule-based method to distinguish between "a" and "an" as a post-process.

For the preposition errors, we only consider deletion and replacement of an existing preposition. The classification framework is similar to determiner errors. We consider classification on preposition nodes (nodes whose POS tag is preposition). We use prepositions as labels to indicate which preposition should be used. and use "$\emptyset$" to denote that the preposition should be deleted. We use the same definition of LP and RP as the correction of determiner errors. Detailed feature templates we use to correct preposition errors are listed in table 6. Similar to the previous work(Xing et al., 2013), we find that adding more prepositions will not improve the performance in our experiments. Thus we only consider a fixed set of prepositions: {in, for, to, of, on}.

Previous works such as Rozovskaya et al. (2013) show that Naive Bayes model and averaged perceptron model show better results than other classification models. These classifiers can give a reasonably good performance when there are limited amount of training data. In our system, we use large amount of automatically generated training data based on the parsed Gigaword corpus instead of the limited training data provided by CoNLL-2013.

Take generating training data for determiner errors as an example. We generate training data based on the parsed Gigaword corpus C described in section 2. Each sentence S in C is a dependency tree T. We use each noun node N on T as one training instance. If N is modified by "the", its label will be "THE". If N is modified by "a" or "an", its label will be "A". Otherwise its label will be "NULL". Then we just omit the determiner modifier and generate features based on table 5. Generating training data for preposition errors is the same, except we use preposition nodes instead of noun nodes.

By generating training instances in this way, we can get large amount of training data. Therefore we think it is a good time to try different classification models with enough training data. We experiment on Naive Bayes, Averaged Perceptron, SVM and Maximum Entropy models (ME) in a 5-fold cross validation on the training data. We find ME achieves the highest accuracy. Therefore we use ME as the classification model in our system.

4 Experiment

4.1 Experiment Settings

In the experiments, we use our parsed Gigaword corpus as the training data, use the training data provided by CoNLL-2013 as the develop data, and use the test data of CoNLL-2013 as test data directly. In the general module, the training data is used for the training of TreeNode Language Model. In the special module, the training data is used for training individual classification models.

We use the M2 scorer (Dahlmeier and Ng, 2012b) provided by the organizer of CoNLL-2013 for the evaluation of our system. The M2 scorer is widely used as a standard scorer in previous systems. Because we make comparison with the state-of-art systems on the CoNLL-2013 corpus, we use the same evaluation metric F_1 score of M2 scorer as the evaluation metric.

In reality, some sentences may have more than one kind of possible correction. As the example in "The books of that boy is on the desk.", the corresponding correction can be either "The books of that boy are on the desk." or "The book of that boy is on the desk.". The gold test data can only con-

Word Features	w_{LP} , w_{LP-1}, w_{LP-2}, w_{RP}, w_{RP+1}, w_{RP+2}, $w_{LP-2}w_{LP-1}$, $w_{LP-1}w_{LP}$, $w_{LP}w_{RP}$, $w_{RP}w_{RP+1}$, $w_{RP+1}w_{RP+2}$, $w_{LP-2}w_{LP-1}w_{LP}$, $w_{LP-1}w_{LP}w_{RP}$, $w_{LP}w_{RP}w_{RP+1}$, $w_{RP}w_{RP+1}w_{RP+2}$
Noun Node Features	NN, $w_{LP}NN$, $w_{LP-1}w_{LP}NN$, $w_{LP-2}w_{LP-1}w_{LP}NN$
Father/Child Node Features	Fa, $w_{RP}Fa$, $w_{RP}w_{RP+1}Fa$, $w_{RP}w_{RP+1}w_{RP+2}Fa$, $Fa\&Ch$

Table 5: Feature templates for the determiner errors. w_i is the word at the ith position. NN is the current noun node. Fa is the father node of the current noun node. Ch is a child node of the current noun node.

Word Features	w_{LP} , w_{LP-1}, w_{LP-2}, w_{RP}, w_{RP+1}, w_{RP+2}, $w_{LP-2}w_{LP-1}$, $w_{LP-1}w_{LP}$, $w_{LP}w_{RP}$, $w_{RP}w_{RP+1}$, $w_{RP+1}w_{RP+2}$, $w_{LP-2}w_{LP-1}w_{LP}$, $w_{LP-1}w_{LP}w_{RP}$, $w_{LP}w_{RP}w_{RP+1}$, $w_{RP}w_{RP+1}w_{RP+2}$
Father/Child Node Features	Fa, $w_{RP}Fa$, $w_{RP}w_{RP+1}Fa$, $w_{RP}w_{RP+1}w_{RP+2}Fa$, $Fa\&Ch$

Table 6: Feature templates for preposition errors. w_i is the word at the ith position. Fa is the father node of the current preposition node. Ch is a child node of the current preposition node.

sider a small portion of possible answers. To relieve this, the CoNLL-2013 shared task allows all participating teams to provide alterative answers if they believe their system outputs are also correct. These alterative answers form the "Revised Data" in the shared task, which indeed help evaluate the outputs of the participating systems. However, the revised data only include alterative corrections from the participating teams. Therefore the evaluation is not that fair for future systems. In our experiment we only use the original test data as the evaluation dataset.

4.2 Experiment Results

We first show the performance of each stage of our system. In our system, the general module and the special module correct grammar errors consequently. Therefore in table 7 we show the performance when each component is added to the system.

Method	**P**	**R**	**F1 score**
TNLM	33.96%	17.71%	23.28%
+Det	32.83%	38.28%	35.35%
+Prep	32.64%	39.20%	35.62%

Table 7: Results of each stage in our system. TNLM is the general module. "+Det" is the system containing the general module and determiner part of special module."+Prep" is the final system

We evaluate the effect of using TreeNode language model for the general module. We compare the TNLM with ordinary tri-gram language model. We use the same amount of training data and the same smoothing strategy (i.e. interpolation) for both of them. Table 8 shows the comparison. The TNLM can improve the F_1 by $+2.1\%$.

Method	**P**	**R**	**F1 score**
Ordinary LM	29.27%	16.68%	21.27%
Our TNLM	**33.96%**	**17.71%**	**23.28%**

Table 8: Comparison for the general module between TNLM and ordinary tri-gram language model on the test data.

Based on the result of the general module using TNLM, we compare our tree level special module against the local classification approach. The special module of our system makes predictions on the dependency tree directly, while local classification approaches make predictions on linear chain of words and decide the article of a noun Phrase or the preposition of a preposition phrase. We use the same word level features for the two approaches except for the local classifiers we do not add tree level features. Table 9 shows the comparison.

When using the parsed Gigaword texts as training data, the quality of the sentences we select will influence the result. For comparison, we randomly select the same amount of sentences from the same source of Gigaword and parse them as a alterative training set. Table 10 shows the comparison between random chosen training data and

Method	P	R	F1 score
Local Classifier	26.38%	39.14%	31.51%
Our Tree-based	**32.64%**	**39.20%**	**35.62%**

Table 9: Comparison for the special module on the test data. The input of the special module is the sentences corrected by the TNLM in the general module.

the selected training data of our system. We can see that the data selection (cleaning) procedure is important for the improvement of system $F1$.

Method	P	R	F1 score
Random	31.89%	35.85%	33.75%
Selected	**32.64%**	**39.20%**	**35.62%**

Table 10: Comparison of training using random chosen sentences and selected sentences.

Method	F1 score
Rozovskaya et al. (2013)	31.20%
Kao et al. (2013)	25.01%
Yoshimoto et al. (2013)	22.17%
Rozovskaya and Roth (2013)	35.20%
Our method	**35.62**%

Table 11: Comparison of $F1$ of different systems on the test data .

4.3 Comparison With Other Systems

We also compare our system with the state-of-art systems. The first two are the top-2 systems at CoNLL-2013 shared task : Rozovskaya et al. (2013) and Kao et al. (2013). The third one is the Treelet Language Model in Yoshimoto et al. (2013). The fourth one is Rozovskaya and Roth (2013), which until now shows the best performance. The comparison on the test data is shown in table 11.

In CoNLL-2013 only 5 kinds of errors are considered. Our system can be slightly modified to handle the case where other errors such as spelling errors should be considered. In that case, we can modify the candidate generation of the general module. We only need to let the generate correction candidates be any possible words that are similar to the original word, and run the same decoding algorithm to get the corrected sentence. As a comparison, the ILP systems should add extra scoring system to score extra kind of errors.

5 Related Works

Early grammatical error correction systems use the knowledge engineering approach (Murata and Nagao, 1994; Bond et al., 1996; Bond and Ikehara, 1996; Heine, 1998). However, manually designed rules usually have exceptions. Therefore, the machine learning approach has become the dominant approach recently. Previous machine learning approaches typically formulates the task as a classification problem. Of all the errors, determiner and preposition errors are the two main research topics (Knight and Chander, 1994; AEHAN et al., 2006; Tetreault and Chodorow, 2008; Dahlmeier and Ng, 2011). Features used in the classification models include the context words, POS tags, language model scores (Gamon, 2010), and tree level features (Tetreault et al., 2010). Models used include maximum entropy (AEHAN et al., 2006; Tetreault and Chodorow, 2008), averaged perceptron, Naive Bayes (Rozovskaya and Roth, 2011), etc. Other errors such as verb form and noun number errors also attract some attention recently (Liu et al., 2010; Tajiri et al., 2012).

Recent research efforts have started to deal with correcting different errors jointly (Gamon, 2011; Park and Levy, 2011; Dahlmeier and Ng, 2012a; Wu and Ng, 2013; Rozovskaya and Roth, 2013). Gamon (2011) uses a high-order sequential labeling model to detect various errors. Park and Levy (2011) models grammatical error correction using a noisy channel model. Dahlmeier and Ng (2012a) uses a beam search decoder, which iteratively corrects to produce the best corrected output. Wu and Ng (2013) and Rozovskaya and Roth (2013) use ILP to decode a global optimized result. The joint learning and joint inference are still at word/phrase level and are based on the noisy context. In the worst case, the time complexity of ILP can reach exponent. In contrast, our system corrects grammar errors at tree level directly, and the decoding is finished with polynomial time complexity.

6 Conclusion and Future work

In this paper we describe our grammar error correction system which corrects errors at tree level directly. We propose a TreeNode Language Model and use it in the general module to correct errors related to verbs and nouns. The TNLM is easy to train and the decoding of corrected sentence is efficient. In the special module, two extra classification models are trained to correct errors related to

determiners and prepositions at tree level directly. Because our current method depends on an automatically parsed corpus, future work may include applying some additional filtering (e.g. Mejer and Crammer (2012)) of the extended training set according to some confidence measure of parsing accuracy.

Abstract

Most existing systems for subcategorization frame (SCF) acquisition rely on supervised parsing and infer SCF distributions at type, rather than instance level. These systems suffer from poor portability across domains and their benefit for NLP tasks that involve sentence-level processing is limited. We propose a new unsupervised, Markov Random Field-based model for SCF acquisition which is designed to address these problems. The system relies on supervised POS tagging rather than parsing, and is capable of learning SCFs at instance level. We perform evaluation against gold standard data which shows that our system outperforms several supervised and type-level SCF baselines. We also conduct task-based evaluation in the context of verb similarity prediction, demonstrating that a vector space model based on our SCFs substantially outperforms a lexical model and a model based on a supervised parser [1].

1 Introduction

Subcategorization frame (SCF) acquisition involves identifying the arguments of a predicate and generalizing about its syntactic frames, where each frame specifies the syntactic type and number of arguments permitted by the predicate. For example, in sentences (1)-(3) the verb *distinguish* takes three different frames, the difference between which is not evident when considering the phrase structure categorization:

(1) **Direct Transitive**: [They]NP [distinguished]VP [the mast]NP [of [ships on the horizon]NP]PP .

(2) **Indirect Transitive:** [They]NP [distinguished]VP [between [me and you]ADVP]PP .

(3) **Ditransitive**: [They]NP [distinguished]VP [him]NP [from [the other boys]NP]PP.

As SCFs describe the syntactic realization of the verbal predicate-argument structure, they are highly valuable for a variety of NLP tasks. For example, verb subcategorization information has proven useful for tasks such as parsing (Carroll and Fang, 2004; Arun and Keller, 2005; Cholakov and van Noord, 2010), semantic role labeling (Bharati et al., 2005; Moschitti and Basili, 2005), verb clustering, (Schulte im Walde, 2006; Sun and Korhonen, 2011) and machine translation (hye Han et al., 2000; Hajič et al., 2002; Weller et al., 2013).

SCF induction is challenging. The argument-adjunct distinction is difficult even for humans, and is further complicated by the fact that both arguments and adjuncts can appear frequently in potential argument head positions (Korhonen et al., 2000). SCFs are also highly sensitive to domain variation so that both the frames themselves and their probabilities vary depending on the meaning and behavior of predicates in the domain in question (e.g. (Roland and Jurafsky, 1998; Lippincott et al., 2010; Rimell et al., 2013), Section 4).

Because of the strong impact of domain variation, SCF information is best acquired automatically. Existing data-driven SCF induction systems, however, do not port well between domains. Most existing systems rely on hand-written rules (Briscoe and Carroll, 1997; Korhonen, 2002; Preiss et al., 2007) or simple co-occurrence statistics (O'Donovan et al., 2005; Chesley and Salmon-Alt, 2006; Ienco et al., 2008; Messiant et al., 2008; Lenci et al., 2008; Altamirano and Alonso i Alemany, 2010; Kawahara and Kurohashi, 2010) applied to the grammatical dependency output of supervised statistical parsers. Even the handful of recent systems

[1] The verb similarity dataset used for the evaluation of our model is publicly available at ie.technion.ac.il/∼roiri/.

that use modern machine learning techniques (Debowski, 2009; Lippincott et al., 2012; Van de Cruys et al., 2012; Reichart and Korhonen, 2013) use supervised parsers to pre-process the data[2].

Supervised parsers are notoriously sensitive to domain variation (Lease and Charniak, 2005). As annotation of data for each new domain is unrealistic, current SCF systems suffer from poor portability. This problem is compounded for the many systems that employ manually developed SCF rules because rules are inherently ignorant to domain-specific preferences. The few SCF studies that focused on specific domains (e.g. biomedicine) have reported poor performance due to these reasons (Rimell et al., 2013).

Another limitation of most current SCF systems is that they produce a *type*-level SCF lexicon (i.e. a lexicon which lists, for a given predicate, different SCF types with their relative frequencies). Such a lexicon provides a useful high-level profile of the syntactic behavior of the predicate in question, but is less useful for downstream NLP tasks (e.g. information extraction, parsing, machine translation) that involve sentence processing and can therefore benefit from SCF information at instance level. Sentences (1)-(3) demonstrate this limitation - a prior distribution over the possible syntactic frames of *distinguish* provides only a weak signal to a sentence level NLP application that needs to infer the verbal argument structure of its input sentences.

We propose a new unsupervised model for SCF induction which addresses these problems with existing systems. Our model does not use a parser or hand-written rules, only a part-of-speech (POS) tagger is utilizes in order to produce features for machine learning. While POS taggers are also sensitive to domain variation, they can be adapted to domains more easily than parsers because they require much smaller amounts of annotated data (Lease and Charniak, 2005; Ringger et al., 2007). However, as we demonstrate in our experiments, domain adaptation of POS tagging may not even be necessary to obtain good results on the SCF acquisition task.

Our model, based on the Markov Random Field (MRF) framework, performs instance-based SCF learning. It encodes syntactic similarities among verb instances across different verb types (derived from a lexical and POS-based feature representation of verb instances) as well as prior beliefs on the tendencies of specific instances of the same verb type to take the same SCF.

We evaluate our model against corpora annotated with verb instance SCFs (Quochi et al., 2012). In addition, following the Levin verb clustering tradition (Levin, 1993) which ties verb meanings with their syntactic properties, we evaluate the semantic predictive power of our clusters. In the former evaluation, our model outperforms a number of strong baselines, including supervised and type-level ones, achieving an accuracy of up to 69.2%. In the latter evaluation a vector space model that utilized our induced SCFs substantially outperforms the output of a type-level SCF system that uses the fully trained Stanford parser.

2 Previous Work

Several SCF acquisition systems are available for English (O'Donovan et al., 2005; Preiss et al., 2007; Lippincott et al., 2012; Van de Cruys et al., 2012; Reichart and Korhonen, 2013) and other languages, including French (Messiant, 2008), Italian (Lenci et al., 2008), Turkish (Uzun et al., 2008), Japanese (Kawahara and Kurohashi, 2010) and Chinese (Han et al., 2008). The prominent input to these systems are grammatical relations (GRs) which express binary dependencies between words (e.g. direct and indirect objects, various types of complements and conjunctions). These are generated by some parsers (e.g. (Briscoe et al., 2006)) and can be extracted from the output of others (De-Marneffe et al., 2006).

Two representative systems for English are the Cambridge system (Preiss et al., 2007) and the BioLexicon system which was used to acquire a substantial lexicon for biomedicine (Venturi et al., 2009). These systems extract GRs at the verb instance level from the output of a parser: the RASP general-language unlexicalized parser[3] (Briscoe et al., 2006) and the lexicalized Enju parser tuned to the biomedical domain (Miyao and Tsujii, 2005), respectively. They generate potential SCFs by mapping GRs to a predefined SCF inventory using a set of manually developed rules (the Cambridge system) or by simply considering the sets of GRs including verbs in question as potential SCFs (BioLexicon). Finally, a type level lexicon

[2](Lippincott et al., 2012) does not use a parser, but the syntactic frames induced by the system do not capture *sets of* arguments for verbs, so are not SCFs in a traditional sense.

[3]A so-called unlexicalized parser is a parser trained without explicit SCF annotations.

is built through noisy frame filtering (based on frequencies or on external resources and annotations), which aims to remove errors from parsing and argument-adjunct distinction. Clearly, these systems require extensive manual work: a-priori definition of an SCF inventory and rules, manually annotated sentences for training a supervised parser, SCF annotations for parser lexicalization, and manually developed resources for optimal filtering.

A number of recent works have applied modern machine learning techniques to SCF induction, including point-wise co-occurrence of arguments (Debowski, 2009), a Bayesian network model (Lippincott et al., 2012), multi-way tensor factorization (Van de Cruys et al., 2012) and Determinantal Point Processes (DPPs) -based clustering (Reichart and Korhonen, 2013). However, all of these systems induce type-level SCF lexicons and, except from the system of (Lippincott et al., 2012) that is not capable of learning traditional SCFs, they all rely on supervised parsers.

Our new system differs from previous ones in a number of respects. First, in contrast to most previous systems, our system provides SCF analysis for each verb instance in its sentential context, yielding more precise SCF information for systems benefiting from instance-based analysis. Secondly, it addresses SCF induction as an unsupervised clustering problem, avoiding the use of supervised parsing or any of the sources of manual supervision used in previous works. Our system relies on POS tags - however, we show that it is not necessary to train a tagger with in-domain data to obtain good performance on this task, and therefore our approach provides a more domain-independent solution to SCF acquisition.

We employ POS-tagging instead of unsupervised parsing for two main reasons. First, while a major progress has been made on unsupervised parsing (e.g. (Cohen and Smith, 2009; Berg-Kirkpatrick et al., 2010)), the performance is still considerably behind that of supervised parsing. For example, the state-of-the-art discriminative model of (Berg-Kirkpatrick et al., 2010) achieves only 63% directed arc accuracy for WSJ sentences of up to 10 words, compared to more than 95% obtained with supervised parsers. Second, current unsupervised parsers produce unlabeled structures which are substantially less useful for SCF acquisition than labeled structures produced by supervised parsers (e.g. grammatical relations).

Finally, a number of recent works addressed related tasks such as argument role clustering for SRL (Lang and Lapata, 2011a; Lang and Lapata, 2011b; Titvo and Klementiev, 2012) in an unsupervised manner. While these works differ from ours in the task (clustering arguments rather than verbs) and the level of supervision (applying a supervised parser), like us they analyze the verb argument structure at the instance level.

3 Model

We address SCF induction as an unsupervised verb instance clustering problem. Given a set of plain sentences, our algorithm aims to cluster the *verb instances* in its input into syntactic clusters that strongly correlate with SCFs. In this section we introduce a Markov Random Field (MRF) model for this task: Section 3.1 describes our model's structure, components and objective; Section 3.2 describes the model potentials and the knowledge they encode; and Section 3.3 describes how clusters are induced from the model.

3.1 Model Structure

We implement our model in the MRF framework (Koller and Friedman, 2009). This enables us to encode the two main sources of information that govern SCF selection in verb instances: (1) At the sentential context, the verbal syntactic frame is encoded through syntactic features. Verb instances with similar feature representations should therefore take the same syntactic frame; and (2) At the global context, per verb type SCF distributions tend to be Zipfian (Korhonen et al., 2000). Instances of the same verb type should therefore be biased to take the same syntactic frame.

Given a collection of plain input sentences, we denote the number of verb instances in the collection with n, and the number of data-dependent equivalence classes (ECs) with K (see below for their definition), and define an undirected graphical model (MRF), $G = (V, E, L)$. We define the vertex set as $V = X \cup C$, with $X = \{x_1, \ldots, x_n\}$ consisting of one vertex for every verb instance in the input collection, and $C = \{c_1 \ldots c_K\}$ consisting of one vertex for each data-dependent EC. The set of labels used by the model, L, corresponds to the syntactic frames taken by the verbs in the input data. The edge set E is defined through the model's potentials that are described below.

We encode information in the model through three main sets of potentials: one set of *singleton potentials* - defined over individual model vertexes, and two sets of *pairwise potentials* - defined between pairs of vertexes. The first set consists of a singleton potential for each vertex in the model. Reflecting the Zipfian distribution of SCFs across the instances of the same verb type, these potentials encourage the model to assign such verb instances to the same frame (cluster). The information encoded in these potentials is induced via a pre-processing clustering step. The second set consists of a pairwise potential for each pair of vertexes $x_i, x_j \in X$ - that is, for each verb instance pair in the input, across verb types. These potentials encode the belief, computed as feature-based similarity (see below), that their verb instance arguments implement the same SCF.

Finally, potentials from the last set bias the model to assign the same SCF to high cardinality sets of cross-type verb instances based on their syntactic context. While these are pairwise potentials defined between verb instance vertexes (X) and EC vertexes (C), they are designed so that they bias the assignment of all verb instance vertexes that are connected to the same EC vertex towards the same frame assignment ($l \in L$). The two types of pairwise potentials complement each other by modeling syntactic similarities among verb instance pairs, as well as among higher cardinality verb instance sets.

The resulted maximum aposteriori problem (MAP) takes the following form:

$$MAP(V) = \arg\max_{x,c \in V} \sum_{i=1}^{n} \theta_i(x_i) + \sum_{i=1}^{n}\sum_{j=1}^{n} \theta_{i,j}(x_i, x_j) +$$

$$\sum_{i=1}^{n}\sum_{j=1}^{K} \phi_{i,j}(x_i, c_j) \cdot I(x_i \in EC_j) + \sum_{i=1}^{K}\sum_{j=1}^{K} \xi_{i,j}(c_i, c_j)$$

where the predicate $I(x_i \in EC_j)$ returns 1 if the i-th verb instance belongs the j-th equivalence class and 0 otherwise. The ξ pairwise potentials defined between EC vertexes are very simple potentials designed to promise different assignments for each pair of EC vertexes. They do so by assigning a $-\infty$ score to assignments where their argument vertexes take the same frame and a 0 otherwise. In the rest of this section we do not get back to this simple set of potentials.

A graphical illustration of the model is given in Figure 1. Note that we could have selected a richer model structure, for example, by defining a similarity potential over all verb instance vertexes that share an equivalence class. However, as the figure demonstrates, even the structure of the pruned version of our model (see Section 3.3) usually contains cycles, which makes inference NP-hard (Shimony, 1994). Our design choices aim to balance between the expressivity of the model and the complexity of inference. In Section 3.3 we describe the LP relaxation algorithm we use for inference.

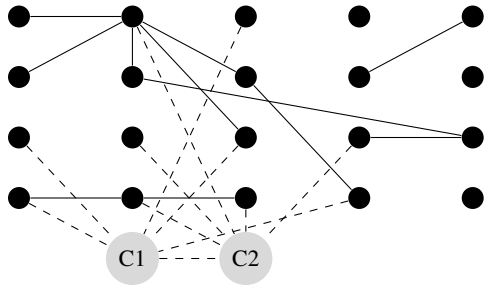

Figure 1: A graphical illustration of our model (after pruning, see Sec. 3.3) for twenty verb instances ($|X| = 20$), each represented with a black vertex, and two equivalence classes (ECs), each represented with a gray vertex ($|C| = 2$). Solid lines represent edges (and $\theta_{i,j}$ pairwise potentials) between verb instance vertexes. Dashed lines represent edges between verb instance vertexes and EC vertexes ($\phi_{i,j}$ pairwise potentials) or between EC vertexes ($\xi_{i,j}$ pairwise potentials) .

3.2 Potentials and Encoded Knowledge

Pairwise Syntactic Similarity Potentials. The pairwise syntactic similarity potentials are defined for each pair of verb instance vertexes, $x_i, x_j \in X$. They are designed to encourage the model to assign verb instances with similar fine-grained feature representations to the same frame ($l \in L$) and verb instances with dissimilar representations to different frames. For this aim, for every verb pair i, j with feature representation vectors v_i, v_j and verb instance vertexes $x_i, x_j \in X$, we define the following potential function:

$$\theta_{i,j}(x_i = l_1, x_j = l_2) = \left\{ \begin{array}{ll} \lambda(v_i, v_j) & \text{if } l_1 = l_2 \\ 0 & \text{otherwise} \end{array} \right\}$$

Where $l_1, l_2 \in L$ are label pairs and λ is a verb instance similarity function. Below we describe the feature representation and the λ function.

The verb instance feature representation is defined through the following process. For each

word instance in the input sentences we first build a basic feature representation (see below). Then, for each verb instance we construct a final feature representation defined to be the concatenation of that verb's basic feature representation with the basic representations of the words in a size 2 window around the represented verb. The final feature representation for the i-th verb instance in our dataset is therefore defined to be $v_i = [w_{-2}, w_{-1}, vb_i, w_{+1}, w_{+2}]$, where w_{-k} and w_{+k} are the basic feature representations of the words in distance $-k$ or $+k$ from the i-th verb instance in its sentence, and vb_i is the basic feature representation of that verb instance.

Our basic feature representation is inspired from the feature representation of the MST parser (McDonald et al., 2005) except that in the parser the features represent a directed edge in the complete directed graph defined over the words in a sentence that is to be parsed, while our features are generated for word n-grams. Particularly, our feature set is a concatenation of two sets derived from the MST set described in Table 1 of (McDonald et al., 2005) in the following way: (1) In both sets the parent word in the parser's set is replaced with the represented word; (2) In one set every child word in the parser's set is replaced by the word to the left of the represented word and in the other set it is replaced by the word to its right. This choice of features allows us to take advantage of a provably useful syntactic feature representation without the application of any parse tree annotation or parser.

We compute the similarity between the syntactic environments of two verb instances, i, j, using the following equation:

$$\lambda(v_i, v_j) = W \cdot \cos(v_i, v_j) - S$$

Where W is a hyperparameter designed to bias verb instances of the same verb type towards the same frame. Practically, W was tuned to be 3 for instances of the same type, and 1 otherwise [4].

While the cosine function is the standard measure of similarity between two vectors, its values are in the $[0, 1]$ range. In the MRF modeling framework, however, we must encode a negative pairwise potential value between two vertexes in order to encourage the model to assign different labels (frames) to them. We therefore added the positive hyperparameter S which was tuned, without access to gold standard manual annotations, so that there is an even number of negative and positive pairwise syntactic similarity potentials after the model is pruned (see Section 3.3) [5].

Type Level Singleton Potentials. The goal of these potentials is to bias verb instances of the same type to be assigned to the same syntactic frame while still keeping the instance based nature of our algorithm. For this aim, we applied Algorithm 1 for pre-clustering of the verb instances and encoded the induced clusters into the local potentials of the corresponding $x \in X$ vertexes. For every $x \in X$ the singleton potential is therefore defined to be:

$$\theta_i(x_i = l) = \left\{ \begin{array}{ll} F \cdot \max \lambda & \text{if } l \text{ is induced by Algorithm 1} \\ 0 & \text{otherwise} \end{array} \right\}$$

where $\max \lambda$ is the maximum λ score across all verb instance pairs in the model and $F = 0.2$ is a hyperparamter.

Algorithm 1 has two hyperparameters: T and M, the first is a similarity cut-off value used to determine the initial set of clusters, while the second is used to determine whether two clusters are similar enough to be merged. We tuned these hyperparameters, without manually annotated data, so that the number of clusters induced by this algorithm will be equal to the number of gold standard SCFs. T was tuned so that the first part of the algorithm generates an excessive number of clusters, and M was then tuned so that these clusters are merged to the desired number of clusters.

The λ function, used to measure the similarity between two verbs, is designed to bias the instances of the same verb type to have a higher similarity score. Algorithm 1 therefore tends to assign such instances to the same cluster. In our experiments that was always the case for this algorithm.

High Cardinality Verb Sets Potentials. This set of potentials aims to bias larger sets of verb instances to share the same SCF. It is inspired by (Rush et al., 2012) who demonstrated, that syntactic structures that appear at the same syntactic context, in terms of the surrounding POS tags, tend to manifest similar syntactic behavior. While they demonstrated the usefulness of their method for dependency parsing and POS tagging, we implement it for higher level SCFs.

We identified syntactic contexts that imply similar SCFs for verb instances appearing inside them.

[4] All hyperparameters that require gold-standard annotation for tuning, were tuned using held-out data (Section 4).

[5] The values in practice are $S = 0.43$ for labour legislation and $S = 0.38$ for environment.

Algorithm 1 Verb instance pre-clustering algorithm. $\hat{\lambda}$ is the average λ score between the members of its cluster arguments. T and M are hyperparametes tuned without access to gold standard data.

Contexts are characterized by the coarse POS tag to the left and to the right of the verb instance. While the number of context sets is bounded only by the number of frames our model is designed to induce, in practice we found that defining two equivalence sets led to the best performance gain, and the sets we used are presented in Table 1.

In order to encode this information into our MRF, each set of syntactic contexts is associated with an equivalence class (EC) vertex $c \in C$ and the verb instance vertexes of all verbs that appear in a context from that set are connected with an edge to c. The pairwise potential between a vertex $x \in X$ and its equivalence class is defined to be:

$$\phi_{i,j}(x_i = l_1, c_j = l_2) = \left\{ \begin{array}{ll} U & \text{if } l_1 = l_2 \\ 0 & \text{otherwise} \end{array} \right\}$$

$U = 10$ is a hyperparameter that strongly biases x vertexes to get the same SCF as their EC vertex.

3.3 Verb Cluster Induction

In this section we describe how we induce verb instance clusters from our model. This process is based on the following three steps: (1) Graph pruning; (2) Induction of an Ensemble of approximate MAP inference solutions in the resulted graphical model; and, (3) Induction of a final clustering solution based on the ensemble created at step 2. Below we explain the necessity of each of these steps and provide the algorithmic details.

EC-1		EC-2	
Left	Right	Left	Right
,	D	V	T
N	D	R	T
V	.	N	D
R	D	R	N

Table 1: POS contexts indicative for the syntactic frame of the verb instance they surround. D: *determiner*, N: *noun*, V: *verb*, T: the preposition *'to'* (which has its own POS tag in the WSJ POS tag set which we use), R: *adverb*. EC-1 and EC-2 stand for the first and second equivalence class respectively. In addition, the following contexts where associated with both ECs: $(T, D), (T, N), (N, N)$ and (V, I) where I stands for a preposition.

Graph Pruning. The edge set of our model consists of an edge for every pair of verb instance vertexes and of the edges that connect verb instance vertexes and equivalence class vertexes. This results in a large tree-width graph which substantially complicates MRF inference. To alleviate this we prune all edges with a positive score lower than p_+ and all edges with a negative score higher than p_-, where p_+ and p_- are manually tuned hyperparametes [6].

MAP Inference. For most reasonable values of p_+ and p_- our graph still contains cycles even after it is pruned, which makes inference NP-hard (Shimony, 1994). Yet, thanks to our choice of an edge-factorized model, there are various approximate inference algorithms suitable for our case.

We applied the message passing algorithm for linear-programming (LP) relaxation of the MAP assignment (MPLP, (Sontag et al., 2008)). LP relaxation algorithms for the MAP problem define an upper bound on the original objective which takes the form of a linear program. Consequently, a minimum of this upper bound can be found using standard LP solvers or, more efficiently, using specialized message passing algorithms (Yanover et al., 2006). The MPLP algorithm described in (Sontag et al., 2008) is appealing in that it iteratively computes tighter upper bounds on the MAP objective (for details see their paper).

Cluster Ensemble Generation and a Final Solution. As our MAP objective is non-convex,

[6] The values used in practice are $p_+ = 0.28, p_- = -0.17$ for the labour legislation dataset, and $p_+ = 0.25$, $p_- = -0.20$ for the environment set.

the convergent point of an optimization algorithm applied to it is highly sensitive to its initialization. To avoid convergence to arbitrary local maxima which may be of poor quality, we turn to a perturbation protocol where we repeatedly introduce random noise to the MRF's potential functions and then compute the approximate MAP solution of the resulted model using the MPLP algorithm. Noising was done by adding an ϵ term to the $lambda$ values described in section 3.2 [7]. This protocol results in a set of cluster (label) assignments for the involved verb instances, which we treat as an ensemble of experts from which a final, high quality, solution is to be induced.

The basic idea in ensemble learning is that if several experts independently cluster together two verb instances, our belief that these verbs belong in the same cluster should increase. (Reichart et al., 2012) implemented this idea through the k-way normalized cut clustering algorithm (Yu and Shi, 2003). Its input is an undirected graph $\hat{G} = (\hat{V}, \hat{E}, \hat{W})$ where $\hat{V}$ is the set of vertexes, $\hat{E}$ is the set of edges and $\hat{W}$ is a non-negative and symmetric edge weight matrix. To apply this model to our task, we construct the input graph $\hat{G}$ from the labelings (frame assignments) contained in the ensemble. The graph vertexes $\hat{V}$ correspond to the verb instances and the (i, j)-th entry of the matrix $\hat{W}$ is the number of ensemble members that assign the same label to the i-th and j-th verb instances.

For $A, B \subseteq \hat{V}$ define:

$$links(A, B) = \sum_{i \in A, j \in B} \hat{W}(i, j)$$

Using this definition, the normalized link ratio of A and B is defined to be:

$$NormLinkRatio(A, B) = \frac{links(A, B)}{links(A, \hat{V})}$$

The k-way normalized cut problem is to minimize the links that leave a cluster relative to the total weight of the cluster. Denote the set of clusterings of $\hat{V}$ that consist of k clusters by $\hat{C} = \{\hat{c_1}, \ldots \hat{c_t}\}$ and the j-th cluster of the i-th clustering by $\hat{c_{ij}}$. Then

$$c^* = \underset{\hat{c_i} \in \hat{C}}{\operatorname{argmin}} \sum_{j=1}^{k} NormLinkRatio(\hat{c_{ij}}, \hat{V} - \hat{c_{ij}})$$

The algorithm of (Yu and Shi, 2003) solves this problem very efficiently as it avoids the heavy eigenvalues and eigenvectors computations required by traditional approaches.

4 Experiments and Results

Our model is unique compared to existing systems in two respects. First, it does not utilize supervision in the form of either a supervised syntactic parser and/or manually crafted SCF rules. Consequently, it induces unnamed frames (clusters) that are not directly comparable to the named frames induced by previous systems. Second, it induces syntactic frames at the verb instance, rather than type, level. Evaluation, and especially comparison to previous work, is therefore challenging.

We therefore evaluate our system in two ways. First, we compare its output, as well as the output of a number of clustering baselines, to the gold standard annotation of corpora from two different domains (the only publicly available ones with instance level SCF annotation, to the best of our knowledge). Second, in order to compare the output of our system to a rule-based SCF system that utilizes a supervised syntactic parser, we turn to a task-based evaluation. We aim to predict the degree of similarity between verb pairs and, following (Pado and Lapata, 2007) , we do so using a *syntactic-based* vector space model (VSM). We construct three VSMs - (a) one that derives features from our clusters; (b) one whose features come from the output of a state-of-the-art verb type level, rule based, SCF system (Reichart and Korhonen, 2013) that uses a modern parser (Klein and Manning, 2003); and (c) a standard lexical VSM. Below we show that our system compares favorably in both evaluations.

Data. We experimented with two datasets taken from different domains: labor legislation and environment (Quochi et al., 2012). These datasets were created through web crawling followed by domain filtering. Each sentence in both datasets may contain multiple verbs but only one target verb has been manually annotated with a SCF. The labour legislation domain dataset contains 4415 annotated verb instances (and hence also

[7] ϵ was accepted by first sampling a number in the $[0, 1]$ range using the Java psuodorandom generator and then scaling it to 1% of $\cos(v_i, v_j)$. This value was tuned, without access to gold standard manual annotations, so that there is an even number of negative and positive pairwise syntactic similarity potentials after the model is pruned (Section 3.3).

sentences) of 117 types, and the environmental domain dataset contains 4503 annotated verb instances of 116 types. In both datasets no verb type accounts for more than 4% of the instances and only up to 35 verb types account for 1% of the instances or more. The lexical difference between the corpora is substantial: they share only 42 annotated verb types in total, of which only 2 verb types (responsible for 4.1% and 5.2% of the instances in the environment and labor legislation domains respectively) belong to the 20 most frequent types (responsible for 37.9% and 46.85% of the verb instances in the respective domains) of each corpus.

The 29 members of the SCF inventory are detailed in (Quochi et al., 2012). Table 2, presenting the distribution of the 5 highest frequency frames in each corpus, demonstrates that, in addition to the significant lexical difference, the corpora differ to some extent in their syntactic properties. This is reflected by the substantially different frequencies of the "dobj:iobj-prep:su" and "dobj:su" frames.

As a pre-processing step we first POS tagged the datasets with the Stanford tagger (Toutanova et al., 2003) trained on the standard POS training sections of the WSJ PennTreebank corpus.

4.1 Evaluation Against SCF Gold Standard

Experimental Protocol The computational complexity of our algorithm does not allow us to run it on thousands of verb instances in a feasible time. We therefore repeatedly sampled 5% of the sentences from each dataset, ran our algorithm as well as the baselines (see below) and report the average performance of each method. The number of repetitions was 40 and samples were drawn from a uniform distribution while still promising that the distribution of gold standard SCFs in each sample is identical to their distribution in the entire dataset. Before running this protocol, 5% of each corpus was kept as held-out data on which hyperparameter tuning was performed.

Evaluation Measures and Baselines. We compare our system's output to instance-level gold standard annotation. We use standard measures for clustering evaluation, one measure from each of the two leading measure types: the V measure (Rosenberg and Hirschberg, 2007), which is an information theoretic measure, and greedy many-to-one accuracy, which is a mapping-based measure. For the latter, each induced cluster is first mapped to the gold SCF frame that annotates the highest number of verb instances this induced cluster also annotates and then a standard instance-level accuracy score is computed (see, e.g., (Reichart and Rappoport, 2009)). Both measures scale from 100 (perfect match with gold standard) to 0 (no match).

As mentioned above, comparing the performance of our system with respect to a gold standard to the performance of previous type-level systems that used hand-crafted rules and/or supervised syntactic parsers would be challenging. We therefore compare our model to the following baselines: (a) The *most frequent class (MFC)* baseline which assigns all verb instances with the SCF that is the most frequent one in the *gold standard annotation* of the data; (b) The *Random* baseline which simply assigns every verb instance with a randomly selected SCF; (c) Algorithm 1 of section 3.2 which generates unsupervised verb instance clustering such that verb instances of the same type are assigned to the same cluster; and (d) Finally, we also compare our model against versions where everything is kept fixed, except a subset of potentials which is omitted. This enables us to study the intricacies of our model and the relative importance of its components. For all models, the number of induced clusters is equal to the number of SCFs in the gold standard.

Results Table 3 presents the results, demonstrating that our full model substantially outperforms all baselines. For the first two simple heuristic baselines (*MFC* and *Random*) the margin is higher than 20% for both the greedy M-1 mapping measure and the V measure. Note tat the V score of the MFC baseline is 0 by definition, as it assigns all items to the same cluster. The poor performance of these simple baselines is an indication of the difficulty of our task.

Recall that the type level clustering induced by Algorithm 1 is the main source of type level information our model utilizes (through its singleton potentials). The comparison to the output of this algorithm (the *Type Pre-clustering* baseline) therefore shows the quality of the instance level refinement our model provides. As seen in table 3, our model outperforms this baseline by 6.9% for the M-1 measure and 5.2% for the V measure.

In order to compare our model to its components we exclude either the EC potentials (ϕ and ξ) only (Model - EC), or the EC and the singleton potentials (θ_i, Model - EC - Type pre-clustering). The results show that our model gains much more

Environment		Labour Legislation	
SCF	Frequency	SCF	Frequency
dobj:su	46%	dobj:su	39%
su	9%	dobj:iobj-prep:su	15%
iobj-prep:su	8%	su	10%
dobj:iobj-prep:su	6%	su:xcompto-vbare	8%
su:xcompto-vbare	6%	iobj-prep:su	7%

Table 2: Top 5 most frequent SCFs for the Environment and Labour Legislation datasets used in our experiments.

	Environment		Labour Legislation	
	M-1	V	M-1	V
Full Model	**66.4**	**57.3**	**69.2**	**55.6**
Baselines				
MFC	46.2	0	39.4	0
Random	34.6	28.1	36.5	27.8
Type Pre-clustering	60.1	52.1	62.3	51.4
Model Components				
Model - EC	64.9	56.2	67.4	54.6
Model - EC - Type pre-clustering	48.3	48.9	45.7	44.7

Table 3: Results for our full model, the baselines (*Type Pre-clustering*: the pre-clustering algorithm (Algorithm 1 of section 3.2), *MFC*: the most frequent class (SCF) in the gold standard annotation and *Random*: random SCF assignment) and the model components. The full model outperforms all other models across measures and datasets.

from the type level information encoded through the singleton potentials than from the EC potentials. Yet, EC potentials do lead to an improvement of up to 1.5% in M-1 and up to 1.1% in V and are therefore responsible for up to 26.1% and 21.2% of the improvement over the type pre-clustering baseline in terms of M-1 and V, respectively.

4.2 Task Based Evaluation

We next evaluate our model in the context of vector space modeling for verb similarity prediction (Turney and Pantel, 2010). Since most previous word similarity works used noun datasets, we constructed a new verb pair dataset, following the protocol used in the collection of the wordSimilarity-353 dataset (Finkelstein et al., 2002).

Our dataset consists of 143 verb pairs, constructed from 122 unique verb lemma types. The participating verbs appear ≥ 10 times in the concatenation of the labour legislation and the environment datasets. Only pairs of verbs that were considered at least remotely similar by human judges (independent of those that provided the similarity scores) were included. A similarity score between 1 and 10 was assigned to each pair by 10 native English speaking annotators and were then averaged in order to get a unique pair score.

Our first baseline is a standard VSM based on lexical collocations. In this model features correspond to the number of collocations inside a size 2 window of the represented verb with each of the 5000 most frequent nouns in the Google n-gram corpus (Goldberg and Orwant, 2013). Since our corpora are limited in size, we use the collocation counts from the Google corpus.

We used our model to generate a vector representation of each verb in the following way. We run the model 5000 times, each time over a set of verbs consisting of one instance of each of the 122 verb types participating in the verb similarity set. The output of each such run is transformed to a binary vector for each participating verb, where all coordinates are assigned the value of 0, except from the one that corresponds to the cluster to which the verb was assigned which has the value of 1. The final vector representation is a concatenation of the 5000 binary vectors. Note that for this task we did not use the graph cut algorithm to generate a final clustering from the multiple MRF

runs. Instead we concatenated the output of all these runs into one feature representation that facilitates similarity prediction. For our model we estimated the verb pair similarity using the Tanimato similarity score for binary vectors:

$$T(X,Y) = \frac{\sum_i X_i \wedge Y_i}{\sum_i x_i \vee Y_i}$$

For the baseline model, where the features are collocation counts, we used the standard cosine similarity.

Our second baseline is identical to our model, except that: (a) the data is parsed with the Stanford parser (version 3.3.0, (Klein and Manning, 2003)) which was trained with sections 2-21 of the WSJ corpus; (b) the phrase structure output of the parser is transformed to the CoNLL dependency format using the official CoNLL 2007 conversion script (Johansson and Nugues, 2007); and then (c) the SCF of each verb instance is inferred using the rule-based system used by (Reichart and Korhonen, 2013). The vector space representation for each verb is then created using the process we described for our model and the same holds for vector comparison. This baseline allows direct comparison of frames induced by our SCF model with those derived from a supervised parser's output.

We computed the Pearson correlation between the scores of each of the models and the human scores. The results demonstrate the superiority of our model in predicting verb similarity: the correlation of our model with the human scores is 0.642 while the correlation of the lexical collocation baseline is 0.522 and that of the supervised parser baseline is only 0.266. The results indicate that in addition to their good alignment with SCFs, our clusters are also highly useful for verb meaning representation. This is in line with the verb clustering theory of the Levin tradition (Levin, 1993) which ties verb meaning with their syntactic properties. We consider this an intriguing direction of future work.

5 Conclusions

We presented an MRF-based unsupervised model for SCF acquisition which produces verb instance level SCFs as output. As opposed to previous systems for the task, our model uses only a POS tagger, avoiding the need for a statistical parser or manually crafted rules. The model is particularly valuable for NLP tasks benefiting from SCFs that are applied across text domains, and for the many tasks that involve sentence-level processing.

Our results show that the accuracy of the model is promising, both when compared against gold standard annotations and when evaluated in the context of a task. In the future we intend to improve our model by encoding additional information in it. We will also adapt it to a multilingual setup, aiming to model a wide range of languages.

Abstract

PCFGs with latent annotations have been shown to be a very effective model for phrase structure parsing. We present a Bayesian model and algorithms based on a Gibbs sampler for parsing with a grammar with latent annotations. For PCFG-LA, we present an additional Gibbs sampler algorithm to learn annotations from training data, which are parse trees with coarse (unannotated) symbols. We show that a Gibbs sampling technique is capable of parsing sentences in a wide variety of languages and producing results that are on-par with or surpass previous approaches. Our results for Kinyarwanda and Malagasy in particular demonstrate that low-resource language parsing can benefit substantially from a Bayesian approach.

1 Introduction

Despite great progress over the past two decades on parsing, relatively little work has considered the problem of creating accurate parsers for low-resource languages. Existing work in this area focuses primarily on approaches that use some form of cross-lingual bootstrapping to improve performance. For instance, Hwa et al. (2005) use a parallel Chinese/English corpus and an English dependency grammar to induce an annotated Chinese corpus in order to train a Chinese dependency grammar. Kuhn (2004b) also considers the benefits of using multiple languages to induce a monolingual grammar, making use of a measure for data reliability in order to weight training data based on confidence of annotation. Bootstrapping approaches such as these achieve markedly improved results, but they are dependent on the existence of a parallel bilingual corpus. Very few such corpora are readily available, particularly for low-resource languages, and creating such corpora obviously presents a challenge for many practical applications. Kuhn (2004a) shows some of the difficulty in handling low-resource languages by examining various tasks using Q'anjob'al as an example. Another approach is that of Bender et al. (2002), who take a more linguistically-motivated approach by making use of linguistic universals to seed newly developed grammars. This substantially reduces the effort by making it unnecessary to learn the basic parameters of a language, but it lacks the robustness of grammars learned from data.

Recent work on Probabilistic Context-Free Grammars with latent annotations (PCFG-LA) (Matsuzaki et al., 2005; Petrov et al., 2006) have shown them to be effective models for syntactic parsing, especially when less training material is available (Liang et al., 2009; Shindo et al., 2012). The coarse nonterminal symbols found in vanilla PCFGs are refined by latent variables; these latent annotations can model subtypes of grammar symbols that result in better grammars and enable better estimates of grammar productions. In this paper, we provide a Gibbs sampler for learning PCFG-LA models and show its effectiveness for parsing low-resource languages such as Malagasy and Kinyawanda.

Previous PCFG-LA work focuses on the problem of parameter estimation, including expectation-maximization (EM) (Matsuzaki et al., 2005; Petrov et al., 2006), spectral learning (Cohen et al., 2012; Cohen et al., 2013), and variational inference (Liang et al., 2009; Wang and Blunsom, 2013). Regardless of inference method, previous work has used the same method to parse new sentences: a Viterbi parse under a new sentence-specific PCFG obtained from an approximation of the original grammar (Matsuzaki et al., 2005). Here, we provide an alternative approach to parsing new sentences: an extension of the Gibbs sampling algorithm of Johnson et al. (2007), which learns rule probabilities in an unsupervised PCFG.

We use a Gibbs sampler to collect sampled trees theoretically distributed from the true posterior distribution in order to parse. Priors in a Bayesian model can control the sparsity of grammars (which the inside-outside algorithm fails to do), while naturally incorporating smoothing into the model (Johnson et al., 2007; Liang et al., 2009). We also build a Bayesian model for parsing with a treebank, and incorporate information from training data as a prior. Moreover, we extend the Gibbs sampler to learn and parse PCFGs with latent annotations. Learning the latent annotations is a compute-intensive process. We show how a small amount of training data can be used to bootstrap: after running a large number of sampling iterations on a small set, the resulting parameters are used to seed a smaller number of iterations on the full training data.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 290–300,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

This allows us to employ more latent annotations while maintaining reasonable training times and still making full use of the available training data.

To determine the cross-linguistic applicability of these methods, we evaluate on a wide variety of languages with varying amounts of available training data. We use English and Chinese as examples of languages with high data availability, while Italian, Malagasy, and Kinyarwanda provide examples of languages with little available data.

We find that our technique comes near state of the art results on large datasets, such as those for Chinese and English, and it provides excellent results on limited datasets – both artificially limited in the case of English, and naturally limited in the case of Italian, Malagasy, and Kinyarwanda. This, combined with its ability to run off-the-shelf on new languages without any supporting materials such as parallel corpora, make it a valuable technique for the parsing of low-resource languages.

2 Gibbs sampling for PCFGs

Our starting point is a Gibbs Sampling algorithm for vanilla PCFGs introduced by Johnson et al. (2007) for estimating rule probabilities in an unsupervised PCFG. We focus instead on using this algorithm for parsing new sentences and then extending it to learn PCFGs with latent annotations. We begin by summarizing the Bayesian PCFG and Gibbs sampler defined by Johnson et al. (2007).

Bayesian PCFG For a grammar G, each rule r in the set of rules R has an associated probability θ_r. The probabilities for all the rules that expand the same nonterminal A must sum to one: $\sum_{A\to\beta\in R}\theta_{A\to\beta}=1$.

Given an input corpus $\boldsymbol{w}$=($\boldsymbol{w^{(1)}},\cdots,\boldsymbol{w^{(n)}}$), we introduce a latent variable $\boldsymbol{t}$=($t^{(1)},\cdots,t^{(n)}$) for trees generated by G for each sentence. The joint posterior distribution of $\boldsymbol{t}$ and θ conditioned on $\boldsymbol{w}$ is:

$$\begin{aligned} p(\boldsymbol{t},\theta \mid \boldsymbol{w}) &\propto p(\theta)p(\boldsymbol{w}\mid\boldsymbol{t})p(\boldsymbol{t}\mid\theta) \\ &= p(\theta)(\prod_{i=1}^{n} p(w^{(i)}\mid t^{(i)})p(t^{(i)}\mid\theta)) \\ &= p(\theta)(\prod_{i=1}^{n} p(w^{(i)}\mid t^{(i)})\prod_{r\in R}\theta_r^{f_r(t^{(i)})}) \quad (1)\end{aligned}$$

Here $f_r(t)$ is the number of occurrences of rule r in the derivation of $\boldsymbol{t}$; $p(w^{(i)}\mid t^{(i)})=1$ if the yield of $t^{(i)}$ is the sequence $w^{(i)}$, and 0 otherwise.

We use a Dirichlet distribution parametrized by α_A: $Dir(\alpha_A)$ as the prior of the probability distribution for all rules expanding non-terminal A ($p(\theta_A)$). The prior for all θ, $p(\theta)$, is the product of all Dirichlet distributions over all non-terminals $A\in N$: $p(\theta\mid\alpha)=\prod_{A\in N}p(\theta_A\mid\alpha_A)$.

Since the Dirichlet distribution is conjugate to the Multinomial distribution, which we use to model the likelihood of trees, the conditional posterior of θ_A can be updated as follows:

$$\begin{aligned} p_G(\theta\mid\boldsymbol{t},\alpha) &\propto p_G(\boldsymbol{t}\mid\theta)p(\theta\mid\alpha) \\ &\propto (\prod_{r\in R}\theta_r^{f_r(\boldsymbol{t})})(\prod_{r\in R}\theta_r^{\alpha_r-1}) \\ &= \prod_{r\in R}\theta_r^{f_r(\boldsymbol{t})+\alpha_r-1} \quad (2)\end{aligned}$$

which is still a Dirichlet distribution with updated parameter $f_r(\boldsymbol{t})+\alpha_r$ for each rule $r\in R$.

Gibbs sampler The parameters of the PCFG model can be learned from an annotated corpus by simply counting rules. However, parsing cannot be done directly with standard CKY as with standard PCFGs, so we use the Gibbs sampling algorithm presented in Johnson et al. (2007). An additional motivation for using this algorithm is that Johnson et al. use it for learning without annotated structures, and in future work we seek to learn from fewer, and at times partial, annotations.

An advantage of using Gibbs sampling for Bayesian inference, as opposed to other approximation algorithms such as Variational Bayesian inference (VB) and Collapsed Variational Bayesian inference (CVB), is that Markov Chain Monte Carlo (MCMC) algorithms are guaranteed to converge to a sample from the true posterior under appropriate conditions (Taddy, 2011). Both VB and CVB converge to inaccurate and locally optimal solutions, like EM. In some models, CVB can achieve more accurate results due to weaker assumptions (Wang and Blunsom, 2013). Another advantage of Gibbs sampling is that the sampler allows for parallel computation by allowing each sentence to be sampled entirely independently of the others. After each parallel sampling stage, all model parameters are updated in a single step, and the process then repeats (see §2).

To sample the joint posterior $p(\boldsymbol{t},\theta\mid\boldsymbol{w})$, we sample production probabilities θ and then trees $\boldsymbol{t}$ from these conditional distributions:

$$p(\boldsymbol{t}\mid\theta,\boldsymbol{w},\alpha)=\prod_{i=1}^{n}p(t_i\mid w_i,\theta) \quad (3)$$

$$p(\theta\mid\boldsymbol{t},\boldsymbol{w},\alpha)=\prod_{A\in N}Dir(\theta_A\mid f_A(\boldsymbol{t})+\alpha_A) \quad (4)$$

Step 1: Sample Rule Probabilities. Given trees $\boldsymbol{t}$ and prior α, the production probabilities θ_A for each nonterminal $A\in N$ are sampled from a Dirichlet distribution with parameters $f_A(\boldsymbol{t})+\alpha_A$. $f_A(\boldsymbol{t})$ is a vector, and each component of $f_A(\boldsymbol{t})$, is the number of occurrences of one rule expanding nonterminal A.

Step 2: Sample Tree Structures. To sample trees from $p(t_i\mid\boldsymbol{w_i},\theta)$, we use the efficient sampling scheme used in previous work (Goodman, 1998; Finkel et al., 2006; Johnson et al., 2007). There are two parts to this algorithm. The first constructs an inside table as in the Inside-Outside algorithm for PCFGs (Lary and Young, 1990). The second selects the tree by recursively sampling productions from top to bottom.

Require: A is parent node of binary rule; $w_{i,k}$ is a span of words: $i+1<k$
function TREESAMPLER(A, i, k)
for $i < j < k$ and pair of child nodes of A:B, C **do**
$P(j, B, C) = \frac{\theta_{A\to BC}\cdot p_{B,i,j}\cdot p_{C,j,k}}{\cdot} p_{A,i,k}$
end for
Sample $j*, B*, C*$ from multinomial distribution for (j, B, C) with probabilities calculated above
return $j*, B*, C*$
end function

Algorithm 1: Sampling split position and rule to expand parent node

Consider a sentence $\boldsymbol{w}$, with sub-spans $w_{i,k} = (w_{i+1}, \cdots, w_k)$. Given $\boldsymbol{\theta}$, we construct the inside table with entries $p_{A,i,k}$ for each nonterminal and each word span $w_{i,k} : 0 \le i < k \le l$, where $p_{A,i,k} = P_{G_A}(w_{i,k}|\theta)$ is the probability that words i through k were produced by the non-terminal A. The table is computed recursively by

$$p_{A,k-1,k} = \theta_{A\to w_k} \quad (5)$$

$$p_{A,i,k} = \sum_{A\to BC\in R}\sum_{i<j<k} \theta_{A\to BC}\cdot p_{B,i,j}\cdot p_{C,j,k} \quad (6)$$

for all $A, B, C \in N$ and $0 \le i < j < k \le l$.

The resulting inside probabilities are then used to generate trees from the distribution of all valid trees of the sentence. The tree is generated from top to bottom recursively with the function $TreeSampler$ defined in Algorithm 1.

In unsupervised PCFG learning, the rule probabilities can be resampled using the sampled trees, then used to reparse the corpus, and so on. We use this property to refine latent annotations for the PCFG-LA model described in the next section.

3 PCFG with latent annotations

When labeled trees are available, rule frequencies can be directly extracted and used as priors for a PCFG. However, when learning PCFG-LAs, we must learn the fine-grained rules from the coarse trees, so we extend the Gibbs sampler to assign latent annotations to unannotated trees. The resulting learned PCFG-LA parser outputs samples of annotated trees so that we can obtain unannotated trees after marginalizing.

3.1 Model

With the PCFG-LA model (Matsuzaki et al., 2005; Petrov et al., 2006) fine-grained CFG rules are automatically induced from training, effectively providing a form of feature engineering without human intervention. Given $H = \{1, \cdots, K\}$, a set of latent annotation symbols, and $x \in H$:

- $\theta_{A[x]\to U}$ is the probability of rule $A[x] \to U$, where $U \in N\times N \cup T$. The probabilities for all rules that expand the same annotated non-terminal must sum to one.
- $\beta_{A[x],B,C\to y,z}$ is the probability of assigning latent annotation y, z to child nodes B, C of $A[x]$. $\sum_{y,z\in H\times H}\beta_{A[x],B,C\to y,z} = 1$.

The inputs to the PCFG-LA are a CFG G with finite number of latent annotations for each non-terminal, an initial guess of probabilities of grammar rule θ_0, and a prior α_θ is learned from training.

The joint posterior distribution of $\boldsymbol{t}$ and θ, β conditioned on $\boldsymbol{w}$ is:

$$\begin{aligned} p(\boldsymbol{t}, \theta, \beta \mid \boldsymbol{w}) &\propto p(\theta, \beta)p(\boldsymbol{w} \mid \boldsymbol{t})p(\boldsymbol{t} \mid \theta, \beta) \\ &= p(\theta)p(\beta)(\prod_{i=1}^{n} p(w_i \mid t_i)p(t_i \mid \theta, \beta)) \end{aligned} \quad (7)$$

We assume that θ and β are independent to get $P(\theta, \beta) = P(\theta)P(\beta)$.

To learn parameters θ, β, we use a Dirichlet distribution as a prior for both θ and β. The distribution for all rules expanding $A[x]$ is:

$$P(\theta \mid \alpha^\theta) = \prod_{A\in N, x\in H} P(\theta_{A[x]} \mid \alpha^\theta_{A[x]}) \quad (8)$$

The distribution for latent annotations associated with child nodes of $A[x] \to BC$ is:

$$P(\beta \mid \alpha^\beta) = \prod_{y,z\in H\times H} P(\beta_{A[x],B,C} \mid \alpha^\beta_{A[x],B,C}). \quad (9)$$

With this setting, the conditional posterior of $\theta_{A[x]}$ and $\beta_{A[x],B,C}$ can be updated, as in §2. For all unary and binary rules r expanding $A[x]$:

$$\theta_{A[x]} \mid \boldsymbol{t}, \alpha^\theta \sim Dir(f_r(\boldsymbol{t}) + \alpha^\theta_r) \quad (10)$$

Here, $f_r(\boldsymbol{t})$ is the number of occurrence of annotated rule r in $\boldsymbol{t}$. Also, for combination of latent annotations $y, z \in H \times H$ assigned to B, C in rule $A[x] \to B, C$:

$$\beta_{A[x],B,C} \mid \boldsymbol{t}, \alpha^\beta \sim Dir(f_d(\boldsymbol{t}) + \alpha^\beta_d) \quad (11)$$

Here, $f_d(\boldsymbol{t})$ is the number of occurrences of combination d in $\boldsymbol{t}$.

3.2 Learning PCFG-LAs from raw text

To learn from raw text, we extend the sampler in §2 to PCFG-LA. Given priors $\alpha^\theta, \alpha^\beta$ and raw text, the algorithm alternates between two steps. The first samples trees for the entire corpus; the second samples θ and β from Dirichlet distributions with updated parameters, combining priors and counts from sampled trees. The algorithm then alternates between these steps until convergence. The outputs are samples of θ, β and annotated trees.

The parsing process is specified in Algorithm 2. The first step assigns a tree to a sentence, say $w_{0,l}$. We first

Require: $w_1, \cdots, w_n$ are raw sentences; θ_0, β_0 are initial values; $\alpha^\theta, \alpha^\beta$ are priors; M is the number of iterations
function PARSE($w_1, .., w_n, \theta_0, \beta_0, \alpha^\theta, \alpha^\beta, M$)
for iteration $i = 1$ to M **do**
for sentence $s = 1$ to n **do**
Calculate Inside Table
Sample tree nodes and associated latent annotations, get tree structure $t_s^{(i)}$
end for
Sample $\theta^{(i)}$, $\beta^{(i)}$
end for
for sentence $s = 1$ to n **do**
Marginalize the latent annotations to get unannotated trees $T_s^{(1)}, \cdots, T_s^{(M)}$
Find the mode of $T_s^{(1)}, \cdots, T_s^{(M)}$: T_s
end for
return $T_1, \cdots, T_n$
end function

Algorithm 2: Parsing new sentences

construct an inside table (see §2). Each entry in the table stores the probability that a word span is produced by a given annotated nonterminal. For root node S, with θ, β and inside table $p_{A[x],i,k}$, we sample one annotation based on all $p_{S[x],0,l}$, $x \in H$. Assume that we sampled x for S, we further sample a rule to expand $S[x]$ and possible splits of the span $w_{0,l}$ jointly. Assume that we sampled nonterminals B, C to expand $S[x]$, where B is responsible for $w_{0,j}$ and C is responsible for $w_{j,l}$. We further sample annotations for B, C together, say y, z. Then we sample rules and split positions to expand $B[y]$ and $C[z]$, and continue until reaching the terminals.

This algorithm alone could be used for unsupervised learning of PCFG-LA if we input a non-informed or weakly-informed prior α^θ and α^β. With access to unannotated trees for training, we only need to assign latent annotations to them and then use the frequencies of these annotated rules as the prior when parsing. The details of training when trees are available are illustrated in §3.3.

Once we have trees (with latent annotations), the step of sampling θ and β from a Dirichlet distribution is direct. We need to count the number of occurrences $f_r(t)$ for each rule r like $A[x] \to U, U \in N \times N \cup T$ in updated annotated trees $\boldsymbol{t}$, and draw $\theta_{A[x]}$ from the updated Dirichlet distribution $Dir(f_{A[x]}(\boldsymbol{t}) + \alpha^\theta_{A[x]})$. We also need to count the number of occurrences of $f_d(t)$ for each combination of $yz \in H \times H$ assigned to B, C given $A[x] \to B, C$ in $\boldsymbol{t}$, and draw $\beta_{A[x],B,C}$ from the updated Dirichlet distribution $Dir(f_{A[x],B,C}(\boldsymbol{t}) + \alpha^\beta_{A[x],B,C})$ similarly.

To parse a sentence, we first calculate the inside table and then sample the tree.

Calculate the inside table. Given $\boldsymbol{\theta}, \boldsymbol{\beta}$ and a string $\boldsymbol{w}$=$w_{0,l}$, we construct a table with entries $p_{A[x],i,k}$ for each $A \in N$, $x \in H$ and $0 \le i < k \le l$, where $p_{A[x],i,k} = P_{G_{A[x]}}(w_{i,k}|\theta, \beta)$ is the probability that words i through k were produced by the annotated nonterminal $A[x]$. The table can be computed recursively, for all $A \in N$, $x \in H$, by

$$p_{A[x],k-1,k} = \theta_{A[x] \to w_k} \tag{12}$$

$$p_{A[x],i,k} = \sum_{A[x] \to BC : BC \in N \times N} \sum_{j : i<j<k} \sum_{yz \in H \times H} \theta_{A[x] \to BC} \beta_{A[x]BC \to yz} p_{B[y],i,j} p_{C[z],j,k} \tag{13}$$

Sample the tree, top to bottom. First, from start symbol S, sample latent annotation from multinomial with probability $\pi_{S[x]} p_{S[x],0,l}$ for each $x \in H$. Next, given annotated non-terminal $A[x]$ and i, k, sample possible child nodes and split positions from multinomial with probability:

$$p(B, C, j) = \frac{1}{p_{A[x],i,k}} \cdot \sum_{y,z \in H} \theta_{A[x] \to BC} \beta_{A[x]BC \to yz} p_{B[y],i,j} p_{C[z],j,k} \tag{14}$$

Here the probability is calculated by marginalizing all possible latent annotations for B, C, and $\theta_{A[x] \to BC} \beta_{A[x]BC \to yz}$ is the probability of choosing $B[y], C[z]$ to expand $A[x]$, and $p_{B[y],i,j} p_{C[z],j,k}$ are the probabilities for $B[y]$ and $C[z]$ to be responsible for word span $w_{i,j}$ and $w_{j,k}$ respectively. And $p_{A[x],i,k}$ is the normalizing term.

Third, given $A[x], B, C, i, j, k$, sample annotations for B, C from multinomial with probability:

$$p(y, z) = \frac{\beta_{A[x]BC \to yz} p_{B[y],i,j} p_{C[z],j,k}}{\sum_{y,z} \beta_{A[x]BC \to yz} p_{B[y],i,j} p_{C[z],j,k}} \tag{15}$$

A crucial aspect of this procedure is that all trees can be sampled independently. This parallel process produces a substantial speed gain that is important particularly when using more latent annotations. After all trees have been sampled (independently), the counts from each individual tree are combined prior to the next sampling iteration.

3.3 Learning from coarse training trees

In training, we need to learn the probabilities of fine-grained rules given coarsely-labeled trees. We perform Gibbs sampling on the training data by first iteratively sampling probabilities and then assigning annotations to tree nodes. We use the average counts of annotated production rules from sampled trees to produce the prior α^θ and α^β incorporated into parsing raw sentences.

We first index the non-terminal nodes of each tree T by $1, 2, \cdots$ from top to bottom, and left to right. Then the sampler iterates between two steps. The first samples θ, β given annotated trees (as in §3.2). The second samples latent annotations for nonterminal nodes

Require: $T_1, \cdots, T_n$ are fully parsed trees; θ_0, β_0 are initial values; $\alpha^{\theta_0}, \alpha^{\beta_0}$ are priors; M is the number of iterations
function ANNO($T_1, \cdots, T_n, \theta_0, \beta_0, \alpha^{\theta_0}, \alpha^{\beta_0}, M$)
for iteration $i = 1$ to M **do**
for sentence $s = 1$ to n **do**
Calculate inside probability
Sample latent annotations for each node in the tree, get tree with latent annotations $t_s^{(i)}$
end for
Sample $\theta^{(i)}$, $\beta^{(i)}$
end for
return Mean of number of occurrences of production rules and associated latent annotations from all sampled annotated trees
end function

Algorithm 3: Learning prior from training

in parsed trees, which also takes two steps. The first step is to, for each node in the tree, calculate and store the probability that the node is annotated by x. The second step is to jointly sample latent annotations for child nodes of root nodes, and then continue this process from top to bottom until reaching the pre-terminal nodes.

Step one: inside probabilities. Given tree T, compute $b_T^i[x]$ for each non-terminal i recursively:

1. If node N_i is a pre-terminal node above terminal symbol w, then for $x \in H$

$$b_T^i[x] = \theta_{N_i[x] \to w} \tag{16}$$

2. Otherwise, let j, k be two child nodes of i, then for $x \in H$

$$b_T^i[x] = \sum_{y,z \in H} \theta_{N_i[x] \to N_j N_k} \beta_{N_i[x] N_j N_k \to y,z} b_T^j[y] b_T^k[z] \tag{17}$$

Step two: outside sampling. Given inside probability $b_T^i[x]$ for every non-terminal i and all latent annotations $x \in H$, we sample the latent annotations from top to bottom:

1. If node i is the root node ($i = 1$), then sample $x \in H$ from a multinomial distribution with $f_T^i[x] = \pi(N_i[x])$.

2. For a parent node with sampled latent annotation $N_i[x]$ with children N_j, N_k, sample latent annotations for these two nodes from a multinomial distribution with

$$f_T^i[y,z] = \frac{1}{b_T^i[x]} \cdot \theta_{N_i[x] \to N_j N_k} \beta_{N_i[x] N_j N_k \to y,z} b_T^j[y] b_T^k[z] \tag{18}$$

After training, we take the average counts of sampled annotated rules and combinations of latent annotations as priors to parse raw sentences.

4 Experiments[1]

Our goal is to understand parsing efficacy using sampling and latent annotations for low-resource languages, so we perform experiments on five languages with varying amount of training data. We compare our results to a number of previously established baselines. First, for all languages, we use both a standard unsmoothed PCFG and the Bikel parser, trained on the training corpus. Additionally, we compare to state-of-the-art results for both English and Chinese, which have an existing body of work in PCFGs using a Bayesian framework. For Chinese, we compare to Huang & Harper (2009), using their results that only use the Chinese Treebank (CTB). For English, we compare to Liang et al. (2009). Prior results for parsing the constituency version of the Italian data are available from Alicante et al. (2012), but as they make use of a different version of the treebank including extra sentences, and additionally use the extensive functional tags present in the corpus, we do not directly compare our results to theirs.[2]

4.1 Data

English (ENG) and Chinese (CHI) are the two main languages used for this work; they are commonly used in parser evaluation and have previous examples of statistical parsers using a Bayesian framework. And since we primarily are interested in parsing low-resource languages, we include results for Kinyarwanda (KIN) and Malagasy (MLG) as examples of languages without substantial existing treebanks. Finally, as a middle-ground language, we use Italian (ITL).

For English, we use the Wall-Street Journal section of the Penn Treebank (WSJ) (Marcus et al., 1993). The data split is sections 02-21 for training, section 22 for development, and section 23 for testing. For Chinese, the Chinese Treebank (CTB5) (Xue et al., 2005) was used. The data split is files 81-899 for training, files 41-80 for development, and files 1-40/900-931 for testing.

The ITL data is from the Turin University Treebank (TUT) (Bosco et al., 2000) and consists of 2,860 Italian sentences from a variety of domains. It was split into training, development, and test sets with a 70/15/15 percentage split.

The KIN texts are transcripts of testimonies by survivors of the Rwandan genocide provided by the Kigali Genocide Memorial Center, along with a few BBC news articles. The MLG texts are articles from the websites Lakroa and La Gazette and Malagasy Global Voices. Both datasets are described in Garrette and Baldridge (2013). The KIN and MLG data is very small compared to ENG and CHI: the KIN dataset con-

[1] Code available at github.com/jmielens/gibbs-pcfg-2014, along with instructions for replicating experiments when possible

[2] As part of a standardized pre-processing step, we strip functional tags, which makes a direct comparison to their results inappropriate.

tains 677 sentences, while the MLG dataset has only 113. Also, we simulated a small training set for ENG data by using only section 02 of the WSJ for training.

4.2 Experimental Setup

As a preprocessing step, all trees are converted into Chomsky Normal-Form such that all non-terminal productions are binary and all unary chains are removed.

Additional standard normalization is performed. Functional tags (e.g. the *SBJ* part of NP-SBJ), empty nodes (traces), and indices are removed. Our binarization is simple: given a parent, select the rightmost child as the head and add a stand-in node that contains the remainder of the original children; the process then recurses. This simple technique uses no explicit head-finding rules, which eases cross-linguistic applicability.

From this normalized data, we train latent PCFGs with K=1,2,4,8,16,32 (where K=1 is equivalent to the plain PCFG described in section 2).

4.3 Practical refinements

Unknown word handling. We use a similar unknown word handling procedure to Liang et al. (2009). From our raw corpus we extract features associated with every word, these features include surrounding context words as well as substring suffix/prefix features. Using these features we produce fifty clusters using k-means. Then, as a pre-parsing step, we replace all words occurring less than five times with their cluster label - this simulates unknown words for training. Finally, during evaluation, any word not seen in training was also replaced with its corresponding cluster label. This final step is simple because there are no 'unknown unknowns' in our corpus, as the clustering has been performed over the entire corpus prior to training. This approach is similar to methods for unsupervised POS-tag induction that also utilize clusters in this manner (Dasgupta & Ng, 2007).

We compare this unknown word handling method to one in which the clustering and a classifier is trained not on the corpus under consideration, but rather on a separate corpus of unrelated data. This comparison was made to understand the effects of including the evaluation set in the training data (without labels) versus training on out-of-domain texts. This is a more realistic measurement of out-of-the-box performance of a trained model.

Jump-starting sampling. In the basic setup, training high K-value models takes a prohibitively long time, so we also consider a jump-start technique that allows larger annotation values (such as K=16) to be run in less time. We train these high-K value models first on a highly reduced training set (5% of the full training set) for a large number of iterations, and then use the found θ values as the starting point for training on the full training set for a small number of iterations. Although many of the estimated parameters on the reduced set will be zero, the prior allows us to eventually recover this information in the full set. This allows us to train on the full training set, which is desirable relative to training on a reduced set, while still allowing the model sufficient iterations to burn in. The fact that we are likely starting in a fairly good position within the search space (due to estimating θ from the corpus) also likely helps enable these lower iteration counts.

System	K=1	K=2	K=4	K=8	K=16
Unsmoothed PCFG	40.2	—	—	—	—
Bikel Parser	57.9	—	—	—	—
Liang et al. 07	60.5	71.1	77.2	**79.2**	78.2
Berkeley Parser	60.8	**74.4**	**78.4**	79.1	**78.7**
Gibbs PCFG	**61.0**	71.3	76.6	78.7	78.0

Table 1: F1 scores for small English training data experiments. 'K' is the number of latent annotations – K=1 represents a vanilla, unannotated PCFG.

5 Results

We start with Tables 1 and 2, which show performance when training on section 02 of the WSJ (pretending English is a "low-resource" language). The results show that the basic Gibbs PCFG (where K=1), with an F-score of 61.0, substantially outperforms not only an unsmoothed PCFG (the simplest baseline), but also the Bikel parser (Bikel, 2004b) trained on the same amount of data. Table 1 also shows further large gains are obtained from using latent annotations—from 60.5 for K=1 to 78.7 for K=8.

The Gibbs PCFG also compares quite favorably to the PCFG-LA of Liang et al. (2009)—slightly better for K=1 and K=2 and slightly worse for K=4 and K=8. Table 2 shows that the Gibbs PCFG is able to produce results with a smaller amount of variance relative to the Berkeley Parser, even at low training sizes. This trend is repeated in Table 3, which shows that the Gibbs PCFG also produces less variance when training on different single sections of the WSJ relative to the Berkeley Parser, although it again produces slightly lower F1 scores.

We also use the small English corpus to determine the effects of weighting the prior when sampling annotations, varying α between 0.1 and 10.0. Though performance is not sensitive to varying α for larger corpora, Figure 1 shows it can make a substantial difference for smaller corpora (with an optimal value was obtained with an α value of 5 for this small training set). This seems to indicate that the lower counts associated with the smaller training sets should be compensated for by weighting those counts more heavily when processing the evaluation set, as we had anticipated.

System	WSJ Sec. 02	KIN	MLG
Berkeley Parser	**78.3** $\pm$ **0.93**	60.6 $\pm$ 1.1	52.2 $\pm$ 2.0
Gibbs PCFG	76.7 $\pm$ 0.63	**67.2** $\pm$ **0.92**	**57.5** $\pm$ **1.1**

Table 2: F1 scores with standard deviation over ten runs of small training data, K=4.

System	F1 / StDev
Berkeley Parser	**77.5** ± **2.1**
Gibbs PCFG	77.0 ± 1.4

Table 3: F1 scores with standard deviations over twenty runs, training on individual WSJ sections (02-21).

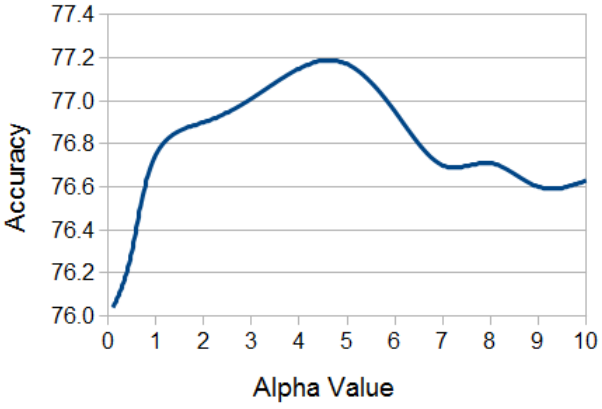

Figure 1: Accuracy by varying α levels for small English data.

To evaluate the effectiveness of the jump-start technique, we ran the full ENG data set with K=4 to compare the results from the full training setup to jump-starting. For this, we performed 100 training iterations on the reduced training set (WSJ section 02) and then used the resulting θ values to seed training on the full training set. Those training runs varied between three and nine iterations, and the results are shown in Figure 2. The full ENG K=4 F-score is 86.2, so these results represent a slight step back. Nonetheless, the technique is still valuable in that it allows for inferring latent annotations for higher K-values than would typically be available to us in a reasonable timeframe.

Table 4 shows the results for the main experiments. Sampling a vanilla PCFG (K=1) produces results that are not state-of-the-art, but still good overall and always better than an unsmoothed PCFG. The benefits of the latent annotations are further shown in the increase

Condition	ENG	CHI	ITA	KIN	MLG
Unsmoothed PCFG	69.9	66.8	62.1	45.9	49.2
Liang et al. 07	87.1	—	—	—	—
Huang & Harper09	—	**84.1**	—	—	—
Bikel Parser	86.9	81.1	**74.5**	55.7	49.5

Gibbs PCFG,K=2	82.6	79.8	69.3	65.0	57.0
Gibbs PCFG,K=4	86.0	82.3	71.9	67.2	57.8
Gibbs PCFG,K=16	87.2	83.2	72.4	**68.1**	**58.2**
Gibbs PCFG,K=32	87.4	83.4	71.0	66.8	55.3

Table 4: F1 scores for experiments on sampled PCFGs. Note that Wang and Blunsom (2013) obtain an ENG F-score of 77.9% using collapsed VB for K=2. Though they do not give exact numbers, their Fig. 7 indicates an F-score of about 87% for K=16.

Figure 2: F-Score for K=4, varying full-set training iterations (with and without 100x jump start).

of F1 score in all languages, as compared to the vanilla PCFG. Experiments were run up to K=32 primarily due to time constraint. Although previous literature results report increases up to the equivalent of K=64, it may be the case that higher K values with no merge step more easily lead to overfitting in our model – reducing the effectiveness of those high values, as shown by the overall poorer performance on several languages at K=32 when compared to K=16 as well as the general levelling-off seen at the high K values.

For English and Chinese, the previous Bayesian framework parsers outperform our own, but only by around two points. Additionally, our parsing of Chinese improves on the Bikel parser (trained on our training data) despite the fact that the Bikel parser makes use of language specific optimizations. Our parser needs no changes to switch languages.

The Gibbs PCFG with K=16 is superior to the strong Bikel and Berkeley Parser benchmarks for both KIN and MLG, a promising result for future work on parsing low-resource languages in general. Note also that our parser exhibits less variance than Berkeley Parser especially for KIN and MLG, which supports the fact that the variance of Berkeley Parser is higher for models with few subcategories (Petrov et al., 2006).

Examples of the improvement across latent annotations for a given tree are shown in Figure 3. The details of the noun phrase 'no major bond offerings' were the same for each tree, and are thus abstracted here. The low K-value tree (K=2) is shown in 3a, and primarily suffers from issues related to the prepositional phrase, 'in Europe friday'. In particular, the low K-value tree incorrectly groups 'Europe friday' as a noun phrase object of 'in'.

The higher K-value tree (K=8) is shown in 3b. This tree manages to correctly analyze the prepositional phrase, accurately separately the temporal locative 'Friday' from the actual prepositional phrase of 'in Europe'. However, the high K-value tree makes a

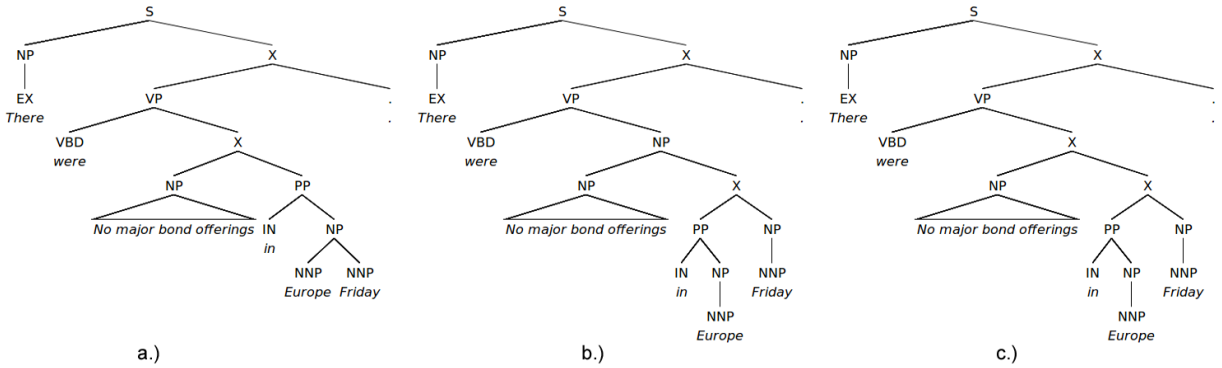

Figure 3: Examples of tree progression in the Gibbs PCFG with a) K=2, b) K=8, and c) gold tree.

different mistake that the low K-value tree did not; it groups 'no major bond offerings in Europe Friday' as a noun phrase, when it should be three separate phrases (two noun phrases and a prepositional phrase). This error may be related to the additional latent annotations. With more available noun phrase subtypes, it may be the case that a more unusual noun phrase could be permitted that would have been too low probability with only a few subtypes.

To determine whether the substantial range in F1 scores across languages are primarily the result of the much larger training corpora available for certain languages, two extreme training set reduction experiments were conducted. The training sets for all languages were reduced to a total of either 100 or 500 sentences. This process was repeated 10 times in a cross-validation setup, where 10 separate sets of sentences were selected for each language. The results of these experiments are shown in Table 5.

We conclude that while data availability is a major factor in the higher performance of English and Chinese in our original experiments, it is not the only issue. Clearly, either the linguistic facts of particular languages or perhaps choices of formalism and annotation conventions in the corpora make some of the languages more difficult to parse than others. The primary questions is why Gibbs-PCFG is able to achieve higher relative performance on the KIN/MLG datasets when compared to the other parsers, and why this advantage does not necessarily transfer to the extreme small-scale versions of the ENG/CHI/ITL data. Preliminary investigation into the properties of the corpora have revealed a number of potential answers. For instance, the POS tagsets for KIN/MLG are substantially reduced compared to the other corpora, and there are differences in the branching factor of the native versions of the corpora as well: a typical maximum branching factor for a tree in ENG/CHI/ITL is around 4-5, while for KIN/MLG it is almost always 2 (natively binary). Branching factors above 5 essentially never occur in KIN/MLG, while they are not rare in ENG/CHI/ITL. The question of exactly why the Gibbs-PCFG seems to perform well on these corpora remains an open question, but these differences could provide a starting point for future analysis.

Condition	In-Domain	Out-of-Domain
Full English (K=4)	**86.0**	83.3
Small English (K=4)	**76.6**	75.7
Kinyarwanda (K=4)	**67.2**	65.1
Malagasy (K=4)	**57.8**	55.4

Table 6: Effect of differing regimes for handling unknown words.

In addition to the actual F1 scores, the relative uniformity of the standard deviation results indicates that the individual parsers are not that much different in terms of their ability to provide consistent results at these small data extremes, as opposed to the slightly higher training levels where the Gibbs-PCFG generated smaller variances.

Considering the effects of unknown word handling, Table 6 shows that using the evaluation set when creating the unknown word classifier does improve overall parsing accuracy when compared to an unknown word handler that is trained on out-of-domain texts. This shows that results reported in previous work somewhat overstate the accuracy of these parsers when used in the wild—which matters greatly in the low-resource setting.

6 Conclusion

Our experiments demonstrate that sampling vanilla PCFGs, as well as PCFGs with latent annotations, is feasible with the use of a Gibbs sampler technique and produces results that are in line with previous parsers on controlled test sets. Our results also show that our methods are effective on a wide variety of languages—including two low-resource languages—with no language-specific model modifications needed.

Additionally, although not a uniform winner, the Gibbs-PCFG shows a propensity for performing well on naturally small corpora (here, KIN/MLG). The exact reason for this remains slightly unclear, but the fact that a similar advantage is not found for extremely small versions of large corpora indicates that our approach may be particularly well-suited for application in real low-resource environments as opposed to a sim-

ulated environment.

Having established this procedure and its relative tolerance for low amounts of data, we would like to extend the model to make use of partial bracketing information instead of complete trees, perhaps in the form of Fragmentary Unlabeled Dependency Grammar annotations (Schneider et al., 2013). This would allow the sampling procedure to potentially operate using corpora with lighter annotations than full trees, making initial annotation effort not quite as heavy and potentially increasing the amount of available data for low-resource languages. Additionally, using the expert partial annotations to help restrict the sample space could provide good gains in terms of training time.

Abstract

We introduce the task of incremental semantic role labeling (iSRL), in which semantic roles are assigned to incomplete input (sentence prefixes). iSRL is the semantic equivalent of incremental parsing, and is useful for language modeling, sentence completion, machine translation, and psycholinguistic modeling. We propose an iSRL system that combines an incremental TAG parser with a semantically enriched lexicon, a role propagation algorithm, and a cascade of classifiers. Our approach achieves an SRL F-score of 78.38% on the standard CoNLL 2009 dataset. It substantially outperforms a strong baseline that combines gold-standard syntactic dependencies with heuristic role assignment, as well as a baseline based on Nivre's incremental dependency parser.

1 Introduction

Humans are able to assign semantic roles such as agent, patient, and theme to an incoming sentence before it is complete, i.e., they incrementally build up a partial semantic representation of a sentence prefix. As an example, consider:

(1) The athlete realized [her goals]$_{\text{PATIENT/THEME}}$ were out of reach.

When reaching the noun phrase *her goals*, the human language processor is faced with a semantic role ambiguity: *her goals* can either be the PATIENT of the verb *realize*, or it can be the THEME of a subsequent verb that has not been encountered yet. Experimental evidence shows that the human language processor initially prefers the PATIENT role, but switches its preference to the *theme* role when it reaches the subordinate verb *were*. Such semantic garden paths occur because human language processing occurs word-by-word, and are well attested in the psycholinguistic literature (e.g., Pickering et al., 2000).

Computational systems for performing semantic role labeling (SRL), on the other hand, proceed non-incrementally. They require the whole sentence (typically together with its complete syntactic structure) as input and assign all semantic roles at once. The reason for this is that most features used by current SRL systems are defined globally, and cannot be computed on sentence prefixes.

In this paper, we propose incremental SRL (iSRL) as a new computational task that mimics human semantic role assignment. The aim of an iSRL system is to determine semantic roles while the input unfolds: given a sentence prefix and its partial syntactic structure (typically generated by an incremental parser), we need to (a) identify which words in the input participate in the semantic roles as arguments and predicates (the task of **role identification**), and (b) assign correct semantic labels to these predicate/argument pairs (the task of **role labeling**). Performing these two tasks incrementally is substantially harder than doing it non-incrementally, as the processor needs to commit to a role assignment on the basis of incomplete syntactic and semantic information. As an example, take (1): on reaching *athlete*, the processor should assign this word the AGENT role, even though it has not seen the corresponding predicate yet. Similarly, upon reaching *realized*, the processor can complete the AGENT role, but it should also predict that this verb also has a PATIENT role, even though it has not yet encountered the argument that fills this role. A system that performs SRL in a fully incremental fashion therefore needs to be able to assign **incomplete semantic roles,** unlike existing full-sentence SRL models.

The uses of incremental SRL mirror the applications of incremental parsing: iSRL models can be used in language modeling to assign better string probabilities, in sentence completion systems to

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 301–312,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

provide semantically informed completions, in any real time application systems, such as dialog processing, and to incrementalize applications such as machine translation (e.g., in speech-to-speech MT). Crucially, any comprehensive model of human language understanding needs to combine an incremental parser with an incremental semantic processor (Padó et al., 2009; Keller, 2010).

The present work takes inspiration from the psycholinguistic modeling literature by proposing an iSRL system that is built on top of a cognitively motivated incremental parser, viz., the Psycholinguistically Motivated Tree Adjoining Grammar parser of Demberg et al. (2013). This parser includes a predictive component, i.e., it predicts syntactic structure for upcoming input during incremental processing. This makes PLTAG particularly suitable for iSRL, allowing it to predict incomplete semantic roles as the input string unfolds. Competing approaches, such as iSRL based on an incremental dependency parser, do not share this advantage, as we will discuss in Section 4.3.

2 Related Work

Most SRL systems to date conceptualize semantic role labeling as a supervised learning problem and rely on role-annotated data for model training. Existing models often implement a two-stage architecture in which role identification and role labeling are performed in sequence. Supervised methods deliver reasonably good performance with F-scores in the low eighties on standard test collections for English (Màrquez et al., 2008; Björkelund et al., 2009).

Current approaches rely primarily on syntactic features (such as path features) in order to identify and label roles. This has been a mixed blessing as the path from an argument to the predicate can be very informative but is often quite complicated, and depends on the syntactic formalism used. Many paths through the parse tree are likely to occur infrequently (or not at all), resulting in very sparse information for the classifier to learn from. Moreover, as we will discuss in Section 4.4, such path information is not always available when the input is processed incrementally. There is previous SRL work employing Tree Adjoining Grammar, albeit in a non-incremental setting, as a means to reduce the sparsity of syntax-based features. Liu and Sarkar (2007) extract a rich feature set from TAG derivations and demonstrate that this improves SRL performance.

In contrast to incremental parsing, incremental semantic role labeling is a novel task. Our model builds on an incremental Tree Adjoining Grammar parser (Demberg et al., 2013) which predicts the syntactic structure of upcoming input. This allows us to perform incremental parsing and incremental SRL in tandem, exploiting the predictive component of the parser to assign (potentially incomplete) semantic roles on a word-by-word basis. Similar to work on incremental parsing that evaluates incomplete trees (Sangati and Keller, 2013), we evaluate the incomplete semantic structures produced by our model.

3 Psycholinguistically Motivated TAG

Demberg et al. (2013) introduce Psycholinguistically Motivated Tree Adjoining Grammar (PLTAG), a grammar formalism that extends standard TAG (Joshi and Schabes, 1992) in order to enable incremental parsing. Standard TAG assumes a lexicon of **elementary trees**, each of which contains at least one lexical item as an **anchor** and at most one leaf node as a **foot node,** marked with $A*$. All other leaves are marked with $A\downarrow$ and are called **substitution nodes.** Elementary trees that contain a foot node are called **auxiliary trees**; those that do not are called **initial trees**. Examples for TAG elementary trees are given in Figure 1a–c.

To derive a TAG parse for a sentence, we start with the elementary tree of the head of the sentence and integrate the elementary trees of the other lexical items of the sentence using two operations: **adjunction** at an internal node and **substitution** at a substitution node (the node at which the operation applies is the **integration point**). Standard TAG derivations are not guaranteed to be incremental, as adjunction can happen anywhere in a sentence, possibly violating left-to-right processing order. PLTAG addresses this limitation by introducing **prediction trees,** elementary trees without a lexical anchor. These can be used to predict syntactic structure anchored by words that appear later in an incremental derivation. The use of prediction trees ensures that fully connected **prefix trees** can be built for every prefix of the input sentence.

Each node in a prediction tree carries **markers** to indicate that this node was predicted, rather than being anchored by the current sentence prefix. An example is Figure 1d, which contains a prediction tree with marker "1". In PLTAG, markers are eliminated through a new operation called **verification**, which matches them with the nodes

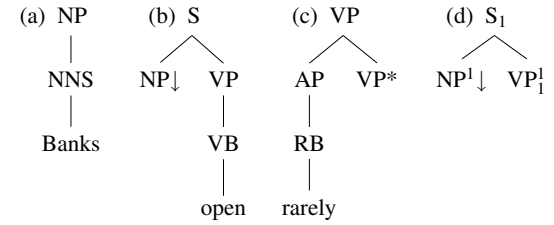

Figure 1: PLTAG lexicon entries: (a) and (b) initial trees, (c) auxiliary tree, (d) prediction tree.

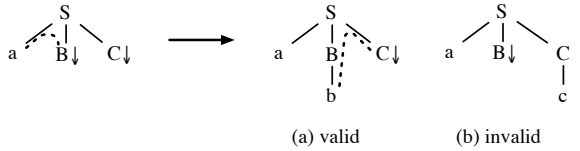

Figure 3: The current fringe (dashed line) indicates where valid substitutions can occur. Other substitutions result in an invalid prefix tree.

of non-predictive elementary trees. An example of a PLTAG derivation is given in Figure 2. In step 1, a prediction tree is introduced through substitution, which then allows the adjunction of an adverb in step 2. Step 3 involves the verification of the marker introduced by the prediction tree against the elementary tree for *open*.

In order to efficiently parse PLTAG, Demberg et al. (2013) introduce the concept of **fringes**. Fringes capture the fact that in an incremental derivation, a prefix tree can only be combined with an elementary tree at a limited set of nodes. For instance, the prefix tree in Figure 3 has two substitution nodes, for *B* and *C*. However, only substitution into *B* leads to a valid new prefix tree; if we substitute into *C*, we obtain the tree in Figure 3b, which is not a valid prefix tree (i.e., it represents a non-incremental derivation).

The parsing algorithm proposed by Demberg et al. (2013) exploits fringes to tabulate intermediate results. It manipulates a chart in which each cell (i, f) contains all the prefix trees whose first i leaves are the first i words and whose current fringe is f. To extend the prefix trees for i to the prefix trees for $i+1$, the algorithm retrieves all current fringes f such that the chart has entries in the cell (i, f). For each such fringe, it needs to determine the elementary trees in the lexicon that can be combined with f using substitution or adjunction. In spite of the large size of a typical TAG lexicon, this can be done efficiently, as it only requires matching the current fringes. For each match, the parser then computes the new prefix trees and its new current fringe f' and enters it into cell $(i+1, f')$.

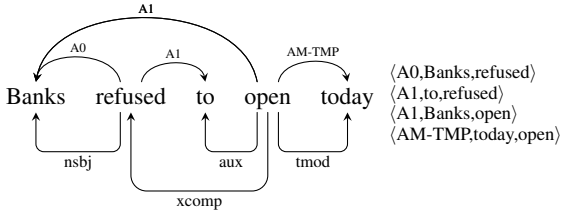

Figure 4: Syntactic dependency graph with semantic role annotation and the accompanying semantic triples, for *Banks refused to open today*.

Demberg et al. (2013) convert the Penn Treebank (Marcus et al., 1993) into TAG format by enriching it with head information and argument/modifier information from Propbank (Palmer et al., 2005). This makes it possible to decompose the Treebank trees into elementary trees as proposed by Xia et al. (2000). Prediction trees can be learned from the converted Treebank by calculating the connection path (Mazzei et al., 2007) at each word in a tree. Intuitively, a prediction tree for word w_n contains the structure that is necessary to connect w_n to the prefix tree $w_1 \ldots w_{n-1}$, but is not part of any of the elementary trees of $w_1 \ldots w_{n-1}$. Using this lexicon, a probabilistic model over PLTAG operations can be estimated following Chiang (2000).

4 Model

4.1 Problem Formulation

In a typical semantic role labeling scenario, the goal is to first identify words that are predicates in the sentence and then identify and label all the arguments for each predicate. This translates into spotting specific words in a sentence that represent the predicate's arguments, and assigning predefined semantic role labels to them. Note that in this work we focus on verb predicates only. The output of a semantic role labeler is a set of semantic dependency triples $\langle l, a, p \rangle$, with $l \in \mathcal{R}$, and $a, p \in \mathbf{w}$, where $\mathcal{R}$ is a set of semantic role labels denoting a specific relationship between a predicate and an argument (e.g., ARG0, ARG1, ARGM in Propbank), $\mathbf{w}$ is the list of words in the sentence, l denotes a specific role label, a the argument, and p the predicate. An example is shown in Figure 4.

As discussed in the introduction, standard semantic role labelers make their decisions based on evidence from the whole sentence. In contrast, our aim is to assign semantic roles incrementally, i.e.,

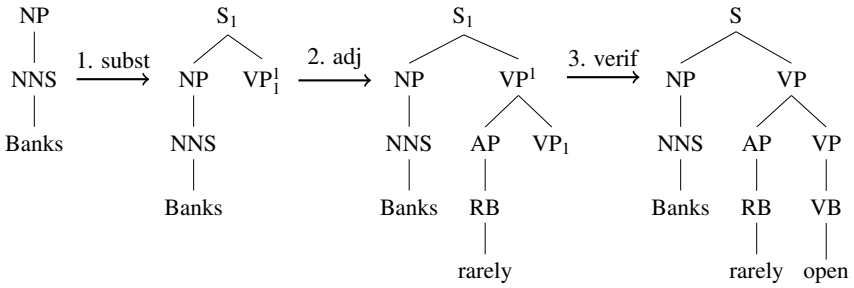

Figure 2: Incremental parse for *Banks rarely open* using the operations substitution (with a prediction tree), adjunction, and verification.

we want to produce a set of (potentially incomplete) semantic dependency triples for each prefix of the input sentence. Note that not every word is an argument to a predicate, therefore the set of triples will not necessarily change at every input word. Furthermore, the triples themselves may be incomplete, as either the predicate or the argument may not have been observed yet (**predicate-incomplete** or **argument-incomplete** triples).

Our iSRL system relies on PLTAG, using a semantically augmented lexicon. We parse an input sentence incrementally, applying a novel incremental role propagation algorithm (IRPA) that creates or updates existing semantic triple candidates whenever an elementary (or prediction) tree containing role information is attached to the existing prefix tree. As soon as a triple is completed we apply a two-stage classification process, that first identifies whether the predicate/argument pair is a good candidate, and then disambiguates role labels in case there is more than one candidate.

4.2 Semantic Role Lexicon

Recall that Propbank is used to construct the PLTAG treebank, in order to distinguish between arguments and modifiers, which result in elementary trees with substitution nodes, and auxiliary trees, i.e., trees with a foot node, respectively (see Figure 1). Conveniently, we can use the same information to also enrich the extracted lexicon with the semantic role annotations, following the process described by Sayeed and Demberg (2013).[1] For arguments, annotations are retained on the substitution node in the parental tree, while for modifiers, the role annotation is displayed on the foot node of the auxiliary tree. Note that we display role annotation on traces that are leaf nodes, which enables us to recover long-range dependencies (third and fifth tree in Figure 5a). Likewise, we annotate prediction trees with semantic roles, which enables our system to predict upcoming incomplete triples.

Our annotation procedure unavoidably introduces some role ambiguity, especially for frequently occurring trees. This can give rise to two problems when we generate semantic triples incrementally: IRPA tends to create many spurious candidate semantic triples for elementary trees that correspond to high frequency words (e.g., prepositions or modals). Secondly, a semantic triple may be identified correctly but is assigned several role labels. (See the elementary tree for *refuse* in Figure 5a.) We address these issues by applying classifiers for role label disambiguation at every parsing operation (substitution, adjunction, or verification), as detailed in Section 4.4.

4.3 Incremental Role Propagation Algorithm

The main idea behind IRPA is to create or update existing semantic triples as soon as there is available role information during parsing. Our algorithm (lines 1–6 in Algorithm 1) is applied after every PLTAG parsing operation, i.e., when an elementary or prediction tree $\mathcal{T}$ is adjoined to a particular integration point node π_{ip} of the prefix tree of the sentence, via substitution or adjunction (lines 3–4).[2] In case an elementary tree $\mathcal{T}_v$ verifies a prediction tree $\mathcal{T}_{pr}$ (lines 5–6), the same methodology applies, the only difference being that we have to tackle multiple integration point nodes $\mathcal{T}_{pr,ip}$, one for each prediction marker of $\mathcal{T}_{pr}$ that matches the corresponding nodes in $\mathcal{T}_v$.

For simplicity of presentation, we will use a concrete example, see Figure 5. Figure 5a shows the lexicon entries for the words of the sentence

[1] Contrary to Sayeed and Demberg (2013) we put role label annotations for PPs on the preposition rather than their NP child, following of the CoNLL 2005 shared task (Carreras and Màrquez, 2005).

[2] Prediction tree $\mathcal{T}_{pr}$ in our algorithm is only used during verification, so it set to nil for substitution and adjunction operations.

Banks refused to open. Naturally, some nodes in the lexicon trees might have multiple candidate role labels. For example, the substitution NP node of the second tree takes two labels, namely A0 and A1. These stem from different role *signatures* when the same elementary tree occurs in different contexts during training (A1 only on the NP; A0 on the NP and A1 on S). For simplicity's sake, we collapse different signatures, and let a classifier labeller to disambiguate such cases (see Section 4.4).

Algorithm 1 Incremental Role Propagation Alg.

```
1:  procedure IRPA(π_ip, T, T_pr)
2:      Σ ← ∅        ▷ Σ is a dictionary of (π_ip, ⟨l,a,p⟩) pairs
3:      if parser operation is substitution or adjunction then
4:          CREATE-TRIPLES(π_ip, T)
5:      else if parser operation is verification then
6:          CREATE-TRIPLES-VERIF(π_ip, T, T_pr)
        return set of triples ⟨l,a,p⟩ for prefix tree π
7:  procedure CREATE-TRIPLES(π_ip, T)
8:      if HAS-ROLES(π_ip) then
9:          UPDATE-TRIPLE(π_ip, T)
10:     else if HAS-ROLES(T) then
11:         T_ip ← substitution or foot node of T
12:         ADD-TRIPLE(π_ip, T_ip, T)
13:     for all remaining nodes n ∈ T with roles do
14:         ADD-TRIPLE(π_ip, n, T)        ▷ incomplete triples
15: procedure CREATE-TRIPLES-VERIF(π_ip, T_v, T_pr)
16:     if HAS-ROLES(T_v) then
17:         anchor ← lexeme of T_v
18:         for all T_ip ← node in T_v with role do
19:             T_pr,ip ← matching node of T_ip in T_pr
20:             CREATE-TRIPLES(T_pr,ip, T_v)
        ▷ Process the rest of covered nodes in T_pr with roles
21:     for all remaining T_pr,ip ← node in T_pr with role do
22:         UPDATE-TRIPLE(T_pr,ip, T_pr)
23: function UPDATE-TRIPLE(π_ip, T)
24:     dep ← FIND-INCOMPLETE(Σ, T_ip)
25:     anchor ← lexeme of T
26:     if anchor of T is predicate then
27:         SET-PREDICATE(dep, anchor)
28:     else if anchor of T is argument then
29:         SET-ARGUMENT(dep, anchor)
        return dep
30: procedure ADD-TRIPLE(π_ip, T_ip, T)
31:     dep ← ⟨[roles of T_ip], nil, nil⟩
32:     anchor ← lexeme of T
33:     if anchor of T is predicate then
34:         SET-PREDICATE(dep, anchor)
35:         SET-ARGUMENT(dep, head of π_ip)
36:     else if anchor of T is argument then
37:         if T is auxiliary then                ▷ adjunction
38:             SET-ARGUMENT(dep, anchor)
39:         else        ▷ substitution: arg is head of prefix tree
40:             SET-ARGUMENT(dep, head of T_ip)
41:             pred ← find dep ∈ Σ with matching π_ip
42:             SET-PREDICATE(dep, pred)
43:     Σ ← (π_ip, dep)
```

Once we process *Banks*, the prefix tree becomes the lexical entry for this word, see the first column of Figure 5b. Next, we process *refused*: the parser substitutes the prefix tree into the elementary tree $\mathcal{T}$ of *refused*;[3] the integration point π_{ip} on the prefix tree is the topmost NP. Since the operation is a substitution (line 3), we create triples between $\mathcal{T}$ and π_{ip} via CREATE-TRIPLES (lines 7–12). π_{ip} does not have any role information (line 8), so we proceed to add a new semantic triple between the role-labeled integration point $\mathcal{T}_{ip}$, i.e., substitution NP node of $\mathcal{T}$, and π_{ip}, via ADD-TRIPLE (lines 30–43). First, we create an incomplete semantic triple with all roles from $\mathcal{T}_{ip}$ (line 31). Then we set the predicate to the anchor of $\mathcal{T}$ to be the word *refused*, and the argument to be the head word of the prefix tree, *Banks* (lines 34–35). Note that predicate identification is a trivial task based on part-of-speech information in the elementary tree.[4]

Then, we add the pair (NP $\rightarrow$ ⟨{A0,A1},Banks, refused⟩) to a dictionary (line 43). Storing the integration point along with the semantic triple is essential, to be able to recover incomplete triples in later stages of the algorithm. Finally, we repeat this process for all remaining nodes on $\mathcal{T}$ that have roles, in our example the substitution node S (lines 13–14). This outputs an incomplete triple, ⟨{A1},nil,refused⟩.

Next, the parser decides to substitute a prediction tree (third tree in Figure 5a) into the substitution node S of the prefix tree. Since the integration point is on the prefix tree and has role information (line 8), the corresponding triple should already be present in our dictionary. Upon retrieving it, we set the nil argument to the anchor of the incoming tree. Since it is a prediction tree, we set it to the root of the tree, namely S_2 (phrase labels in triples are denoted by italics), but mark the triple as yet incomplete. This distinction allows us to fill in the correct lexical information once it becomes available, i.e, when the tree gets verified. We also add an incomplete triple for the trace t in the subject position of the prediction tree, as described above. Note that this triple contains multiple roles; this is expected given that prediction trees are unlexicalized and occur in a wide variety of contexts.

When the next verb arrives, the parser successfully verifies it against the embedded prediction

[3] PLTAG parsing operations can occur in two ways: An elementary tree can be substituted into the substitution node of the prefix tree, or the prefix tree can be substituted into a node of an elementary tree. The same holds for adjunction.

[4] Most predicates can be identified as anchors of non-modifier auxiliary trees. However, there are exceptions to this rule, i.e., modifier auxiliary trees and non-modifier non-auxiliary trees being also verbs in our lexicon, hence the use of the more reliable POS tags.

	IRPA	MaltParser
Banks	–	–
refused	⟨{A0,A1},Banks,refused⟩, ⟨A1,S_2,refused⟩, ⟨{A0,A1,A2},*t*,nil⟩	⟨A0,Banks,refused⟩
to	–	–
open	⟨A1,to,refused⟩, ⟨A1,Banks,open⟩	⟨A1,to,refused⟩, ⟨A0,Banks,open⟩
today	⟨AM-TMP,today,open⟩	⟨AM-TMP,today,open⟩

Table 1: Complete and incomplete semantic triple generation, comparing IRPA and a system that maps gold-standard role labels onto MaltParser incremental dependencies for Figure 4.

tree within the prefix tree (last step of Figure 5b). Our algorithm first cycles through all nodes that match between the verification tree $\mathcal{T}_v$ and the prediction tree $\mathcal{T}_{pr}$ and will complete or create new triples via CREATE-TRIPLES (lines 18–20). In our example, the second semantic triple gets completed by replacing S_2 with the head of the subtree rooted in S. Normally, this would be the verb *open*, but in this case the verb is followed by the infinitive marker *to*, hence we heuristically set it to be the argument of the triple instead, following Carreras and Màrquez (2005). For the last triple, we set the predicate to the anchor of $\mathcal{T}_v$ *open*, and now are able to remove the excess role labels A0 and A2. This illustrated how the lexicalized verification tree disambiguates the semantic information stored in the prediction tree. Finally, trace *t* is set to the closest NP head that is below the same phrase subtree, in this case *Banks*. Note that *Banks* is part of two triples as shown in the last tree of Figure 5b: it is either an A0 or an A1 for *refused* and an A1 for *open*.

We are able to create incomplete semantic triples after the prediction of the upcoming verb at step 2, as shown in Figure 5b. This is not possible using an incremental dependency parser such as MaltParser (Nivre et al., 2007) that lacks a predictive component. Table 1 illustrates this by comparing the output of IRPA for Figure 5b with the output of a baseline system that maps role labels onto the syntactic dependencies in Figure 4, generated incrementally by MaltParser (see Section 5.3 for a description of the MaltParser baseline). MaltParser has to wait for the verb *open* before outputting the relevant semantic triples. In contrast, IRPA outputs incomplete triples as soon as the information is available, and later on updates its decision. (MaltParser also incorrectly assigns A0 for the *Banks–open* pair.)

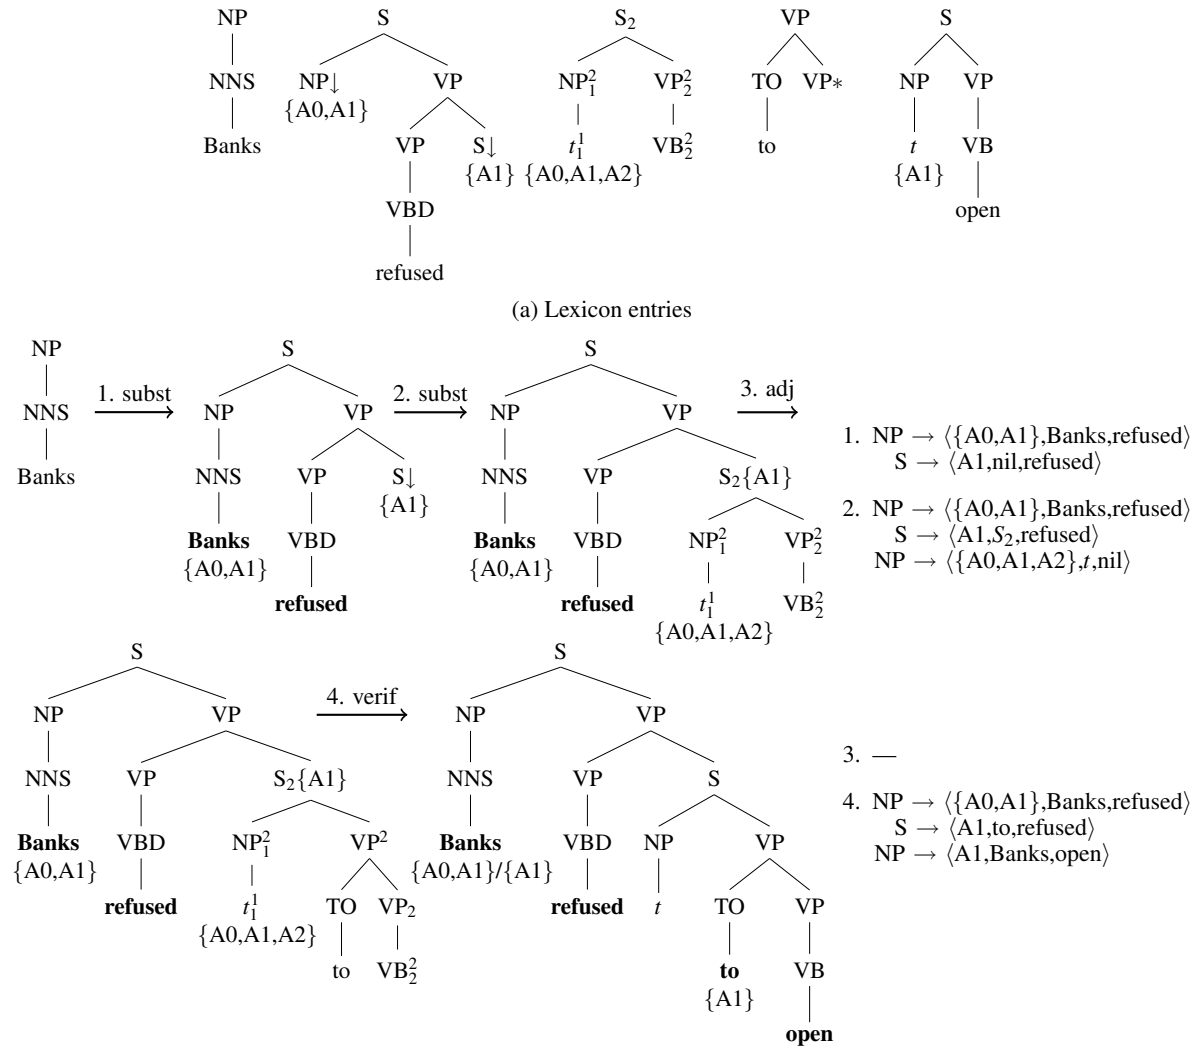
4.4 Argument Identification and Role Label Disambiguation

IRPA produces semantic triples for every role annotation present in the lexicon entries, which will often overgenerate role information. Furthermore, some triples have more than one role label attached to them. During verification, we are able to filter out the majority of labels in the corresponding prediction trees; However, most triples are created via substitution and adjunction.

In order to address these problems we adhere to the following classification and ranking strategy: after each semantic triple gets completed, we perform a binary classification that evaluates its suitability as a whole, given bilexical and syntactic information. If the triple is identified as a good candidate, then we perform multi-class classification over role labels: we feed the same bilexical and syntactic information to a logistic classifier, and get a ranked list of labels. We then use this list to re-rank the existing ambiguous role labels in the semantic triple, and output the top scoring ones.

The identifier is a binary L2-loss support vector classifier, and the role disambiguator an L2-regularized logistic regression classifier, both implemented using the efficient LIBLINEAR framework of Fan et al. (2008). The features used are based on Björkelund et al. (2009) and Liu and Sarkar (2007), and are listed in Table 2.

The bilexical features are: predicate POS tag, predicate lemma, argument word form, argument POS tag, and position. The latter indicates the position of the argument relative to the predicate, i.e., before, on, or after. The syntactic features are: the predicate and argument elementary trees without the anchors (to avoid sparsity), the category of the integration point node on the prefix tree where the elementary tree of the argument attaches to, an alphabetically ordered set of the categories of the fringe nodes of the prefix tree after attaching the argument tree, and the path of PLTAG operations applied between the argument and the predicate. Note that most of the original features used by Björkelund et al. (2009) and others are not applicable in our context, as they exploit information that is not accessible incrementally. For example, sibling information to the right of the word is not available. Furthermore, our PLTAG parser does not compute syntactic dependencies, hence these cannot serve as features (and in any case not all dependencies are available incrementally, see Figure 4). To counterbalance this, we use local syntactic information stored in the fringe of the pre-



(a) Lexicon entries

fix tree. We also store the series of operations applied by our parser between argument and predicate, in an effort to emulate the effect of recovering longer-range patterns.

5 Experimental Design

5.1 PLTAG and Classifier Training

We extracted the semantically-enriched lexicon and trained the PLTAG parser by converting the Wall Street Journal part of Penn Treebank to PLTAG format. We used Propbank to retrieve semantic role annotation, as described in Section 4.2. We trained the PLTAG parser according to Demberg et al. (2013) and evaluated the parser on section 23, on sentences with 40 words or less, given gold POS tags for each word, and achieved a labeled bracket F_1 score of 79.41.

In order to train the argument identification and role label disambiguation classifiers, we used the English portion of the CoNLL 2009 Shared Task (Hajič et al., 2009; Surdeanu et al., 2008). It consists of the Penn Treebank, automatically converted to dependencies following Johansson and

Nugues (2007), accompanied by semantic role label annotation for every argument pair. The latter is converted from Propbank based on Carreras and Màrquez (2005). We extracted the bilexical features for the classifiers directly from the gold standard annotation of the training set. The syntactic features were obtained as follows: for every sentence in the training set we applied IRPA using the trained PLTAG parser, with gold standard lexicon entries for each word of the input sentence. This ensures near perfect parsing accuracy. Then for each semantic triple predicted incrementally, we extracted the relevant syntactic information in order to construct training vectors. If the identified predicate-argument pair was in the gold standard then we assigned a positive label for the identification classifier, otherwise we flagged it as negative. For those pairs that are not identified by IRPA but exist in the gold standard (false negatives), we extracted syntactic information from already identified similar triples, as follows: We first look for correctly identified arguments, wrongly attached to a different predicate and re-create the triple with correct predicate/argument information. If no argument is found, we then pick the argument in the list of identified arguments for a correct predicate with the same POS-tag as the gold-standard argument. In the case of the role label disambiguation classifier we just assign the gold label for every correctly identified pair, and ignore the (possibly ambiguous) predicted one. After tuning on the development set, the argument identifier achieved an accuracy of 92.18%, and the role label disambiguation classifier, 82.37%.

5.2 Evaluation

The focus of this paper is to build a system that is able to output semantic role labels for predicate-argument pairs incrementally, as soon as they become available. In order to properly evaluate such a system, we need to measure its performance incrementally. We propose two different cumulative scores for assessing the (possibly incomplete) semantic triples that have been created so far, as the input is processed from left to right, *per word.* The first metric is called Unlabeled Prediction Score (UPS) and gets updated for every identified argument or predicate, even if the corresponding semantic triple is incomplete. Note that UPS does not take into account the role label, it only measures predicate and argument identification. In this respect it is analogous to unlabeled dependency accuracy reported in the parsing literature. We expect a model that is able to predict semantic roles to achieve an improved UPS result compared to a system that does not do prediction, as illustrated in Table 1. Our second score, Combined Incremental SRL Score (CISS), measures the identification of complete semantic role triples (i.e., correct predicate, predicate sense, argument, and role label) per word; by the end of the sentence, CISS coincides with standard combined SRL accuracy, as reported in CoNLL 2009 SRL-only task. This score is analogous to labeled dependency accuracy in parsing.

Note that conventional SRL systems such as Björkelund et al. (2009) typically assume gold standard syntactic information. In order to emulate this, we give our parser gold standard lexicon entries for each word in the test set; these contain all possible roles observed in the training set for a given elementary tree (and all possible senses for each predicate). This way the parser achieves a syntactic parsing F_1 score of 94.24, thus ensuring the errors of our system can be attributed to IRPA and the classifiers. Also note that we evaluate on verb predicates only, therefore trivially reducing the task of predicate identification to the simple heuristic of looking for words in the sentence with a verb-related POS tag and excluding auxiliaries and modals. Likewise, predicate sense disambiguation on verbs presumably is trivial, as we observed almost no ambiguity of senses among lexicon entries of the same verb (we adhered to a simple majority baseline, by picking the most frequent sense, given the lexeme of the verb, in the few ambiguous cases). It seems that the syntactic information held in the elementary trees discriminates well among different senses.

5.3 System Comparison

We evaluated three configurations of our system. The first configuration (iSRL) uses all semantic roles for each PLTAG lexicon entry, applies the PLTAG parser, IRPA, and both classifiers to perform identification and disambiguation, as described in Section 4. The second one (Majority-Baseline), solves the problem of argument identification and role disambiguation without the classifiers. For the former we employ a set of heuristics according to Lang and Lapata (2014), that rely on gold syntactic dependency information, sourced from CoNLL input. For the latter, we choose the most frequent role given the gold standard dependency relation label for the particular argument. Note that dependencies have been produced in view of the whole sentence and not incrementally.

System	Prec	Rec	F1
iSRL-Oracle	91.00	80.26	85.29
iSRL	81.48	75.51	78.38
Majority-Baseline	71.05	58.10	63.92
Malt-Baseline	60.90	46.14	52.50

Table 3: Full-sentence combined SRL score

This gives the baseline a considerable advantage especially in case of longer range dependencies. The third configuration (iSRL-Oracle), is identical to iSRL, but uses the gold standard roles for each PLTAG lexicon entry, and thus provides an upper-bound for our methodology. Finally, we evaluated against Malt-Baseline, a variant of Majority-Baseline that uses the MaltParser of Nivre et al. (2007) to provide labeled syntactic dependencies MaltParser is a state-of-the-art shift-reduce dependency parser which uses an incremental algorithm. Following Beuck et al. (2011), we modified the parser to provide intermediate output at each word by emitting the current state of the dependency graph before each shift step. We trained MaltParser using the arc-eager algorithm (which outperformed the other parsing algorithms available with MaltParser) on the CoNLL dataset, achieving a labeled dependency accuracy of 89.66% on section 23.

6 Results

Figures 6 and 7 show the results on the incremental SRL task. We plot the F_1 for Unlabeled Prediction Score (UPS) and Combined Incremental SRL Score (CISS) per word, separately for sentences of lengths 10, 20, 30, and 40 words. The task gets harder with increasing sentence length, hence we can only meaningfully compare the average scores for sentence of the same length. (This approach was proposed by Sangati and Keller 2013 for evaluating the performance of incremental parsers.)

The UPS results in Figure 6 clearly show that our system (iSRL) outperforms both baselines on unlabeled argument and predicate prediction, across all four sentence lengths. Furthermore, we note that the iSRL system achieves a near-constant performance for all sentence prefixes. Our PLTAG-based prediction/verification architecture allows us to correctly predict incomplete semantic role triples, even at the beginning of the sentence. Both baselines perform worse than the iSRL system in general. Moreover, the Malt-Baseline performs badly on the initial sentence prefixes (up to word 10), presumably as it does not benefit from syntactic prediction, and thus cannot generate incomplete triples early in the sentence, as illustrated in Table 1. The Majority-Baseline also does not do prediction, but it has access to gold-standard syntactic dependencies, and thus outperforms the Malt-Baseline on initial sentence prefixes. Note that due to prediction, our system tends to over-generate incomplete triples in the beginning of sentences, compared to non-incremental output, which may inflate UPS for the first words. However, this cancels out later in the sentence if triples are correctly completed; failure to do so would decrease UPS. The near-constant performance of our output illustrates this phenomenon. Finally, the iSRL-Oracle outperforms all other systems, as it benefits from correct role labels and correct PLTAG syntax, thus providing an upper limit on performance.

The CISS results in Figure 7 present a similar picture. Again, the iSRL system outperforms both baselines at all sentence lengths. In addition, it shows particularly strong performance (almost at the level of the iSRL-Oracle) at the beginning of the sentence. This presumably is due to the fact that our system uses prediction and is able to identify correct semantic role triples earlier in the sentence. The baselines also show higher performance early in the sentence, but to a lesser degree.

Table 3 reports traditional combined SRL scores for full sentences over all sentence lengths, as defined for the CoNLL task. Our iSRL system outperforms the Majority-Baseline by almost 15 points, and the Malt-Baseline by 25 points. It remains seven points below the iSRL-Oracle upper limit.

Finally, in order to test the effect of syntactic parsing on our system, we also experimented with a variant of our iSRL system that utilizes all lexicon entries for each word in the test set. This is similar to performing the CoNLL 2009 joint task, which is designed for systems that carry out both syntactic parsing and semantic role labeling. This variant achieved a full sentence F-score of 68.0%, i.e., around 10 points lower than our iSRL system. This drop in score correlates with the difference in syntactic parsing F-score between the two versions of PLTAG parser (94.24 versus 79.41), and is expected given the high ambiguity of the lexicon entries for each word. Note, however, that the full-parsing version of our system still outperforms Malt-Baseline by 15 points.

7 Conclusions

In this paper, we introduced the new task of incremental semantic role labeling and proposed a system that solves this task by combining an incremental TAG parser with a semantically enriched lexicon, a role propagation algorithm, and a cascade of classifiers. This system achieved a full-sentence SRL F-score of 78.38% on the standard CoNLL dataset. Not only is the full-sentence score considerably higher than the Majority-Baseline (which is a strong baseline, as it uses gold-standard syntactic dependencies), but we also observe that our iSRL system performs well incrementally, i.e., it predicts both complete and incomplete semantic role triples correctly early on in the sentence. We attributed this to the fact that our TAG-based architecture makes it possible to predict upcoming syntactic structure together with the corresponding semantic roles.

Abstract

The informal nature of social media text renders it very difficult to be automatically processed by natural language processing tools. Text normalization, which corresponds to restoring the non-standard words to their canonical forms, provides a solution to this challenge. We introduce an unsupervised text normalization approach that utilizes not only lexical, but also contextual and grammatical features of social text. The contextual and grammatical features are extracted from a word association graph built by using a large unlabeled social media text corpus. The graph encodes the relative positions of the words with respect to each other, as well as their part-of-speech tags. The lexical features are obtained by using the longest common subsequence ratio and edit distance measures to encode the surface similarity among words, and the double metaphone algorithm to represent the phonetic similarity. Unlike most of the recent approaches that are based on generating normalization dictionaries, the proposed approach performs normalization by considering the context of the non-standard words in the input text. Our results show that it achieves state-of-the-art F-score performance on standard datasets. In addition, the system can be tuned to achieve very high precision without sacrificing much from recall.

1 Introduction

Social text, which has been growing and evolving steadily, has its own lexical and grammatical features (Choudhury et al., 2007; Eisenstein, 2013). *lol* meaning *laughing out loud*, *xoxo* meaning *kissing*, *4u* meaning *for you* are among the most commonly used examples of this jargon. In addition, these informal expressions in social text usually take many different lexical forms when generated by different individuals (Eisenstein, 2013). The limited accuracies of the Speech-to-Text (STT) tools in mobile devices, which are increasingly being used to post messages on social media platforms, along with the scarcity of attention of the users result in additional divergence of social text from more standard text such as from the newswire domain. Tools such as spellchecker and slang dictionaries have been shown to be insufficient to cope with this challenge long time ago (Sproat et al., 2001). In addition, most Natural Language Processing (NLP) tools including named entity recognizers and dependency parsers generally perform poorly on social text (Ritter et al., 2010).

Text normalization is a preprocessing step to restore non-standard words in text to their original (canonical) forms to make use in NLP applications or more broadly to understand the digitized text better (Han and Baldwin, 2011). For example, *talk 2 u later* can be normalized as *talk to you later* or similarly *enormoooos, enrmss* and *enourmos* can be normalized as *enormous*. Other examples of text messages from Twitter and their corresponding normalized forms are shown in Table 1.

The non-standard words in text are referred to as Out of Vocabulary (OOV) words. The normalization task restores the OOV words to their In Vocabulary (IV) forms. Social text is continuously evolving with new words and named entities that are not in the vocabularies of the systems (Hassan and Menezes, 2013). Therefore, not every OOV word (e.g. *iPhone, WikiLeaks or tok-*

Table 1: Sample tweets and their normalized forms.

enizing) should be considered for normalization. The OOV tokens that should be considered for normalization are referred to as ill-formed words. Ill-formed words can be normalized to different canonical words depending on the context of the text. For example, let's consider the two examples in Table 1. "y" is normalized as "you" in the first one and as "why" in the second one.

In this paper, we propose a graph-based text normalization method that utilizes both contextual and grammatical features of social text. The contextual information of words is modeled by a word association graph that is created from a large social media text corpus. The graph represents the relative positions of the words in the social media text messages and their Part-of-Speech (POS) tags. The lexical similarity features among the words are modeled using the longest common subsequence ratio and edit distance that encode the surface similarity and the double metaphone algorithm that encodes the phonetic similarity. The proposed approach is unsupervised, which is an important advantage over supervised systems, given the continuously evolving language in the social media domain. The same OOV word may have different appropriate normalizations depending on the context of the input text message. Recently proposed dictionary-based text normalization systems perform dictionary look-up and always normalize the same OOV word to the same IV word regardless of the context of the input text (Han et al., 2012; Hassan and Menezes, 2013). On the other hand, the proposed approach does not only make use of the general context information in a large corpus of social media text, but it also makes use of the context of the OOV word in the input text message. Thus, an OOV word can be normalized to different IV words depending on the context of the input text.

2 Related Work

Early work on text normalization mostly made use of the noisy channel model. The first work that had a significant performance improvement over the previous research was by Brill and Moore (2000). They proposed a novel noisy channel model for spell checking based on string to string edits. Their model depended on probabilistic modeling of sub-string transformations.

Toutanova and Moore (2002) improved this approach by extending the error model with phonetic similarities over words. Their approach is based on learning rules to predict the pronunciation of a single letter in the word depending on the neighbouring letters in the word.

Choudhury et al. (2007) developed a supervised Hidden Markov Model based approach for normalizing Short Message Service (SMS) texts. They proposed a word for word decoding approach and used a dictionary based method to normalize commonly used abbreviations and non-standard usage (e.g. "howz" to "how are" or "aint" to "are not"). Cook and Stevenson (2009) extended this model by introducing an unsupervised noisy channel model. Rather than using one generic model for all word formations as in (Choudhury et al., 2007), they used a mixture model in which each different word formation type is modeled explicitly.

The limitations of these methods were that they did not consider contextual features and assumed that tokens have unique normalizations. In the text normalization task several OOV tokens are ambiguous and without contextual information it is not possible to build models that can disambiguate transformations correctly.

Aw et al. (2006) proposed a phrase-based statistical machine translation (MT) model for the text normalization task. They defined the problem as translating the SMS language to the English language and based their model on two submodels: a word based language model and a phrase based lexical mapping model (channel model). Their system also benefits from the input context and they argue that the strength of their model is in its ability to disambiguate mapping as in "2" → "two" *or* "to", and "w" → "with" *or* "who". Making use of the whole conversation, this is the closest approach to ours in the sense of utilizing contextual sensitivity and coverage.

Pennell and Liu (2011) on the other hand, proposed a character level MT system, that is robust to new abbreviations. In their two phased system, a character level trained MT model is used to produce word hypotheses and a trigram LM is used to choose a hypothesis that fits into the input context.

The MT based models are supervised models, a drawback of which is that they require annotated data. Annotated training data is not readily available and is difficult to create especially for the rapidly evolving social media text (Yang and Eisenstein, 2013).

More recent approaches handled the text normalization task by building normalization lexicons. Han and Baldwin (2011) developed a two phased model, where they only consider the ill-formed OOV words for normalization. First, a confusion set is generated using the lexical and phonetic distance features. Later, the candidates in the confusion set are ranked using a mixture of dictionary look up, word similarity based on lexical edit distance, phonemic edit distance, prefix sub-string, suffix sub-string and longest common subsequence (LCS), as well as context support metrics. Chrupala (2014) on the other hand achieved lower word error rates without using any lexical resources.

Gouws et al. (2011) investigated the distinct contributions of features that are highly depended on user-centric information such as the geological location of the users and the twitter client that the tweet is received from. Using such user-based contextual metrics they modelled the transformation distributions across populations.

Liu et al. (2012) proposed a broad coverage normalization system, which integrates an extended noisy channel model, that is based on enhanced letter transformations, visual priming, string and phonetic similarity. They try to improve the performance of the top n normalization candidates by integrating human perspective modeling.

Yang and Eisenstein (2013) introduced an unsupervised log linear model for text normalization. Their joint statistical approach uses local context based on language modeling and surface similarity. Along with dictionary based models, Yang and Eisenstein's model have obtained a significant improvement on the performance of text normalization systems.

Another relevant study is conducted by Hassan and Menezes (2013), who generated a normalization lexicon using Markov random walks on a contextual similarity lattice that they created using 5-gram sequences of words. The best normalization candidates are chosen using the average hitting time and lexical similarity features. Context of a word in the center of a 5-gram sequence is defined by the other words in the 5-gram. Even if one word is not the same, the context is considered to be different. This is a relatively conservative way for modeling the prior contexts of words. In our model, we filtered candidate words based on their grammatical properties and let each neighbouring token to contribute to the prior context of a word, which leads to both a higher recall and a higher precision.

3 Methodology

In this paper, we propose a graph-based approach that models both contextual and lexical similarity features among an ill-formed OOV word and candidate IV words. An input text is first preprocessed by tokenizing and Part-Of-Speech (POS) tagging. If the text contains an OOV word, the normalization candidates are chosen by making use of the contextual features, which are extracted from a pre-generated directed word association graph, as well as lexical similarity features. Lexical similarity features are based on edit distance, longest common subsequence ratio, and double metaphone distance. In addition, a slang dictionary[1] is used as an external resource to enrich the normalization candidate set. The details of the approach are explained in the following subsections.

3.1 Preprocessing

After tokenization, the next step in the pipeline is POS tagging each token using a POS tagger specifically designed for social media text. Unlike the regular POS taggers designed for well-written newswire-like text, social media POS taggers provide a broader set of tags specific to the peculiarities of social text (Owoputi et al., 2013; Gimpel et al., 2011). Using this extended set of tags we can identify tokens such as discourse markers (e.g. rt for retweets, cont. for a tweet whose content follows up in the coming tweet) or URLs. This enables us to model better the context of the words in social media text. A sample preprocessed sentence is shown in Table 3.

[1] http://www.noslang.com

As shown in Table 2, after preprocessing, each token is assigned a POS tag with a confidence score between 0 and 1[2]. Later, we use these confidence scores in calculating the edge weights in our context graph. Note that even though the words *w* and *beatiful* are misspelled, they are tagged correctly by the tagger, with lower confidence scores though.

Token	*POS tag*	Tag confidence
with	*Preposition*	0.9963
a	*Determiner*	0.9980
beautiful	*Adjective*	0.9971
smile	*Noun*	0.9712
w	*Preposition*	0.7486
a	*Determiner*	0.9920
beatiful	*Adjective*	0.9733
smile	*Noun*	0.9806

Table 2: Sample POS tagger output

3.2 Graph construction

Contextual information of words is modeled through a word association graph created by using a large corpus of social media text. The graph encodes the relative positions of the POS tagged words in the text with respect to each other. After preprocessing, each text message in the corpus is traversed in order to extract the nodes and the edges of the graph. A node is defined with four properties: *id, oov, freq* and *tag*. The token itself is the *id* field. The *freq* property indicates the node's frequency count in the dataset. The *oov* field is set to True if the token is an OOV word. Following the prior work by Han and Baldwin, (2011) we used the GNU Aspell dictionary (v0.60.6) to determine whether a word is OOV or not. We also edited the output of Aspell dictionary to accept letters other than "a" and "i" as OOV words. A portion of the graph that covers parts of the sample sentence in Table 3 is shown in Figure 1.

In the created word association graph, each node is a unique set of a token and its POS tag. This helps us to identify the candidate IV words for a given OOV word by considering not only lexical and contextual similarity, but also grammatical similarity in terms of POS tags. For example, if the token *smile* has been frequently seen as a Noun or a Verb, and not in other forms in the dataset (e.g. Table 4), this provides evidence that it is not a good normalization candidate for an OOV token that has been tagged as a Pronoun. On the other hand, *smile* can be a good candidate for a Noun or a Verb OOV token, if it is lexically and contextually similar to it.

[2]CMU Ark Tagger (v0.3.2)

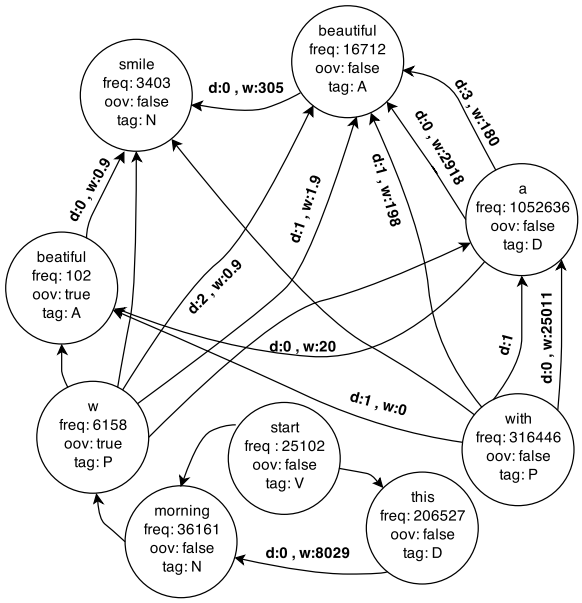

Figure 1: Portion of the word association graph for part of the sample sentence in Table 3. (d: distance, w: edge weight).

node id	**freq**	**oov**	**tag**
smile	3	False	A
smile	3403	False	N
smile	2796	False	V

Table 4: The different nodes in the word association graph representing the token *smile* tagged with different POS tags.

An edge is created between two nodes in the graph, if the corresponding word pair (i.e. token/POS pair) are contextually associated. Two words are considered to be contextually associated if they satisfy the following criteria:

- The two words co-occur within a maximum word distance of $t_{distance}$ in a text message in the corpus.
- Each word has a minimum frequency of $t_{frequency}$ in the corpus.

The directionality of the edges is based on the sequence of words in the text messages in the corpus. In other words, an edge between two nodes is directed from the earlier seen token towards the later seen token in a message. For example, Figure 2 shows the edges that would be derived

Let's$_L$	start$_V$	this$_D$	morning$_N$	w$_P$	a$_D$	beatiful$_A$	smile$_N$	.$_C$

Table 3: Sample tokenized, POS tagged sentence (L: nominal+verbal, V: verb, D: determiner, N: noun, P: Preposition, A: adjective, C: punctuation).

from a text including the phrase "with a beautiful smile". The direction (from,to) and the distance together represent a unique triplet. For each pair of nodes with a specific distance there is an edge with a positive weight, if the two nodes are contextually associated. Each co-occurrence of two contextually associated nodes increases the weight of the edge between them with an average of the nodes' POS tag confidence scores in the text message considered. If we are to expand the graph with the example phrase "with a beautiful smile", the weight of the edge with distance 2 from the node *with*|*P* to the node *smile*|*N* would increase by $(0.9963 + 0.9712)/2$, since the confidence score of the POS tag for the token *with* is 0.9963 and the confidence score of the POS tag of the token *smile* is 0.9712 as shown in Table 2.

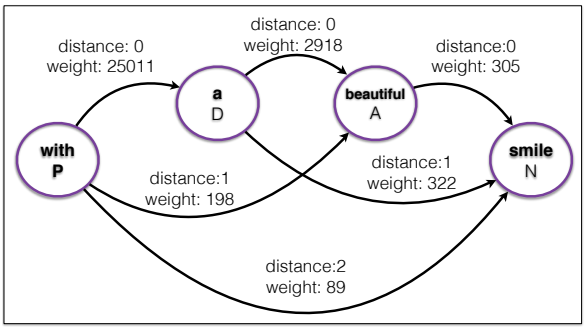

Figure 2: Sample nodes and edges from the word association graph.

3.3 Graph-based Contextual Similarity

Our graph-based contextual similarity method is based on the assumption that an IV word that is the canonical form of an OOV word appears in the same context with the corresponding OOV word. In other words, the two nodes in the graph share several neighbors that co-occur within the same distances to the corresponding two words in social media text. We also assume that an OOV word and its canonical form should have the same POS tag.

Given an input text for normalization, the next step after preprocessing is finding the normalization candidates for each OOV token in the input text. For each ill-formed OOV token o_i in the input text, first the list of tokens that co-occur with o_i in the input text and their positional distances to o_i are extracted. This list is called the neighbor list of token o_i, i.e., NL(o_i).

For each neighbor node n_j in NL(o_i), the word association graph is traversed, and the edges *from* or *to* the node n_j are extracted. The resulting edge list EL(o_i) has edges in the form of (n_j, c_k) or (c_k, n_j), where c_k is a candidate canonical form of the OOV word o_i. Here the neighbor node n_j can be an OOV node, but the candidate node c_k is chosen among the IV nodes. The edges in EL(o_i) are filtered by the relative distance of n_j to o_i as given in the NL(o_i). Any edge between n_j and c_k, whose distance is not the same as the distance between n_j and o_i is removed.

In addition to distance based filtering, POS tag based filtering is also performed on the edges in EL(o_i). Each candidate node should have the same POS tag with the corresponding OOV token. For the OOV token o_i that has the POS tag T_i, all the edges that include candidates with a tag other than T_i are removed from the edge list EL(o_i).

Figure 3 represents a portion from the graph where the neighbors and candidates of the OOV node "beatiful" are shown. In the sample sentence in Table 3 there are two OOV tokens to be normalized, $o_1 = w$ and $o_2 =$ *beatiful*. The neighbor list of o_2, NL(o_2) includes $n_1 = w$, $n_2 = a$ and $n_3 =$ *smile*. For each neighbor in NL(o_2), the candidate nodes ($c_1 =$ *broken*, $c_2 =$ *nice*, $c_3 =$ *new*, $c_4 =$ *beautiful*, $c_5 =$ *big*, $c_6 =$ *best*, $c_7 =$ *great*) are extracted. As shown in Figure 3, there are 11 lines representing the edges between the neighbors of the OOV token and the candidate nodes. These are representative edges in EL(o_2). Each member of the edge list has the same tag (A for Adjective) as the OOV node "beatiful" and the same distance to the corresponding neighbor node of the OOV node.

Each edge in EL(o_i) consists of a neighbor node n_j, a candidate node c_k and an edge weight edgeWeight(n_j, c_k). The edge weight represents the likelihood or the strength of association between the neighbor node n_j and the candidate node c_k. As described in the previous section the edge weights are computed based on the frequency

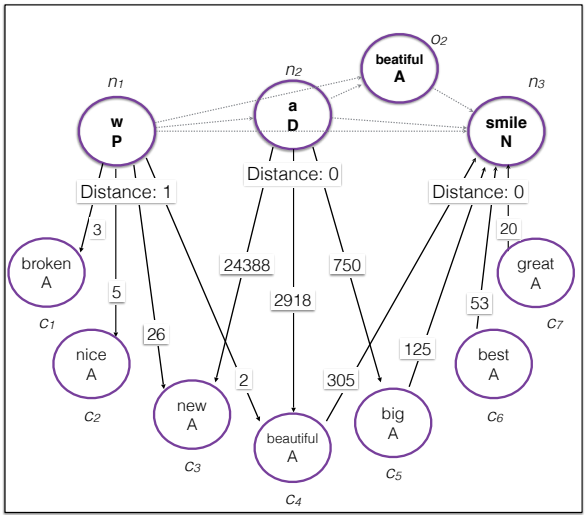

Figure 3: A portion of the graph that includes the OOV token "beatiful", its neighbors and the candidate nodes that each neighbor is connected to. Thick lines show the edge list with relative weights.

of co-occurrence of two tokens, as well as the confidence scores of their POS tags.

The edge weights of the edges in EL(o_2) are shown in Figure 3. The edges that are connected to the OOV neighbor "w" have smaller edge weights such as 3, 5, and 26. On the other hand, the edges that are connected to common words have higher weights. For example, the weight of the edge between the nodes "a" and "new" is 24388. This indicates that they are more common words, and frequently co-occur in the same form ("a new"). Although this edge weight metric is reasonable for identifying the most likely canonical form for the OOV word o_i, it has the drawback of favoring words with high frequencies like common words or stop words. Therefore, to avoid overrated words and get contextually related candidates, we normalize the edge weight edgeWeight(n_j, c_k) with the frequency of the candidate node c_k as shown in Equation 1.

Equation 1 provides a metric that captures contextual similarity based on binary associations. In order to achieve a more comprehensive contextual coverage, a contextual similarity feature is built based on the sum of the binary association scores of several neighbors. As shown in Equation 2, for a candidate node c_k the total edge weight score is the sum of the normalized edge weight scores EWNorm(n_j, c_k), which are the edge weights coming from the different neighbors of the OOV token o_i. We expect this contextual similarity feature to favor and identify the candidates which are (i) related to many neighbors, and (ii) have a high association score with each neighbor.

$$EWNorm(n_j, c_k) = edgeWeight(n_j, c_k)/freq(c_k) \quad (1)$$

$$EW\_Score(o_i, c_k) = \sum_{EL(o_i)} EWNorm(n_j, c_k) \quad (2)$$

Our word association graph includes both OOV and IV tokens, and our OOV detection depends on the spellchecker which fails to identify some OOV tokens that have the same spelling with an IV word. In order to propose better canonical forms, the frequencies of the normalization candidates in the social media corpus have also been incorporated to the contextual similarity feature. Nodes with higher frequencies lead to tokens that are in their most likely grammatical forms.

The final contextual similarity of the token o_i and the candidate c_k is the weighted sum of the total edge weight score and the frequency score of the candidate (see Equation 3). The frequency score of the candidate is a real number between 0 and 1. It is proportional to the frequency of the candidate with respect to the frequencies of the other candidates in the corpus. Since the total edge weight score is our primary contextual resource, we may want to favor edge weight scores. We give the frequency score a weight $0 \leq \beta \leq 1$ to be able to limit its effect on the total contextual similarity score.

$$\begin{aligned} contSimScore(o_i, c_k) = \; & EW\_Score(o_i, c_k) \\ & + \beta * freqScore(c_k) \end{aligned} \quad (3)$$

Hereby, we have the candidate list CL(o_i) for the OOV token o_i that includes all the unique candidates in EL(o_i) and their contextual similarity scores calculated.

3.4 Lexical Similarity

Following the prior work in (Han and Baldwin, 2011; Hassan and Menezes, 2013), our lexical similarity features are based on edit distance (Levenshtein, 1966), double metaphone (phonetic edit distance) (Philips, 2000), and a similarity function

($simCost$) (Contractor et al., 2010) which is defined as the ratio of the Longest Common Subsequence Ratio (LCSR) (Melamed, 1999) of two words and the Edit Distance (ED) between their skeletons (Equations 4 and 5), where the skeleton of a word is obtained by removing its vowels.

$$LCSR(o_j, c_k) = LCS(o_j, c_k)/maxLength(o_j, c_k) \quad (4)$$

$$simCost(o_j, c_k) = LCSR(o_j, c_k)/ED(o_j, c_k) \quad (5)$$

Following the tradition that is inspired from (Kaufmann and Kalita, 2010), before lexical similarity calculations, any repetitions of characters three or more times in OOV tokens are reduced to two (e.g. *goooood* is reduced to *good*). Then, the edit distance, phonetic edit distance, and simCost between each candidate in CL(o_i) and the OOV token o_i are calculated. Edit distance and phonetic edit distance are used to filter the candidates. Any candidate in CL(o_i) with an edit distance greater than t_{edit} and phonetic edit distance greater than $t_{phonetic}$ to o_i is removed from the candidate list CL(o_i).

$$\begin{aligned} lexSimScore(o_i, c_k) = \; & simCost(o_i, c_k) \\ & + \lambda * editScore(o_i, c_k) \end{aligned} \quad (6)$$

For the remaining candidates, the total lexical similarity score (Equation 6) is calculated using simCost and edit distance score[3]. Similar to contextual similarity score, here we have one main lexical similarity feature and one minor lexical similarity feature. The major lexical similarity feature is simCost, whereas the edit distance score is the minor feature. We assigned a weight $0 \leq \lambda \leq 1$ to the edit distance score to be able to lower its contribution while calculating the total lexical similarity score.

3.5 External Score

Since some social media text messages are extremely short and contain several OOV words, they do not provide sufficient context, i.e., IV neighbors, to enable the extraction of good candidates from the word association graph. Therefore, we extended the candidate list obtained through contextual similarity as described in the previous section, by including all the tokens in the word association graph that satisfy the edit distance and phonetic edit distance criteria. We also incorporated candidates from external resources, in other words from a slang dictionary and a transliteration table of numbers and pronouns. If a candidate occurs in the slang dictionary or in the transliteration table as a correspondence to its OOV word, it is assigned an external score of 1, otherwise it is assigned an external score of 0.

The transliterations were first used by (Gouws et al., 2011). Besides the token and its transliteration we also use its POS tag information, which was not available in their system.

The external score favors the well known interpretations of common OOV words. However, unlike the dictionary based methodologies, our system does not return the corresponding unabbreviated word in the slang dictionary or in the transliteration table directly. Only an external score gets assigned and the candidate still needs to compete with other candidates which may have higher contextual similarities and one of those contextually more similar candidates may be returned as the correct normalization instead of the candidate found equivalent to the OOV word in the slang dictionary (or in the transliteration table).

3.6 Overall Scoring

As shown in Equation 7, the final score of a candidate IV token c_k for an OOV token o_i is the sum of its lexical similarity score, contextual similarity score and external score with respect to o_i.

$$\begin{aligned} \text{candScore}(o_i, c_k) = \; & \text{lexSimScore}(o_i, c_k) \\ & + \text{contSimScore}(o_i, c_k) \\ & + \text{externalScore}(o_i, c_k) \end{aligned} \quad (7)$$

4 Experiments

4.1 Datasets

We used the LexNorm1.1 (LN) dataset (Han and Baldwin, 2011) and Pennell and Liu (2014)'s trigram dataset to evaluate our proposed approach. LexNorm1.1 contains 549 tweets with 1184 manually annotated ill-formed OOV tokens. It has been used by recent text normalization studies for evaluation, which enables us to directly compare our performance results with results obtained by the recent previous work (Han and Baldwin, 2011; Pennell and Liu, 2011; Han et al., 2012; Liu et al., 2012; Hassan and Menezes, 2013; Yang and Eisenstein, 2013; Chrupala, 2014). The trigram

[3] an approximate string comparison measure (between 0.0 and 1.0) using the edit distance https://sourceforge.net/projects/febrl/

dataset is an SMS-like corpus collected from twitter status updates sent via SMS. The dataset does not include the complete tweet text but trigrams from tweets and one OOV word in each trigram is annotated. In total 4661 twitter status messages and 7769 tokens are annotated.

4.2 Graph Generation

We used a large corpus of social media text to construct our word association graph. We extracted 1.5 GB of English tweets from Stanford's 476 million Twitter Dataset (Yang and Leskovec, 2011). The language identification of tweets was performed by using the langid.py Python library (Lui and Baldwin, 2012; Baldwin and Lui, 2010).

CMU Ark Tagger (v0.3.2), which is a social media specific POS tagger achieving an accuracy of 95% over social media text (Owoputi et al., 2013; Gimpel et al., 2011), is used for tokenizing and POS tagging the tweets. We used the twitter tagset which includes some extra POS tags specific to social media including URLs and emoticons, Twitter hashtags (#), and twitter at-mentions (@). We made use of these social media specific tags to disambiguate some OOV tokens.

After tokenization, we removed the tokens that were POS tagged as mention (e.g. @brendon), discourse marker (e.g. RT), URL, email address, emoticon, numeral, and punctuation. The remaining tokens are used to build the word association graph. After constructing the graph we only kept the nodes with a frequency greater than 8. For the performance related reasons, the relatedness thresholds $t_{distance}$ and $t_{frequency}$ were chosen as 3 and 8, respectively. The resulting graph contains 105428 nodes and 46609603 edges.

4.3 Candidate Set Generation

While extending the candidate set with lexical features we use $t_{edit} \leq 2 \ \vee \ t_{phonetic} \leq 1$ to keep up with the settings in (Han and Baldwin, 2011). In other words, IV words that are within 2 character edit distance or 1 character edit distance of a given OOV word under phonemic transcription were chosen as lexical similarity candidates. The values for the λ and β parameters in Equations 3 and 6 are set to 0.5. We did not tune these parameters for optimized performance. We selected the value of 0.5 in order to give less weight (half weight) to our minor contextual and lexical similarity features compared to the major ones.

4.4 Normalization Candidates

Most of the prior work assume perfect detection of ill-formed words during test set decoding (Liu et al., 2012; Han and Baldwin, 2011; Pennell and Liu, 2011; Yang and Eisenstein, 2013). To be able to compare our results with studies that do not assume that ill-formed words have been preidentified (Chrupala, 2014; Hassan and Menezes, 2013; Han et al., 2012) we used our graph and built a dictionary to identify the ill-formed words.

Following Han and Baldwin (2011) and Yang and Eisenstein (2013), we created a dictionary by choosing the nodes in our graph that have a frequency property higher than 20. Filtering this dictionary of 49657 words using GNU Aspell dictionary (v0.60.6) we produced a set of 26773 "invocabulary" (IV) words. In our second setup our system does not attemp to normalize the words in this set.

4.5 Results and Analysis

In this paper we introduced a new contextual approach for text normalization. The lexical similarity score described in Section 3.4 and the external score described in Section 3.5 depend on the work of Han and Baldwin (2011). With small changes made to the previously proposed method we took it as a baseline in our study.

As contextual layer we proposed two metrics extracted from the word association graph. The first one depends on the total edge weights between candidates and OOV neighbours, the second one is based on the frequencies of the candidates in the corpus.

As the evaluation metrics we used precision, recall, and F-Measure. Precision calculates the proportion of correctly normalized words among the words for which we produced a normalization. Recall shows the amount of correct normalizations over the words that require normalization (ill-formed OOV words). The main metric that we consider while evaluating the performance of our system is F-Measure which is the harmonic mean of precision and recall.

We investigated the impact of lexSimScore and externalScore seperately on both datasets (Table 5). Using only lexSimScore the system achieved an F-measure of 28.24% on the LexNorm1.1 dataset and 38.70% on the Trigram dataset, which shows that lexical similarity alone is not enough for a good normalization system.

However, the externalScore which is the layer that is more aware of the Internet jargon, along with some social text specific rule based transliterations performs better than expected on both datasets. Mixing these two layers we reach our baseline that is adopted from (Han and Baldwin, 2011). This baseline setup obtained an F-measure of 77.12% on LexNorm1.1, which is slightly better than the result (75.30%) reported by the original system of Han and Baldwin (2011).

The results obtained by our proposed Contextual Word Association Graph (CWA-Graph) system on the LexNorm1.1 and trigram datasets, as well as the results of recent studies that used the same datasets for evaluation are presented in Table 5. The ill-formed words are assumed to have been pre-identified in advance.

Method	Dataset	Precision	Recall	F-measure
lexSimScore	LN	28.28	28.20	28.24
externalScore	LN	64.69	64.52	64.60
lexSimScore+externalScore	LN	77.22	77.02	77.12
Han and Baldwin (2011)	LN	75.30	75.30	75.30
Liu *et al.* (2012)	LN	84.13	78.38	81.15
Yang and Eisenstein (2013)	LN	82.09	**82.09**	82.09
CWA-Graph	LN	**85.50**	79.22	**82.24**
lexSimScore	Trigram	39.10	38.40	38.70
externalScore	Trigram	44.20	43.30	43.80
lexSimScore+externalScore	Trigram	65.50	64.20	64.80
Pennell and Liu (2011)	Trigram	69.7	**69.7**	69.7
CWA-Graph	Trigram	**77.2**	68.8	**72.8**

Table 5: Results obtained when ill-formed words are assumed to have been pre-identified in advance.

Our CWA-Graph approach achieves the best F-measure (82.24%) and precision (85.50%) among the recent previous studies. The high precision value is obtained without compromising much from recall (79.22%). Our recall is the second best among others. The F-score (82.09%) obtained by Yang and Eisenstein (2013)'s system is close to ours and the second best F-score, which on the other hand, has a lower precision.

Without any modification to our system or to the parameters, we were able to improve the results obtained by Pennell and Liu (2011) on the trigram SMS-like dataset. The trigram nature of the dataset resulted in input texts which are (short thus) very limited with regard to contextual information. Nevertheless, our system achieved 72.8% F-Measure using this contextual information even though it is limited.

Along the systems (presented in Table 5) that assume ill-formed tokens have been pre-identified perfectly by an oracle, there are also systems that are not based on this assumption but contain ill-formed word identification components (Han et al., 2012; Hassan and Menezes, 2013; Chrupala, 2014). We used the method described in Section 4.4 to identify the candidate tokens for normalization. Table 6 shows our results compared with the results of other systems that perform ill-formed word detection prior to normalization. We could label 1141 tokens correctly as ill-formed among 1184 ill-formed tokens. We achieved a word error rate (WER) of 2.6%, where Chrupala (2014) reported 4.8% and Han et al. (2012) reported 6.6% WER on the Lexnorm1.1 dataset.

Method	Dataset	Precision	Recall	F-measure
Han et al. (2012)	LN	70.00	17.90	28.50
Hassan and Menezes (2013)	LN	85.37	56.40	69.93
CWA-Graph	LN	**85.87**	**76.52**	**80.92**

Table 6: Results obtained without assuming that ill-formed words have been pre-identified.

As shown in Table 5 some systems have equal precision and recall values (Yang and Eisenstein, 2013; Han and Baldwin, 2011; Pennell and Liu, 2011). Those systems normalize all ill-formed words. On the other hand, our system does not return a normalization, if there are no candidates that are lexically similar, grammatically correct, and contextually close enough. For this reason, we managed to achieve a higher precision compared to the other systems. Our system returns a normalization candidate for an OOV word only if it achieves a similarity score (contextual, lexical, external, or some degree of each feature) above a threshold value. The default threshold used in the system is set equal to the maximum score that can be obtained by lexical features. Thus, we only retrieve candidates that obtain a non-zero contextual similarity score (conSimScore). The results shown at Table 7 and Table 8 demonstrate that CWA-Graph can obtain even higher values of precision by increasing the percentage of contextual context of candidates. It achieved 94.1% precision on the LexNorm1.1 dataset, where the highest precision reported at the same recall level is 85.37% (Hassan and Menezes, 2013). The precision of the normalization system can be set (e.g. as high, medium, low) depending on the application where it will be used.

Our motivation behind introducing the λ and β parameters was to investigate the importance

conSimScore >	Precision	Recall	F-measure
0	**85.5**	**79.2**	**82.2**
0.1	88.8	75.1	81.4
0.2	91.1	72.8	80.9
0.3	92.3	67.6	78.0
0.5	94.1	56.4	70.5

Table 7: Comparison of results for different threshold values on LexNorm1.1, the setup we have used for our other experiments is shown in bold.

conSimScore >	Precision	Recall	F-measure
0	**77.2**	**68.8**	**72.8**
0.1	80.9	65.8	72.6
0.2	84.2	60.8	70.6
0.3	87.6	54.6	67.3
0.4	89.5	47.1	61.7
0.5	90.8	42.1	57.6

Table 8: Comparison of results for different threshold values on trigram dataset, the setup we have used for our other experiments is shown in bold.

of the minor features compared to our major features (described in Sections 3.3 and 3.4). For the experiments reported in Tables 5, 6, 7 and 8 we set the λ and β values to 0.5. We did not tune these parameters for optimized performance. Rather, our aim was to give less weight (half weight) to the minor features compared to the major ones. To analyze the effects of the lambda and beta parameters, we plotted the performance of the system on the LexNorm1.1 data set by varying their values (see Figure 4). It is shown that for λ and β values greater than 0.3 the performance of the system is quite robust. The F-score varies between 80.4% and 82.9%.

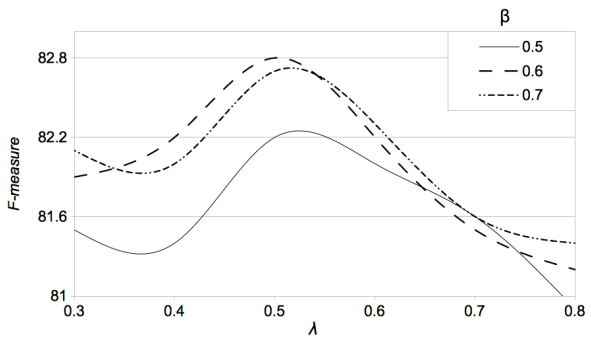

Figure 4: The effect of λ and β on the system performance.

5 Conclusion

In this paper, we present an unsupervised graph-based approach for contextual text normalization. The task of normalization is highly dependent on understanding and capturing the dynamics of the informal nature of social text. Our word association graph is built using a large unlabeled social media corpus. It helps to derive contextual analysis on both clean and noisy data.

It is important to emphasize the difference between corpus based contextual information and contextual information of the input text (input context). Most recent unsupervised systems for text normalization only make use of corpus based context information. However, this approach is led by statistical information. In other words, it finds which IV word the OOV word is commonly normalized to, regardless of the context of the OOV word in the input text message. A major strength of our approach is that it utilizes both corpus based contextual information and input based contextual information. We use corpus based statistical information to connect/associate the words in the contextual word association graph. On the other hand, the neighbors of an OOV word in the input text provide us input based context information. Using input context to find normalizations helps us identify the correct normalization, even if it is not the statistically dominant one.

We compared our approach with the recent social media text normalization systems and achieved state-of-the-art precision and F-measure scores. We reported our results on two datasets. The first one is the standard text normalization dataset (Lexnorm1.1) derived from Twitter. Our results on this dataset showed that our system can serve as a high precision text normalization system which is highly preferable as an NLP preprocessing step. The second dataset we tested our approach is a SMS-like trigram dataset. The tests showed that the proposed system can perform good on SMS data as well.

The system does not require a clean corpus or an annotated corpus. The contextual word association graph can be built by using the publicly available social media text.

ReNoun: Fact Extraction for Nominal Attributes

Mohamed Yahya*

Abstract

Search engines are increasingly relying on large knowledge bases of facts to provide direct answers to users' queries. However, the construction of these knowledge bases is largely manual and does not scale to the long and heavy tail of facts. Open information extraction tries to address this challenge, but typically assumes that facts are expressed with verb phrases, and therefore has had difficulty extracting facts for noun-based relations.

We describe ReNoun, an open information extraction system that complements previous efforts by focusing on nominal attributes and on the long tail. ReNoun's approach is based on leveraging a large ontology of noun attributes mined from a text corpus and from user queries. ReNoun creates a seed set of training data by using specialized patterns and requiring that the facts mention an attribute in the ontology. ReNoun then generalizes from this seed set to produce a much larger set of extractions that are then scored. We describe experiments that show that we extract facts with high precision and for attributes that cannot be extracted with verb-based techniques.

1 Introduction

One of the major themes driving the current evolution of search engines is to make the search experience more efficient and mobile friendly for users by providing them concrete answers to queries. These answers, that apply to queries about entities that the search engine knows about (e.g., famous individuals, organizations or locations) complement the links that the search engine typically returns (Sawant and Chakrabati, 2013; Singhal, 2012; Yahya et al., 2012). To support such answers, the search engine maintains a knowledge base that describes various attributes of an entity (e.g., `(Nicolas Sarkozy, wife, Carla Bruni)`). Upon receiving a query, the search engine tries to recognize whether the answer is in its knowledge base.

For the most part, the aforementioned knowledge bases are constructed using manual techniques and carefully supervised information extraction algorithms. As a result, they obtain high coverage on head attributes, but low coverage on tail ones, such as those shown in Table 1. For example, they may have the answer for the query *"Sarkozy's wife"*, but not for *"Hollande's ex-girlfriend"* or *"Google's philanthropic arm"*. In addition to broadening the scope of query answering, extending the coverage of the knowledge base to long tail attributes can also facilitate providing *Web answers* to the user. Specifically, the search engine can use lower-confidence facts to *corroborate* an answer that appears in text in one of the top Web results and highlight them to the user.

This paper describes *ReNoun*, an open-information extraction system that focuses on extracting facts for long tail attributes. The observation underlying our approach is that attributes from the long tail are typically expressed as *nouns*, whereas most previous work on open-information extraction (e.g., Mausam et al. (2012)) extend techniques for extracting attributes expressed in *verb* form. Hence, the main contribution of our work is to develop an extraction system that complements previous efforts, focuses on nominal attributes and is effective for the long tail. To that end, ReNoun begins with a large but imperfect ontology of nominal attributes that is extracted from text and the query stream (Gupta et al., 2014). ReNoun proceeds by using a small set of high-precision extractors that exploit the nominal na-

ture of the attributes to obtain a training set, and then generalizes from the training set via distant supervision to find a much larger set of extraction patterns. Finally, ReNoun scores extracted facts by considering how frequently their patterns extract triples and the *coherence* of these patterns, i.e., whether they extract triples for semantically similar attributes. Our experiments demonstrate that ReNoun extracts a large body of high precision facts, and that these facts are not extracted with techniques based on verb phrases.

2 Preliminaries

The goal of ReNoun is to extract triples of the form `(S,A,O)`, where `S` is *subject*, `A` is the *attribute*, and `O` is the *object*. In our setting, the attribute is always a noun phrase. We refer to the subject and object as the *arguments* of the attribute.

ReNoun takes as input a set of attributes, which can be collected using the methods described in Gupta el al. (2014), Lee et al. (2012), and Pasca and van Durme (2007). In this work, we use Biperpedia (Gupta et al., 2014), which is an ontology of nominal attributes automatically extracted from Web text and user queries. For every attribute, Biperpedia supplies the Freebase (Bollacker et al., 2008) domain type (e.g., whether the attribute applies to people, organizations or hotels). Since the attributes themselves are the result of an extraction algorithm, they may include false positives (i.e., attributes that do not make sense).

The focus of ReNoun is on attributes whose values are concrete objects (e.g., `wife`, `protege`, `chief-economist`). Other classes of attributes that we do not consider in this work are (1) numeric (e.g., `population`, `GDP`) that are better extracted from Web tables (Cafarella et al., 2008), and (2) vague (e.g., `culture`, `economy`) whose value is a narrative that would not fit the current mode of query answering on search engines.

We make the distinction between the *fat head* and *long tail* of attributes. To define these two sets, we ordered the attributes in decreasing order of the number of occurrences in the corpus [1]. We defined the fat head to be the attributes until the point N in the ordering such that the sum of the total number of occurrences of attributes before N equaled the number of total occurrences of the attributes after N. In our news corpus, the fat head included 218 attributes (i.e., $N = 218$) and the long tail included 60K attributes. Table 2 shows examples from both.

Fat head	daughter, headquarters president, spokesperson,
Long tail	chief economist, defender, philanthropic arm, protege

Table 2: Examples of fat head and long tail attributes.

The output of ReNoun is a set of *facts*, where each fact could be generated by multiple extractions. We store the provenance of each extraction and the number of times each fact was extracted.

Noun versus verb attributes

ReNoun's goal is to extract facts for attributes expressed as noun phrases. A natural question is whether we can exploit prior work on open information extraction, which focused on extracting relations expressed as verbs. For example, if we can extract facts for the attribute `advised` or `is advisor of`, we can populate the noun attribute `advisor` with the same facts. In Section 7.2 we demonstrate that this approach is limited for several reasons.

First, attributes in knowledge bases are typically expressed as noun phrases. Table 3 shows that

[1] The occurrences were weighted by the number of semantic classes they occur with in the ontology because many classes overlap.

Knowledge Base	%Nouns	%Verbs
Freebase	97	3
DBpedia	96	4

Table 3: Percentage of attributes expressed as nouns phrases among the 100 attributes with the most facts.

the vast majority of the attributes in both Freebase and DBpedia (Auer et al., 2007) are expressed as nouns even for the fat head (and even more so for the long tail). Hence, if we extract the verb form of attributes we would need to translate them into noun form, which would require us to solve the paraphrasing problem and introduce more sources of error (Madnani and Dorr, 2010). Second, as we dig deeper into the long tail, attributes tend to be expressed in text more in noun form rather than verb form. One of the reasons is that the attribute names tend to get longer and therefore unnatural to express as verbs (e.g. *chief privacy officer*, *automotive division*). Finally, there is often a subtle difference in meaning between verb forms and noun forms of attributes. For example, it is common to see the phrase *"Obama advised Merkel on saving the Euro,"* but that would not necessarily mean we want to say that *Obama* is an advisor of *Angela Merkel*, in the common sense of `advisor`.

Processed document corpus

ReNoun extracts facts from a large corpus of 400M news articles. We exploit rich synactic and linguistic cues, by processing these documents with a natural language processing pipeline comprising of – dependency parsing, noun phrase chunking, named entity recognition, coreference resolution, and entity resolution to Freebase. The chunker identifies nominal mentions in the text that include our attributes of interest. As discussed later in the paper, we exploit the dependency parse, coreference and entity resolution heavily during various stages of our pipeline.

3 Overview of ReNoun

Since ReNoun aims at extracting triples for attributes not present in head-heavy knowledge bases, one key challenge is that we do not have any labeled data (i.e. known facts) for such attributes, especially in the long tail. Therefore ReNoun has an initial seed fact extraction step that automatically generates a small corpus of relatively precise seed facts for all attributes, so that distant supervision can be employed. The second big challenge is to filter the noise from the resulting extractions.

ReNoun's extraction pipeline, shown in Figure 1, is composed of four stages.

Seed fact extraction: We begin by extracting a small number of high-precision facts for our attributes. For this step, we rely on manually specified lexical patterns that are specifically tailored for noun phrases, but are general enough to be independent of any specific attributes. When applying such patterns, we exploit coreference to make the generated seed facts more precise by requiring the attribute and object noun phrases of a seed fact to refer to the same real-world entity. This is elaborated further in Section 4.

Extraction pattern generation: Utilizing the seed facts, we use distant supervision (Mintz et al., 2009) to learn a set of dependency parse patterns that are used to extract a lot more facts from the text corpus.

Candidate generation: We apply the learned dependency parse patterns from the previous stage to generate a much larger set of extractions. We aggregate all the extractions that give rise to the same fact and store with them the provenance of the extraction. The extractions generated here are called candidates because they are assigned scores that determine how they are used. The application consuming an extraction can decide whether to discard an extraction or use it, and in this case the manner in which it is used, based on the scores we attach to it and the application's precision requirements.

Scoring: In the final stage, we score the facts, reflecting our confidence in their correctness. Intuitively, we give a pattern a high score if it extracts many facts that have semantically similar attributes, and then propagate this score to the facts extracted by the pattern (Section 6).

4 Seed fact extraction

Since we do not have facts, but only attributes, the first phase of ReNoun's pipeline is to extract a set of high-precision seed facts that are used to train more general extraction patterns. ReNoun extracts seed facts using a manually crafted set of extraction rules (see Table 4). However, the extraction rules and the application of these rules are tailored to our task of extracting noun-based attributes.

Specifically, when we apply an extraction rule to generate a triple `(S,A,O)`, we require that (1) `A` is an attribute in our ontology, and (2) the value of `A` and the object `O` corefer to the same real-world

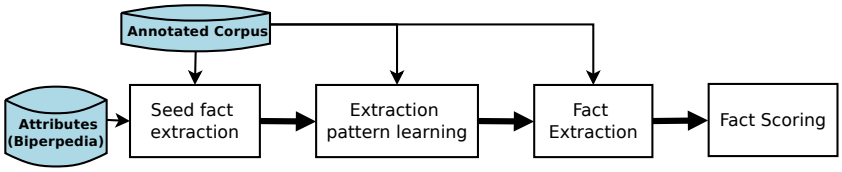

Figure 1: Extraction Pipeline: we begin with a set of high-precision extractors and use distant supervision to train other extractors. We then apply the new extractors and score the resulting triples based on the frequency and coherence of the patterns that produce them.

1. *the* A *of* S, O – the CEO of Google, Larry Page
2. *the* A *of* S *is* O – the CEO of Google is Larry Page
3. O, S A – Larry Page, Google CEO
4. O, S*'s* A – Larry Page, Google's CEO
5. O, [*the*] A *of* S – Larry Page, [the] CEO of Google
6. SAO – Google CEO Larry Page
7. S A, O – Google CEO, Larry Page
8. S*'s* A, O – Google's CEO, Larry Page

Table 4: High precision patterns used for seed fact extraction along with an example of each. Here, the object (O) and the attribute (A) corefer and the subject (S) is in close proximity. In all examples, the resulting fact is `(Google, CEO, Larry Page)`. Patterns are not attribute specific.

entity. For example, in Figure 2, `CEO` is in our ontology and we can use a coreference resolver to infer that `CEO` and `Larry Page` refer to the same entity. The use of coreference follows from the simple observation that objects will often be referred to by nominals, many of which are our attributes of interest. Since the sentence matches our sixth extraction rule, ReNoun extracts the triple `(Google, CEO, Larry Page)`.

Document:
"[Google]$_1$ [CEO]$_2$ [Larry Page]$_2$ started his term in 2011, when [he]$_2$ succeeded [Eric Schmidt]$_3$. [Schmidt]$_3$ has since assumed the role of executive chairman of [the company]$_1$."

(a)

Coreference clusters:

#	Phrases	Freebase ID
1	**Google**, the company	/m/045c7b
2	**Larry Page**, CEO, he	/m/0gjpq
3	**Eric Schmidt**, Schmidt	/m/01gqf4

(b)

Figure 2: Coreference clusters: (a) a document annotated with coreference clusters; (b) a table showing each cluster with the representative phrases in bold and the Freebase ID to which each cluster maps.

We rely on a coreference resolver in the spirit of Haghighi and Klein (2009). The resolver clusters the mentions of entities in a document so the references in each cluster are assumed to refer to the same real-world entity. The resolver also chooses for each cluster a *representative phrase*, which is a proper noun or proper adjective (e.g., *Canadian*). Other phrases in the same cluster can be other proper nouns or adjectives, common nouns like *CEO* or pronouns like *he* in the example. Each cluster is possibly linked by an entity resolver to a Freebase entity using a unique Freebase ID. Figure 2(b) shows the coreference clusters from the sample document, with representative phrases in bold, along with the Freebase ID of each cluster. Note that in our example the phrase *executive chairman*, which is also in our ontology of attributes, is not part of any coreference cluster. Therefore, the fact centered around this attribute in the example will not be part of the seed extractions, but could be extracted in the next phase. The resulting facts use Freebase IDs for the subject and object (for readability, we will use entity names in the rest of this work). In summary, our seed extraction proceeds in two steps. First, we find sentences with candidate attribute-object pairs that corefer and in which the attribute is in our ontology. Second, we match these sentences against our hand-crafted rules to generate the extractions. In Section 7 we show that the precision of our seed facts is 65% for fat head attributes and 80% for long tail ones.

5 Pattern and candidate fact generation

In this section we describe how ReNoun uses the seed facts to learn a much broader set of extraction patterns. ReNoun uses the learned patterns to extract many more candidate facts that are then assigned scores reflecting their quality.

5.1 Dependency patterns

We use the seed facts to learn patterns over dependency parses of text sentences. A dependency parse of a sentence is a directed graph whose vertices correspond to tokens labeled with the word and the POS tag, and the edges are syntactic relations between the corresponding tokens (de Marneffe et al., 2006). A *dependency pattern* is a subgraph of a dependency parse where some words have been replaced by variables, but the POS tags

have been retained (called *delexicalization*). A dependency pattern enables us to extract sentences with the same dependency parse as the sentence that generated the pattern, modulo the delexicalized words. We note that one big benefit of using dependency patterns is that they generalize well, as they ignore extra tokens in the sentence that do not belong to the dependency subgraph of interest.

5.2 Generating dependency patterns

The procedure for dependency pattern generation is shown in Algorithm 1, and Figure 3 shows an example of its application. The input to the algorithm is the ontology of attributes, the seed facts (Section 4), and our processed text corpus (Section 2).

Algorithm 1: Dependency pattern generation

input : Set of attributes $\mathcal{A}$, Seed facts I, Corpus D.
$\mathcal{P}$:= An empty set of dependency pattern-attribute pairs.
foreach *sentence* $s \in D$ **do**
  foreach *triple* $t = (S, A, O)$ *found in* s **do**
    if $t \in I$ **then**
      $G(s)$ = dependency parse of s
      P' = minimal subgraph of $G(s)$ containing the head tokens of S, A and O
      P = Delexicalize(P', S, A, O)
      $\mathcal{P} = \mathcal{P} \cup \{\langle P, A \rangle\}$
return $\mathcal{P}$

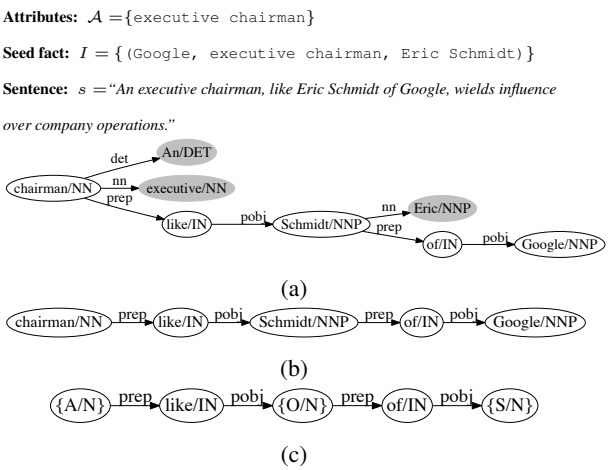

Figure 3: Dependency pattern generation using seed facts, corresponding to Algorithm 1: (a) shows the input to the procedure (dependency parse partially shown); (b) P'; (c) P.

The procedure iterates over the sentences in the corpus, looking for matches between a sentence s and a seed fact f. A sentence s matches f if s contains (i) the attribute in f, and (ii) phrases in coreference clusters that map to the same Freebase IDs as the subject and object of f. When a match is found, we generate a pattern as follows.

We denote by P' the minimal subgraph of the dependency parse of s containing the head tokens of the subject, attribute and object (Figure 3 (b)). We delexicalize the three vertices corresponding to the head tokens of the subject, attribute and object by variables indicating their roles. The POS tag associated with the attribute token is always a noun. The subject and object are additionally allowed to have pronouns and adjectives associated with their tokens. All POS tags corresponding to nouns are lifted to N, in order to match the various types of nouns. We denote the resulting dependency pattern by P and add it to our output, associated with the matched attribute. We note that in principle, the vertex corresponding to the head of the attribute does not need to be delexicalized. However, we do this to improve the efficiency of pattern-matching, since we will often have patterns for different attributes differing only at the attribute vertex.

It is important to note that because of the manner in which the roles of subject and object were assigned during seed fact extraction, the patterns ReNoun generates clearly show which argument will take the role of the subject, and which will take the role of the object. This is in contrast to previous work such as Ollie (Mausam at al., 2012), where the assignment depends on the order in which the arguments are expressed in the sentence from which the fact is being extracted. For example, from the sentence *"Opel was described as GM's most successful subsidiary."* and the seed fact `(GM, subsidiary, Opel)`, the pattern that ReNoun generates will consistently extract facts like `(BMW, subsidiary, Rolls-Royce)`, and not the incorrect inverse, regardless of the relative ordering of the two entities in the sentence.

At this point we have dependency patterns capable of generating more extractions for their seed fact attributes. For efficient matching, we use the output of Algorithm 1 to generate a map from dependency patterns to their attributes with entries like that shown in Figure 4(a). This way, a pattern match can be propagated to all its mapped attributes in one shot, as we explain in Section 5.3. Finally, we discard patterns that do not pass a support threshold, where support is the number of distinct seed facts from which a pattern could be generated.

attributes: {executive chairman, creative director, ...}

(a)

"An executive chairman, like Steve Chase of AOL, is responsible for representing the company."

↓

(AOL, executive chairman, Steve Chase)

(b)

"A creative director, like will.i.am of 3D Systems, may also be referred to as chief creative officer."

↓

(3D Systems, creative director, will.i.am)

(c)

Figure 4: A dependency pattern and its use in extraction: (a) the pattern in our running example and the set of attributes to which it applies; (b) and (c) sentences matching the pattern and the resulting extractions.

attributes: {ex-wife, boyfriend, ex-partner}

$frequency(P) = 574, coherence(P) = 0.429$

Example: *"Putin has two children with his ex-wife, Lyudmila."*

(a)

attributes: {ex-wife, general manager, subsidiary,... }

$frequency(P) = 52349038, coherence(P) = 0.093$

Example: *"Chelsea F.C. general manager José Mourinho..."*

(b)

Figure 5: (a) a coherent pattern extracting facts for semantically similar attributes and (b) an incoherent pattern.

5.3 Applying the dependency patterns

Given the learned patterns, we can now generate new extractions. Each match of a pattern against the corpus will indicate the heads of the potential subject, attribute and object. The noun phrase headed by the token matching the {A/N} vertex is checked against the set of attributes to which the pattern is mapped. If the noun phrase is found among these attributes, then a triple (S, A, O) is constructed from the attribute and the Freebase entities to which the tokens corresponding to the S and O nodes in the pattern are resolved. This triple is then emitted as an extraction along with the pattern that generated it. Figure 4(b) and (c) show two sentences that match the dependency pattern in our running example and the resulting extractions.

Finally, we aggregate our extractions by their generated facts. For each fact f, we save the distinct dependency patterns that yielded f and the total number of times it was found in the corpus.

6 Scoring extracted facts

In this section we describe how we score the candidate facts extracted by applying the dependency patterns in Section 5. Recall that a fact may be obtained from multiple extractions, and assigning scores to each fact (rather than each extraction) enables us to consider all extractions of a fact in aggregate.

We score facts based on the patterns which extract them. Our scheme balances two characteristics of a pattern: its frequency and coherence. *Pattern frequency* is defined as the number of extractions produced by the pattern. Our first observation is that patterns with a large number of extractions are always able to produce correct extractions (in addition to incorrect ones). We also observe that generic patterns produce more erroneous facts compared to more targeted ones. To capture this, we introduce *pattern coherence*, which reflects how targeted a pattern is based on the attributes to which it applies. For example, we observed that if an extraction pattern yields facts for the coherent set of attributes ex-wife, boyfriend, and ex-partner, then its output is consistently good. On the other hand, a pattern that yields facts for a less coherent set of attributes ex-wife, general manager, and subsidiary is more likely to produce noisy extractions. Generic, more incoherent patterns are more sensitive to noise in the linguistic annotation of a document. Figure 5 shows an example pattern for each case, along with its frequency and coherence.

We capture coherence of attributes using word-vector representations of attributes that are created over large text corpora (Mikolov et al., 2013). The word-vector representation $v(w)$ for a word w (multi-word attributes can be preprocessed into single words) is computed in two steps. First, the algorithm counts the number of occurrences of a word w_1 that occurs within the text window centered at w (typically a window of size 10), producing an intermediate vector that potentially has a non-zero value for every word in the corpus. The intermediate vector is then mapped to a much smaller dimension (typically less than 1000) to produce $v(w)$. As shown in (Mikolov et al., 2013), two words w_1 and w_2 for which the cosine dis-

tance between $v(w_1)$ and $v(w_2)$ is small tend to be semantically similar. Therefore, a pattern is coherent if it applies to attributes deemed similar as per their word vectors.

Given an extraction pattern P that extracts facts for a set of attributes $\mathcal{A}$, we define the coherence of P to be the average pairwise coherence of all attributes in $\mathcal{A}$, where the pairwise coherence of two attributes a_1 and a_2 is the cosine distance between $v(a_1)$ and $v(a_2)$.

Finally, we compute the score of a fact f by summing the product of frequency and coherence for each pattern of f as shown in Equation 1.

$$S(f) = \sum_{P \in Pat(f)} frequency(P) \times coherence(P) \quad (1)$$

7 Experimental Evaluation

We describe a set of experiments that validate the contributions of ReNoun. In Sections 7.2 and 7.3 we validate our noun-centric approach: we show that extractions based on verb phrases cannot yield the results of ReNoun and that NomBank, the resource used by state of the art in semantic role-labeling for nouns, will not suffice either. In Sections 7.4-7.6 we evaluate the different components of ReNoun and its overall quality, and in Section 7.7 we discuss the cases in which ReNoun was unable to extract any facts.

7.1 Setting

We used the fat head (FH) and long tail (LT) attributes and annotated news corpus described in Section 2. When evaluating facts, we used majority voting among three human judges, unless otherwise noted. The judges were instructed to consider facts with inverted subjects and objects as incorrect. For example, while `(GM, subsidiary, Opel)` is correct, its inverse is incorrect.

7.2 Verb phrases are not enough

State-of-art open information extraction systems like Ollie (Mausam at al., 2012) assume that a relation worth extracting is expressed somewhere in verb form. We show this is not the case and justify our noun-centric approach. In this experiment we compare ReNoun to a custom implementation of Ollie that uses the same corpus as ReNoun and supports multi-word attributes. While Ollie does try to find relations expressed as nouns, its seed facts are relations expressed as verbs.

We randomly sampled each of FH and LT for 100 attributes for which ReNoun extracts facts and asked a judge to find potentially equivalent Ollie relations. Note that we did not require the judge to find exactly the same triple (thereby biasing the experiment towards finding more attribute matches). Furthermore, the judge was instructed that a verb phrase like *advised by* should be considered a match to the ReNoun attribute `advisor`. However, looking at the data, most facts involving the relation *advised* are not synonymous with the *advisor* relation as we think of it (e.g., *"Obama advised Merkel on saving the Euro"*). This observation suggests that there is an even more subtle difference between the meaning of verb expressions and noun-based expressions in text. This experiment, therefore, gives an upper bound on the number of ReNoun attributes that Ollie can cover.

ReNoun	**Ollie**
flagship company	-
railway minister	-
legal affairs correspondent	-
spokesperson	be spokesperson of
president-elect	be president elect of
co-founder	be co-founder of

Table 5: ReNoun attributes with and without a corresponding Ollie relation.

For FH, not surprisingly, we could find matches for 99 of the 100 attributes. However, for LT, only 31 of the 100 attributes could be found, even under our permissive setting. Most attributes that could not be matched were multi-word noun phrases. While in principle, one could use the Ollie patterns that apply to the head of a multi-word attribute, we found that we generate more interesting patterns for specific multi-word attributes. Table 5 shows examples of attributes with and without verb mappings in Ollie.

We also compare in the other direction and estimate the portion of Ollie relations centered around nouns for which ReNoun fails to extract facts. For this experiment, we randomly sampled 100 Ollie relations that contained common nouns whose objects are concrete values, and looked for equivalent attributes in ReNoun extractions. ReNoun extracts facts for 48 of the Ollie relations. Among the 52 relations with no facts, 25 are not in Biperpedia (which means that ReNoun cannot extract facts for them no matter what). For the other 27 relations, ReNoun did not extract facts for the following reasons. First, some relations expressed actions, which cannot be expressed using nouns only, and are not considered attributes describing the subject entity (e.g., `citation of` in *"Obama's citation*

of the Bible"). Second, some relations have the object (a common noun) embedded within them (e.g., `have microphone in`) and do not have corresponding attributes that can be expressed using nouns only. The remaining relations either have meaningless extractions or use common noun phrases as arguments. ReNoun only uses proper nouns (i.e., entities) for arguments because facts with common noun arguments are rarely interesting without more context. We note that the majority of the 25 Ollie relations without corresponding Biperpedia attributes also fall into one of the three categories above.

7.3 Comparison against NomBank

In principle, the task of extracting noun-mediated relations can be compared to that of semantic role labeling (SRL) for nouns. The task in SRL is to identify a relation, expressed either through a verb or a noun, map it to a semantic frame, and map the arguments of the relation to the various roles within the frame. State of the art SRL systems, such as that of Johansson and Nugues (2008), are trained on NomBank (Meyers et al., 2004) for handling nominal relations, which also means that they are limited by the knowledge it has. We asked a judge to manually search NomBank for 100 attributes randomly drawn from each of FH and LT for which ReNoun extracts facts. For multi-word attributes, we declare a match if its head word was found. We were able to find 80 matches for the FH attributes and 42 for LT ones. For example, we could not find entries for the noun attributes `coach` or `linebacker` (of a football team). This result is easy to explain by the fact that NomBank only has 4700 attributes.

In addition, for some nouns, the associated frames do not allow for the extraction of triples. For example, all frames for the noun `member` specify one argument only, so in the sentence *"John became a member of ACM"*, the output relation is `(ACM, member)` instead of the desired triple `(ACM, member, John)`.

As we did with Ollie, we also looked at nouns from NomBank for which ReNoun does not extract facts. Out of a random sample of 100 NomBank nouns, ReNoun did not extract facts for 29 nouns (four of which are not in Biperpedia). The majority of the missed nouns cannot be used by ReNoun because they either take single arguments (instead of two) or take either prepositional phrases or common nouns (instead of proper nouns correponding to entities) as one their arguments.

7.4 Quality of seed facts

In Section 4, we described our method for extracting seed facts for our attributes. Applying the method to our corpus resulted in 139M extractions, which boiled down to about 680K unique facts covering 11319 attributes. We sampled 100 random facts from each of FH and LT, and obtained 65% precision for FH seed facts and 80% precision for LT ones. This leads us to two observations.

First, the precision of seed facts for LT attributes is high, which makes them suitable for use as a building block in a distant supervision scheme to learn dependency parse patterns. We are primarily interested in LT attributes, which earlier approaches cannot deal with satisfactorily as we demonstrated above.

Second, LT attributes have higher precision than FH attributes. One reason is that multi-word attributes (which tend to be in LT) are sometimes incorrectly chunked, and only their head words are recognized as attributes (which are more likely to be in FH). For example, in the phrase *"America's German coach, Klinsmann"*, the correct attribute is `German coach` (LT), but bad chunking may produce the attribute `coach` (FH) with `Germany` as the subject. Another reason is that FH attributes are likely to occur in speculative contexts where the presence of the attribute is not always an assertion of a fact. (While both FH and LT attributes can be subject to speculative contexts, we observe this more for FH than LT in our data.) For example, before a person is a `railway minister` of a country, there is little mention of her along with the attribute. However, before a person is elected `president`, there is more media about her candidacy. Speculative contexts, combined with incorrect linguistic analysis of sentences, can result in incorrect seed facts (e.g., from *"Republican favorite for US president, Mitt Romney, visited Ohio"*, we extract the incorrect seed fact `(US, president, Mitt Romney)`).

7.5 Candidate generation

Using the seed facts, we ran our candidate generation algorithm (Section 5). In the first step of the algorithm we produced a total of about 2 million unique dependency patterns. A third of these

patterns could extract values for exactly one attribute. Manual inspection of these long tail patterns showed that they were either noise, or do not generalize. We kept patterns supported by at least 10 seed facts, yielding more than 30K patterns.

We then applied the patterns to the corpus. The result was over 460M extractions, aggregated into about 40M unique facts. Of these, about 22M facts were for LT attributes, and 18M for FH. We now evaluate the quality of these facts.

7.6 Scoring extracted facts

In Section 6, we presented a scheme for scoring facts using pattern frequency and coherence. To show its effectiveness we (i) compare it against other scoring schemes, and (ii) show the quality of the top-k facts produced using this scheme, for various k. To compute coherence, we generated attribute word vectors using the word2vec[2] tool trained on a dump of Wikipedia.

First, we compare the quality of our scoring scheme (FREQ_COH) with three other schemes as shown in Table 6. The scheme FREQ is identical to FREQ_COH except that all coherences are set to 1. PATTERN counts the number of distinct patterns that extract the fact while PATTERN_COH sums the pattern coherences. We generated a random sample of 252 FH and LT nouns with no entity disambiguation errors by the underlying natural language processing pipeline. The justification is that none of the schemes we consider here capture such errors. Accounting for such errors requires elaborate signals from the entity linking system, which we leave for future work. For each scoring scheme, we computed the Spearman's rank correlation coefficient ρ between the scores and manual judgments (by three judges). A larger ρ indicates more correlation, and computing ρ was statistically significant (p-value$<$0.01) for all schemes.

Scheme	Spearman's ρ
FREQ	0.486
FREQ_COH	0.495
PATTERN	0.265
PATTERN_COH	0.257

Table 6: Scoring schemes

FREQ and FREQ_COH dominate, which shows that considering the frequency with which patterns perform extraction helps. The two schemes, however, are very close to each other. We observed that adding coherence helps when two facts have similar frequencies, but this effect is tempered when considering a large number of facts.

[2]https://code.google.com/p/word2vec/

	FH		LT	
k	Precision	#Attr	Precision	#Attr
10^2	1.00	8	1.00	50
10^3	0.98	36	1.00	294
10^4	0.96	78	0.98	1548
10^5	0.82	106	0.96	5093
10^6	0.74	124	0.70	7821
All	0.18	141	0.26	11178

Table 7: Precision of random samples of the top-k scoring facts, along with the attribute yield.

Second, we evaluate the scoring of facts generated by ReNoun by the precision of top-k results for several values of k. In this evaluation, facts with disambiguation errors are counted as wrong. The particular context in which ReNoun is applied will determine where in the ordering to set the threshold of facts to consider. We compute precision based on a sample of 50 randomly chosen facts for each k. Table 7 shows the precision results, along with the number of distinct attributes (#Attr) for which values are extracted at each k.

As we can see, ReNoun is capable of generating a large number of high quality facts ($\geq$70% precise at 1M), which our scoring method manages to successfully surface to the top. The major sources of error were (i) incorrect dependency parsing mainly due to errors in boilerplate text removal from news documents, (ii) incorrect coreference resolution of pronouns, (iii) incorrect entity resolution against Freebase, and (iv) cases where a triple is not sufficient (e.g., `ambassador` where both arguments are countries.)

7.7 Missed extractions

We analyze why ReNoun does not extract facts for certain attributes. For FH, we investigate all the 77 attributes for which ReNoun is missing facts. For LT, there are about 50K attributes without corresponding facts, and we use a random sample of 100 of those attributes.

Cause	FH	LT	Example
Vague	23	37	`culture`
Numeric	4	26	`rainfall`
Object not KB entity	11	6	`email`
Plural	30	15	`member firms`
Bad attribute / misspell	3	4	`newsies`
Value expected	6	12	`nationality`
Total	77	100	

Table 8: Analysis of attributes with no extractions.

Table 8 shows the categorization of the missed attributes. The first three categories are cases that are currently outside the scope of ReNoun: vague attributes whose values are long narratives, numeric attributes, and typed attributes (e.g., email) whose values are not modeled as Freebase entities. The next two categories are due to limitations of the ontology, e.g., plural forms of attributes are not always synonymized with singular forms and some attributes are bad. Finally, the "Value expected" category contains the attributes for which ReNoun *should* have extracted values. One reason for missing values is that the corpus itself does not contain values of all attributes. Another reason is that some attributes are not verbalized in text. For example, attributes like `nationality` are usually not explicitly stated when expressed in text.

8 Related Work

Open information extraction (OIE) was introduced by Banko et al. (2007). For a pair of noun phrases, their system, TEXTRUNNER, looks for the attribute (or more generally the relation) in the text between them and uses a classifier to judge the trustworthiness of an extraction. WOE^{parse} (Wu and Weld, 2010) extends this by using dependency parsing to connect the subject and object. Both systems assume that the attribute is between its two arguments, an assumption that ReNoun drops since it is not suitable for nominal attributes.

Closest to our work are ReVerb (Fader et al., 2011) and Ollie (Mausam at al., 2012). ReVerb uses POS tag patterns to locate verb relations and then looks at noun phrases to the left and right for arguments. Ollie uses the ReVerb extractions as its seeds to train patterns that can further extract triples. While Ollie's patterns themselves are not limited to verb relations (they also support noun relations), the ReVerb seeds are limited to verbs, which makes Ollie's coverage on noun relations also limited. In comparison, ReNoun take a noun-centric approach and extracts many facts that do not exist in Ollie.clo

ClausIE (Del Corro and Gemulla, 2013) is an OIE framework that exploits knowledge about the grammar of the English language to find clauses in a sentence using its dependency parse. The clauses are subsequently used to generate extractions at multiple granularities, possibly with more than triples. While ClausIE comes with a predefined set of rules on how to extract facts from a dependency parse, ReNoun learns such rules from its seed facts.

Finally, Nakashole et al. (2014) and Mintz et al. (2009) find additional facts for attributes that already have facts in a knowledge base. In contrast, ReNoun is an OIE framework whose goal is to find facts for attributes without existing facts.

9 Conclusions

We described ReNoun, an open information extraction system for nominal attributes that focuses on the long tail. The key to our approach is to start from a large ontology of nominal attributes and apply noun-specific manual patterns on a large preprocessed corpus (via standard NLP components) to extract precise seed facts. We then learn a set of dependency patterns, which are used to generate a much larger set of candidate facts. We proposed a scoring function for filtering candidate facts based on pattern frequency and coherence. We demonstrated that the majority of long tail attributes in ReNoun do not have corresponding verbs in Ollie. Finally, our experiments show that our scoring function is effective in filtering candidate facts (top-1M facts are $\geq$70% precise).

In the future, we plan to extend ReNoun to extract triples whose components are not limited to Freebase IDs. As an example, extending ReNoun to handle numerical or typed attributes would involve extending our extraction pattern learning to accommodate units (e.g., kilograms) and other special data formats (e.g., addresses).

Acknowledgments

We would like to thank Luna Dong, Anjuli Kannan, Tara McIntosh, and Fei Wu for many discussions about the paper.

Hierarchical Discriminative Classification for Text-Based Geolocation

Benjamin Wing[†] **Jason Baldridge**[†]
[†]Department of Linguistics, University of Texas at Austin
ben@benwing.com, jbaldrid@utexas.edu

Abstract

Text-based document geolocation is commonly rooted in language-based information retrieval techniques over geodesic grids. These methods ignore the natural hierarchy of cells in such grids and fall afoul of independence assumptions. We demonstrate the effectiveness of using logistic regression models on a hierarchy of nodes in the grid, which improves upon the state of the art accuracy by several percent and reduces mean error distances by hundreds of kilometers on data from Twitter, Wikipedia, and Flickr. We also show that logistic regression performs feature selection effectively, assigning high weights to geocentric terms.

1 Introduction

Document geolocation is the identification of the location—a specific latitude and longitude—that forms the primary focus of a given document. This assumes that a document can be adequately associated with a *single* location, which is only valid for certain documents, generally of fairly small size. Nonetheless, there are many natural situations in which such collections arise. For example, a great number of articles in Wikipedia have been manually geotagged; this allows those articles to appear in their geographic locations in geobrowsers like Google Earth. Images in social networks such as Flickr may be geotagged by a camera and their textual tags can be treated as documents. Likewise, tweets in Twitter are often geotagged; in this case, it is possible to view either an individual tweet or the collection of tweets for a given user as a document, respectively identifying the location as the place from which the tweet was sent or the home location of the user.

Early work on document geolocation used heuristic algorithms, predicting locations based on toponyms in the text (named locations, determined with the aid of a gazetteer) (Ding et al., 2000; Smith and Crane, 2001). More recently, various researchers have used topic models for document geolocation (Ahmed et al., 2013; Hong et al., 2012; Eisenstein et al., 2011; Eisenstein et al., 2010) or other types of geographic document summarization (Mehrotra et al., 2013; Adams and Janowicz, 2012; Hao et al., 2010). A number of researchers have used metadata of various sorts for document or user geolocation, including document links and social network connections. This research has sometimes been applied to Wikipedia (Overell, 2009) or Facebook (Backstrom et al., 2010) but more commonly to Twitter, focusing variously on friends and followers (McGee et al., 2013; Sadilek et al., 2012), time zone (Mahmud et al., 2012), declared location (Hecht et al., 2011), or a combination of these (Schulz et al., 2013).

We tackle document geolocation using supervised methods based on the textual content of documents, ignoring their metadata. Metadata-based approaches can achieve great accuracy (e.g. Schulz et al. (2013) obtain 79% accuracy within 100 miles for a US-based Twitter corpus, compared with 49% using our methods on a comparable corpus), but are very specific to the particular corpus and the types of metadata it makes available. For Twitter, the metadata includes the user's declared location and time zone, information which greatly simplifies geolocation and which is unavailable for other types of corpora, such as Wikipedia. In many cases essentially no metadata is available at all, as in historical corpora in the digital humanities (Lunenfeld et al., 2012), such as those in the Perseus project (Crane, 2012). Text-based approaches can be applied to all types of corpora; metadata can be additionally incorporated when available (Han and Cook, 2013).

We introduce a hierarchical discriminative classification method for text-based geotagging. We

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 336–348,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

apply this to corpora in three languages (English, German and Portuguese). This method scales well to large training sets and greatly improves results across a wide variety of corpora, beating current state-of-the-art results by wide margins, including Twitter users (Han et al., 2014, henceforth Han14; Roller et al., 2012, henceforth Roller12); Wikipedia articles (Roller12; Wing and Baldridge, 2011, henceforth WB11); and Flickr images (O'Hare and Murdock, 2013, henceforth OM13). Importantly, this is the first method that improves upon straight uniform-grid Naive Bayes on all of these corpora, in contrast with *k*-d trees (Roller12) and the current state-of-the-art technique for Twitter users of geographically-salient feature selection (Han14).

We also show, contrary to Han14, that logistic regression when properly optimized is more accurate than state-of-the-art techniques, including feature selection, and fast enough to run on large corpora. Logistic regression itself very effectively picks out words with high geographic significance. In addition, because logistic regression does not assume feature independence, complex and overlapping features of various sorts can be employed.

2 Data

We work with six large datasets: two of geotagged tweets, three of Wikipedia articles, and one of Flickr photos. One of the two Twitter datasets is primarily localized to the United States, while the remaining datasets cover the whole world.

TWUS is a dataset of tweets compiled by Roller12. A document in this dataset is the concatenation of all tweets by a single user, as long as at least one of the user's tweets is geotagged with specific, GPS-assigned latitude/longitude coordinates. The earliest such tweet determines the user's location. Tweets outside of a bounding box covering the contiguous United States (including parts of Canada and Mexico) were discarded, as well as users that may be spammers or robots (based on the number of followers, followees and tweets). The resulting dataset contains 38M tweets from 450K users, of which 10,000 each are reserved for the development and test sets.

TWWORLD is a dataset of tweets compiled by Han et al. (2012). It was collected in a similar fashion to TWUS but differs in that it covers the entire Earth instead of primarily the United States, and consists only of geotagged tweets. Non-English tweets and those not near a city were removed, and non-alphabetic, overly short and overly infrequent words were filtered. The resulting dataset consists of 1.4M users, with 10,000 each reserved for the development and test sets.

ENWIKI13 is a dataset consisting of the 864K geotagged articles (out of 14M articles in all) in the November 4, 2013 English Wikipedia dump. It is comparable to the dataset used in WB11 and was processed using an analogous fashion. The articles were randomly split 80/10/10 into training, development and test sets.

DEWIKI14 is a similar dataset consisting of the 324K geotagged articles (out of 1.71M articles in all) in the July 5, 2014 German Wikipedia dump.

PTWIKI14 is a similar dataset consisting of the 131K geotagged articles (out of 817K articles in all) in the June 24, 2014 Portuguese Wikipedia dump.

COPHIR (Bolettieri et al., 2009) is a large dataset of images from the photo-sharing social network Flickr. It consists of 106M images, of which 8.7M are geotagged. Most images contain user-provided tags describing them. We follow algorithms described in OM13 in order to make direct comparison possible. This involves removing photos with empty tag sets and performing *bulk upload filtering*, retaining only one of a set of photos from a given user with identical tag sets. The resulting reduced set of 2.8M images is then divided 80/10/10 into training, development and test sets. The tag set of each photo is concatenated into a single piece of text (in the process losing user-supplied tag boundary information in the case of multi-word tags).

Our code and processed corpora are available for download.[1]

3 Supervised models for document geolocation

The dominant approach for text-based geolocation comes from language modeling approaches in information retrieval (Ponte and Croft, 1998; Manning et al., 2008). For this general strategy, the Earth is sub-divided into a grid, and then each training set document is associated with the cell that contains it. Some model (typically Naive Bayes) is then used to characterize each cell and

[1] https://github.com/utcompling/textgrounder/wiki/WingBaldridge_EMNLP2014

enable new documents to be assigned a latitude and longitude based on those characterizations. There are several options for constructing the grid and for modeling, which we review next.

3.1 Geodesic grids

The simplest grid is a uniform rectangular one with cells of equal-sized degrees, which was used by Serdyukov et al. (2009) for Flickr images and WB11 for Twitter and Wikipedia. This has two problems. Compared to a grid that takes document density into account, it over-represents rural areas at the expense of urban areas. Furthermore, the rectangles are not equal-area, but shrink in width away from the equator (although the shrinkage is mild until near the poles). Roller12 tackle the former issue by using an adaptive grid based on *k*-d trees, while Dias et al. (2012) handle the latter issue with an equal-area quaternary triangular mesh.

An additional issue with geodesic grids is that a single metro area may be divided between two or more cells. This can introduce a statistical bias known as the *modifiable areal unit problem* (Gehlke and Biehl, 1934; Openshaw, 1983). One way to mitigate this, implemented in Roller12's code but not investigated in their paper, is to divide a cell in a *k*-d tree in such a way as to produce the maximum margin between the dividing line and the nearest document on each side.

A more direct method is to use a city-based representation, either with a full set of sufficiently-sized cities covering the Earth and taken from a comprehensive gazetteer (Han14) or a limited, pre-specified set of cities (Kinsella et al., 2011; Sadilek et al., 2012). Han14 amalgamate cities into nearby larger cities within the same state (or equivalent); an even more direct method would use census-tract boundaries when available. Disadvantages of these methods are the dependency on time-specific population data, making them unsuitable for some corpora (e.g. 19th-century documents); the difficulty in adjusting grid resolution in a principled fashion; and the fact that not all documents are near a city (Han14 find that 8% of tweets are "rural" and cannot predicted by their model).

We construct rectangular grids, since they are very easy to implement and Dias et al. (2012)'s triangular mesh did not yield consistently better results over Wikipedia. We use both uniform grids and *k*-d tree grids with midpoint splitting.

3.2 Naive Bayes

A geodesic grid of sufficient granularity creates a large decision space, when each cell is viewed as a label to be predicted by some classifier. This situation naturally lends itself to simple, scalable language-modeling approaches. For this general strategy, each cell is characterized by a *pseudo-document* constructed from the training documents that it contains. A test document's location is then chosen based on the cell with the most similar language model according to standard measures such as Kullback-Leibler (KL) divergence (Zhai and Lafferty, 2001), which seeks the cell whose language model is closest to the test document's, or Naive Bayes (Lewis, 1998), which chooses the cell that assigns the highest probability to the test document.

Han14, Roller12 and WB11 follow this strategy, using KL divergence in preference to Naive Bayes. However, we find that Naive Bayes in conjunction with Dirichlet smoothing (Smucker and Allan, 2006) works at least as well when appropriately tuned. Dirichlet smoothing is a type of discounting model that interpolates between the unsmoothed (maximum-likelihood) document distribution $\tilde{\theta}_{d_i}$ of a document d_i and the unsmoothed distribution $\tilde{\theta}_D$ over all documents. A general interpolation model for the smoothed distribution θ_{d_i} has the following form:

$$P(w|\theta_{d_i}) = (1 - \lambda_{d_i})P(w|\tilde{\theta}_{d_i}) + \lambda_{d_i}P(w|\tilde{\theta}_D) \quad (1)$$

where the discount factor λ_{d_i} indicates how much probability mass to reserve for unseen words. For Dirichlet smoothing, λ_{d_i} is set as:

$$\lambda_{d_i} = 1 - \frac{|d_i|}{|d_i| + m} \quad (2)$$

where $|d_i|$ is the size of the document and m is a tunable parameter. This has the effect of relying more on d_i's distribution and less on the global distribution for larger documents that provide more evidence than shorter ones. Naive Bayes models are estimated easily, which allows them to handle fine-scale grid resolutions with potentially thousands or even hundreds of thousands of non-empty cells to choose among.

Figure 1 shows a choropleth map of the behavior of Naive Bayes, plotting the rank of cells for

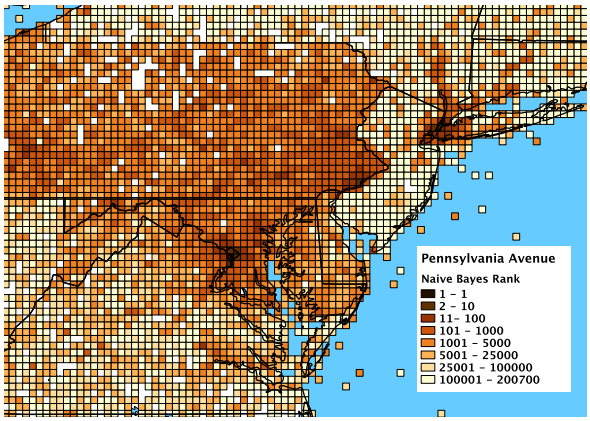

Figure 1: Relative Naive Bayes rank of cells for ENWIKI13 test document *Pennsylvania Avenue (Washington, DC)*, surrounding the true location.

the test document *Pennsylvania Avenue (Washington, DC)* in ENWIKI13, for a uniform 0.1° grid. The top-ranked cell is the correct one.

3.3 Logistic regression

The use of discrete cells over the Earth's surface allows any classification strategy to be employed, including discriminative classifiers such as logistic regression. Logistic regression often produces produces better results than generative classifiers at the cost of more time-consuming training, which limits the size of the problems it may be applied to. Training is generally unable to scale to encompass several thousand or more distinct labels, as is the case with fine-scale grids of the sort we may employ. Nonetheless we find flat logistic regression to be effective on most of our large-scale corpora, and the hierarchical classification strategy discussed in §4 allows us to take advantage of logistic regression without incurring such a high training cost.

3.4 Feature selection

Naive Bayes assumes that features are independent, which penalizes models that must accommodate many features that are poor indicators and which can gang up on the good features. Large improvements have been obtained by reducing the set of words used as features to those that are geographically salient. Cheng et al. (2010; 2013) model word locality using a unimodal distribution taken from Backstrom et al. (2008) and train a classifier to identify geographically local words based on this distribution. This unfortunately requires a large hand-annotated corpus for training. Han14 systematically investigate various feature selection methods for finding geo-indicative words, such as information gain ratio (IGR) (Quinlan, 1993), Ripley's K statistic (O'Sullivan and Unwin, 2010) and geographic density (Chang et al., 2012), showing significant improvements on TWUS and TWWORLD (§2).

For comparison with Han14, we test against an additional baseline: Naive Bayes combined with feature selection done using IGR. Following Han14, we first eliminate words which occur less than 10 times, have non-alphabetic characters in them or are shorter than 3 characters. We then compute the IGR for the remaining words across all cells at a given cell size or bucket size, select the top $N\%$ for some *cutoff percentage* N (which we vary in increments of 2%), and then run Naive Bayes at the same cell size or bucket size.

4 Hierarchical classification

To overcome the limitations of discriminative classifiers in terms of the maximum number of cells they can handle, we introduce hierarchical classification (Silla Jr. and Freitas, 2011) for geolocation. Dias et al. (2012) use a simple two-level generative hierarchical approach using Naive Bayes, but to our knowledge no previous work implements a multi-level discriminative hierarchical model with beam search for geolocation.

To construct the hierarchy, we start with a root cell c_{root} that spans the entire Earth and from there build a tree of cells at different scales, from coarse to fine. A cell at a given level is subdivided to create smaller cells at the next level of resolution that altogether cover the same area as their parent.

We use the *local classifier per parent* approach to hierarchical classification (Silla Jr. and Freitas, 2011) in which an independent classifier is learned for every node of the hierarchy above the leaf nodes. The probability of any node in the hierarchy is the product of the probabilities of that node and all of its ancestors, up to the root. This is defined recursively as:

$$\begin{aligned} P(c_{root}) &= 1.0 \\ P(c_j) &= P(c_j|\uparrow c_j)P(\uparrow c_j) \end{aligned} \quad (3)$$

where $\uparrow c_j$ indicates c_j's parent in the hierarchy.

In addition to allowing one to use many classifiers that each have a manageable number of outcomes, the hierarchical approach naturally lends itself to beam search. Rather than computing the

probability of every leaf cell using equation 3, we use a stratified beam search: starting at the root cell, keep the b highest-probability cells at each level until reaching the leaf node level. With a tight beam—which we show to be very effective—this dramatically reduces the number of model evaluations that must be performed at test time.

Grid size parameters Two factors determine the size of the grids at each level. The first-level grid is constructed the same as for Naive Bayes or flat logistic regression and is controlled by its own parameter. In addition, the *subdivision factor* N determines how we subdivide each cell to get from one level to the next. Both factors must be optimized appropriately.

For the uniform grid, we subdivide each cell into NxN subcells. In practice, there may actually be fewer subcells, because some of the potential subcells may be empty (contain no documents).

For the *k*-d grid, if level 1 is created using a bucket size B (i.e. we recursively divide cells as long as their size exceeds B), then level 2 is created by continuing to recursively divide cells that exceed a smaller bucket size B/N. At this point, the subcells of a given level-1 cell are the leaf cells contained with the cell's geographic area. The construction of level 3 proceeds similarly using bucket size B/N^2, etc.

Note that the subdivision factor has a different meaning for uniform and *k*-d tree grids. Furthermore, because creating the subdividing cells for a given cell involves dividing by N^2 for the uniform grid but N for the *k*-d tree grid, greater subdivision factors are generally required for the *k*-d tree grid to achieve similar-scale resolution.

Figure 2 shows the behavior of hierarchical LR using *k*-d trees for the test document *Pennsylvania Avenue (Washington, DC)* in ENWIKI13. After ranking the first level, the beam zooms in on the top-ranked cells and constructs a finer *k*-d tree under each one (one such subtree is shown in the top-right map callout).

5 Experimental Setup

Configurations. We experiment with several methods for configuring the grid and selecting the best cell. For grids, we use either a **uniform** or ***k*-d** tree grid. For uniform grids, the main tunable parameter is grid size (in **degrees**), while for *k*-d trees it is bucket size (**BK**), i.e. the number of documents above which a node is divided in two.

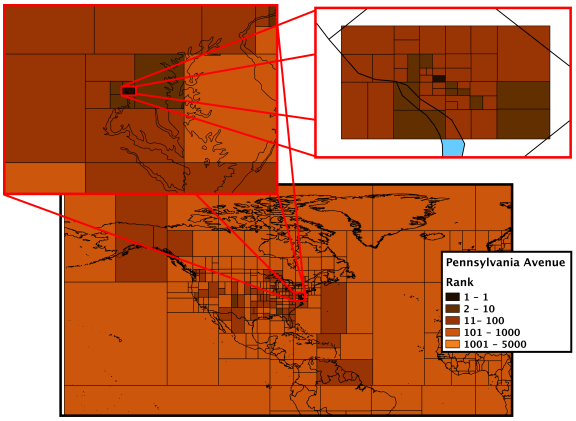

Figure 2: Relative hierarchical LR rank of cells for ENWIKI13 test document *Pennsylvania Avenue (Washington, DC)*, surrounding the true location. The first callout simply expands a portion of level 1, while the second callout shows a level 1 cell subdivided down to level 2.

For cell choice, the options are:

- **NB**: Naive Bayes baseline
- **IGR**: Naive Bayes using features selected by information gain ratio
- **FlatLR**: logistic regression model over all leaf nodes
- **HierLR**: product of logistic regression models at each node in a hierarchical grid (eq. 3)

For Dirichlet smoothing in conjunction with Naive Bayes, we set the Dirichlet parameter $m = 1,000,000$, which we found worked well in preliminary experiments. For hierarchical classification, there are additional parameters: subdivision factor (**SF**) and beam size (**BM**) (§4), and hierarchy depth (**D**) (§6.4). All of our test-set results use a depth of three levels.

Due to its speed and flexibility, we use Vowpal Wabbit (Agarwal et al., 2014) for logistic regression, estimating parameters with limited-memory BFGS (Nocedal, 1980; Byrd et al., 1995). Unless otherwise mentioned, we use 26-bit feature hashing (Weinberger et al., 2009) and 40 passes over the data (optimized based on early experiments on development data) and turn off the hold-out mechanism. For the subcell classifiers in hierarchical classification, which have fewer classes and much less data, we use 24-bit features and 12 passes.

Evaluation. To measure geolocation performance, we use three standard metrics based on *error distance*, i.e. the distance between the correct location and the predicted location. These metrics are **mean** and **median** error distance (Eisenstein et

al., 2010) and *accuracy at 161 km* (**acc@161**), i.e. within a 161-km radius, which was introduced by Cheng et al. (2010) as a proxy for accuracy within a metro area. All of these metrics are independent of cell size, unlike the measure of cell accuracy (fraction of cells correctly predicted) used in Serdyukov et al. (2009). Following Han14, we use acc@161 on development sets when choosing algorithmic parameter values such as cell and bucket sizes.

6 Results

6.1 Twitter

We show the effect of varying cell size in Table 1 and *k*-d tree bucket size in Figure 3. The number of non-empty cells is shown for each cell size and bucket size. For NB, this is the number of cells against which a comparison must be made for each test document; for FlatLR, this is the number of classes that must be distinguished. For HierLR, no figure is given because it varies from level to level and from classifier to classifier. For example, with a uniform grid and subdivision factor of 3, each level-2 subclassifier will have between 1 and 9 labels to choose among, depending on which cells are empty.

Method	Cell Size (Deg)	Cell Size (km)	#Class	Acc. @161	Mean (km)	Med. (km)
NB	0.17°		11,671	36.6	929.5	496.4
	0.50°		2,838	35.4	889.3	466.6
IGR, CU90%	1.5°		501	45.9	787.5	255.6
FlatLR	5°	556	59	35.4	727.8	248.7
	4°	445	99	44.4	718.8	227.9
	3°	334	159	47.3	721.3	186.2
	2.5°	278	208	47.5	743.9	198.9
	2°	223	316	46.9	737.7	209.9
	1.5°	167	501	46.6	762.6	226.9

HierLR, D2, SF2, BM5	4°	–	–	48.6	**695.2**	182.2
HierLR, D2, SF2, BM2	3°	–	–	**49.0**	725.1	174.6
HierLR, D3, SF2, BM2	3°	–	–	**49.0**	718.9	**173.8**
HierLR, D2, SF2, BM5	2.5°	–	–	48.2	740.9	187.7

Table 1: Dev set performance for TwUS, with uniform grids. HierLR and IGR parameters optimized using acc@161. Best metric numbers for a given method are underlined, except that overall best numbers are in bold.

FlatLR does much better than NB and IGR, and HierLR is still better. This is despite logistic regression needing to operate at a much lower resolution.[2] Interestingly, uniform-grid 2-level HierLR does better at 4° with a subdivision factor of 2 than the equivalent FlatLR run at 2°.

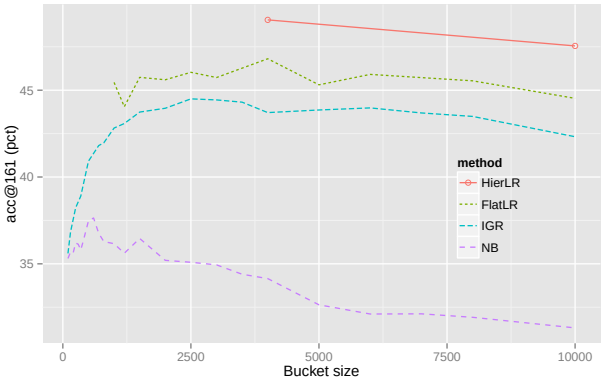

Figure 3: Dev set performance for TwUS, with *k*-d tree grids.

Table 2 shows the test set results for the various methods and metrics described in §5, on both TwUS and TwWorld.[3] HierLR is the best across all metrics; the best acc@161km and median error is obtained with a uniform grid, while HierLR with *k*-d trees obtains the best mean error.

Compared with vanilla NB, our implementation of NB using IGR feature selection obtains large gains for TwUS and moderate gains for TwWorld, showing that IGR can be an effective geolocation method for Twitter. This agrees in general with Han14's findings. We can only compare our figures directly with Han14 for *k*-d trees—in this case they use a version of the same software we use and report figures within 1% of ours for TwUS. Their remaining results are computed using a city-based grid and an NB implementation with add-one smoothing, and are significantly worse than our uniform-grid NB and IGR figures using Dirichlet smoothing, which is known to significantly outperform add-one smoothing (Smucker and Allan, 2006). For example, for NB they report 30.8% acc@161 for TwUS and 20.0% for TwWorld, compared with our 36.2% and 30.2% respectively. We suspect an additional reason for the discrepancy is due to the limitations of their city-based grid, which has no tunable parameter to optimize the grid size and requires that test instances not near a city be reported as incorrect.

Our NB figures also beat the KL divergence figures reported in Roller12 for TwUS (which they term UTGeo2011), perhaps again due to the dif-

[2] The limiting factor for resolution for us was the 24-hour per job limit on our computing cluster.

[3] Note that for TwWorld, it was necessary to modify the parameters normally passed to Vowpal Wabbit, moving up to 27-bit features and 96 passes, and 24-bit features with 24 passes in sublevels of HierLR.

Corpus	TwUS				TwWorld			
Method	Parameters	A@161	Mean	Med.	Parameters	A@161	Mean	Med.

ference in smoothing methods.

6.2 Wikipedia

Table 3 shows results on the test set of EnWiki13 for various methods. Table 5 shows the corresponding results for DeWiki14 and PtWiki14. In all cases, the best parameters for each method were determined using acc@161 on the development set, as above.

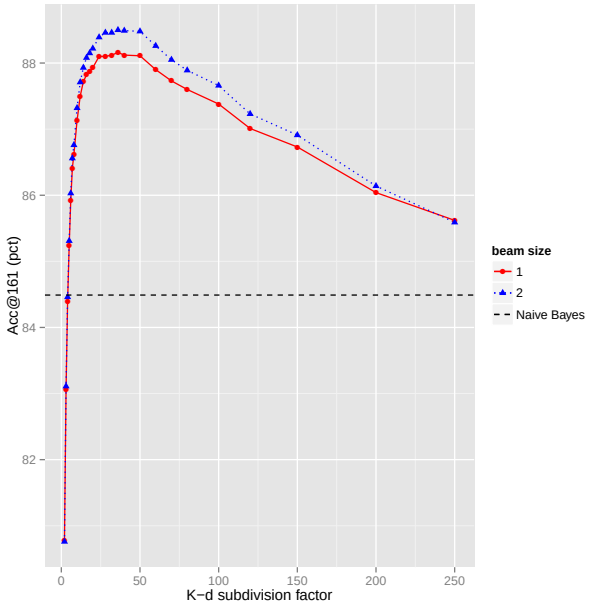

Figure 4: Plot of subdivision factor vs. acc@161 for the EnWiki13 dev set with 2-level *k*-d tree HierLR, bucket size 1500. Beam sizes above 2 yield little improvement.

HierLR is clearly the stand-out winner among all methods and metrics, and particularly so for the *k*-d tree grid. This is achieved through a high subdivision factor, especially in a 2-level hierarchy, where a factor of 36 is best, as shown in Figure 4 for EnWiki13. (For a 3-level hierarchy, the best subdivision factor is 12.)

Unlike for TwUS, FlatLR simply cannot compete with NB in the larger Wikipedias (EnWiki13 and DeWiki14). EnWiki13 especially has dense coverage across the entire world, whereas TwUS only covers the United States and parts of Canada and Mexico. Thus, there are a much larger number of non-empty cells at a given resolution and much coarser resolution required, especially with the uniform grid. For example, at 7.5° there are 933 non-empty cells, comparable to 1° for TwUS. Table 4 shows the number of classes and runtime for FlatLR and HierLR at different parameter values. The hierarchical classification approach is clearly essential for allowing us to scale the discriminative approach for a large, dense dataset across the whole world.

Method	Param	#Class	A@161	Med.	Runtime
FlatLR Uniform	10°	648	19.2	314.1	11h
	8.5°	784	26.5	248.5	16h
	7.5°	933	30.1	232.0	19h
FlatLR *k*-d	BK5000	257	57.1	133.5	5h
	BK2500	501	67.5	94.9	9h
	BK1500	825	74.7	69.9	16h
HierLR Uniform	7.5°,SF2,BM1	—	85.2	67.8	23h
	7.5°,SF3,BM5	—	86.1	34.2	27h
HierLR *k*-d	BK1500,SF5,BM1	—	88.2	19.6	23h

Table 4: Performance/runtime for FlatLR and 3-level HierLR on the EnWiki13 dev set, with varying parameters.

Moving from larger to smaller Wikipedias, FlatLR becomes more competitive. In particular, FlatLR outperforms NB and is close to HierLR for PtWiki14, the smallest of the three (and significantly smaller than TwUS). In this case, the relatively small size of the dataset and its greater geographic specificity (many articles are located in Brazil or Portugal) allows for a fine enough resolution to make FlatLR perform well—comparable to or even finer than NB.

In all of the Wikipedias, NB *k*-d outperforms

Corpus	EnWiki13				CoPhIR			
Method	Parameters	A@161	Mean	Med.	Parameters	A@161	Mean	Med.

FlatLR *k*-d	BK1500	74.8	253.2	70.0	BK3000	57.7	1961.4	72.5
HierLR Uniform	7.5°, SF3, BM5	86.2	228.3	34.0	7°, SF4, BM5	65.3	1590.2	**16.7**
HierLR *k*-d	BK1500, SF12, BM2	**88.9**	**168.7**	**15.3**	BK100000, SF15, BM5	**66.0**	**1453.3**	17.9

Table 3: Performance on the test sets of EnWiki13 and CoPhIR for different methods and metrics.

NB uniform, and HierLR outperforms both, but by greatly varying amounts, with only a 1% difference for DeWiki14 but 12% for PtWiki14. It's unclear what causes these variations, although it's worth noting that Roller12's NB *k*-d figures on an older English Wikipedia corpus were are noticeably higher than our figures: They report 90.3% acc@161, compared with our 84.5%. We verified that this is due to corpus differences: we obtain their performance when we run on their Wikipedia corpus. This suggests that the various differences may be due to vagaries of the individual corpora, e.g. the presence of differing numbers of geotagged stub articles, which are very short and thus hard to geolocate.

As for IGR, though it is competitive for Twitter, it performs badly here—in fact, it is even worse than plain Naive Bayes for all three Wikipedias (likewise for CoPhIR, in the next section).

6.3 CoPhIR

Table 3 shows results on the test set of CoPhIR for various methods, similarly to the EnWiki13 results. HierLR is again the clear winner. Unlike for EnWiki13, FlatLR is able to do fairly well. IGR performs poorly, especially when combined with *k*-d.

In general, as can be seen, for CoPhIR the median figures are very low but the mean figures very high, meaning there are many images that can be very accurately placed while the remainder are very difficult to place. (The former images likely have the location mentioned in the tags, while the latter do not.)

For CoPhIR, and also TwWorld, HierLR performs best when the root level is significantly coarser than the cell or bucket size that is best for FlatLR. The best setting for the root level appears to be correlated with cell accuracy, which in general increases with larger cell sizes. The intuition here is that HierLR works by drilling down from a single top-level child of the root cell. Thus, the higher the cell accuracy, the greater the fraction of test instances that can be improved in this fashion, and in general the better the ultimate values of the main metrics. (The above discussion isn't strictly true for beam sizes above 1, but these tend to produce marginal improvements, with little if any gain from going above a beam size of 5.) The large size of a coarse root-child cell, and correspondingly poor results for acc@161, can be offset by a high subdivision factor, which does not materially slow down the training process.

Our NB results are not directly comparable with OM13's results on CoPhIR because they use various cell-based accuracy metrics while we use cell-size-independent metrics. The closest to our acc@161 metric is their Ac1 metric, which at a cell size of 100 km corresponds to a 300km-per-side square at the equator, roughly comparable to our 161-km-radius circle. They report Ac1 figures of 57.7% for term frequency and 65.3% for user frequency, which counts the number of distinct users in a cell using a given term and is intended to offset bias resulting from users who upload a large batch of similar photos at a given location. Our term frequency figure of 65.0% significantly beats theirs, but we found that user frequency actually degraded our dev set results by 5%. The reason for this discrepancy is unclear.

6.4 Parameterization variations

Optimizing for median. Note that better values for the other metrics, especially median, can be achieved by specifically optimizing for these metrics. In general, the best parameters for median are finer-scale than those for acc@161: smaller grid sizes and bucket sizes, and greater subdivision factors. This is especially revealing in EnWiki13 and CoPhIR. For example, on the EnWiki13

Corpus	DEWIKI14				PTWIKI14			
Method	Parameters	A@161	Mean	Med.	Parameters	A@161	Mean	Med.
NB Uniform	1°	88.4	257.9	35.0	1°	76.6	470.0	48.3
NB *k*-d	BK25	89.3	192.0	**7.6**	BK100	77.1	325.0	45.9
IGR Uniform	2°, CU82%	87.1	312.9	68.2	2°, CU54%	71.3	594.6	89.4
IGR *k*-d	BK50, CU100%	86.0	226.8	10.9	BK100, CU100%	71.3	491.9	57.7
FlatLR Uniform	5°	55.1	340.4	150.1	2°	88.9	320.0	70.8
FlatLR *k*-d	BK350	82.0	193.2	24.5	BK25	86.8	320.8	30.0
HierLR Uniform	7°, SF3, BM5	88.5	184.8	30.0	7°, SF2, BM5	88.6	223.5	64.7
HierLR *k*-d	BK3500, SF25, BM5	**90.2**	**122.5**	8.6	BK250, SF12, BM2	**89.5**	**186.6**	**27.2**

Table 5: Performance on the test sets of DEWIKI14 and PTWIKI14 for different methods and metrics.

dev set, the "best" uniform NB parameter of 1.5°, as optimized on acc@161, yields a median error of 56.1 km, but an error of just 16.7 km can be achieved with the parameter setting 0.25° (which, however, drops acc@161 from 83.8% to 78.3% in the process). Similarly, for the COPHIR dev set, the optimized uniform 2-level HierLR median error of 46.6 km can be reduced to just 8.1 km by dropping from 7° to 3.5° and bumping up the subdivision factor from 4 to 35—again, causing a drop in acc@161 from 68.6% to 65.5%.

Hierarchy depth. We use a 3-level hierarchy throughout for the test set results. Evaluation on development data showed that 2-level hierarchies perform comparably for several data sets, but are less effective overall. We did not find improvements from using more than three levels. When using a simple local classifier per parent approach as we do, which chains together spines of related but independently trained classifiers when assigning a probability to a leaf cell, most of the benefit presumably comes from simply enabling logistic regression to be used with fine-grained leaf cells, overcoming the limitations of FlatLR. Further benefits of the hierarchical approach might be achieved with the data-biasing and bottom-up error propagation techniques of Bennett and Nguyen (2009) or the hierarchical Bayesian approach of Gopal et al. (2012), which is able to handle large-scale corpora and thousands of classes.

6.5 Feature Selection

The main focus of Han14 is identifying geographically salient words through feature selection. Logistic regression performs feature selection naturally by assigning higher weights to features that better discriminate among the target classes.

Table 6 shows the top 20 features ranked by feature weight for a number of different cells, labeled by the largest city in the cell. The features were produced using a uniform 5° grid, trained using 27-bit features and 40 passes over TWUS. The high number of bits per feature were chosen to ensure as few collisions as possible of different features (as it would be impossible to distinguish two words that were hashed together).

Most words are clearly region specific, consisting of cities, states and abbreviations, sports teams (*broncos*, *texans*, *niners*, *saints*), well-known streets (*bourbon*, *folsom*), characteristic features (*desert*, *bayou*, *earthquake*, *temple*), local brands (*whataburger*, *soopers*, *heb*), local foods (*gumbo*, *poutine*), and dialect terms (*hella*, *buku*).

which have geographic significance, while the bottom words are quite common. To some extent this is a feature of IGR, since it divides by the binary entropy of each word, which is directly related to its frequency. However, it shows why cutoffs around 90% of the original feature set are necessary to achieve good performance on the Twitter corpora. (IGR does not perform well on Wikipedia or CoPhIR, as shown above.)

7 Conclusion

This paper demonstrates that major performance improvements to geolocation based only on text can be obtained by using a hierarchy of logistic regression classifiers. Logistic regression also allows for the use of complex, interdependent features, beyond the simple unigram models commonly employed. Our preliminary experiments did not show noticeable improvements from bigram or character-based features, but it is possible that higher-level features such as morphological, part-of-speech or syntactic features could yield further performance gains. And, of course, these improved text-based models may help decrease error even further when metadata (e.g. time zone and declared location) are available.

An interesting extension of this work is to rely upon the natural clustering of related documents. Joint modeling of geographic topics and locations has been attempted (see §1), but has generally been applied to much smaller corpora than those considered here. Skiles (2012) found significant improvements by clustering the training documents of large-scale corpora using K-means, training separate models from each cluster, and estimating a test document's location with the cluster model returning the best overall similarity (e.g. through KL divergence). Bergsma et al. (2013) likewise cluster tweets using K-means but predict location only at the country level. Such methods could be combined with hierarchical classification to yield further gains.

Probabilistic Models of Cross-Lingual Semantic Similarity in Context Based on Latent Cross-Lingual Concepts Induced from Comparable Data

Ivan Vulić and Marie-Francine Moens
Department of Computer Science
KU Leuven, Belgium
{ivan.vulic|marie-francine.moens}@cs.kuleuven.be

Abstract

We propose the first probabilistic approach to modeling cross-lingual semantic similarity (CLSS) in context which requires only comparable data. The approach relies on an idea of projecting words and sets of words into a shared latent semantic space spanned by language-pair independent latent semantic concepts (e.g., cross-lingual topics obtained by a multilingual topic model). These latent cross-lingual concepts are induced from a comparable corpus without any additional lexical resources. Word meaning is represented as a probability distribution over the latent concepts, and a change in meaning is represented as a change in the distribution over these latent concepts. We present new models that modulate the isolated out-of-context word representations with contextual knowledge. Results on the task of suggesting word translations in context for 3 language pairs reveal the utility of the proposed contextualized models of cross-lingual semantic similarity.

1 Introduction

Cross-lingual semantic similarity (CLSS) is a metric that measures to which extent words (or more generally, text units) describe similar semantic concepts and convey similar meanings across languages. Models of cross-lingual similarity are typically used to automatically induce bilingual lexicons and have found numerous applications in information retrieval (IR), statistical machine translation (SMT) and other natural language processing (NLP) tasks. Within the IR framework, the output of the CLSS models is a key resource in the models of dictionary-based cross-lingual information retrieval (Ballesteros and Croft, 1997; Lavrenko et al., 2002; Levow et al., 2005; Wang and Oard, 2006) or may be utilized in query expansion in cross-lingual IR models (Adriani and van Rijsbergen, 1999; Vulić et al., 2013). These CLSS models may also be utilized as an additional source of knowledge in SMT systems (Och and Ney, 2003; Wu et al., 2008). Additionally, the models are a crucial component in the cross-lingual tasks involving a sort of cross-lingual knowledge transfer, where the knowledge about utterances in one language may be transferred to another. The utility of the transfer or annotation projection by means of bilingual lexicons obtained from the CLSS models has already been proven in various tasks such as semantic role labeling (Padó and Lapata, 2009; van der Plas et al., 2011), parsing (Zhao et al., 2009; Durrett et al., 2012; Täckström et al., 2013b), POS tagging (Yarowsky and Ngai, 2001; Das and Petrov, 2011; Täckström et al., 2013a; Ganchev and Das, 2013), verb classification (Merlo et al., 2002), inducing selectional preferences (Peirsman and Padó, 2010), named entity recognition (Kim et al., 2012), named entity segmentation (Ganchev and Das, 2013), etc.

The models of cross-lingual semantic similarity from parallel corpora rely on word alignment models (Brown et al., 1993; Och and Ney, 2003), but due to a relative scarceness of parallel texts for many language pairs and domains, the models of cross-lingual similarity from comparable corpora have gained much attention recently.

All these models from parallel and comparable corpora provide *ranked lists of semantically similar words* in the target language *in isolation* or *invariably*, that is, they do not explicitly iden-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 349–362,

tify and encode different senses of words. In practice, it means that, given the sentence *"The coach of his team was not satisfied with the game yesterday."*, these context-insensitive models of similarity are not able to detect that the Spanish word *entrenador* is more similar to the polysemous word *coach* in the context of this sentence than the Spanish word *autocar*, although *autocar* is listed as the most semantically similar word to *coach* globally/invariably without any observed context. In another example, while Spanish words *partido*, *encuentro*, *cerilla* or *correspondencia* are all highly similar to the ambiguous English word *match* when observed in isolation, given the Spanish sentence *"She was unable to find a match in her pocket to light up a cigarette."*, it is clear that the strength of semantic similarity should change in context as only *cerilla* exhibits a strong semantic similarity to *match* within this particular sentential context.

Following this intuition, in this paper we investigate models of cross-lingual semantic similarity in context. The context-sensitive models of similarity target to *re-rank* the lists of semantically similar words based on the co-occurring contexts of words. Unlike prior work (e.g., (Ng et al., 2003; Prior et al., 2011; Apidianaki, 2011)), *we explore these models in a particularly difficult and minimalist setting that builds only on co-occurrence counts and latent cross-lingual semantic concepts induced directly from comparable corpora, and which does not rely on any other resource (e.g., machine-readable dictionaries, parallel corpora, explicit ontology and category knowledge)*. In that respect, the work reported in this paper extends the current research on purely statistical data-driven distributional models of cross-lingual semantic similarity that are built upon the idea of latent cross-lingual concepts (Haghighi et al., 2008; Daumé III and Jagarlamudi, 2011; Vulić et al., 2011; Vulić and Moens, 2013) induced from non-parallel data. While all the previous models in this framework are context-insensitive models of semantic similarity, we demonstrate how to build context-aware models of semantic similarity within the same probabilistic framework which relies on the same shared set of latent concepts.

The main contributions of this paper are:

- We present a new probabilistic approach to modeling cross-lingual semantic similarity in context based on latent cross-lingual semantic concepts induced from non-parallel data.
- We show how to use the models of cross-lingual semantic similarity in the task of suggesting word translations in context.
- We provide results for three language pairs which demonstrate that contextualized models of similarity significantly outscore context-insensitive models.

2 Towards Cross-Lingual Semantic Similarity in Context

Latent Cross-Lingual Concepts. Latent cross-lingual concepts/senses may be interpreted as language-independent semantic concepts present in a multilingual corpus (e.g., document-aligned Wikipedia articles in English, Spanish and Dutch) that have their language-specific representations in different languages. For instance, having a multilingual collection in English, Spanish and Dutch, and then discovering a latent semantic concept on *Soccer*, that concept would be represented by words (actually probabilities over words $P(w|z_k)$, where w denotes a word, and z_k denotes k-th latent concept): {*player, goal, coach, ...*} in English, *balón (ball), futbolista (soccer player), equipo (team), ...*} in Spanish, and {*wedstrijd (match), elftal (soccer team), doelpunt (goal), ...*} in Dutch. Given a multilingual corpus $\mathcal{C}$, the goal is to learn and extract a set $\mathcal{Z}$ of K latent cross-lingual concepts $\{z_1, \ldots, z_K\}$ that optimally describe the observed data, that is, the multilingual corpus $\mathcal{C}$. Extracting cross-lingual concepts actually implies learning *per-document concept distributions* for each document in the corpus, and discovering language-specific representations of these concepts given by *per-concept word distributions* in each language.

$\mathcal{Z} = \{z_1, \ldots, z_K\}$ represents the set of K latent cross-lingual concepts present in the multilingual corpus. These K semantic concepts actually span a latent cross-lingual semantic space. Each word w, irrespective of its actual language, may be represented in that latent semantic space as a K-dimensional vector, where each vector component is a conditional concept score $P(z_k|w)$.

A number of models may be employed to induce the latent concepts. For instance, one could use cross-lingual Latent Semantic Indexing (Dumais et al., 1996), probabilistic Principal Component Analysis (Tipping and Bishop, 1999), or a probabilistic interpretation of non-negative matrix

factorization (Lee and Seung, 1999; Gaussier and Goutte, 2005; Ding et al., 2008) on concatenated documents in aligned document pairs. Other more recent models include matching canonical correlation analysis (Haghighi et al., 2008; Daumé III and Jagarlamudi, 2011) and multilingual probabilistic topic models (Ni et al., 2009; De Smet and Moens, 2009; Mimno et al., 2009; Boyd-Graber and Blei, 2009; Zhang et al., 2010; Fukumasu et al., 2012).

Due to its inherent language pair independent nature and state-of-the-art performance in the tasks such as bilingual lexicon extraction (Vulić et al., 2011) and cross-lingual information retrieval (Vulić et al., 2013), the description in this paper relies on the multilingual probabilistic topic modeling (MuPTM) framework. We draw a direct parallel between latent cross-lingual concepts and latent cross-lingual topics, and we present the framework from the MuPTM perspective, but the proposed framework is generic and allows the usage of all other models that are able to compute probability scores $P(z_k|w)$. These scores in MuPTM are induced from their output language-specific *per-topic word distributions*. The multilingual probabilistic topic models output probability scores $P(w_i^S|z_k)$ and $P(w_j^T|z_k)$ for each $w_i^S \in V^S$ and $w_j^T \in V^T$ and each $z_k \in \mathcal{Z}$, and it holds $\sum_{w_i^S \in V^S} P(w_i^S|z_k) = 1$ and $\sum_{w_j^T \in V^T} P(w_j^T|z_k) = 1$. The scores are then used to compute scores $P(z_k|w_i^S)$ and $P(z_k|w_j^T)$ in order to represent words from the two different languages in the same latent semantic space in a uniform way.

Context-Insensitive Models of Similarity. Without observing any context, the standard models of semantic word similarity that rely on the semantic space spanned by latent cross-lingual concepts in both monolingual (Dinu and Lapata, 2010a; Dinu and Lapata, 2010b) and multilingual settings (Vulić et al., 2011) typically proceed in the following manner. Latent language-independent concepts (e.g., cross-lingual topics or latent word senses) are estimated on a large corpus. The K-dimensional vector representation of the word $w_1^S \in V^S$ is:

$$vec(w_1^S) = [P(z_1|w_1^S), \ldots, P(z_K|w_1^S)] \quad (1)$$

Similarly, we are able to represent any target language word w_2^T in the same latent semantic space by a K-dimensional vector with scores $P(z_k|w_2^T)$. Each word regardless of its language is represented as a distribution over K latent concepts. The similarity between w_1^S and some word $w_2^T \in V^T$ is then computed as the similarity between their K-dimensional vector representations using some of the standard similarity measures (e.g., the Kullback-Leibler or the Jensen-Shannon divergence, the cosine measure). These methods use only global co-occurrence statistics from the training set and do not take into account any contextual information. They provide only *out-of-context word representations* and are therefore able to deliver only *context-insensitive models of similarity*.

Defining Context. Given an occurrence of a word w_1^S, we build its context set $Con(w_1^S) = \{cw_1^S, \ldots, cw_r^S\}$ that comprises r words from V^S that co-occur with w_1^S in a defined *contextual scope* or granularity. In this work we do not investigate the influence of the context scope (e.g., document-based, paragraph-based, window-based contexts). Following the recent work from Huang et al. (2012) in the monolingual setting, we limit the contextual scope to the *sentential context*. However, we emphasize that the proposed models are designed to be fully functional regardless of the actual chosen context granularity. e.g., when operating in the sentential context, $Con(w_1^S)$ consists of words occurring in the same sentence with the particular instance of w_1^S. Following Mitchell and Lapata (2008), for the sake of simplicity, we impose the *bag-of-words* assumption, and do not take into account the order of words in the context set as well as context words' dependency relations to w_1^S. Investigating different context types (e.g., dependency-based) is a subject of future work.

By using all words occurring with w_1^S in a context set (e.g., a sentence) to build the set $Con(w_1^S)$, we do not make any distinction between "informative and "uninformative" context words. However, some context words bear more contextual information about the observed word w_1^S and are stronger indicators of the correct word meaning in that particular context. For instance, in the sentence *"The coach of his team was not satisfied with the game yesterday"*, words *game* and *team* are strong clues that *coach* should be translated as *entrenador* while the context word *yesterday* does not bring any extra contextual information that could resolve the ambiguity.

Therefore, in the final context set $Con(w_1^S)$ it is useful to retain only the context words that re-

ally bring extra semantic information. We achieve that by exploiting the same latent semantic space to provide the similarity score between the observed word w_1^S and each word $cw_i^S, i = 1, \ldots, r$ from its context set $Con(w_1^S)$. Each word cw_i^S may be represented by its vector $vec(cw_i^S)$ (see eq. (1)) in the same latent semantic space, and there we can compute the similarity between its vector and $vec(w_1^S)$. We can then sort the similarity scores for each cw_i^S and retain only the top scoring M context words in the final set $Con(w_1^S)$. The procedure of *context sorting and pruning* should improve the semantic cohesion between w_1^S and its context since only informative context features are now present in $Con(w_1^S)$, and we reduce the noise coming from uninformative contextual features that are not semantically related to w_1^S. Other options for the context sorting and pruning are possible, but the main goal in this paper is to illustrate the core utility of the procedure.

3 Cross-Lingual Semantic Similarity in Context via Latent Concepts

Representing Context. The probabilistic framework that is supported by latent cross-lingual concepts allows for having the K-dimensional vector representations in the same latent semantic space spanned by cross-lingual topics for: (1) Single words regardless of their actual language, and (2) Sets that comprise multiple words. Therefore, *we are able to project the observed source word, all target words, and the context set of the observed source word to the same latent semantic space spanned by latent cross-lingual concepts*.

Eq. (1) shows how to represent single words in the latent semantic space. Now, we present a way to address compositionality, that is, we show how to build the same representations in the same latent semantic space beyond the word level. We need to compute a conditional concept distribution for the context set $Con(w_1^S)$, that is, we have to compute the probability scores $P(z_k|Con(w_1^S))$ for each $z_k \in \mathcal{Z}$. Remember that the context $Con(w_1^S)$ is actually a set of r (or M after pruning) words $Con(w_1^S) = \{cw_1^S, \ldots, cw_r^S\}$. Under the *single-topic assumption* (Griffiths et al., 2007) and following Bayes' rule, it holds:

$$P(z_k|Con(w_1^S)) = \frac{P(Con(w_1^S)|z_k)P(z_k)}{P(Con(w_1^S))} = \frac{P(cw_1^S, \ldots, cw_r^S|z_k)P(z_k)}{\sum_{l=1}^{K} P(cw_1^S, \ldots, cw_r^S|z_l)P(z_l)} \quad (2)$$

$$= \frac{\prod_{j=1}^{r} P(cw_j^S|z_k)P(z_k)}{\sum_{l=1}^{K} \prod_{j=1}^{r} P(cw_j^S|z_l)P(z_l)} \quad (3)$$

Note that here we use a simplification where we assume that all $cw_j^S \in Con(w_1^S)$ are conditionally independent given z_k. The assumption of the conditional independence of unigrams is a standard heuristic applied in *bag-of-words* model in NLP and IR (e.g., one may observe a direct analogy to probabilistic language models for IR where the assumption of independence of query words is imposed (Ponte and Croft, 1998; Hiemstra, 1998; Lavrenko and Croft, 2001)), but we have to forewarn the reader that in general the equation $P(cw_1^S, \ldots, cw_r^S|z_k) = \prod_{j=1}^{r} P(cw_j^S|z_k)$ is not exact. However, by adopting the conditional independence assumption, in case of the uniform topic prior $P(z_k)$ (i.e., we assume that we do not posses any prior knowledge about the importance of latent cross-lingual concepts in a multilingual corpus), eq. (3) may be further simplified:

$$P(z_k|Con(w_1^S)) \approx \frac{\prod_{j=1}^{r} P(cw_j^S|z_k)}{\sum_{l=1}^{K} \prod_{j=1}^{r} P(cw_j^S|z_l)} \quad (4)$$

The representation of the context set in the latent semantic space is then:

$$vec(Con(w_1^S)) = [P(z_1|Con(w_1^S)), \ldots, P(z_K|Con(w_1^S))]$$

We can then compute the similarity between words and sets of words given in the same latent semantic space in a uniform way, irrespective of their actual language. We use all these properties when building our context-sensitive CLSS models.

One remark: As a by-product of our modeling approach, by this procedure for computing representations for sets of words, we have in fact paved the way towards compositional cross-lingual models of similarity which rely on latent cross-lingual concepts. Similar to compositional models in monolingual settings (Mitchell and Lapata, 2010; Rudolph and Giesbrecht, 2010; Baroni and Zamparelli, 2010; Socher et al., 2011; Grefenstette and Sadrzadeh, 2011; Blacoe and Lapata, 2012; Clarke, 2012; Socher et al., 2012) and multilingual settings (Hermann and Blunsom, 2014; Kočiský et al., 2014), the representation of a set of words (e.g., a phrase or a sentence) is exactly the same as the representation of a single word; it is simply a K-dimensional real-valued vector. Our work on inducing structured representations of words and

text units beyond words is similar to (Klementiev et al., 2012; Hermann and Blunsom, 2014; Kočiský et al., 2014), but unlike them, we do not need high-quality sentence-aligned parallel data to induce bilingual text representations. Moreover, this work on compositionality in multilingual settings is only preliminary (e.g., we treat phrases and sentences as bags-of-words), and in future work we will aim to include syntactic information in the composition models as already done in monolingual settings (Socher et al., 2012; Hermann and Blunsom, 2013).

Intuition behind the Approach. Going back to our novel CLSS models in context, these models rely on the representations of words and their contexts in the same latent semantic space spanned by latent cross-lingual concepts/topics. The models differ in the way the contextual knowledge is fused with the out-of-context word representations.

The key idea behind these models is to represent a word w_1^S in the latent semantic space as a distribution over the latent cross-lingual concepts, but now with an additional modulation of the representation after taking its local context into account. The modulated word representation in the semantic space spanned by K latent cross-lingual concepts is then:

$$vec(w_1^S, Con(w_1^S)) = [P'(z_1|w_1^S), \ldots, P'(z_K|w_1^S)] \quad (5)$$

where $P'(z_K|w_1^S)$ denotes the recalculated (or modulated) probability score for the conditional concept/topic distribution of w_1^S after observing its context $Con(w_1^S)$. For an illustration of the key idea, see fig. 1. The intuition is that the context helps to disambiguate the true meaning of the occurrence of the word w_1^S. In other words, after observing the context of the word w_1^S, fewer latent cross-lingual concepts will share most of the probability mass in the modulated context-aware word representation.

Model I: Direct-Fusion. The first approach makes the conditional distribution over latent semantic concepts directly dependent on both word w_1^S and its context $Con(w_1^S)$. The probability score $P'(z_k|w_1^S)$ from eq. (5) for each $z_k \in \mathcal{Z}$ is then given as $P'(z_k|w_1^S) = P(z_k|w_1^S, Con(w_1^S))$.

We have to estimate the probability $P(z_k|w_1^S, Con(w_1^S))$, that is, the probability that word w_1^S is assigned to the latent concept/topic z_k given its context $Con(w_1^S)$:

$$P(z_k|w_1^S, Con(w_1^S)) = \frac{P(z_k, w_1^S)P(Con(w_1^S)|z_k)}{\sum_{l=1}^{K} P(z_l, w_1^S)P(Con(w_1^S)|z_l)} \quad (6)$$

Since $P(z_k, w_1^S) = P(w_1^S|z_k)P(z_k)$, if we closely follow the derivation from eq. (3) which shows how to project context into the latent semantic space (and again assume the uniform topic prior $P(z_k)$), we finally obtain the following formula:

$$P'(z_k|w_1^S) \approx \frac{P(w_1^S|z_k)\prod_{j=1}^{r} P(cw_j^S|z_k)}{\sum_{l=1}^{K} P(w_1^S|z_l)\prod_{j=1}^{r} P(cw_j^S|z_l)} \quad (7)$$

The ranking of all words $w_2^T \in V^T$ according to their similarity to w_1^S may be computed by detecting the similarity score between their representation in the K-dimensional latent semantic space and the modulated source word representation as given by eq. (5) and eq. (7) using any of the existing similarity functions (Lee, 1999; Cha, 2007). The similarity score $Sim(w_1^S, w_2^T, Con(w_1^S))$ between some $w_2^T \in V^T$ represented by its vector $vec(w_2^T)$ and the observed word w_1^S given its context $Con(w_1^S)$ is computed as:

$$\begin{aligned} &sim(w_1^S, w_2^T, Con(w_1^S)) \\ &= SF\Big(vec\big(w_1^S, Con(w_1^S)\big), vec\big(w_2^T\big)\Big) \end{aligned} \quad (8)$$

where SF denotes a similarity function. Words are then ranked according to their respective similarity scores and the best scoring candidate may be selected as the best translation of an occurrence of the word w_1^S given its local context. Since the contextual knowledge is integrated directly into the estimation of probability $P(z_k|w_1^S, Con(w_1^S))$, we name this context-aware CLSS model the *Direct-Fusion* model.

Model II: Smoothed-Fusion. The next model follows the modeling paradigm established within the framework of language modeling (LM), where the idea is to "back off" to a lower order N-gram in case we do not possess any evidence about a higher-order N-gram (Jurafsky and Martin, 2000). The idea now is to smooth the representation of a word in the latent semantic space induced only by the words in its local context with the out-of-context type-based representation of that word induced directly from a large training corpus. In other words, the modulated probability score $P'(z_k|w_1^S)$ from eq. (5) is calculated as:

$$P'(z_k|w_1^S) = \lambda_1 P(z_k|Con(w_1^S)) + (1-\lambda_1)P(z_k|w_1^S) \quad (9)$$

where λ_1 is the interpolation parameter, $P(z_k|w_1^S)$ is the out-of-context conditional concept probability score as in eq. (1), and $P(z_k|Con(w_1^S))$ is given by eq. (3). This model compromises between the pure contextual word representation and

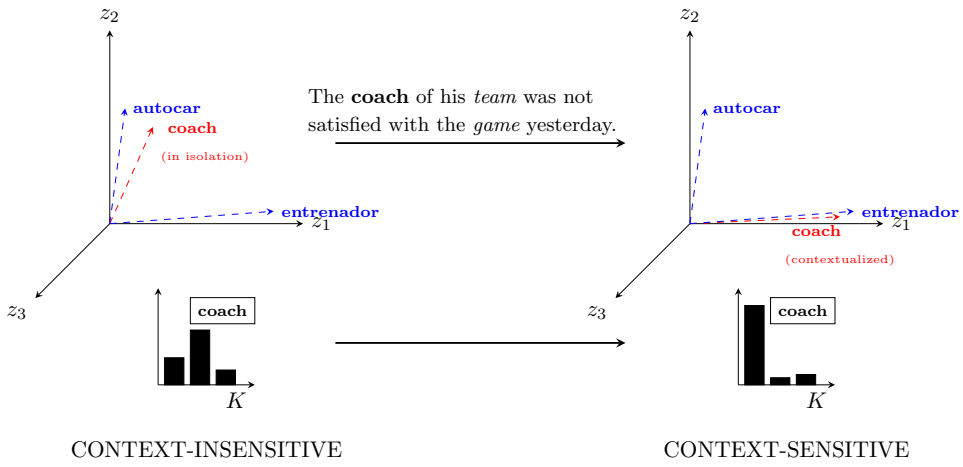

Figure 1: An illustrative toy example of the main intuitions in our probabilistic framework for building context sensitive models with only three latent cross-lingual concepts (axes z_1, z_2 and z_3): A change in meaning is reflected as a change in a probability distribution over latent cross-lingual concepts that span a shared latent semantic space. A change in the probability distribution may then actually steer an English word *coach* towards its correct (Spanish) meaning in context.

the out-of-context word representation. In cases when the local context of word w_1^S is informative enough, the factor $P(z_k|Con(w_1^S))$ is sufficient to provide the ranking of terms in V^T, that is, to detect words that are semantically similar to w_1^S based on its context. However, if the context is not reliable, we have to smooth the pure context-based representation with the out-of-context word representation (the factor $P(z_k|w_1^S)$). We call this model the *Smoothed-Fusion* model.

The ranking of words $w_2^T \in V^T$ then finally proceeds in the same manner as in Direct-Fusion following eq. (8), but now using eq. (9) for the modulated probability scores $P'(z_k|w_1^S)$.

Model III: Late-Fusion. The last model is conceptually similar to Smoothed-Fusion, but it performs smoothing at a later stage. It proceeds in two steps: (1) Given a target word $w_2^T \in V^T$, the model computes similarity scores separately between (i) the context set $Con(w_1^S)$ and w_2^T, and (ii) the word w_1^S in isolation and w_2^T (again, on the type level); (2) It linearly combines the obtained similarity scores. More formally, we may write:

$$\begin{aligned} &Sim(w_1^S, w_2^T, Con(w_1^S)) \\ &= \lambda_2 SF\Big(vec(Con(w_1^S)), vec(w_2^T)\Big) \\ &+ (1-\lambda_2) SF\Big(vec(w_1^S), vec(w_2^T)\Big) \end{aligned} \quad (10)$$

where λ_2 is the interpolation parameter. Since this model computes the similarity with each target word separately for the source word in isolation and its local context, and combines the obtained similarity scores after the computations, this model is called *Late-Fusion*.

4 Experimental Setup

Evaluation Task: Suggesting Word Translations in Context. Given an occurrence of a polysemous word $w_1^S \in V^S$ in the source language L_S with vocabulary V^S, the task is to choose the correct translation in the target language L_T of that particular occurrence of w_1^S from the given set $\mathcal{T} = \{t_1^T, \ldots, t_q^T\}$, $\mathcal{T} \subseteq V^T$, of its q possible translations/meanings (i.e., its translation or sense inventory). The task of *suggesting a word translation in context* may be interpreted as ranking the q translations with respect to the observed local context $Con(w_1^S)$ of the occurrence of the word w_1^S. The best scoring translation candidate in the ranked list is then the suggested correct translation for that particular occurrence of w_1^S after observing its local context $Con(w_1^S)$.

Training Data. We use the following corpora for inducing latent cross-lingual concepts/topics, i.e., for training our multilingual topic model: (i) a collection of 13,696 Spanish-English Wikipedia article pairs (Wiki-ES-EN), (ii) a collection of 18,898 Italian-English Wikipedia article pairs, (iii) a collection of 7,612 Dutch-English Wikipedia article pairs (Wiki-NL-EN), and (iv) the Wiki-NL-EN corpus augmented with 6,206 Dutch-English document pairs from Europarl (Koehn, 2005) (Wiki+EP-NL-EN). The corpora were previously used in (Vulić and Moens, 2013). No explicit use is made of sentence-level alignments in Europarl.

Table 2: Sets of 15 ambiguous words in Spanish, Italian and Dutch from our test set accompanied by the sets of their respective possible senses/translations in English.

All corpora are theme-aligned comparable corpora, i.e, the aligned document pairs discuss similar themes, but are in general not direct translations (except for Europarl). By training on Wiki+EP-NL-EN we want to test how the training corpus of higher quality affects the estimation of latent cross-lingual concepts that span the shared latent semantic space and, consequently, the overall results in the task of suggesting word translations in context. Following prior work (Koehn and Knight, 2002; Haghighi et al., 2008; Prochasson and Fung, 2011; Vulić and Moens, 2013), we retain only nouns that occur at least 5 times in the corpus. We record lemmatized word forms when available, and original forms otherwise. We use TreeTagger (Schmid, 1994) for POS tagging and lemmatization.

Test Data. We have constructed test datasets in Spanish (ES), Italian (IT) and Dutch (NL), where the aim is to find their correct translation in English (EN) given the sentential context. We have selected 15 polysemous nouns (see tab. 2 for the list of nouns along with their possible translations) in each of the 3 languages, and have manually extracted 24 sentences (not present in the training data) for each noun that capture different meanings of the noun from Wikipedia. In order to construct datasets that are balanced across different possible translations of a noun, in case of q different translation candidates in $\mathcal{T}$ for some word w_1^S, the dataset contains exactly $24/q$ sentences for each translation from $\mathcal{T}$. In total, we have designed 360 sentences for each language

pair (ES/IT/NL-EN), 1080 sentences in total.[1]. We have used 5 extra nouns with 20 sentences each as a development set to tune the parameters of our models. As a by-product, we have built an initial repository of ES/IT/NL ambiguous words. Tab. 1 presents a small sample from the IT evaluation dataset, and illustrates the task of suggesting word translations in context.

Evaluation Procedure. Our task is to present the system a list of possible translations and let the system decide a *single most likely translation* given the word and its sentential context. Ground truth thus contains one word, that is, one correct translation for each sentence from the evaluation dataset. We have manually annotated the correct translation for the ground truth[1] by inspecting the discourse in Wikipedia articles and the interlingual Wikipedia links. We measure the performance of all models as *Top 1* accuracy (Acc_1) (Gaussier et al., 2004; Tamura et al., 2012). It denotes the number of word instances from the evaluation dataset whose top proposed candidate in the ranked list of translation candidates from $\mathcal{T}$ is exactly the correct translation for that word instance as given by ground truth over the total number of test word instances (360 in each test dataset).

Parameters. We have tuned λ_1 and λ_2 on the development sets. We set $\lambda_1 = \lambda_2 = 0.9$ for all language pairs. We use sorted context sets (see sect. 2) and perform a cut-off at $M = 3$ most descriptive context words in the sorted context sets for all models. In the following section we discuss the utility of this context sorting and pruning, as well as its influence on the overall results.

Inducing Latent Cross-Lingual Concepts. Our context-aware models are generic and allow experimentations with different models that induce latent cross-lingual semantic concepts. However, in this particular work we present results obtained by a multilingual probabilistic topic model called bilingual LDA (Mimno et al., 2009; Ni et al., 2009; De Smet and Moens, 2009). The BiLDA model is a straightforward multilingual extension of the standard LDA model (Blei et al., 2003). For the details regarding the modeling, generative story and training of the bilingual LDA model, we refer the interested reader to the aforementioned relevant literature.

We have used the Gibbs sampling procedure (Geman and Geman, 1984) tailored for BiLDA in particular for training and have experimented with different number of topics K in the interval $300 - 2500$. Here, we present only the results obtained with $K = 2000$ for all language pairs which also yielded the best or near-optimal performance in (Dinu and Lapata, 2010b; Vulić et al., 2011). Other parameters of the model are set to the typical values according to Steyvers and Griffiths (2007): $\alpha = 50/K$ and $\beta = 0.01$. [2]

Models in Comparison. We test the performance of our Direct-Fusion, Smoothed-Fusion and Late-Fusion models, and compare their results with the context-insensitive CLSS models described in sect. 2 (*No-Context*). We provide results with two different similarity functions: (1) We have tested different SF-s (e.g., the Kullback-Leibler and the Jensen-Shannon divergence, the cosine measure) on the K-dimensional vector representations, and have detected that in general the best scores are obtained with the Bhattacharyya coefficient (*BC*) (Cha, 2007; Kazama et al., 2010), (2) Another similarity method we use is the so-called *Cue* method (Griffiths et al., 2007; Vulić et al., 2011), which models the probability that a target word t_i^T will be generated as an association response given some cue source word w_1^S. In short, the method computes the score $P(t_i^T|w_1^S) = P(t_i^T|z_k)P(z_k|w_1^S)$. We can use the scores $P(t_i^T|w_1^S)$ obtained by inputting out-of-context probability scores $P(z_k|w_1^S)$ or modulated probability scores $P'(z_k|w_1^S)$ to produce the ranking of translation candidates.

5 Results and Discussion

The performance of all the models in comparison is displayed in tab. 3. These results lead us to several conclusions:

(i) All proposed context-sensitive CLSS models suggesting word translations in context significantly outperform context-insensitive CLSS models, which are able to produce only word translations in isolation. The improvements in results when taking context into account are ob-

[1] Available at `http://people.cs.kuleuven.be/~ivan.vulic/software/`

[2] We are well aware that different hyper-parameter settings (Asuncion et al., 2009; Lu et al., 2011), might have influence on the quality of learned latent cross-lingual concepts/topics and, consequently, the quality of latent semantic space, but that analysis is not the focus of this work. Additionally, we perform *semantic space pruning* (Reisinger and Mooney, 2010; Vulić and Moens, 2013). All computations are performed over the best scoring 100 cross-lingual topics according to their respective scores $P(z_k|w_i^S)$ similarly to (Vulić and Moens, 2013).

Direction:	ES→EN		IT→EN		NL→EN (Wiki)		NL→EN (Wiki+EP)	
Model	Acc_1 (SF=BC)	Acc_1 (SF=Cue)	Acc_1 (SF=BC)	Acc_1 (SF=Cue)	Acc_1 (SF=BC)	Acc_1 (SF=Cue)	Acc_1 (SF=BC)	Acc_1 (SF=Cue)
No-Context	.406	.406	.408	.408	.433	.433	.433	.433
Direct-Fusion	.617	.575	.714	.697	.603	.592	.606	.636
Smoothed-Fusion	.664	**.703***	.731	**.789***	**.669**	**.712***	**.692**	**.761***
Late-Fusion	**.675**	.667	**.742**	.728	.667	.644	.683	.722

Table 3: Results on the 3 evaluation datasets. Translation direction is ES/IT/NL→EN. The improvements of all contextualized models over non-contextualized models are statistically significant according to a chi-square statistical significance test ($p<0.05$). The asterisk (*) denotes significant improvements of Smoothed-Fusion over Late-Fusion using the same significance test.

served for all 3 language pairs. The large improvements in the results (i.e., we observe an average relative increase of 51.6% for the BC+Direct-Fusion combination, 64.3% for BC+Smoothed-Fusion, 64.9% for BC+Late-Fusion, 49.1% for Cue+Direct-Fusion, 76.7% for Cue+Smoothed-Fusion, and 64.5% for Cue+Late-Fusion) confirm that the local context of a word is essential in acquiring correct word translations for polysemous words, as isolated non-contextualized word representations are not sufficient.

(ii) The choice of a similarity function influences the results. On average, the Cue method as SF outperforms other standard similarity functions (e.g., Kullback-Leibler, Jensen-Shannon, cosine, BC) in this evaluation task. However, it is again important to state that *regardless of the actual choice of SF, context-aware models that modulate out-of-context word representations using the knowledge of local context outscore context-insensitive models that utilize non-modulated out-of-context representations* (with all other parameters equal).

(iii) The Direct-Fusion model, conceptually similar to a model of word similarity in context in monolingual settings (Dinu and Lapata, 2010a), is outperformed by the other two context-sensitive models. In Direct-Fusion, the observed word and its context are modeled in the same fashion, that is, the model does not distinguish between the word and its surrounding context when it computes the modulated probability scores $P'(z_k|w_1^S)$ (see eq. (7)). Unlike Direct-Fusion, the modeling assumptions of Smoothed-Fusion and Late-Fusion provide a clear distinction between the observed word w_1^S and its context $Con(w_1^S)$ and combine the out-of-context representation of w_1^S and its contextual knowledge into a smoothed LM-inspired probabilistic model. As the results reveal, that strategy leads to better overall scores. The best scores in general are obtained by Smoothed-Fusion, but it is also outperformed by Late-Fusion in several experimental runs where BC was used as SF. However, the difference in results between Smoothed-Fusion and Late-Fusion in these experimental runs is not statistically significant according to a chi-squared significance test ($p < 0.05$).

(iv) The results for Dutch-English are influenced by the quality of training data. The performance of our models of similarity is higher for models that rely on latent-cross lingual topics estimated from the data of higher quality (i.e., compare the results when trained on Wiki and Wiki+EP in tab. 3). The overall quality of our models of similarity is of course dependent on the quality of the latent cross-lingual topics estimated from training data, and the quality of these latent cross-lingual concepts is further dependent on the quality of multilingual training data. This finding is in line with a similar finding reported for the task of bilingual lexicon extraction (Vulić and Moens, 2013).

(v) Although Dutch is regarded as more similar to English than Italian or Spanish, we do not observe any major increase in the results on both test datasets for the English-Dutch language pair compared to English-Spanish/Italian. That phenomenon may be attributed to the difference in size and quality of our training Wikipedia datasets. Moreover, while the probabilistic framework proposed in this chapter is completely language pair agnostic as it does not make any language pair dependent modeling assumptions, we acknowledge the fact that all three language pairs comprise languages coming from the same phylum, that is, the Indo-European language family. Future extensions of our probabilistic modeling framework also include porting the framework to other more distant language pairs that do not share the same roots nor the same alphabet (e.g., English-Chinese/Hindi).

Analysis of Context Sorting and Pruning. We

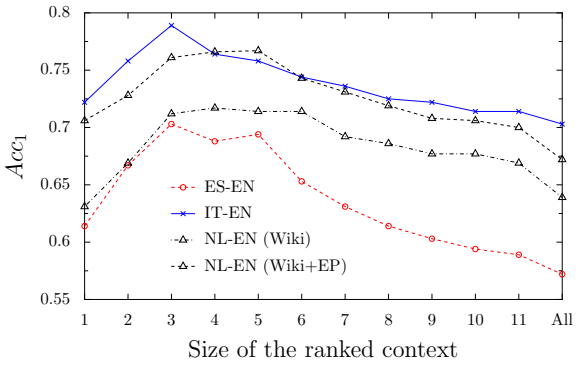

Figure 2: The influence of the size of sorted context on the accuracy of word translation in context. The model is Cue+Smoothed-Fusion.

also investigate the utility of context sorting and pruning, and its influence on the overall results in our evaluation task. Therefore, we have conducted experiments with sorted context sets that were pruned at different positions, ranging from 1 (only the most similar word to w_1^S in a sentence is included in the context set $Con(w_1^S)$) to *All* (all words occurring in a same sentence with w_1^S are included in $Con(w_1^S)$). The monolingual similarity between w_1^S and each potential context word in a sentence has been computed using BC on their out-of-context representations in the latent semantic space spanned by cross-lingual topics. Fig. 2 shows how the size of the sorted context influences the overall results. The presented results have been obtained by the Cue+Smoothed-Fusion combination, but a similar behavior is observed when employing other combinations.

Fig. 2 clearly indicates the importance of context sorting and pruning. The procedure ensures that only the most semantically similar words in a given scope (e.g., a sentence) influence the choice of a correct meaning. In other words, closely semantically similar words in the same sentence are more reliable indicators for the most probable word meaning. They are more informative in modulating the out-of-context word representations in context-sensitive similarity models. We observe large improvements in scores when we retain only the top M semantically similar words in the context set (e.g., when M=5, the scores are 0.694, 0.758, 0.717, and 0.767 for ES-EN, IT-EN, NL-EN (Wiki) and NL-EN (Wiki+EP), respectively; while the same scores are 0.572, 0.703, 0.639 and 0.672 when M=*All*).

6 Conclusions and Future Work

We have proposed a new probabilistic approach to modeling cross-lingual semantic similarity in context, which relies only on co-occurrence counts and latent cross-lingual concepts which can be estimated using only comparable data. The approach is purely statistical and it does not make any additional language-pair dependent assumptions; it does not rely on a bilingual lexicon, orthographic clues or predefined ontology/category knowledge, and it does not require parallel data.

The key idea in the approach is to represent words, regardless of their actual language, as distributions over the latent concepts, and both out-of-context and contextualized word representations are then presented in the same latent space spanned by the latent semantic concepts. A change in word meaning after observing its context is reflected in a change of its distribution over the latent concepts. Results for three language pairs have clearly shown the importance of the newly developed modulated or "contextualized" word representations in the task of suggesting word translations in context.

We believe that the proposed framework is only a start, as it ignites a series of new research questions and perspectives. One may further examine the influence of context scope (e.g., document-based vs. sentence-based vs. window-based contexts), as well as context selection and aggregation (see sect. 2) on the contextualized models. For instance, similar to the model from Ó Séaghdha and Korhonen (2011) in the monolingual setting, one may try to introduce dependency-based contexts (Padó and Lapata, 2007) and incorporate the syntax-based knowledge in the context-aware CLSS modeling. It is also worth studying other models that induce latent semantic concepts from multilingual data (see sect. 2) within this framework of context-sensitive CLSS modeling. One may also investigate a similar approach to context-sensitive CLSS modeling that could operate with explicitly defined concept categories (Gabrilovich and Markovitch, 2007; Cimiano et al., 2009; Hassan and Mihalcea, 2009; Hassan and Mihalcea, 2011; McCrae et al., 2013).

Acknowledgments

We would like to thank the anonymous reviewers for their comments and suggestions. This research has been carried out in the framework of the Smart Computer-Aided Translation Environment (SCATE) project (IWT-SBO 130041).

Abstract

The current approaches to Semantic Role Labeling (SRL) usually perform role classification for each predicate separately and the interaction among individual predicate's role labeling is ignored if there is more than one predicate in a sentence. In this paper, we prove that different predicates in a sentence could help each other during SRL. In multi-predicate role labeling, there are mainly two key points: argument identification and role labeling of the arguments shared by multiple predicates. To address these issues, in the stage of argument identification, we propose novel predicate-related features which help remove many argument identification errors; in the stage of argument classification, we adopt a discriminative reranking approach to perform role classification of the shared arguments, in which a large set of global features are proposed. We conducted experiments on two standard benchmarks: Chinese PropBank and English PropBank. The experimental results show that our approach can significantly improve SRL performance, especially in Chinese PropBank.

1 Introduction

Semantic Role Labeling (SRL) is a kind of shallow semantic parsing task and its goal is to recognize some related phrases and assign a joint structure (WHO did WHAT to WHOM, WHEN, WHERE, WHY, HOW) to each predicate of a sentence (Gildea and Jurafsky, 2002). Because of the ability of encoding semantic information, SRL has been applied in many tasks of NLP, such as question and answering (Narayanan and Harabagir, 2004), information extraction (Surdeanu et al., 2003; Christensen et al., 2005), and machine translation (Wu and Fung, 2009; Liu and Gildea, 2010; Xiong et al., 2012; Zhai et al., 2012).

The justices will be **forced** to **reconsider** the questions.

[A1] [Pred]

[A0] [Pred] [A1]

Figure 1: A sentence from English PropBank, with an argument shared by multiple predicates

Currently, an SRL system works as follows: first identify argument candidates and then perform classification for each argument candidate. However, this process only focuses on one independent predicate without considering the internal relations of multiple predicates in a sentence. According to our statistics, more than 80% sentences in Propbank carry multiple predicates. One example is shown in Figure 1, in which there are two predicates 'Force' and 'Reconsider'. Moreover, the constituent 'the justices' is shared by the two predicates and is labeled as A1 for 'Force' but as A0 for 'Reconsider'. We call this phenomenon of the shared arguments **Role Transition** . Intuitively, all predicates in a sentence are closely related to each other and the internal relations between them would be helpful for SRL.

This paper has made deep investigation on multi-predicate semantic role labeling. We think there are mainly two key points: argument identification and role labeling of the arguments shared by multiple predicates. We adopt different strategies to address these two issues.

During argument identification, there are a large number of identification errors caused by the poor performance of auto syntax trees. However, many of these errors can be removed, if we take other predicates into consideration. To achieve this purpose, we propose novel predicates-related features which have been proved to be effective to recog-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 363–373,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

nize many identification errors. After these features added, the precision of argument identification improves significantly by 1.6 points and 0.9 points in experiments on Chinese PropBank and English PropBank respectively, with a slight loss in recall.

Role labeling of the shared arguments is another key point. The predicates and their shared argument could be considered as a joint structure, with strong dependencies between the shared argument's roles. If we consider linguistic basis for joint modeling of the shared argument's roles, there are at least two types of information to be captured. The first type of information is the compatibility of Role Transition among the shared argument's roles. A noun phrase may be labeled as A0 for a predicate and at the same time, it can be labeled as A1 for another predicate. However, there are few cases that a noun phrase is labeled as A0 for a predicate and as AM-ADV for another predicate at the same time. Secondly, joint modeling the shared arguments could explore global information. For example, in '*The columbia mall is expected to open*', there are two predicates 'expect' and 'open' and a shared argument 'the columbia mall'. Because this shared argument is before 'open' and the predicate 'open' is in active voice, a base classifier often incorrectly label this argument A0 for 'open'. But if we observe that the argument is also an argument of 'expect', it should be labeled as A1 for 'expect' and 'open'.

Motivated by the above observations, we attempt to jointly model the shared arguments' roles. Specifically, we utilize the discriminative reranking approach that has been successfully employed in many NLP tasks. Typically, this method first creates a list of n-best candidates from a base system, and then reranks them with arbitrary features (both local and global), which are either not computable or are computationally intractable within the base model.

We conducted experiments on Chinese PropBank and English PropBank. Results show that compared with a state-of-the-art base model, the accuracy of our joint model improves significantly by 2.4 points and 1.5 points on Chinese PropBank and English PropBank respectively, which suggests that there are substantial gains to be made by jointly modeling the shared arguments of multiple predicates.

Our contributions can be summarized as follows:

- To the best of our knowledge, this is the first work to investigate the mutual effect of multiple predicates' semantic role labeling.
- We present a rich set of features for argument identification and shared arguments' classification that yield promising performance.
- We evaluate our method on two standard benchmarks: Chinese PropBank and English PropBank. Our approach performs well in both, which suggests its good universality.

The remainder of this paper is organized as follows. Section 2 gives an overview of our approach. We discuss the mutual effect of multi-predicate' argument identification and argument classification in Section 3 and Section 4 respectively. The experiments and results are presented in Section 5. Some discussion and analysis can be found in Section 6. Section 7 discusses the related works. Finally, the conclusion and future work are in Section 8.

2 Approach Overview

As illustrated in Figure 2, our approach follows the standard separation of the task of semantic role labeling into two phases: **Argument Identification** and **Argument Classification** . We investigate the effect of multiple predicates in Argument Identification and Argument Classification respectively. Specifically, in the stage of Argument Identification, we introduce new features related to predicates which are effective to recognize many argument identification errors. In the stage of Argument Classification, we concentrate on the classification of the arguments shared by multiple predicates. We first use a base model to generate n-best candidates for the shared arguments and then construct a joint model to rerank the n-best list, in which a rich set of global features are proposed.

3 Argument Identification

In this section, we investigate multi-predicate' mutual effects in Argument Identification. Argument Identification is to recognize the arguments from all candidates of each predicate. Here, we use the Maximum Entropy (ME) classifier to perform binary classification. As a discriminative model, ME can easily incorporate arbitrary features and

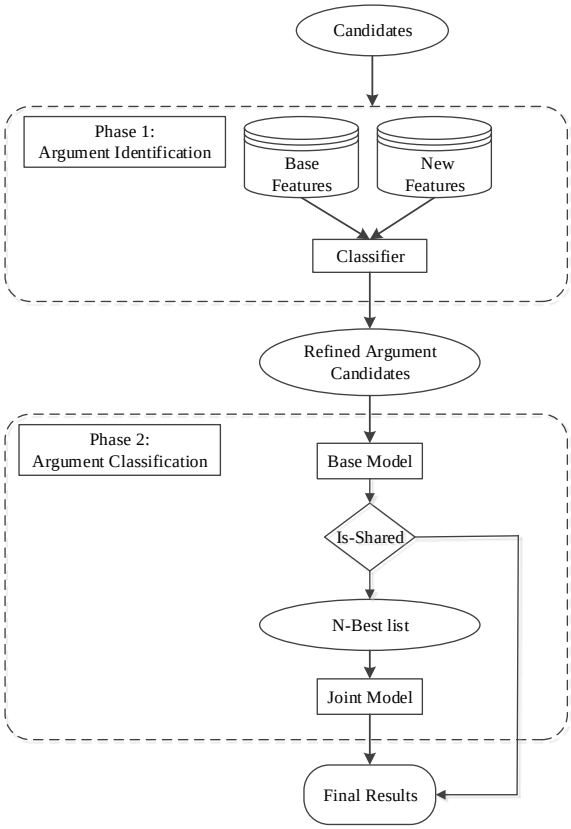

Figure 2: The overview of our approach

achieve good performance. The model is formulated as follows:

$$p(y|x) = \frac{1}{Z(x)} \exp(\sum_i \theta_i f_i(x, y)) \quad (1)$$

in which x is the input sample, y(0 or 1) is the output label, $f(x, y)$ are feature functions and $Z(x)$ is a normalization term as follows:

$$Z(x) = \sum_y \exp(\sum_i \theta_i f_i(x, y))$$

3.1 Base Features

Xue (2008) took a critical look at the features used in SRL and achieved good performance. So, we use the same features in Xue (2008) as the base features:

- Predicate lemma
- Path from node to predicate
- Head word
- Head word's part-of-speech
- Verb class (Xue, 2008)
- Predicate and Head word combination
- Predicate and Phrase type combination
- Verb class and Head word combination
- Verb class and Phrase type combination

3.2 Additional Features

In the SRL community, it is widely recognized that the overall performance of a system is largely determined by the quality of syntactic parsers (Gildea and Palmer, 2002), which is particularly notable in the identification stage. Unfortunately, the state-of-the-art auto parsers fall short of the demands of applications. Moreover, when there are multiple predicates, or even multiple clauses in a sentence, the problem of syntactic ambiguity increases drastically (Kim et al., 2000). For example, in Figure 3, there is a sentence with two consecutive predicates '是' (is) and '开发' (develop). Compared with the gold tree, the auto tree is less preferable, which makes the classifier easily mistake '建筑' (building) as an argument of '开发' (develop) with base features. But this identification error can be removed if we note that there is another predicate '是' (is) before '开发' (devel-

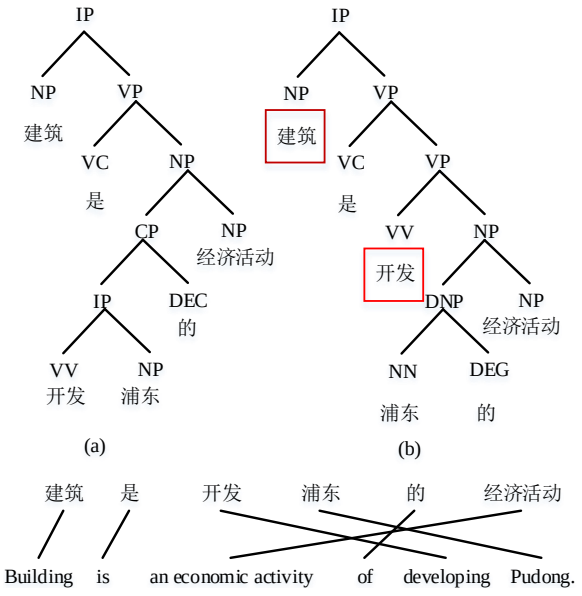

Figure 3: An example from Chinese PropBank. Tree (a) is the gold syntax tree and (b) is parsed by a state of-the-art parser Berkeley parser. On tree (b), '建筑' (building) is mistaken as an argument of '开发' (develop) with base features.

op). Similar examples with the pattern 'NP + 是 + VV' can be found in PropBank, in which the subject NP of the sentence is usually not an argument of the latter predicate. Thus, '是' (is) is an effective clue to detect this kind of identification error.

It is challenging to obtain a fully correct syntax tree for a complex sentence with multiple predicates. Therefore, base features that heavily rely on syntax trees often fail in discriminating arguments from candidates as demonstrated in Figure 3. However, by considering the elements of neighboring predicates, we could capture useful clues like in the above example and remove many identification errors. Below, we define novel predicaterelated features to encode these 'clues' to refine candidates.

There are mainly five kinds of features as follows.

- **Is the given predicate the nearest one?**

  This is a binary feature that indicates whether the predicate is the nearest one to the candidate.

- **Local adjunct**

  This is a binary feature designed for adjective and adverbial phrases. Some adjunct phrases, such as '仅' (only), have a limited sphere of influence. If the candidate is 'local' but the given predicate is not the nearest one, the candidate is often not an argument for the given predicate. To collect local adjuncts, we traverse the whole training set to get the initial lexicon of adjuncts and refine it manually.

- **Cut-Clause**

  This type of feature is a binary feature designed to distinguish identification errors of noun phrase candidates. If a noun phrase candidate is separated from the given predicate by a clause consisting of a NP and VP, the candidate is usually not the argument of the given predicate.

- **Different Relative Positions with Conjunctions**

  This is a binary feature that describes whether the candidate and the predicate are located in different positions as separated by conjunctions such as '但是' (but). Conjunctions are often used to concatenate two clauses, but the first clause commonly describes one proposition and the second clause describes another one. Thus, if the candidate and the given predicate have different positions relative to the conjunctions, the candidate is usually not the argument of the given predicate.

- **Consecutive Predicates Sequence**

  When multiple predicates appear in a sentence consecutively, parse errors frequently occurs due to the problems of syntactic ambiguity as demonstrated in Figure 2. To indicate such errors, sequence features of the candidates and consecutive predicates are defined specifically. For instance, for the candidate '建筑' (building) of '开发' (develop), the features are 'cand-是-开发' and 'cand-是-VV', in which we use 'cand' to represent the position of the candidate.

4 Argument Classification

In this section, we investigate multi-predicate' mutual effects in Argument Classification. Argument Classification is to assign a label to each argument candidate recognized by the phase of Argument Identification.

4.1 Base Model

A conventional method in Argument Classification is to assign a label to each argument candidate by a classifier independently. We call this kind of method Base Model. In the base model, we still adopt ME (1) as our classifier; all base features of Argument Identification are contained (shown in subsection 3.1). In addition, there are some other features:

- Position: the relative position of the candidate argument compared to the predicate
- Subcat frame: the syntactic rule that expands the parent of the verb
- The first and the last word of the candidate
- Phrase type: the syntactic tag of the candidate argument
- Subcat frame+: the frame that consists of the NPs (Xue, 2008).

4.2 Joint Model

As discussed briefly in Section 1, there are many dependencies between the shared arguments' labeling for different predicates, but the base model completely ignores such useful information. To incorporate these dependencies, we employ the discriminative reranking method. Here, we first establish a unified framework for reranking. For an input x, the generic reranker selects the best output y^* among the set of candidates $GEN(x)$ according to the scoring function:

$$y^* = \underset{y \in GEN(x)}{\operatorname{argmax}} \; score(y) \tag{2}$$

In our task, $GEN(x)$ is a set of the n-best candidates generated from the base model. As usual, we calculate the score of a candidate by the dot product between a high dimensional feature and a weight W:

$$score(y) = W \cdot f(y) \tag{3}$$

We estimate the weight W using the averaged perceptron algorithm (Collins, 2002a) which is well known for its fast speed and good performance in similar large-parameter NLP tasks (Huang, 2008). The training algorithm of the generic averaged perceptron is shown in Table 1. In line 5, the algorithm updates W with the difference (if any) between the feature representations of the best scoring candidate and the gold candidate. We also use a refinement called "averaged parameters" that the final weight vector W is the average of weight vectors over T iterations and N samples. This averaging effect has been shown to reduce overfitting and produces more stable results (Collins, 2002a).

Pseudocode: Averaged Structured Perceptron
1: **Input**: training data(x_t, y_t^*) for $t = 1, ..., T$;
2: $\bar{w}^{(0)} \leftarrow 0$; $v \leftarrow 0$; $i \leftarrow 0$
3: **for** n in 1,...,N **do**
4: **for** t in $1, ..., T$ **do**
5: $\bar{w}^{(i+1)} \leftarrow$ update $\bar{w}^{(i)}$ according to (x_t, y_t^*)
6: $v \leftarrow v + \bar{w}^{i+1}$
7: $i \leftarrow i + 1$
8: $\bar{w} \leftarrow v//(N * T)$
9: **return** $\bar{w}$

Table 1: The perceptron training algorithm

4.3 Features for Joint Model

Here, we introduce features used in the joint model. For clear illustration, we describe these features in the context of the example in Figure 1.

Role Transition (RT): a binary feature to indicate whether the transitions among roles of the candidate are reasonable. Because all roles are assigned to the same candidate, all role transitions should be compatible. For instance, if an argument is labeled as AM-TMP for one predicate, it cannot be labeled as AM-LOC for another predicate. This feature is constructed by traversing the training data to ascertain whether transitions between all roles are reasonable. In Table 2, we list some role transitions which are obtained from the training data of experiments on Chinese PropBank.

Roles and Predicates' Sequence (RPS): a joint feature template that concatenates roles and the given predicates. For the gold candidate 'Arg1, Arg0', the feature is 'Arg1-force, Arg0-reconsider'.

Roles and Predicates' Sequence with Relative Orders (RPSWR): the template is similar to the above one except that relative orders between roles and predicates are added. If the shared argument is before the given predicate, the feature is described as 'Role-Predicate'; otherwise, the feature is 'Predicate-Role'. And, if the predicate's voice is passive, the order is reversed. Thus, for the gold candidate 'Arg1, Arg0', this feature is 'force-Arg1, Arg0-reconsider'.

Roles and Phrase Type Sequence (RPTS)

Roles and Head Word Sequence (RHWS)

Roles and Head Word's POS Sequence (RHWPS)

These three features are utilized to explore the shared argument's relations with roles.

Time and Location Class (TLC): We find there are much confusions between AM-TMP and AM-LOC in the base model. To fix these errors, we add two features: Time and Location Class. For these features, we just collect phrases labeled as AM-TMP and AM-LOC from the training data. When the argument belongs to Time or Location Class, we add a sequence template consisting of 'Role-Time' for Time Class or 'Role-Location' for Location Class. For the gold candidate 'Arg1, Arg0', the feature is 'Arg1-none, Arg0-none' because 'the justices' belongs neither to Time Class nor to Location Class.

Role	Arg0	Arg1	Arg2	AM-LOC	AM-TMP	AM-ADV	AM-MNR	AM-TPC
Arg0	+	+	+	+	+	+	+	+
Arg1	+	+	+	+	-	+	+	+
Arg2	+	+	+	+	-	-	-	+
AM-LOC	+	+	+	+	-	+	-	+
AM-TMP	+	-	-	-	+	+	-	-
AM-ADV	+	-	+	-	+	+	-	-
AM-MNR	+	+	-	-	-	-	+	-
AM-TPC	+	+	+	+	+	+	-	+

Table 2: Some role transitons from Chinese PropBank. "+" means reasonable role transition and "-" means illegal.

5 Experiments

5.1 Experimental Setting

To evaluate the performance of our approach, we have conducted on two standard benchmarks: Chinese PropBank and English PropBank. The experimental setting is as follows:

Chinese:

We use Chinese Proposition Bank 1.0. All data are divided into three parts. 648 files (from chtb_081.fid to chtb_899.fid) are used as the training set. 40 files (from chtb_041.fid to chtb_080.fid) constitutes the development set. The test set consists of 72 files (chtb_001.fid to chtb_040.fid and chtb_900.fid to chtb_931.fid). This data setting is the same as in (Xue, 2008; Sun et al., 2009). We adopt Berkeley Parser[1] to carry out auto parsing for SRL and the parser is retrained on the training set. We used n =10 joint assignments for training the joint model and testing.

English:

We choose English Propbank as the evaluation corpus. According to the traditional partition, the training set consists of the annotations in Sections 2 to 21, the development set is Section 24, and the test set is Section 23. This data setting is the same as in (Xue and Palmer, 2004; Toutanova et al., 2005). We adopt Charniak Parser[2] to carry out auto parsing for SRL and the parser is retrained on the training set. We used n =10 joint assignments for training the joint model and testing.

5.2 Experiment on Argument Identification

We first investigate the performance of our approach in Argument Identification.

For the task of Argument Identification (AI), we adopt auto parser to produce auto parsing trees for SRL. The results are shown in Table 3. We can see that in the experiment of Chinese, the F1 score reaches to 78.79% with base features. While after additional predicates-related features are added, the precision has improved by 1.6 points with slight loss in recall, which leads to the improvement of 0.6 points in F1. The similar effect occurred in the experiment of English. After additional features added in the identification module, the precision is improved by about 0.9 points with a slight loss in recall, leading to an improvement of 0.3 points in F1. However, the improvement in English is slight smaller than in Chinese. We think the main reason is that there are less parse errors in English than in Chinese. All results demonstrate that the novel predicted-related features are effective in recognizing many identification errors which are difficult to discriminate with base features.

5.3 Experiment on Argument Classification

5.3.1 Results

Errors produced in AI will influenced the evaluation of Argument Classification (AC). So, to evaluate fairly we assume that the argument constituents of a predicate are already known, and the

En	Base	93.85
	Joint	**95.33***

Table 5: Comparison with Base Model on shared arguments. Scores marked by "*" are significantly better ($p < 0.05$) than base model.

task is only to assign the correct labels to the constituents. The evaluation criterion is Accuracy.

The results of the base model are shown in Table 4. We first note that in testing set, there are a large number of shared arguments, which weighs about one quarter of all arguments in Chinese and 14% in English. Therefore, the fine processing of these arguments is essential for argument classification. However, the base model cannot handle these shared arguments so well in Chinese that the accuracy of the shared arguments is lower by about 1.4 points than the average value of all arguments. Nevertheless, from Table 5 we can see that our joint model's accuracy on the shared arguments reaches 93.74%, 2.4 points higher than the base model in Chinese. Although the base model obtain good performance on shared arguments of English, our joint model's performance reaches 95.33%, 1.5 points higher than the base model. This indicates that even though the base model is optimized to utilize a large set of features and achieves the state-of-the-art performance, it is still advantageous to model the joint information of the shared arguments.

Another point to note is that our joint model in resolving English SRL task is not so good as in Chinese SRL. There are mainly two reasons. The first reason is that the shared arguments occur less in English than in Chinese so that training samples are insufficient for our discriminative model. The second reason is the annotation of some intransitive verbs. In English PropBank, there is a class of intransitive verbs such as "land" (known as verbs of variable behavior), for which the argument can be tagged as either ARG0 or ARG1. Here, we take examples from the guideline[3] of English PropBank to explain.

"A bullet (ARG1) landed at his feet"

"He (ARG0) landed"

In the above examples, the two arguments and the predicate 'land' have the same relative order and voice but the arguments have different labels for their respective predicates. In fact, according to the intention of the annotator, ARG0 and ARG1 are both correct. Unfortunately, in English PropBank, there is only one gold label for each argument, which leads to much noise for our joint model. Moreover, such situations are not rare in the corpus.

5.3.2 Feature Performance

We investigate effects of the features of joint model to the performance and results are shown in Table 6. Each row shows the improvement over the baseline when that feature is used in the joint model. We can see that features proposed are beneficial to the performance of the joint model. But some features like 'RPS' and 'RPSRO' play a more important role.

Features	Chinese	English

TCL	91.93	94.23
All	**93.74**	**95.33**

Table 6: Features performance in the Joint Model. We use first letter of words to represent features.

5.4 SRL Results

We also conducted the complete experiment on the auto parse trees. The results are shown in Table 7. In experiments on Chinese PropBank, we can see that after novel predicate-related features are added in the stage of Argument Identification, our model outperforms the base model by 0.5 points

[3] http://verbs.colorado.edu/propbank/EPB-AnnotationGuidelines.pdf

		$F_1(\%)$

Chinese	Xue(2008)	71.90
	Sun et al.(2009)	74.12
	Ours	75.31
English	Surdeanu and Turmo(2005)	76.46
	Ours	77.00

Table 8: Comparison with Other Methods

in F1. Furthermore, after incorporating the joint module, the performance goes up to 75.31%, 1.3 points higher than the base model. We obtain similar observations in experiments on English PropBank, but due to reasons illustrated in Subsection 5.3, the performance of our method is slight better than the base model.

We compare our method with others and the results are shown in Table 8. In Chinese, Xue (2008) and Sun et al. (2009) are pioneer works in Chinese SRL. Our approach outperforms these approaches by about 3.4 and 1.9 F1 points respectively. In English SRL, we compare out method with Surdeanu and Turmo (2005) which is best result obtained with single parse tree as the input in CONLL 2005 SRL evaluation. Our approach is better than their approach which ignores the relation of multiple predicates' SRL.

6 Discussion and Analysis

In this section, we discuss some case studies that illustrate the advantages of our model. Some examples from our experiments are shown in Table 9. In example (1), the argument is a prepositional phrase '在 普及 九 年 义务 教育 的 同时' (at the same time of compulsory education) and shared by two predicates '得到' (witness) and '扩大' (expand). In the corpus, a prepositional phrase is commonly labeled as ARGM-LOC and ARGM-TMP. Thus, the base model labeled the argument into these classes but one as ARGM-LOC, another as ARGM-TMP. Unfortunately, ARGM-LOC for '得到' (witness) is wrong while our joint model outputs both correct answers, which benefits from the role transition feature. From Table 1, we can see that the role transition between ARGM-TMP and ARGM-LOC is impossible, which lowers the score of candidates containing both ARGM-LOC and ARGM-TMP in the joint model. Thus, the joint model is more likely to output the gold candidate.

In example (2), the argument is '海拉尔 飞机场' (Hailar Airport) and shared by two predicates '扩建' (expand) and '成为' (become). Because of the high similarity of the features in the base model, the argument for both predicates is classified into the same class ARG0, but the label for '扩建' (expand) is wrong. Nevertheless, our joint model obtains both correct labels, which benefits from the global features. After searching the training data, we find some similar examples to this one, such as '地铁 运行 里程 已 扩建 至 1 2 0 公里' (The railway operation mileage is expanded to 120 kilometers), in which '地铁 运行 里程' (the railway operation mileage) is labeled as ARG1 for '扩建' (expand) but ARG0 for '至' (to). We think these samples provide evidence for our joint model while these information has not been captured by the base model.

In example (3), the argument is '国内外 知名度很 高 的 大 集团' (a large group with high reputation) and shared by predicates '发展' (develop) and '为' (become). Different from the above cases in which only one label is wrong in the base model, both labels for '发展' (develop) and '为' (become) are misclassified by the base model. However, our method still gets correct answers for both predicates, which also benefits from the global features.

7 Related work

Our work is related to semantic role labeling and discriminative reranking. In this section, we briefly review these two types of work.

On Semantic Role Labeling

Gildea and Jurafsky (2002) first presented a system based on a statistical classifier which is trained on a hand-annotated corpora FrameNet. In their pioneering work, they used a gold or autoparsed syntax tree as the input and then extracted various lexical and syntactic features to identify the

semantic roles for a given predicate. After Gildea and Jurafsky (2002), there have been a large number of works on automatic semantic role labeling. Based on a basic discriminative model, Punyakanok et al. (2004) constructed an integer linear programming architecture, in which the dependency relations among arguments are implied in the constraint conditions. Toutanova et al. (2008) proposed a joint model to explore relations of all arguments of the same predicate. Unlike them, this paper focus on mining relations of different predicates' semantic roles in one sentence. And, there have been many extensions in machine learning models (Moschitti et al., 2008), feature engineering (Xue and Palmer, 2004), and inference procedures (Toutanova et al., 2005; Punyakanok et al., 2008; Zhuang and Zong, 2010a; Zhuang and Zong, 2010b).

Sun and Jurafsky (2004) did the preliminary work on Chinese SRL without employing any large semantically annotated corpus of Chinese. They just labeled the predicate-argument structures of ten specified verbs to a small collection of Chinese sentences, and utilized Support Vector Machine to identify and classify the arguments. They made the first attempt on Chinese SRL and produced promising results. After the PropBank (Xue and Palmer, 2003) was built, Xue and Palmer (2004) and Xue (2008) took a critical look at features of argument detection and argument classification. Unlike others' using syntax trees as the input of SRL, Sun et al. (2009) performed Chinese semantic role labeling with shallow parsing. Li et al. (2010) explored joint syntactic and semantic parsing of Chinese to further improve the performance of both syntactic parsing and SRL.

However, to the best of our knowledge, in the literatures, there is no work related to multi-predicate semantic role labeling.

On Discriminative Reranking

Discriminative reranking is a common approach in the NLP community. Its general procedure is that a base system first generates n-best candidates and with the help of global features, we obtain better performance through reranking the n-best candidates. It has been shown to be effective for various natural language processing tasks,such as syntactic parsing (Collins, 2000; Collins, 2002b; Collins and Koo, 2005; Charniak and Johnson, 2005; Huang, 2008), semantic parsing (Lu et al., 2008; Ge and Mooney, 2006), part-of-speech tagging (Collins, 2002a), named entity recognition (Collins, 2002c), machine translation (Shen et al., 2004) and surface realization in generation (Konstas and Lapata, 2012).

8 Conclusion and Feature Work

This paper investigates the interaction effect among multi-predicate's SRL. Our investigation has shown that there is much interaction effect of multi-predicate's SRL both in Argument Identification and in Argument Classification. In the stage of argument identification, we proposed novel features related to predicates and successfully removed many argument identification errors. In the stage of argument classification, we concentrate on the classification of the arguments shared by multiple predicates. Experiments have shown

that the base model often fails in classifying the shared arguments. To perform the classification of the shared arguments, we propose a joint model and with the help of the global features, our joint model yields better performance than the base model. To the best of our knowledge, this is the first work of investigating the interaction effect of multi-predicate's SRL.

In the future, we will explore more effective features for multi-predicate's identification and classification. Since we adopt reranking approach in the shared arguments' classification, the performance is limited by n-best list. Also, we would like to explore whether there is another method to resolve the problem.

Acknowledgments

We thank the three anonymous reviewers for their helpful comments and suggestions. We would also like to thank Nianwen Xue for help in baseline system, and Tao Zhuang, Feifei Zhai, Lu Xiang and Junjie Li for insightful discussions. Werdy: Recognition and Disambiguation of Verbs and Verb Phrases with Syntactic and Semantic Pruning

Luciano Del Corro **Rainer Gemulla** **Gerhard Weikum**
Max-Planck-Institut für Informatik
Saarbrücken, Germany
{ delcorro, rgemulla, weikum }@mpi-inf.mpg.de

Abstract

Word-sense recognition and disambiguation (WERD) is the task of identifying word phrases and their senses in natural language text. Though it is well understood how to disambiguate noun phrases, this task is much less studied for verbs and verbal phrases. We present Werdy, a framework for WERD with particular focus on verbs and verbal phrases. Our framework first identifies multi-word expressions based on the syntactic structure of the sentence; this allows us to recognize both contiguous and non-contiguous phrases. We then generate a list of candidate senses for each word or phrase, using novel syntactic and semantic pruning techniques. We also construct and leverage a new resource of pairs of senses for verbs and their object arguments. Finally, we feed the so-obtained candidate senses into standard word-sense disambiguation (WSD) methods, and boost their precision and recall. Our experiments indicate that Werdy significantly increases the performance of existing WSD methods.

1 Introduction

Understanding the semantics of words and multi-word expressions in natural language text is an important task for automatic knowledge acquisition. It serves as a fundamental building block in a wide area of applications, including semantic parsing, question answering, paraphrasing, knowledge base construction, etc. In this paper, we study the task of word-sense recognition and disambiguation (WERD) with a focus on verbs and verbal phrases. Verbs are the central element in a sentence, and the key to understand the relations between sets of entities expressed in a sentence.

We propose Werdy, a method to (i) automatically recognize in natural language text both single words and multi-word phrases that match entries in a lexical knowledge base (KB) like WordNet (Fellbaum, 1998), and (ii) disambiguate these words or phrases by identifying their senses in the KB. WordNet is a comprehensive lexical resource for word-sense disambiguation (WSD), covering nouns, verbs, adjectives, adverbs, and many multi-word expressions. In the following, the notion of an *entry* refers to a word or phrase in the KB, whereas a *sense* denotes the lexical synset of the entry's meaning in the given sentence.

A key challenge for recognizing KB entries in natural language text is that entries often consist of multiple words. In WordNet-3.0 more than 40% of the entries are multi-word. Such entries are challenging to recognize accurately for two main reasons: First, the components of multi-word entries in the KB (such as *fiscal year*) often consist of components that are themselves KB entries (*fiscal* and *year*). Second, multi-word entries (such as *take a breath*) may not appear consecutively in a sentence ("He takes a deep breath."). Werdy addresses the latter problem by (conceptually) matching the syntactic structure of the KB entries to the syntactic structure of the input sentence. To address the former problem, Werdy identifies all possible entries in a sentence and passes them to the disambiguation phase (*take*, *breath*, *take a breath*, ...); the disambiguation phase provides more information about which multi-word entries to keep. Thus, our method solves the recognition and the disambiguation tasks jointly.

Once KB entries have been identified, Werdy

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 374–385,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

disambiguates each entry against its possible senses. State-of-the-art methods for WSD (Navigli, 2009) work fairly well for nouns and noun phrases. However, the disambiguation of verbs and verbal phrases has received much less attention in the literature.

WSD methods can be roughly categorized into (i) methods that are based on supervised training over sense-annotated corpora (e.g., Zhong and Ng (2010)), and (ii) methods that harness KB's to assess the semantic relatedness among word senses for mapping entries to senses (e.g., Ponzetto and Navigli (2010)). For these methods, mapping verbs to senses is a difficult task since verbs tend to have more senses than nouns. In WordNet, including monosemous words, there are on average 1.24 senses per noun and 2.17 per verb.

To disambiguate verbs and verbal phrases, Werdy proceeds in multiple steps. First, Werdy obtains the set of candidate senses for each recognized entry from the KB. Second, it reduces the set of candidate entries using novel syntactic and semantic pruning techniques. The key insight behind our syntactic pruning is that each verb sense tends to occur in a only limited number of *syntactic patterns*. For example, the sentence "Albert Einstein remained in Princeton" has a subject ("Albert Einstein"), a verb ("remained") and an adverbial ("in Princeton"), it follows an SVA clause pattern. We can thus safely prune verb senses that do not match the syntactic structure of the sentence. Moreover, each verb sense is compatible with only a limited number of *semantic argument types* (such as *location*, *river*, *person*, *musician*, etc); this phenomena is called *selectional preference* or *selectional restriction*. Senses that are compatible only with argument types not present in the sentence can be pruned. Our pruning steps are based on the idea that a verb selects the categories of its arguments both syntactically (c-selection) and semantically (s-selection). In the final step, Werdy employs a state-of-the-art general WSD method to select the most suitable sense from the remaining candidates. Since incorrect senses have already been greatly pruned, this step significantly gains accuracy and efficiency over standard WSD.

Our semantic pruning technique builds on a newly created resource of pairs of senses for verbs and their object arguments. For example, the WordNet verb sense ⟨*play*-1⟩ (i.e., the 1st sense of the verb entry "play") selects as direct object the noun sense ⟨*sport*-1⟩. We refer to this novel resource as the *VO Sense Repository*, or VOS repository for short.[1] It is constructed from the WordNet gloss-tags corpus, the SemCor dataset, and a small set of manually created VO sense pairs.

We evaluated Werdy on the SemEval-2007 coarse-grained WSD task (Navigli et al., 2007), both with and without automatic recognition of entries. We found that our techniques boost state-of-the-art WSD methods and obtain high-quality results. Werdy significantly increases the precision and recall of the best performing baselines.

The rest of the paper is organized as follows. Section 2 gives an overview of Werdy components. Section 3 presents the entry recognition, and Sections 4 and 5 discuss our novel syntactic and semantic pruning techniques. Section 6 presents the Semantic VO Repository and how we constructed it. Section 7 gives the results of our evaluation. Section 8 discusses related work.

2 Overview of Werdy

Werdy consists of four steps: (i) entry recognition, (ii) syntactic pruning, (iii) semantic pruning, and (iv) word-sense disambiguation. The novel contribution of this paper is in the first three steps, and in the construction of the VO sense repository. Each of these steps operates on the clause level, i.e., we first determine the set of clauses present in the input sentence and then process clauses separately. A *clause* is a part of a sentence that expresses some statement or coherent piece of information. Clauses are thus suitable minimal units for automatic text understanding tasks (Del Corro and Gemulla, 2013); see Sec.3 for details.

In the *entry-recognition step* (Sec. 3), Werdy obtains for the input sentence a set of potential KB entries along with their part-of-speech tags. The candidate senses of each entry are obtained from WordNet. For instance, in the sentence "He takes a deep and long breath", the set of potential entries includes *take* (verb, 44 candidate senses), *take a breath* (verb, 1 candidate sense), and *breath* (noun, 5 candidate senses). Note that in contrast to Werdy, most existing word-sense disambiguation methods assume that entries have already been (correctly) identified.

[1] The VOS repository, Werdy's source code, and results of our experimental study are available at `http://people.mpi-inf.mpg.de/~corrogg/`.

In the *syntactic-pruning step* (Sec. 4), we eliminate candidate senses that do not agree with the syntactic structure of the clause. It is well-established that the syntactic realization of a clause is intrinsically related with the sense of its verb (Quirk et al., 1985; Levin, 1993; Hanks, 1996; Baker et al., 1998; Palmer et al., 2005). Quirk et al. (1985) identified seven possible clause types in the English language (such as "subject verb adverbial", SVA). We make use of techniques inspired by Del Corro and Gemulla (2013) to identify the clause type of each clause in the sentence. We then match the clause type with the set of WordNet frames (e.g., "somebody verb something") that WordNet provides for each verb sense, and prune verb senses for which there is no match.

In the *semantic-pruning step* (Sec. 5), we further prune the set of candidate senses by taking the semantic types of direct objects into account. Similarly to the syntactic relation mentioned above, a verb sense also imposes a (selectional) restriction on the semantic type of its arguments (Quirk et al., 1985; Levin, 1993; Hanks, 1996; Baker et al., 1998; Palmer et al., 2005). For instance, the verb *play* with sense *participate in games or sports* requires an object argument of type ⟨*game*-1⟩[2], ⟨*game*-3⟩, or ⟨*sport*-1⟩. Senses that do not match the arguments found in the clause are pruned. This step is based on the newly constructed VOS Repository (Sec. 6). Note that when there is no direct object, only the syntactic pruning step applies.

3 Entry Recognition

The key challenge in recognizing lexical KB entries in text is that entries are not restricted to single words. In addition to named entities (such as people, places, etc.), KB's contain multi-word expressions. For example, WordNet-3.0 contains entries such as *take place* (verb), *let down* (verb), *take into account* (verb), *be born* (verb), *high school* (noun), *fiscal year* (noun), and *Prime Minister* (noun). Note that each individual word in a multi-word entry is usually also an entry by itself, and can even be part of several multi-word entries. To ensure correct disambiguation, all potential multi-word entries need to be recognized (Finlayson and Kulkarni, 2011), even when they do not appear as consecutive words in a sentence.

Werdy addresses these challenges by exploring the syntactic structure of both the input sentence and the lexical KB entries. The structure of the sentence is captured in a dependency parse (DP). Given a word in a sentence, Werdy conceptually generates all subtrees of the DP starting at that word, and matches them against the KB. This process can be performed efficiently as WordNet entries are short and can be indexed appropriately. To match the individual words of a sentence against the words of a KB entry, we follow the standard approach and perform lemmatization and stemming (Finlayson, 2014). To further handle personal pronouns and possessives, we follow Arranz et al. (2005) and normalize personal pronouns (I, you, my, your, ...) to *one's*, and reflexive pronouns (myself, yourself, ...) to *oneself*.

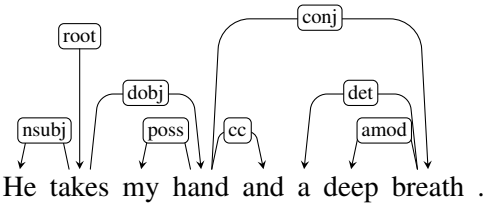

Figure 1: An example dependency parse

Consider the example sentence "He takes my hand and a deep breath". We first identify the clauses and their DP's (Fig. 1) using the method of Del Corro and Gemulla (2013), which also processes coordinating conjunctions. We obtain clauses "He takes my hand" and "He takes a deep breath", which we process separately. To obtain possible entries for the first clause, we start with its head word (*take*) and incrementally consider its descendants (*take hand*, *take one's hand*, ...). The exploration is terminated as early as possible; for example, we do not consider *take one's hand* because there is no WordNet entry that contains both *take* and *hand*. For the second clause, we start with *take* (found in WordNet), then expand to *take breath* (not found but can occur together), then *take a breath* (found), then *take a deep breath* (not found, cannot occur together) and so on.

Note that the word "take" in the sentence refer to two different entries and senses: "take" for the first clause and "take a breath" for the second clause. In this stage no decisions are made about selecting entries and disambiguating them; these decisions are made in the final WSD stage of Werdy.

We tested Werdy's entry-recognizer on the SemEval-2007 corpus. We detected the correct en-

[2]We use the notation ⟨*WordNet entry*-sense number⟩.

Pattern	Clause type	Example	WN frame example [frame number]
SV_i	SV	AE died.	Somebody verb [2]

Table 1: Clause types and examples of matching WordNet frames

tries for all but two verbs (out of more than 400). The two missed entries (*take up* and *get rolling*) resulted from incorrect dependency parses.

4 Syntactic Pruning

Once the KB entries have been recognized, Werdy prunes the set of possible senses of each verb entry by considering the syntactic structure of the clause in which the entry occurs. This pruning is based on the observation that each verb sense may occur only in a limited number of "clause types", each having specific semantic functions (Quirk et al., 1985). When the clause type of the sentence is incompatible with a candidate sense of an entry, this sense is eliminated.

Werdy first detects in the input sentence the set of clauses and their constituents. A clause consists of one *subject* (S), one *verb* (V), and optionally an *indirect object* (O), a *direct object* (O), a *complement* (C) and one or more *adverbials* (A). Not all combinations of clause constituents appear in the English language. When we classify clauses according to the grammatical function of their constituents, we obtain only seven different clause types (Quirk et al., 1985); see Table 1. For example, the sentence "He takes my hand" is of type SVO; here "He" is the subject, "takes" the verb, and "my hand" the object. The clause type can (in principle) be determined by observing the verb type and its complementation (Del Corro and Gemulla, 2013).

For instance, consider the SVA clause "The student remained in Princeton". The verb *remain* has four senses in WN: (1) stay the same; remain in a certain state (e.g., "The dress remained wet"), (2) continue in a place, position, or situation ("He remained dean for another year"), (3) be left; of persons, questions, problems ("There remains the question of who pulled the trigger") or (4) stay behind ("The hostility remained long after they made up"). The first sense of *remain* requires an SVC pattern; the other cases require either SV or SVA. Our example clause is of type SVA so that we can safely prune the first sense.

WordNet provides an important resource for obtaining the set of clause types that are compatible with each sense of a verb. In particular, each verb sense in WordNet is annotated with a set of *frames* (e.g., "somebody verb something") in which they may occur, capturing both syntactic and semantic constraints. There are 35 different frames in total.[3] We manually assigned a set of clause types to each frame (e.g., SVO to frame "somebody verb something"). Table 1 shows an example frame for each of the seven clause types. On average, each WordNet-3.0 verb sense is associated with 1.57 frames; the maximum number of frames per sense is 9. The distribution of frames is highly skewed: More than 61% of the 21,649 frame annotations belong to one of four simple SVO frames (numbers 8, 9, 10 and 11), and 22 out of the 35 frames have less than 100 instances. This skew makes the syntactic pruning step effective for non-SVO clauses, but less effective for SVO clauses.

Werdy directly determines a set of possible frame types for each clause of the input sentence. Our approach is based on the clause-type detection method of Del Corro and Gemulla (2013), but we also consider additional information that is captured in frames but not in clause types. For example, we distinguish different realizations of objects (such as clausal objects from non-clausal objects), which are not captured in the clause type. Given the DP of a clause, Werdy identifies the

[3] See `http://wordnet.princeton.edu/wordnet/man/wninput.5WN.html`.

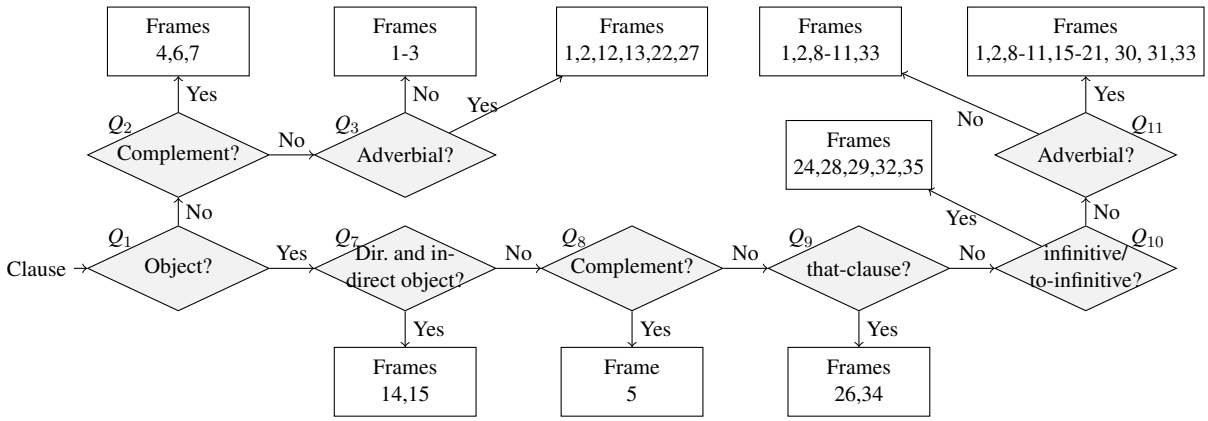

Figure 2: Flow chart for frame detection

set of WN frames that can potentially match the clause as outlined in the flowchart of Fig. 2. Werdy walks through the flowchart; for each question, we check for the presence or absence of a specific constituent of a clause (e.g., a direct object for Q_1) and proceed appropriately until we obtain a set of possible frames. This set is further reduced by considering additional information in the frames (not shown; e.g., that the verb must end on "-ing"). For our example clause "The student remained in Princeton", we first identify possible frames $\{ 1, 2, 12, 13, 22, 27 \}$ using the flowchart (Q_1 no, Q_2 no, Q_3 yes); using the additional information in the frames, Werdy then further prunes this set to $\{ 1, 2, 22 \}$. The corresponding set of remaining candidate sense for *remain* is as given above, i.e., $\{ \langle$*remain*-2$\rangle, \langle$*remain*-3$\rangle, \langle$*remain*-4$\rangle \}$.

Our mapping of clause types to WordNet frames is judiciously designed for the way WordNet is organized. For instance, frames containing adverbials generally do not specify whether or not the adverbial is obligatory; here we are conservative in that we do not prune such frames if the input clause does not contain an adverbial. As another example, some frames overlap or subsume each other; e.g, frame "somebody verb something" (8) subsumes "somebody verb that clause" (26). In some word senses annotated with the more general frame, the more specific one can also apply (e.g., $\langle$*point out*-1$\rangle$ is annotated with 8 but not 26; 26 can apply), in others it does not (e.g., $\langle$*play*-1$\rangle$ is also annotated with 8 but not 26; but here 26 cannot apply). To ensure the effectiveness of syntactic pruning, we only consider the frames that are directly specified in WordNet. This procedure often produces the desired results; in a few cases, however, we do prune the correct sense (e.g., frame 26 for clause "He points out that . . . ").

5 Semantic Pruning

A verb sense imposes a restriction on the semantic type of the arguments it may take and vice versa (Quirk et al., 1985; Levin, 1993; Hanks, 1996; Baker et al., 1998; Palmer et al., 2005; Kipper et al., 2008). This allows us to further prune the verb candidate set by discarding verb senses whose semantic argument is not present in the clause.

WordNet frames potentially allow a shallow type pruning based on the semantics provided for the clause constituents. However we could solely distinguish people ("somebody") from things ("something"), which is too crude to obtain substantial pruning effects. Moreover, this distinction is sometimes ambiguous.

Instead, we have developed a more powerful approach to semantic pruning based on our VOS repository. We remove from the verb candidate set those senses whose semantic argument cannot be present in the sentence. For instance, consider the clause "The man plays football." Suppose that we know that the verb entry *play* with sense $\langle$*play*-1$\rangle$ ("participate in sports") takes an object of type $\langle$*sport*-1$\rangle$; i.e., we have a tuple $\langle$*play*-1, *sport*-1$\rangle$ in our repository. Then, we check whether any of the possible senses of *football*—(i) *sport* or (ii) *ball*—is of type $\langle$*sport*-1$\rangle$. Here the first sense has the correct type (the second sense does not); thus we retain $\langle$*play*-1$\rangle$ as a possible sense for the verb entry *play*. Next, suppose that we consider sense $\langle$*play*-3$\rangle$ ("play on an instrument"), which according to our corpus takes $\langle$*instrument*-6$\rangle$ as argument (i.e., there is a tuple $\langle$*play*-3, *instrument*-6$\rangle$ in our VOS repository). Since none of the senses of *football* is of type $\langle$*instrument*-6$\rangle$, we can safely drop

⟨*play*-3⟩ from our candidate set. We perform this procedure for every verb sense in the candidate set.

Semantic pruning makes use of both VOS repository and the hypernym structure of the noun senses in WordNet. For each sentence, we obtain the possible senses of the direct-object argument of the verb. We then consider each candidate sense of the verb (e.g., ⟨*play*-1⟩), and check whether any of its compatible object-argument senses (from our repository) is a hypernym of any of the possible senses of its actual object argument (in the sentence); e.g., ⟨*sport*-1⟩ is a hypernym of ⟨*football*-1⟩. If so, we retain the verb's candidate sense. If not, either the candidate sense of the verb is indeed incompatible with the object argument in the sentence, or our repository is incomplete. To handle incompleteness to some extent, we also consider hyponyms of the object-argument senses in our repository; e.g., if we observe object *sport* in a sentence and have verb-sense argument ⟨*football*-1⟩ in our corpus, we consider this a match. If the hyponyms lead to a match, we retain the verb's candidate sense; otherwise, we discard it.

6 Verb-Object Sense Repository

We use three different methods to construct the repository. In particular, we harness the sense-annotated WordNet glosses[4] as well as the sense-annotated SemCor corpus (Landes et al., 1998).[5]

The major part of the VOS repository was acquired from WordNet's gloss tags. According to Atkins and Rundell (2008), noun definitions should be expressed in terms of the class to which they belong, and verb definitions should refer to the types of the subjects or objects related to the action. Based on this rationale, we extracted all noun senses that appear in the gloss of each verb sense; each of these noun senses is treated as a possible sense of the object argument of the corresponding verb sense. For example, the gloss of ⟨*play*-1⟩ is "participate in games or sports;" each noun is annotated with its senses (2 and 3 for "games", 1 for "sports"). We extract tuples ⟨*play*-1, *game*-2⟩, ⟨*play*-1, *game*-3⟩, and ⟨*play*-1, *sport*-1⟩ from this gloss. Note that we only extract direct-object arguments, i.e., we do not consider the type of the subject argument of a verb sense. Since the constituents of the predicate are much more important than the subject to determine or describe a verb sense, lexical resources rarely contain information on the subject (Atkins and Rundell, 2008). Similarly, WordNet glosses typically do not provide any information about adverbials. Overall, we collected arguments for 8,657 verb senses (out of WordNet's 13,767 verb senses) and a total of 13,050 ⟨*verb*-#, *object*-#⟩-pairs.

We leveraged the sense-annotated SemCor corpus to further extend our VOS repository. We parsed each sentence in the corpus to obtain the respective pairs of verb sense and object sense. Since sentences are often more specific than glosses, and thus less helpful for constructing our repository, we generalized the so-found object senses using a heuristic method. In particular, we first obtained all the object senses of each verb sense, and then repeatedly generalized sets of *at least two senses* that share a direct hypernym to this hypernym. The rationale is that we only want to generalize if we have some evidence that a more general sense may apply; we thus require at least two hyponyms before we generalize. Using this method, we collected arguments for 1,516 verb senses and a total of 4,131 sense pairs.

Finally, we noticed that the most frequent senses used in the English language are usually so general that their glosses do not contain any relevant semantic argument. For instance, one of the most frequent verbs is ⟨*see*-1⟩, which has gloss "perceive by ⟨*sight*-3⟩". The correct semantic argument ⟨*entity*-1⟩ is so general that it is omitted from the gloss. In fact, our gloss-tag extractor generates tuple ⟨*see*-1, *sight*-3⟩, which is incorrect. We thus manually annotated the 30 most frequent verb senses with their object argument types.

Our final repository contains arguments for 9,335 verb senses and a total of 17,181 pairs. Pairs from SemCor tend to be more specific because they refer to text occurrences. The assumption of taking the nouns of the glosses as arguments seems to be mostly correct, although some errors may be introduced. Consider the pair ⟨*play*-28, *stream*-2⟩ extracted from the gloss "discharge or direct or be discharged or directed as if in a continuous ⟨*stream*-2⟩". Also, in some cases, the glosses may refer to adverbials as in ⟨*play*-14, *location*-1⟩, taken from gloss "perform on a certain ⟨*location*-1⟩". Note that if an argument is missing from our repository, we may prune the correct sense of the verb. If, however, there is an additional, incorrect

[4] http://wordnet.princeton.edu/glosstag.shtml

[5] http://web.eecs.umich.edu/~mihalcea/downloads.html

argument in the repository, the correct verb sense is retained but pruning may be less effective.

7 Evaluation

Dataset. We tested Werdy on the SemEval-2007 coarse-grained dataset.[6] It consists of five sense-annotated documents; the sense annotations refer to a coarse-grained version of WordNet. In addition to sense annotations, the corpus also provides the corresponding KB entries (henceforth termed "gold entries") as well as a POS tag. We restrict our evaluation to verbs that act as clause heads. In total, 461 such verbs were recognized by ClausIE (Del Corro and Gemulla, 2013) and the Stanford Parser (Klein and Manning, 2003).[7]

WSD Algorithms. For the final step of Werdy, we used the KB-based WSD algorithms of Ponzetto and Navigli (2010) and It-Makes-Sense (Zhong and Ng, 2010), a state-of-the-art supervised system that was the best performer in SemEval-2007. Each method only labels entries for which it is sufficiently confident.

Simplified Extended Lesk (SimpleExtLesk). A version of Lesk (1986). Each entry is assigned the sense with highest term overlap between the entry's context (words in the sentence) and both the sense's gloss (Kilgarriff and Rosenzweig, 2000) as well as the glosses of its neighbors (Banerjee and Pedersen, 2003). A sense is output only if the overlap exceeds some threshold; we used thresholds in the range of 1–20 in our experiments. There are many subtleties and details in the implementation of SimpleExtLesk so we used two different libraries: a Java implementation of WordNet::Similarity (Pedersen et al., 2004),[8] which we modified to accept a context string, and DKPro-WSD (Miller et al., 2013) version 1.1.0, with lemmatization, removal of stop words, paired overlap enabled and normalization disabled.

Degree Centrality. Proposed by Navigli and Lapata (2010). The method collects all paths connecting each candidate sense of an entry to the set of candidate senses of the words the entry's context. The candidate sense with the highest degree in the resulting subgraph is selected. We implemented this algorithm using the Neo4j library.[9] We used a fixed threshold of 1 and vary the search depth in range 1–20. We used the candidate senses of all nouns and verbs in a sentence as context.

It-Makes-Sense (IMS). A state-of-the-art, publicly available supervised system (Zhong and Ng, 2010) and a refined version of Chan et al. (2007), which ranked first in the SemEval-2007 coarse grained task. We modified the code to accept KB entries and their candidate senses. We tested both in WordNet-2.1 and 3.0; for the later we mapped Werdy's set of candidates to WordNet-2.1.

Most Frequent Sense (MFS). Selects the most frequent sense (according to WordNet frequencies) among the set of candidate senses of an entry. If there is a tie, we do not label. Note that this procedure differs slightly from the standard of picking the entry with the smallest sense id. We do not follow this approach since it cannot handle well overlapping entries.

MFS back-off. When one of the above methods fails to provide a sense label (or provides more than one), we used the MFS method above with a threshold of 1. This procedure increased the performance in all cases.

Methodology. The disambiguation was performed with respect to coarse-grained sense clusters. The score of a cluster is the sum of the individual scores of its senses (except for IMS which provides only one answer per word); the cluster with the highest score was selected. Our source code and the results of our evaluation are publicly available[10].

The SemEval-2007 task was not designed for automatic entry recognition, for each word or multi-word expression it provides the WordNet entry and the POS tag. We proceeded as follows to handle multi-word entries. In the WSD step, we considered the candidate senses of all recognized entries that overlap with the gold entry. For example, we considered the candidate senses of entries *take*, *breath*, and *take a breath* for gold entry *take a breath*.

The SemEval-2007 task uses WordNet-2.1 but Werdy uses WordNet-3.0. We mapped both the sense keys and clusters from WordNet-2.1 to WordNet-3.0. All senses in WordNet-3.0 that could not be mapped to any cluster were consider to belong each of them to a single sense cluster. Note that this procedure is fair: for such senses

[6] The data is annotated with WordNet 2.1 senses; we converted the annotations to WordNet-3.0 using DKPro-WSD (Miller et al., 2013).

Table 2: Results on SemEval-2007 coarse-grained (verbs as clause heads)

the disambiguation is equivalent to a fine-grained disambiguation, which is harder.

Results. Our results are displayed in Table 2. We ran each algorithm with the gold KB entries provided by in the dataset (+ in column "gold entry) as well as the entries obtained by our method of Sec. 3 (-). We also enabled (+) and disabled (-) the pruning steps as well as the MFS back-off strategy. The highest F1 score was achieved by SimpleExtLesk (DKPro) with pruning and MFS back-off: 81.18 with gold entries and 78.52 with automatic entry recognition. In all cases, our syntactic and semantic pruning strategy increased performance (up to +10.85 F1 points). We next discuss the impact of the various steps of Werdy in detail.

Detailed Analysis. Table 3 displays step-by-step results for DKPro's SimpleExtLesk, for MFS, as well as SimpleExtLesk with MFS back-off, the best performing strategy. The table shows results when only some Werdy's steps are used. We start from a direct use of the respective algorithm with the gold entries of SemEval-2007 after each horizontal line, and then successively add the Werdy steps indicated in the table.

When no gold entries were provided, performance dropped due to the increase of sense candidates for multi-word expressions, which include the possible senses of the expression itself as well as the senses of the entry's parts that are them-

Table 3: Step-by-step results

selves WordNet entries. Our entry recognizer tends to do a good job since it managed to correctly identify all the relevant entries except in two cases (i.e. "take up" and "get rolling"), in which the dependency parse was incorrect. The drop in F1 for our automatic entry recognition was mainly due to incorrect selection of the correct entry of a set of alternative, overlapping entries.

Syntactic pruning did not prune the correct sense in most cases. In 16 cases (with gold entries), however, the correct sense was pruned. Five of these senses were pruned due to incorrect dependency parses, which led to incorrect frame identification. In two cases, the sense was not annotated with the recognized frame in WordNet, although it seemed adequate. In the remaining cases, a general frame from WordNet was incorrectly omitted. Improvements to WordNet's frame annotations may thus make syntactic pruning even more effective.

Semantic pruning also improves performance. Here the correct sense was pruned for 11 verbs, mainly due to the noisiness and incompleteness of our VOS repository. Without using gold entries, we found in total 237 semantic matches between possible verbs senses and possible object senses (200 with gold entries). We also found that our manual annotations in the VOS repository (see Sec. 6) did not affect our experiments.

The results show that syntactic and semantic pruning are beneficial for verb sense disambiguation, but also stress the necessity to improve existing resources. Ideally, each verb sense would be annotated with both the possible clause types or syntactic patterns in which it can occur as well as the possible senses of its objects. Annotations for subjects and adverbial arguments may also be beneficial.

8 Related Work

WSD is a classification task where for every word there is a set of possible senses given by some external resource (as a KB). Two types of methods can be distinguished in WSD. Supervised systems (Dang and Palmer, 2005; Dligach and Palmer, 2008; Chen and Palmer, 2009; Zhong and Ng, 2010) use a classifier to assign senses to words, mostly relying on manually annotated data for training. In principle, these systems suffer from low coverage since the training data is usually sparse. Some authors have tried to overcome this limitation by exploiting linked resources as training data (Shen et al., 2013; Cholakov et al., 2014).

The second WSD approach corresponds to the so-called KB methods (Agirre and Soroa, 2009; Ponzetto and Navigli, 2010; Miller et al., 2012; Agirre et al., 2014). They rely on a background KB (typically WordNet or extended versions (Navigli and Ponzetto, 2012)), where related senses appear close to each other. KB-based algorithms often differ in the way the KB is explored. It has been shown that a key point to enhance performance is the amount of semantic information in the KB (Ponzetto and Navigli, 2010; Miller et al., 2012). Our framework fits this line of work since it is also unsupervised and enriches the background knowledge in order to enhance performance of standard WSD algorithms. A comprehensive overview of WSD systems can be found in Navigli (2009) and Navigli (2012).

To bring WSD to real-world applications, the mapping between text and KB entries is a fundamental first step. It has been pointed that the existence of multi-word expressions imposes multiple challenges to text understanding tasks (Sag et al., 2002). The problem has been addressed by Arranz et al. (2005) and Finlayson and Kulkarni (2011). They find multi-word entries by matching word sequences allowing some morphological and POS variations according to predefined patterns. Our method differs in that we can recognize KB entries that appear discontinuously and in that we do not select the correct entry but generate a set of potential entries.

Linguists have noted the link between verb senses and the syntactic structure and argument types (Quirk et al., 1985; Levin, 1993; Hanks, 1996), and supervised WSD systems were developed to capture this relation (Dang and Palmer, 2005; Chen and Palmer, 2009; Dligach and Palmer, 2008; Cholakov et al., 2014). In Dang and Palmer (2005) and Chen and Palmer (2009), it is shown that WSD tasks can be improved with features that capture the syntactic structure and information about verb arguments and their types. They use features as shallow named entity recognition and the hypernyms of the possible senses of the noun arguments. Dang and Palmer (2005) also included features extracted from PropBank (Palmer et al., 2005) from role labels and frames. Dligach and Palmer (2008) generated a corpus of verb and their arguments (both surface forms), which was used to incorporate a semantic feature to the supervised system.

In our work, we also incorporate syntactic and semantic information. Instead of learning the relation between the verb senses and the syntactic structure, however we incorporate it explicitly using the WordNet frames, which provide information about which verb sense should be consider for a given syntactic pattern. We also incorporate explicitly the semantic relation between each verb sense and its arguments using our VOS repository.

Different resources of semantic arguments for automatic text understanding tasks have been constructed (Baker et al., 1998; Palmer et al., 2005; Kipper et al., 2008; Gurevych et al., 2012; Nakashole et al., 2012; Flati and Navigli, 2013). In (Baker et al., 1998; Palmer et al., 2005; Kipper et al., 2008; Gurevych et al., 2012), the classification of verbs and arguments is focused toward semantic or thematic roles. Nakashole et al. (2012) uses semantic types to construct a taxonomy of binary relations and Flati and Navigli (2013) collected semantic arguments for given textual expressions. For instance, given the verb "break", they extract a pattern "break ⟨*body part*-1⟩". In contrast to existing resources, our VOS repository disambiguates both the verb sense and the senses of its arguments.

9 Conclusion

We presented Werdy, a framework for word-sense recognition and disambiguation with a particular focus on verbs and verbal phrases. Our results indicate that incorporating syntactic and semantic constraints improves the performance of verb sense disambiguation methods. This stresses the necessity of extending and improving the available syntactic and semantic resources, such as WordNet or our VOS repository.

Multi-Resolution Language Grounding with Weak Supervision

Abstract

Language is given meaning through its correspondence with a world representation. This correspondence can be at multiple levels of granularity or *resolutions*. In this paper, we introduce an approach to multi-resolution language grounding in the extremely challenging domain of professional soccer commentaries. We define and optimize a factored objective function that allows us to leverage discourse structure and the compositional nature of both language and game events. We show that finer resolution grounding helps coarser resolution grounding, and vice versa. Our method results in an F1 improvement of more than 48% versus the previous state of the art for fine-resolution grounding[1].

1 Introduction

Language is inextricable from its context. A human language user interprets an utterance in the context of, among other things, their perception of the world. Grounded language acquisition algorithms imitate this setup: language is given meaning through its correspondence with a rich world representation. A solution to the acquisition problem must resolve several ambiguities: the segmentation of the text into meaningful units (spans of words that refer to events); determining which events are being referenced; and finding the proper alignment of events to these units.

Historically, language grounding was only possible over simple controlled domains and rigidly structured language. Current research in grounded language acquisition is moving into real-world environments (Yu and Siskind, 2013). Grounding sports commentaries in game events is a specific instance of this problem that has attracted attention (Liang et al., 2009; Snyder and Barzilay, 2007; Hajishirzi et al., 2012), in part because of the complexity of both the language and the world representation involved.

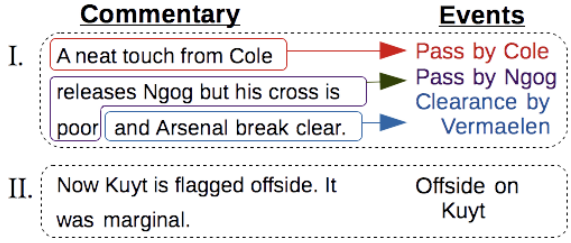

Figure 1: An example of the multiple resolutions at which soccer commentaries refer to events: The utterance level alignments are shown in the black dashed boxes. The first utterance can be further broken into the fragment-level alignments shown; the second cannot be decomposed further.

The language employed in soccer commentaries is difficult to ground due to its dense information structure, novel vocabulary and word senses, and colorful, non-traditional syntax. These challenges conspire to foil most language processing techniques including automated parsers and word-sense disambiguation systems.

In addition to the structural problems presented by the language of soccer commentaries, the problem of reference is further complicated by the fact that for game events (and other real-world phenomena) there is no standardized meaningful linguistic unit. Utterances ranging from a single word to multiple sentences can be used to refer to a single event. For example, in Figure 1 the first four words of commentary (I) refer to a single event, as does the entirety of (II).

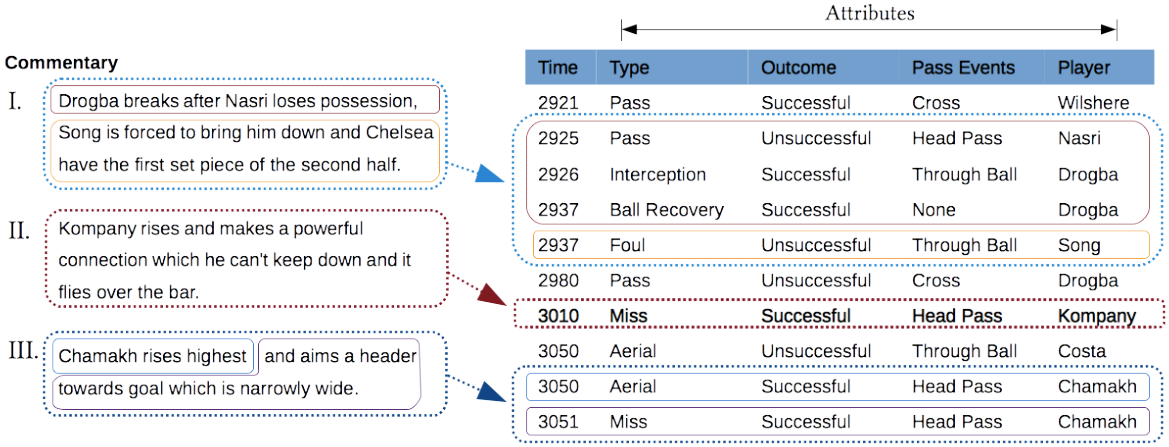

Figure 2: An example of the different levels of granularity present in the soccer data. The dashed boxes on the left denote *utterances* made by the commentators. Solid boxes denote fragments that cannot be decomposed into finer resolution alignments. The table on the right is a portion of the detailed listing of game events.

Turning our attention to Figure 2, sometimes a fragment refers to a combination of events and no further decomposition is available, such as the first fragment of commentary (I). Moreover, it is sometimes desirable to construct a complex of events by determining all the events corresponding to a particular collection of words. For instance, we would want to be able to align the whole of (I) with all the events in the corresponding dashed box. This suggests studying language grounding at multiple levels of granularity (resolutions).

We use *resolution* to describe the continuum of meaningful units which exist in human language[2]. These resolutions interact in a complicated way, with clues from different resolutions sometimes combining to produce an effect and sometimes negating one another. With enough training data, one could hope to learn the details of the interactions of various resolutions. However, the expense of producing or obtaining supervised training data at multiple resolutions is prohibitive.

To address all these complications, we introduce weakly-supervised multi-resolution language grounding. Our method makes use of a factorized objective function which allows us to model the complex interplay of resolutions. Our language model takes advantage of the discourse structure of the commentaries, making it robust enough to handle the unique language of the soccer domain. Finally, our method relies only on loose temporal co-occurrence of events and utterances as supervision and does not require expensive annotated training data.

To test our method we augment the Professional Soccer Commentary Dataset (Hajishirzi et al., 2012) with fragment-level event alignment annotations. This dataset is composed of commentaries for soccer matches paired with event logs produced by Opta Sportsdata and includes human annotated gold alignments[3]. We achieve an F1 improvement of over 48% on fragment-level alignment versus a previous state-of-the-art. We are also able to leverage the interplay of fragment- and utterance- level alignments to improve the previous state-of-the-art utterance-alignment system.

2 Challenges

Syntactic Limitations: Syntax is used to structure the information provided by an utterance, and so it seems intuitive that syntactic relations could be leveraged in this task. For example, consider utterance (III) in Figure 2. The multi-resolution grounding of (III) would provide a *segmentation* of the utterance – or a division of the utterance into the fragments which refer to separate events. In (III), there is an obvious syntactic correlate to the correct segmentation: each verb phrase within the conjunction headed by "and" identifies a separate event. Parsing (III) to an event-based semantics like that of Davidson (1967), one could associate each verb in an utterance with a game event and achieve the desired segmentation.

[2]Though it is tempting to discritize meaning in text, Chafe (1988) shows that readers imbue text with meaningful intonational patterns drawn from the potentially continuous space of auditory signals.

[3]Our updated dataset is available at `http://ssli.ee.washington.edu/tial/projects/multires/`

Unfortunately, there is a preponderance of examples such as (II) in Figure 2, where 4 verbs are used to describe a single "miss" event. (II) illustrates just one of the many difficulties of using syntactic information – elsewhere, events are referenced without an explicit verb whatsoever (such as the use of the phrase "into the books" to refer to a foul event). What is needed instead is a language model that is powerful enough to proscribe some structure yet robust enough to allow the world representation to determine which pieces of language are referring to which referent or set of referents.

Complex Interplay between Resolutions: Language refers at a variety of resolutions, and the relationship between nested reference scopes is complex. A single or few words can indicate entities or properties; full phrases are often needed to denote an action; complex events like a missed shot may take up to several phrases of narration to properly describe. A soccer commentator does not encode every detail necessary for proper alignment and segmentation into their utterances, but rather only enough to make clear to another with similar world knowledge what is meant. A language grounding method is at a severe disadvantage when faced with such implicit information.

Instead, a successful method can make heavy use of the limited lexical, phrasal, and discourse structural cues provided in an utterance, as the different resolutions rely on these different contextual clues to meaning. At finer resolutions one can rely more on the lexical meanings of the words; at medium resolutions, compositionality can be leveraged; at coarser resolutions, discourse features come into play. These cues interact in a complicated way, providing additional challenge.

Consider again Figure 2. In (III), the temporal discourse marker "and" marks the division between the fragments referring to each event. In (I) the same word (used again as a temporal discourse marker) is used to elaborate on the single "foul" event being described in the second fragment. A human (with sufficient understanding of soccer) knows that, despite being separated by the discourse marker, the phrases "bring him down" and "set piece" both refer to the foul. A language grounding algorithm that can model the interaction between such word-level and utterance-level cues can successfully segment both (I) and (III).

Supervision: For language grounding generally, and multi-resolution grounding specifically, supervised training data is expensive to produce. Also, the various grounding domains of interest are highly independent of one another (Liang et al., 2009). In the face of these issues, the ideal correspondence between language and world representation would be learned with as little supervision as possible.

3 Problem Definition

We define the problem of multi-resolution language grounding as follows: Given a temporal evolution of a world state (a sequence of events) and an overlapping natural language text (a sequence of utterances), we want to learn the best correspondences between the language and the world at different levels of granularity (Figure 2).

To set up notations, for each utterance represented as a set of words $W = \{w_1, w_2, \ldots, w_n\}$, we want a segmentation which expresses the relationship of the words to the events which they describe.

Let $\mathcal{S}$ denote a set of all possible segmentations of W. Then $\mathcal{S} = \{S | S \text{ is a segmentation of } W\}$. A segmentation S is in turn a set of non-overlapping fragments ($S = \{s_i\}$), where each fragment is a consecutive sequence of words from the utterance W. For example, for utterance (III) from Figure 2, one possible (incorrect) segmentation is $S = \{s_1, s_2, s_3\}$ for $s_1 = \{$*Chamakh rises highest*$\}$, $s_2 = \{$*and aims a header*$\}$, and $s_3 = \{$*towards goal which is narrowly wide*$\}$.

An alignment consists of a segmentation S and a mapping E from fragments of S to the set of all events $\mathbb{E}$. For example, the segmentation S could be mapped as $E = \{\langle s_1, e_2\rangle, \langle s_2, e_3\rangle, \langle s_3, e_1\rangle\}$, with e_1 being an Aerial Challenge, e_2 being a missed attempt on goal, and e_3 being an out of bounds penalty. Let $\mathcal{E} = \mathcal{S} \times \mathbb{E}$ denote the set of all possible alignments.

As we show in Figure 2, events are composed of the various attributes *Time, Type, Pass Events, Outcome*, and *Player*. For example, the aerial event in Figure 2 has the attributes and values *type:aerial, outcome:successful, pass events:head pass,* and *player:Chamakh*.

Finally, we denote the values for the attributes of each e_j as e_j^a, where a ranges over the different attributes of events as represented in the data.

We define the multi-resolution grounding of W

into $\mathbb{E}$ as the best segmentation S and alignment E that maximize the joint probability distribution:

$$\arg\max_{S \in \mathcal{S}, E \in \mathcal{E}} P(S, E|W) \quad (1)$$

This optimization[4] can be accomplished through the use of supervised learning. However, training data is expensive and tedious to produce for the grounding problem, especially at multiple resolutions. Additionally, the complexity of the language in this domain would result in very sparse associations.

Yet if we knew some of the correct fine-resolution alignments, we could use that information to produce good coarse resolution alignments, and vice versa. Therefore, we formulate a factorized form of the above objective which allows us to learn features specific to aligning at the utterance, fragment, and attribute resolutions. Our method can be optimized with only weak supervision (loose temporal alignments between utterances and a set of events occurring within a window of the utterance time).

We can evaluate such a correspondence in several ways. For each utterance, can we predict the correct events to which this utterance refers? This is the problem of utterance-level alignment.

We can also evaluate based on events: for each event, can we identify the minimal text span(s) which refers to this event? We want a tight correspondence because loose, overlapping alignments are not semantically satisfying. However, we do not want to under associate: human language makes reference at a variety of levels (the word level, the phrase level, the utterance level, and beyond). It is important to correctly identify all and only the words which correspond to a given event. This is the fragment-level alignment problem. We show that good fragment-level alignments will improve utterance-level alignment, and vice versa.

Since events are composed of their attributes, we can imagine a very fine resolution grounding of individual words to individual attributes. In fact, our solution involves producing such a grounding and composing the fragment- and utterance-level alignments therefrom.

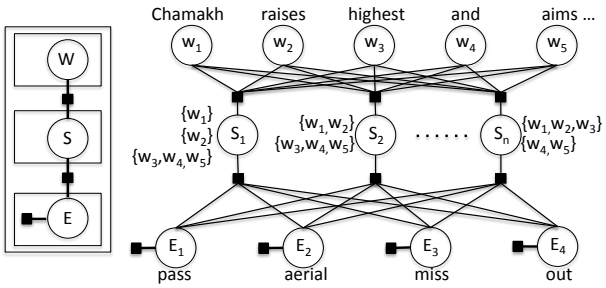

Figure 3: Factor graph for $P(S, E|W)$. Here the w_i are the words of utterance W, S_j are the possible segmentations of W, and E_k are different events.

4 Our Method

We have formulated the grounding problem as an optimization of the joint probability distribution $P(S, E|W)$, which returns the best segmentation and accompanying event alignments given an utterance W. Optimizing this function in the domain of real world language, however, is a difficult problem. Utterances are long here, and there are many events which could be grounded to each. Furthermore, the cardinality of the set of possible segmentations is combinatorially large.

Therefore we decompose Equation 1 using the factor graph depicted in Figure 3. We write the joint probability distribution as a product of the following two potential functions:

$$P(S, E|W) \stackrel{\text{def}}{=} \frac{1}{Z} \prod_{s \in S} \Psi^{\text{align}}(E, s) * \Phi^{\text{seg}}(s, W) \quad (2)$$

where Ψ^{align} is a function for scoring the alignment E for fragment s and Φ^{seg} scores how good a fragment s is for the utterance W, and Z is for normalization.

To optimize Equation 2 it is not practical to search the space of possible S, E combinations (this space is combinatorially large). However, we can optimize the factored form using dynamic programming. We first describe how to find values for each of the potentials in sections 4.1 and 4.2. In section 4.3 we describe the dynamic programming approach to optimization.

4.1 Event Alignments Given Segmentation

The potential function $\Psi^{\text{align}}(E, s)$ takes as inputs a fragment s from segmentation S and a candidate alignment E for S and returns a score for E with

[4] As this and future equations are conditioned on the set of all events $\mathbb{E}$, we omit this variable from the equations for notational simplicity.

regards to s. It is here that we produce the multi-resolution alignments; s can vary in size from a single word to a whole utterance. ψ^{align} decomposes as the following:

$$\Psi^{\text{align}}(E, s) = \Psi^{\text{prior}}(E) * \Psi^{\text{affinity}}(s, E) \quad (3)$$

where the priors (Ψ^{prior}) are confidence scores for an alignment E with the whole utterance as given by Hajishirzi et al. (2012), which fits an exemplar SVM to each utterance/event pair. An exemplar SVM is an SVM fit with one positive and many negative instances, allowing us to define an example by what it is not (Malisiewicz et al., 2011; Shrivastava et al., 2011).

Ψ^{affinity} scores the affinity between a fragment s and the event e_j to which it is aligned. We use the term affinity as a measure of the goodness of an alignment. Intuitively, a fragment s will have a higher affinity for an event e_j if s describes that event well. Formally, the affinity between s and e_j amounts to a product of the affinity between each word $w_i \in s$ and e_j. Since e_j is defined by a collection of attributes, we can compose a score for w_i with e_j from the affinity between w_i and each attribute a of e_j.

$$\begin{aligned}\Psi^{\text{affinity}}(s, E) &= \prod_{w_i \in s, e_j \in E} \psi^{\text{atr.}}(w_i, e_j) \\ &= \prod_{w_i \in s, e_j \in E} \max_a \psi(w_i, e_j^a) \quad (4)\end{aligned}$$

where e_j is the event to which s is aligned in alignment E, $\psi^{\text{atr.}}(w_i, e_j)$ is the affinity between w_i and event e_j, and $\psi(w_i, e_j^a)$ is the affinity between w_i and attribute a of e_j.

In order to determine the affinity of a word and an event attribute, we create *attribute:value classifiers* – one for each *attribute:value pair* that occurs in any event. For example, for goals we create a *type:goal* classifier, and for unsuccessful events we create an *outcome:unsuccessful* classifier.

For the categorical attributes *Type, Outcome,* and *Pass Events*, we fit a linear SVM (Fan et al., 2008) using the utterance-level alignments provided by Ψ^{prior} (the exemplar SVMs) to determine the positive and negative examples. For instance, we use all the utterances which are aligned with an event whose *type* value is "pass" as positive examples for our *type:pass* classifier, and all other utterances as negative examples.

The weight assigned to each dimension in a linear SVM describes the relative importance of that dimension in the classification process. The dimensions of our *attribute:value* SVMs are the words of the corpus, normalized for case and minus punctuation and stop words. Therefore, the affinity of a word w_i and the *attribute:value* e_j^a is the weight of the dimension corresponding to w_i in the e_j^a *attribute:value* classifier. Following others (Liang et al., 2009; Kate and Mooney, 2007), we use string matches to determine the affinity between a word and the *Player* attribute.

In order to make comparisons between the importance of a word in the decision process for different classifiers, we normalize the weight vectors for each. These *attribute:value* classifiers produce our finest resolution alignments, allowing us to define a correspondence between a single word and a single attribute of any event.

By considering e_j in terms of its attributes, we are able to compose a score for e_j with fragment s. This is a kind of double-sided compositional semantics, where both the meaningful signs (s) and their extensions (e_j) are composed of finer-resolution atomic parts (w_i and e_j^a, respectively).

4.2 Segmentations Given Utterances

The potential function $\Phi^{\text{seg}}(s, W)$ from Equation 2 returns a score for a fragment within an utterance. A segmentation can be thought of as the collection of bigrams $\langle w_i, w_{i+1} \rangle$ where w_i is the last word of a fragment which is being used to describe one event and w_{i+1} is the first word of a fragment being used to describe a different event. We will refer to such bigrams as *splitpoints*.

The function Φ^{seg} should favor fragments that begin and end at good *splitpoint* and whose intermediate bigrams are bad *splitpoints*. We formalize this as follows:

$$\Phi^{\text{seg}}(s, W) \propto \frac{\phi(w_{k-1}, w_k) * \phi(w_{k+m}, w_{k+m+1})}{\prod_{j=0}^{m-1} \phi(w_{k+j}, w_{k+j+1})}$$

where fragment s is a span of m consecutive words $\{w_k, ..., w_{k+m}\}$ from W, and ϕ is a score for how good of a *splitpoint* $\langle w_i, w_{i+1} \rangle$ would make (explained below).

Ideally, ϕ will be a classifier which can tell us if a given bigram is a good *splitpoint* for the utterance W. However, ours being an attempt at weakly-supervised learning, we have no labeled examples of correct splitpoints from which

to work. Instead, we employ linguistic knowledge to create a proxy of labels. We will use this proxy to train a classifier to discover the features of good splitpoints which can be generalized and produce a more robust system.

The proxy labeling scheme we developed is based on conservative components common to a variety of theories of discourse. Discourse theories aim to model the relationships which exist between adjacent utterances in a coherent discourse. Since we consider a sports commentary to be a coherent discourse, we can leverage results from discourse theory in producing our proxy labels.

Temporal Discourse: Events in a soccer match occur in a temporal sequence, and so it is reasonable to assume that the language used to describe them will employ temporal discourse relations to distinguish fragments describing separate events. Pitler et al. (2008) have constructed a list of discourse relations which can be easily automatically identified, including temporal discourse relations. These are indicated by the presence of *discourse markers* — alternately known as cue phrases. We hypothesize that cue phrases can be used to identify splitpoints and use them in our proxy labeling scheme. This method is not restricted to temporally related discourse: some contingency, expansion, and comparison relations are also analyzed as "easily identifiable". As such, our segmentation process can also be used to ground language into a world state where these relations would hold.

Prosodic Discourse: We also make use of prosodic discourse cues. Pierrehumbert and Hirschberg (1990) claim that intonational phrases play an important role in discourse segmentation. Therefore, we hypothesize that the edges of intonational phrases are very likely to correspond with correct splitpoints. Viewing the commentary transcriptions as a noisy channel of the actual speech signal, we can identify the intonational phrase boundaries with the punctuation inserted in the transcription process. Chafe (1988) confirms that punctuation in written language has a strong correspondence with intonational phrase boundaries, and an assumption like ours has been successfully implemented in speech synthesis systems (Black and Lenzo, 2000). Thus, we include bigrams containing punctuation as splitpoints in our proxy labels.

Feature Description for *splitpoint* classifier
Is w_i/w_{i+1} a discourse marker?
Is w_i/w_{i+1} punctuation?
Is w_i/w_{i+1} a player name?
Part of speech of w_i/w_{i+1}
Is one of w_i/w_{i+1} a dependent of the other?
Are w_i and w_{i+1} dependents of the same governor?
Dependency relations that hold across splitpoint
Height of w_i/w_{i+1} in the dependency tree
Difference in height of w_i/w_{i+1} in dependency tree
$\psi(w_i, e_j)$ of all words left versus right of splitpoint
Symmetric difference of best affinity scores for w_i/w_{i+1}
Are best affinity scores from the same event?

Table 1: Feature description for splitpoint classifier

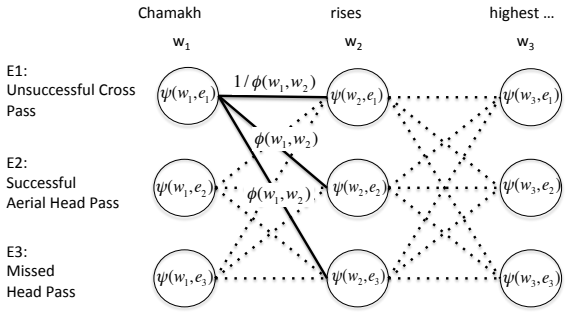

Figure 4: We use a trellis to allow for dynamic programming optimization of the objective function

Splitpoint Classifier: All other bigrams besides those above are labeled as negative examples, and a linear SVM is fit to the data. The features for the classifier include structural, discourse, and statistical features. We make use of dependency parse information from the Stanford dependency parser (De Marneffe and Manning, 2008). The full features list is explained in Table 1.

4.3 Optimization

We want to maximize the function in Equation 1, and we have explained that we can approximate this by maximizing the factored form in Equation 2. By the above methods, we can produce values for the functions Ψ^{align} and Φ^{seg}. What remains is to optimize Equation 2.

We take advantage of the factorization by using a dynamic programming approach to optimization. Figure 4 illustrates the setup. For each word w_i of the utterance, we create a column of nodes in our trellis, with one row for each event $e_j \in E$. The nodes represent the affinity of a given word w_i with event e_j. The weights on these nodes come from $\psi^{\text{atr.}}(w_i, e_j)$ described in section 4.2.

The nodes in column w_i are connected to the nodes in column w_{i+1} by edges whose weights

are drawn from the splitpoint classifier response $\phi(w_i, w_{i+1})$. We label the edges between adjacent nodes corresponding to different events with the responses from the splitpoint classifier, and the inverse of these responses for edges connecting nodes corresponding to the same event.

We then use the Viterbi algorithm (Viterbi, 1967) to find the maximum scoring path through this trellis. The maximum scoring path optimizes Equation 2, and serves as our approximation of the optimization of Equation 1. We choose the top k diverse paths through the trellis and use the associations therein as our alignments. See Figure 5 for a detailed example of how our Viterbi path coincides with the responses from the *attribute:value* classifiers.

5 Experiments

One justification for multi-resolution language grounding would be if finer-resolution grounding improves coarser-resolution grounding and vice versa. If so, we expect that better utterance-level alignments will improve fragment-level alignments, and that in turn those fragment-level alignments will improve utterance-level alignments. We evaluate both of these hypotheses.

5.1 Experimental Setup

Dataset: We use the publicly available Professional Soccer Commentary (PSC) dataset introduced in Hajishirzi et al. (2012). This dataset is composed of professional commentaries from the 2010-2011 season of the English Premier League, along with a human-annotated data feed produced for each game by Opta Sportsdata (Opta, 2012) which describes all events occurring around the ball. Events include passes, shots, misses, cards, tackles, and other relevant game details. Each event category is defined precisely and the feed is annotated by professionals according to strict event description guidelines.

Liang et al. (2009)	0.327	0.418	0.367
Hajishirzi et al. (2012)	0.355	**0.576**	0.439
Our approach	**0.407**	0.520	**0.457**

Table 4: Utterance-level alignment results

The PSC also provides ground truth alignment of full utterances to events in the data feed, and for this work we have augmented it with ground truth fragment-level annotations[5].

We use data from 7 games of the PSC. These games consist of 778 utterances totaling 13,692 words. There are 12,275 events. This data is labeled with ground truth utterance- and fragment-alignments.

Metric: There are 1,295 correct utterance-to-event alignments. For evaluation we use precision, recall, and F1 of our utterance-level alignments.

The evaluation of fragment-level alignments is less straight forward. This is due to the two features of a correct fragment alignment: picking the correct fragment boundaries and associating the fragment with the correct event. We evaluate fragment-level alignment on a per word basis. We consider precision in this task to be the number of correct word to event alignments versus the total number of alignments produced by a system. Recall is the number of correct word to event alignments versus the total gold word to event alignments, of which there are 18,147.

Comparisons: We compare to two previous works: Liang et al. (2009), which produces both segmentation and alignment results; and Hajishirzi et al. (2012), which produces state-of-the-art alignments. When evaluating segmentation, we compare how well the systems perform starting from the raw dataset, and starting from gold utterance-level alignments. This allows us to isolate the segmentation process from the overall system architectures. It also gives us some insight into the effect of event priors on the segmentation and alignment processes.

[5]The full dataset is available at `http://ssli.ee.washington.edu/tial/projects/multires/`

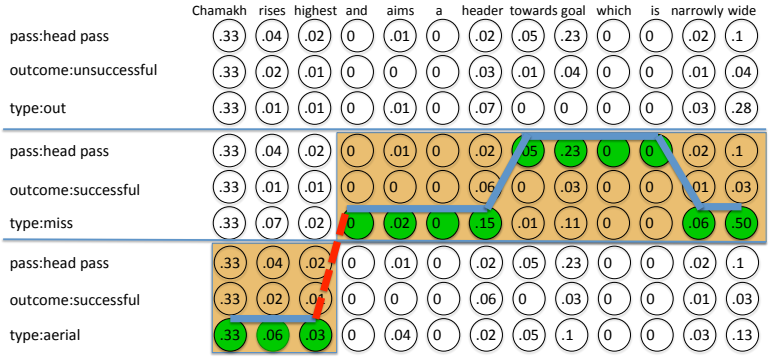

Figure 5: A successful grounding at multiple resolutions. Thin blue lines separate the *attribute:value* pairs corresponding to the three events. Values of $\psi(w_i, e_j)$ are shown on each node. The shaded bands indicate the gold fragment-level alignments. Thick line connecting the green nodes indicates the classifier responses used in the Viterbi best path through our trellis. The red dashed edge indicates a high response from the splitpoint classifier. This figure is best viewed in color.

5.2 Results

We evaluate our method on its alignments at the fragment-level and at the utterance-level. The results are as follows:

Fragment-level: Our results for segmentation can be seen in Tables 2 and 3. Table 2 shows the results achieved on the fragment-level alignment task using human-labeled utterance to event alignments. In this setting, all and only the correct events for each utterance are present. Still, there are several ambiguities in the data. Some fragments are aligned in the gold data with multiple events, and some are aligned to no event. Our method outperforms the previous by a large margin in terms of both precision and recall. We show below how this is due to our system's accommodation of discourse structure when making segmentation decisions and the factored form of our optimization.

Table 3 shows the results for fragment-level alignment by applying each system starting from the raw data. Here, in addition to the ambiguities mentioned above, the problem is further complicated by the fact that some correct events are missing from the alignments produced by each system and some incorrect events are included in these alignments (see Error Analysis below for details). Still our method achieves a significant improvement, with a 48% increase in F1 versus prior work.

Table 5 shows ablation results for the effect of the factors used in our optimization for fragment-level alignments. These results demonstrate the value of each factor in the fragment-level alignment process. We cannot ascribe the benefit of this method to one factor or another alone – it is their concert that improves performance.

Utterance-level: We have posited that good finer-resolution alignments will improve the coarser-resolution utterance to event alignments. Our results confirm this hypothesis. Table 4 shows our results on these alignments. We are able to improve F1 versus a state-of-the-art system which is tuned to maximize its F1 score. The majority of our improvement comes from the increased precision of our system, due to the influence of the finer-resolution fragment-level alignments on these coarser, utterance-level alignments. We provide a detailed example of this below. Ablation results are shown in Table 6.

5.3 Qualitative Analysis

A qualitative analysis of our system reveals the power of our factored objective, double-sided compositional approach, and leveraging of discourse structure. Figure 5 shows the best path through the trellis of the example sentence used in the introduction. For explanatory purposes, we have split every event into its three component attributes. This allows us to see how the *attribute:value* classifiers combine to produce an alignment.

Discourse Structure: The fragment-level alignment we have produced for this utterance is perfect: it correctly identifies the single *splitpoint* and correctly identifies each fragment with the associated event.

The identification of the splitpoint "and" comes from the fact that this word has, among other uses, a discourse connective meaning. Thus, the edges

in our trellis between different events are weighted higher than edges between the same event in the edges between the nodes for "highest" and "and", encouraging the Viterbi path to change events at this point.

Compositionality: We can see effect of the compositional approach we have taken – composing $\psi^{\text{affinity}}(s, e_j)$ from the *attribute:value* classifier scores of each $\psi(w_i, e_j^a)$ – by looking at how the best path makes use of different attributes of the same event. For the "miss" event aligned with the second part of the sentence, we can see that the best path makes use of both values from the *type:miss* and *pass event:head pass* classifiers.

Affinities: A few interesting associations are worth pointing out. First, we note that the word "header" has a stronger affinity for the *type:miss* attribute than it does for the *pass events:head pass* attribute. On first blush, this seems like a mistake in our classifier. However, we can see that even in this single trellis all three events have the *pass events:head pass* attribute. The utterance-level alignment uses this association already, aligning utterances containing the word "header" with events that have a *pass events:head pass* attribute. At a finer-resolution, it is necessary to make a different distinction between events. Our method finds that the presence of the word "header" is a stronger indicator of an event with a *type:miss* attribute, and thus this association is made.

Words that are better for the coarser-resolution association with the *pass events:head pass* attribute are "towards" and "goal". Out of the 10 utterances containing the word "towards" in the dataset, 3 of these are aligned with at least 1 *pass events:head pass* event, making this strong association a correct one. The word "goal" also has an affinity for the *pass events:head pass* attribute due to the fact that many events with this attribute are attempts on goal. This correlates with domain knowledge about soccer, because, although there may be other uses of their head by a player in the game, shots on goal are events which will nearly always be commented upon by an announcer.

Factorization: We have shown that finer-resolution fragment-level alignments can improve utterance-level alignments. From the exemplar SVMs, we are given an utterance-level alignment of the three events shown in the trellis with the utterance. This alignment is incorrect: the gold utterance alignment only includes the bottom two events. But by building an utterance-level alignment from the results of our fragment level alignment, we are left with only the two correct events. We prune the topmost event due to its failure to participate in a finer-resolution alignment.

5.4 Error Analysis

The majority of the errors made on our fragment-level alignments come in one of two flavors: Firstly, we sometimes erroneously identify a fragment as referring to an event when in truth it refers to no event. Commentators often describe facts about players or the weather or previous games which have no extension in the current game. However, our system cannot distinguish such language from the language referring to this game. This is a good avenue for future exploration.

The second set of errors we make in fragmentation are caused by bad event priors. Our current setup cannot increase recall: we can only improve the precision of the utterance-level alignments we are given. Therefore, if an event is overlooked in the first-pass of utterance-level alignments, we cannot reintroduce it through a fragment alignment. This is a direction for future work as well.

6 Related Work

Early semantic parsing work made use of fully supervised training (Zettlemoyer and Collins, 2005; Ge and Mooney, 2006; Snyder and Barzilay, 2007), but more recent work has focused on reducing the amount of supervision required (Artzi and Zettlemoyer, 2013). A few unsupervised approaches exist (Poon and Domingos, 2009; Poon, 2013), but these are specific to translating language into queries in highly structured database and cannot be applied to our more flexible domain.

There are few datasets as detailed as the Professional Soccer Commentary Dataset. Early work in understanding soccer commentaries focused on RoboCup soccer (Chen and Mooney, 2008; Chen et al., 2010; Bordes et al., 2010; Hajishirzi et al., 2011) where simple language describes each event, and events are in a one-to-one correspondence with utterances. Another dataset used for language grounding is the Weather Report Dataset (Liang et al., 2009). Here, again, however, we have mostly single utterances paired with single events, and many alignments are made via numerical string matching rather than learning lex-

ical cues. The NFL Recap dataset (Snyder and Barzilay, 2007) is also laden with numerical fact matching, and does not include the fragment-level segmentation annotation that the PSC dataset provides.

Impressive advances have been made grounding language in instructions. Branavan et al. (2009) and Vogel and Jurafsky (2010) work in the domain of computer technical support instructions, mapping language to actions using reinforcement learning. Matuszek et al. (2012b) parses simple language to robot control instructions. Our work focuses on dealing with a richer space, both in terms of the language used and the world-representation into which it is grounded, and leveraging the multiple resolutions of reference.

An exciting direction of research, closer to our own, aims to ground natural language in visual perception systems. Matuszek et al. (2012a) attempts to learn a joint model of language and object characteristics of a workplace environment. Yu and Siskind (2013) grounds moderately rich language in automatically annotated video clips. Again, the contribution of our work versus the above is in the complexity of the language with which we deal and our multi-resolution model.

7 Conclusion

The problem of grounding complex natural human language such as soccer commentaries is extremely difficult at all resolutions, and it is most challenging at finer resolutions where data is sparsest and small errors cannot be as easily normalized. Our work will help open new avenues of research into this difficult and exciting problem.

This paper presents a new method for the multi-resolution grounding of complex natural language in a detailed world representation. Our factor graph allows us to decompose the grounding problem into the more tractable subproblems of segmenting the language into fragments and aligning the fragments with the world representation. In the segmentation phase, we make use of linguistic theories of discourse to create a proxy of labels from which we learn statistical and structural features of good splitpoints. In the alignment phase, we bootstrap the learning of finer-grained correspondences between the language and the world representation with rough alignments from a state-of-the-art system. We combine these phases in a dynamic programming setup which allows us to efficiently optimize our objective.

We have shown that factoring the acquisition problem into separate alignment and segmentation phases improves performance on several evaluation metrics. We achieve considerable improvements over the previous state of the art on finer-resolution alignments in the domain of professional soccer commentaries, and we show that we can leverage groundings at one resolution to improve alignments in another.

Several extensions of this work are possible. We would like to annotate more games to improve our dataset. We could improve our model by encoding the dynamics of the environment. We did not attempt to learn this information in our process, but it is likely that modeling the event transition probabilities could provide better results. A larger future work would extend the method outlined herein to produce templates for automated commentary generation.

Abstract

Much work in recent years has gone into the construction of large knowledge bases (KBs), such as Freebase, DBPedia, NELL, and YAGO. While these KBs are very large, they are still very incomplete, necessitating the use of inference to fill in gaps. Prior work has shown how to make use of a large text corpus to augment random walk inference over KBs. We present two improvements to the use of such large corpora to augment KB inference. First, we present a new technique for combining KB relations and surface text into a single graph representation that is much more compact than graphs used in prior work. Second, we describe how to incorporate vector space similarity into random walk inference over KBs, reducing the feature sparsity inherent in using surface text. This allows us to combine distributional similarity with symbolic logical inference in novel and effective ways. With experiments on many relations from two separate KBs, we show that our methods significantly outperform prior work on KB inference, both in the size of problem our methods can handle and in the quality of predictions made.

1 Introduction

Much work in recent years has gone into the construction of large knowledge bases, either by collecting contributions from many users, as with Freebase (Bollacker et al., 2008) and DBPedia (Mendes et al., 2012), or automatically from web text or other resources, as done by NELL (Carlson et al., 2010) and YAGO (Suchanek et al., 2007). These knowledge bases contain millions of real-world entities and relationships between them. However, even though they are very large, they are still very incomplete, missing large fractions of possible relationships between common entities (West et al., 2014). Thus the task of *inference* over these knowledge bases, predicting new relationships simply by examining the knowledge base itself, has become increasingly important.

A promising technique for inferring new relation instances in a knowledge base is random walk inference, first proposed by Lao and Cohen (2010). In this method, called the Path Ranking Algorithm (PRA), the knowledge base is encoded as a graph, and random walks are used to find paths that connect the source and target nodes of relation instances. These paths are used as features in a logistic regression classifier that predicts new instances of the given relation. Each path can be viewed as a horn clause using knowledge base relations as predicates, and so PRA can be thought of as a kind of discriminatively trained logical inference.

One major deficiency of random walk inference is the connectivity of the knowledge base graph—if there is no path connecting two nodes in the graph, PRA cannot predict any relation instance between them. Thus prior work has introduced the use of a text corpus to increase the connectivity of the graph used as input to PRA (Lao et al., 2012; Gardner et al., 2013). This approach is not without its own problems, however. Whereas knowledge base relations are semantically coherent and different relations have distinct meanings, this is not

* Research carried out while at the Machine Learning Department, Carnegie Mellon University.

true of surface text. For example, "The Nile *flows through* Cairo" and "The Nile *runs through* Cairo" have very similar if not identical meaning. Adding a text corpus to the inference graph increases connectivity, but it also dramatically increases feature sparsity.

We introduce two new techniques for making better use of a text corpus for knowledge base inference. First, we describe a new way of incorporating the text corpus into the knowledge base graph that enables much more efficient processing than prior techniques, allowing us to approach problems that prior work could not feasibly solve. Second, we introduce the use of vector space similarity in random walk inference in order to reduce the sparsity of surface forms. That is, when following a sequence of edge types in a random walk on a graph, we allow the walk to follow edges that are semantically similar to the given edge types, as defined by some vector space embedding of the edge types. If a path calls for an edge of type "flows through", for example, we accept other edge types (such as "runs through") with probability proportional to the vector space similarity between the two edge types. This lets us combine notions of distributional similarity with symbolic logical inference, with the result of decreasing the sparsity of the feature space considered by PRA. We show with experiments using both the NELL and Freebase knowledge bases that this method gives significantly better performance than prior approaches to incorporating text data into random walk inference.

2 Graph Construction

Our method for knowledge base inference, described in Section 3, performs random walks over a graph to obtain features for a logistic regression classifier. Prior to detailing that technique, we first describe how we produce a graph $\mathcal{G} = (\mathcal{N}, \mathcal{E}, \mathcal{R})$ from a set of knowledge base (KB) relation instances and a set of surface relation instances extracted from a corpus. Producing a graph from a knowledge base is straightforward: the set of nodes $\mathcal{N}$ is made up of the entities in the KB; the set of edge types $\mathcal{R}$ is the set of relation types in the KB, and the typed edges $\mathcal{E}$ correspond to relation instances from the KB, with one edge of type r connecting entity nodes for each (n_1, r, n_2) triple in the KB. Less straightforward is how to construct a graph from a corpus, and how to connect that graph to the KB graph. We describe our methods for each of those below.

To create a graph from a corpus, we first preprocess the corpus to obtain a collection of *surface relations*, such as those extracted by open information extraction systems like OLLIE (Mausam et al., 2012). These surface relations consist of a pair of noun phrases in the corpus, and the verb-like connection between them (either an actual verb, as done by Talukdar et al. (2012), a dependency path, as done by Riedel et al. (2013), or OpenIE relations (Mausam et al., 2012)). The verb-like connections are naturally represented as edges in the graph, as they have a similar semantics to the knowledge base relations that are already represented as edges. We thus create a graph from these triples exactly as we do from a KB, with nodes corresponding to noun phrase types and edges corresponding to surface relation triples.

So far these two subgraphs we have created are entirely disconnected, with the KB graph containing nodes representing entities, and the surface relation graph containing nodes representing noun phrases, with no edges between these noun phrases and entities. We connect these two graphs by making use of the ALIAS relation in the KB, which links entities to potential noun phrase referents. Each noun phrase in the surface relation graph is connected to those entity nodes which the noun phrase can possibly refer to according to the KB. These edges are not the output of an entity linking system, as done by Lao et al. (2012), but express instead the notion that the noun phrase *can* refer to the KB entity. The use of an entity linking system would certainly allow a stronger connection between noun phrase nodes and entity nodes, but it would require much more preprocessing and a much larger graph representation, as each mention of each noun phrase would need its own node, as opposed to letting every mention of the same noun phrase share the same node. This graph representation allows us to add tens of millions of surface relations to a graph of tens of millions of KB relations, and perform all of the processing on a single machine.

As will be discussed in more detail in Section 4, we also allow edge types to optionally have an associated vector that ideally captures something of the semantics of the edge type.

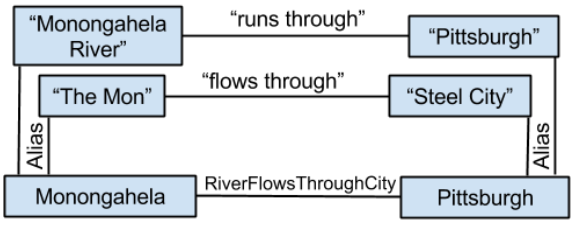
Figure 1 shows the graph constructions used in our experiments on a subset of KB and surface re-

KB Relations:
(Monongahela, RIVERFLOWSTHROUGHCITY, Pittsburgh)
(Pittsburgh, ALIAS, "Pittsburgh")
(Pittsburgh, ALIAS, "Steel City")
(Monongahela, ALIAS, "Monongahela River")
(Monongahela, ALIAS, "The Mon")

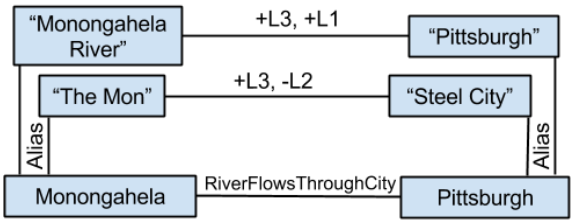
Surface Relations:
("The Mon", "flows through", "Steel City")
("Monongahela River", "runs through", "Pittsburgh")

Embeddings:
"flows through": [.2, -.1, .9]
"runs through": [.1, -.3, .8]

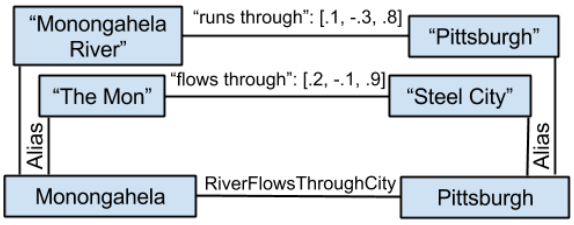
(a) An example data set.



(b) An example graph that combines a KB and surface relations.



(c) An example graph that replaces surface relations with a cluster label, as done by Gardner et al. (2013). Note, however, that the graph structure differs from that prior work; see Section 5.



(d) An example graph that uses vector space representations of surface edges, as introduced in this paper.

Figure 1: Example graph construction as used in the experiments in this paper. A graph using only KB edges is simply a subset of these graphs containing only the RIVERFLOWSTHROUGHCITY edge, and is not shown.

lations. Note that Figures 1b and 1c are shown as rough analogues of graphs used in prior work (described in more detail in Section 5), and we use them for comparison in our experiments.

3 The Path Ranking Algorithm

We perform knowledge base inference using the Path Ranking Algorithm (PRA) (Lao and Cohen, 2010). We begin this section with a brief overview of PRA, then we present our modification to the PRA algorithm that allows us to incorporate vector space similarity into random walk inference.

PRA can be thought of as a method for exploiting local graph structure to generate non-linear feature combinations for a prediction model. PRA generates a feature matrix over pairs of nodes in a graph, then uses logistic regression to classify those node pairs as belonging to a particular relation.

More formally, given a graph $\mathcal{G}$ with nodes $\mathcal{N}$, edges $\mathcal{E}$, and edge labels $\mathcal{R}$, and a set of node pairs $(s_i, t_i) \in \mathcal{D}$, one can create a connectivity matrix where rows correspond to node pairs and columns correspond to edge lables. PRA *augments* this matrix with additional columns corresponding to *sequences* of edge labels, called *path types*, and changes the cell values from representing the presence of an edge to representing the specificity of the connection that the path type makes between the node pair.

Because the feature space considered by PRA is so large (the set of all possible edge label sequences, with cardinality $\sum_{i=1}^{l} |\mathcal{R}|^i$, assuming a bound l on the maximum path length), the first step PRA must perform is *feature selection*, which is done using random walks over the graph. The second step of PRA is *feature computation*, where each cell in the feature matrix is computed using a constrained random walk that follows the path type corresponding to the feature. We now explain each of these steps in more detail.

Feature selection finds path types π that are likely to be useful in predicting new instances of the relation represented by the input node pairs . These path types are found by performing random walks on the graph $\mathcal{G}$ starting at the source and target nodes in $\mathcal{D}$, recording which paths connect some source node with its target. The edge sequences are ranked by frequency of connecting a source node to a corresponding target node, and the top k are kept.

Feature computation. Once a set of path types

is selected as features, the next step of the PRA algorithm is to compute a value for each cell in the feature matrix, corresponding to a node pair and a path type. The value computed is the probability of arriving at the target node of a node pair, given that a random walk began at the source node and was constrained to follow the path type: $\mathrm{p}(t|s, \pi)$.

Once these steps have been completed, the resulting feature matrix can be used with whatever model or learning algorithm is desired; in this and prior work, simple logistic regression has been used as the prediction algorithm.

4 Vector space random walks

Our modifications to PRA are confined entirely to the feature computation step described above; feature selection (finding potentially useful sequences of edge types) proceeds as normal, using the symbolic edge types. When computing feature values, however, we allow a walk to follow an edge that is *semantically similar* to the edge type in the path, as defined by Euclidean distance in the vector space.

More formally, consider a path type π. Recall that π is a sequence of edge types $< e_1, e_2, \ldots, e_l >$, where l is the length of the path; we will use π_i to denote the i^{th} edge type in the sequence. To compute feature values, PRA begins at some node and follows edges of type π_i until the sequence is finished and a target node has been reached. Specifically, if a random walk is at a node n with m outgoing edge types $\{e_1, e_2, \ldots, e_m\}$, PRA selects the edge type from that set which matches π_i, then selects uniformally at random from all outgoing edges of that type. If there is no match in the set, the random walk restarts from the original start node.

We modify the selection of which edge type to follow. When a random walk is at a node n with m outgoing edge types $\{e_1, e_2, \ldots, e_m\}$, instead of selecting only the edge type that matches π_i, we allow the walk to select instead an edge that is close to π_i in vector space. For each edge type at node n, we select the edge with the following probability:

$$p(e_j|\pi_i) \propto \exp(\beta \times v(e_j) \cdot v(\pi_i)),\ \forall j, 1 \leq j \leq m$$

where $v(\cdot)$ is a function that returns the vector representation of an edge type, and β is a spikiness parameter that determines how much weight to give to the vector space similarity. As β approaches infinity, the normalized exponential approximates a delta function on the closest edge type to π_i, in $\{e_1, e_2, \ldots, e_m\}$. If π_i is in the set of outgoing edges, this algorithm converges to the original PRA.

However, if π_i is not in the set of outgoing edge types at a node and all of the edge types are very dissimilar to π_i, this algorithm (with β not close to infinity) will lead to a largely uniform distribution over edge types at that node, and no way for the random walk to restart. To recover the restart behavior of the original PRA, we introduce an additional restart parameter α, and add another value to the categorical distribution before normalization:

$$p(\text{restart}|\pi_i) \propto \exp(\beta * \alpha)$$

When this *restart* type is selected, the random walk begins again, following π_1 starting at the source node. With α set to a value greater than the maximum similarity between (non-identical) edge type vectors, and β set to infinity, this algorithm exactly replicates the original PRA.

Not all edge types have vector space representations: the ALIAS relation cannot have a meaningful vector representation, and we do not use vectors to represent KB relations, finding that doing so was not useful in practice (which makes intuitive sense: KB relations are already latent representations themselves). While performing random walks, if π_i has no vector representation, we fall back to the original PRA algorithm for selecting the next edge.

We note here that when working with vector spaces it is natural to try clustering the vectors to reduce the parameter space. Each path type π is a feature in our model, and if two path types differ only in one edge type, and the differing edge types have very similar vectors, the resultant feature values will be essentially identical for both path types. It seems reasonable that running a simple clustering algorithm over these path types, to reduce the number of near-duplicate features, would improve performance. We did not find this to be the case, however; all attempts we made to use clustering over these vectors gave performance indistinguishable from not using clustering. From this we conclude that the main issue hindering performance when using PRA over these kinds of graphs is one of limited connectivity, not one of too many parameters in the model. Though the

feature space considered by PRA is very large, the number of attested features in a real graph is much smaller, and it is this sparsity which our vector space methods address.

5 Related Work

Knowledge base inference. Random walk inference over knowledge bases was first introduced by Lao and Cohen (2010). This work was improved upon shortly afterward to also make use of a large corpus, by representing the corpus as a graph and connecting it to the knowledge base (Lao et al., 2012). Gardner et al. (2013) further showed that replacing surface relation labels with a representation of a latent embedding of the relation led to improved prediction performance. This result is intuitive: the feature space considered by PRA is exponentially large, and surface relations are sparse. The relations "[river] flows through [city]" and "[river] runs through [city]" have near identical meaning, and both should be very predictive for the knowledge base relation RIVERFLOWSTHROUGHCITY. However, if one of these relations only appears in the training data and the other only appears in the test data, neither will be useful for prediction. Gardner et al. (2013) attempted to solve this issue by finding a latent symbolic representation of the surface relations (such as a clustering) and replacing the edge labels in the graph with these latent representations. This makes it more likely for surface relations seen in training data to also be seen at test time, and naturally improved performance.

This representation, however, is still brittle, as it is still a symbolic representation that is prone to mismatches between training and test data. If the clustering algorithm used is too coarse, the features will not be useful, and if it is too fine, there will be more mismatches. Also, verbs that are on the boundaries of several clusters are problematic to represent in this manner. We solve these problems by modifying the PRA algorithm to directly use vector representations of edge types during the random walk inference.

These two prior techniques are the most directly related work to what we present in this paper, and we compare our work to theirs.

Graph construction. In addition to the incorporation of vector space similarity into the PRA algorithm, the major difference between our work and the prior approaches mentioned above is in the construction of the graph used by PRA. We contrast our method of graph construction with these prior approaches in more detail below.

Lao et al. (2012) represent every word of every sentence in the corpus as a node in the graph, with edges between the nodes representing dependency relationships between the words. They then connect this graph to the KB graph using a simple entity linking system (combined with coreference resolution). The resultant graph is enormous, such that they needed to do complex indexing on the graph and use a cluster of 500 machines to perform the PRA computations. Also, as the edges represent dependency labels, not words, with this graph representation the PRA algorithm does not have access to the verbs or other predicative words that appear in the corpus, which frequently express relations. PRA only uses *edge* types as feature components, not *node* types, and so the rich information contained in the words is lost. This graph construction also would not allow the incorporation of vector space similarity that we introduced, as dependency labels do not lend themselves well to vector space representations.

Gardner et al. (2013) take an approach very similar to the one presented in Section 2, preprocessing the corpus to obtain surface relations. However, instead of creating a graph with nodes representing noun phrases, they added edges from the surface relations directly to the entity nodes in the graph. Using the ALIAS relation, as we do, they added an edge between *every possible* concept pair that could be represented by the noun phrases in a surface relation instance. This leads to some nonsensical edges added to the graph, and if the ALIAS relation has high degree (as it does for many common noun phrases in Freebase), it quickly becomes unscalable—this method of graph construction runs out of disk space when attempting to run on the Freebase experiments in Section 6. Also, in conflating entity nodes in the graph with noun phrases, they lose an important distinction that turns out to be useful for prediction, as we discuss in Section 6.4.[1]

[1]Recent notions of "universal schema" (Riedel et al., 2013) also put KB entities and noun phrases into the same conceptual space, though they opt for using noun phrases instead of the KB entities used by Gardner et al. In general this is problematic, as it relies on some kind of entity linking system as preprocessing, and cannot handle common noun references of proper entities without losing information. Our method, and that of Lao et al., skirts this issue entirely by not trying to merge KB entities with noun phrases.

Other related work. Also related to the present work is recent research on programming languages for probabilistic logic (Wang et al., 2013). This work, called ProPPR, uses random walks to locally ground a query in a small graph before performing propositional inference over the grounded representation. In some sense this technique is like a recursive version of PRA, allowing for more complex inferences than a single iteration of PRA can make. However, this technique has not yet been extended to work with large text corpora, and it does not yet appear to be scalable enough to handle the large graphs that we use in this work. How best to incorporate the work presented in this paper with ProPPR is an open, and very interesting, question.

Examples of other systems aimed at reasoning over common-sense knowledge are the CYC project (Lenat, 1995) and ConceptNet (Liu and Singh, 2004). These common-sense resources could easily be incorporated into the graphs we use for performing random walk inference.

Lines of research that seek to incorporate distributional semantics into traditional natural language processing tasks, such as parsing (Socher et al., 2013a), named entity recognition (Passos et al., 2014), and sentiment analysis (Socher et al., 2013b), are also related to what we present in this paper. While our task is quite different from these prior works, we also aim to combine distributional semantics with more traditional methods (in our case, symbolic logical inference), and we take inspiration from these methods.

6 Experiments

We perform both the feature selection step and the feature computation step of PRA using GraphChi, an efficient single-machine graph processing library (Kyrola et al., 2012). We use MALLET's implementation of logistic regression, with both L1 and L2 regularization (McCallum, 2002). To obtain negative evidence, we used a closed world assumption, treating any (source, target) pair found during the feature computation step as a negative example if it was not given as a positive example. We tuned the parameters to our methods using a coarse, manual grid search with cross validation on the training data described below. The parameters we tuned were the L1 and L2 regularization parameters, how many random walks to perform in the feature selection and computation steps of PRA, and spikiness and restart parameters for vector space walks. The results presented were not very sensitive to changes in these parameters.

Avg. instances/relation	810	200
SVO triples used	404k	28M

Table 1: Statistics of the data used in our experiments.

6.1 Data

We ran experiments on both the NELL and Freebase knowledge bases. The characteristics of these knowledge bases are shown in Table 1. The Freebase KB is very large; to make it slightly more manageable we filtered out relations that did not seem applicable to relation extraction, as well as a few of the largest relations.[2] This still left a very large, mostly intact KB, as can be seen in the table. For our text corpus, we make use of a set of subject-verb-object triples extracted from dependency parses of ClueWeb documents (Talukdar et al., 2012). There are 670M such triples in the data set, most of which are completely irrelevant to the knowledge base relations we are trying to predict. For each KB, we filter the SVO triples, keeping only those which can possibly connect training and test instances of the relations we used in our experiments. The number of SVO triples kept for each KB is also shown in Table 1. We obtained vector space representations of these surface relations by running PCA on the SVO matrix.

We selected 10 NELL relations and 24 Freebase relations for testing our methods. The NELL relations were hand-selected as the relations with the largest number of known instances that had a reasonable precision (the NELL KB is automatically created, and some relations have low precision). We split the known instances of these relations into 75% training and 25% testing, giving on average about 650 training instances and 160 test

[2] We removed anything under /user, /common, /type (except for the relation /type/object/type), /base, and /freebase, as not applicable to our task. We also removed relations dealing with individual music tracks, book editions, and TV epidsodes, as they are very large, very specific, and unlikely to be useful for predicting the relations in our test set.

instances for each relation.

The 24 Freebase relations were semi-randomly selected. We first filtered the 4215 relations based on two criteria: the number of relation instances must be between 1000 and 10000, and there must be no mediator in the relation.[3] Once we selected the relations, we kept all instances of each relation that had some possible connection in the SVO data.[4] This left on average 200 instances per relation, which we again split 75%-25% into training and test sets.

6.2 Methods

The methods we compare correspond to the graphs shown in Figure 1. The KB method uses the original PRA algorithm on just the KB relations, as presented by Lao and Cohen (2010). KB + SVO adds surface relations to the graph (Figure 1b). We present this as roughly analogous to the methods introduced by Lao et al. (2012), though with some significant differences in graph representation, as described in Section 5. KB + Clustered SVO follows the methods of Gardner et al. (2013), but using the graph construction introduced in this paper (Figure 1c; their graph construction techniques would have made graphs too large to be feasible for the Freebase experiments). KB + Vector SVO is our method (Figure 1d).

6.3 Evaluation

As evaluation metrics, we use *mean average precision* (MAP) and *mean reciprocal rank* (MRR), following recent work evaluating relation extraction performance (West et al., 2014). We test significance using a paired permutation test.

The results of these experiments are shown in Table 2 and Table 3. In Table 4 we show average precision for every relation tested on the NELL KB, and we show the same for Freebase in Table 5.

6.4 Discussion

We can see from the tables that KB + Vector SVO (the method presented in this paper) significantly outperforms prior approaches in both MAP and MRR. We believe that this is due to the reduction in feature sparsity enabled by using vector space instead of symbolic representations (as that is the only real difference between KB + Clustered SVO and KB + Vector SVO), allowing PRA to make better use of path types found in the training data. When looking at the results for individual relations in Table 4 and Table 5, we see that KB + Vector SVO outperforms other methods on the majority of relations, and it is a close second when it does not.

We can also see from the results that mean average precision seems a little low for all methods tested. This is because MAP is computed as the precision of *all* possible correct predictions in a ranked list, where precision is counted as 0 if the correct prediction is not included in the list. In other words, there are many relation instances in our randomly selected test set that are not inferrable from the knowledge base, and the low recall hurts the MAP metric. MRR, which judges the precision of the top prediction for each relation, gives us some confidence that the main issue here is one of recall, as MRR is reasonably high, especially on the NELL KB. As further evidence, if we compute average precision for each query node (instead of for each relation), excluding queries for which the system did not return any predictions, MAP ranges from .29 (KB) to .45 (KB + Vector SVO) on NELL (with around 30% of queries having no prediction), and from .40 (KB) to .49 (KB +

[3] A mediator in Freebase is a reified relation instance meant to handle n-ary relations, for instance /film/performance. PRA in general, and our implementation of it in particular, needs some modification to be well-suited to predicting relations with mediators.

[4] We first tried randomly selecting instances from these relations, but found that the probability of selecting an instance that benefited from an SVO connection was negligible. In order to make use of the methods we present, we thus restricted ourselves to only those that had a possible SVO connection.

Table 5: Average precision for each relation tested on the Freebase KB. The best performing method on each relation is bolded. For space considerations, "Clustered SVO" is shortened to "C-SVO" and "Vector SVO" is shortened to "V-SVO" in the table header.

Vector SVO) on Freebase, (where 21% of queries gave no prediction). Our methods thus also improve MAP when calculated in this manner, but it is not an entirely fair metric,[5] so we use standard MAP to present our main results.

One interesting phenomenon to note is a novel use of the ALIAS relation in some of the relation models. The best example of this was found with the relation `/people/ethnicity/languages_spoken`. A high-weighted feature when adding surface relations was the edge sequence <ALIAS, ALIAS INVERSE>. This edge sequence reflects the fact that languages frequently share a name with the group of people that speaks them (e.g., Maori, French). And because PRA can generate compositional features, we also find the following edge sequence for the same relation: </people/ethnicity/included_in_group, ALIAS, ALIAS INVERSE>. This feature captures the same notion that languages get their names from groups of people, but applies it to subgroups within an ethnicity. These features would be very difficult, perhaps impossible, to include in systems that do not distinguish between noun phrases and knowledge base entities, such as the graphs constructed by Gardner et al. (2013), or typical relation extraction systems, which generally only work with noun phrases after performing a heuristic entity linking.

7 Conclusion

We have offered two main contributions to the task of knowledge base inference. First, we have presented a new technique for combining knowledge base relations and surface text into a single graph representation that is much more compact than graphs used in prior work. This allowed us to apply methods introduced previously to much larger problems, running inference on a single machine over the entire Freebase KB combined with tens of millions of surface relations. Second, we have described how to incorporate vector space similarity into random walk inference over knowledge bases, reducing the feature sparsity inherent in using surface text. This allows us to combine distributional similarity with symbolic logical inference in novel and effective ways. With experiments on many relations from two separate knowledge bases, we have shown that our methods significantly outperform prior work on knowledge base inference.

The code and data used in the experiments in this paper are available at http://rtw.ml.cmu.edu/emnlp2014_vector_space_pra/.

[5] MAP is intended to include some sense of recall, but excluding queries with no predictions removes that and opens the metric to opportunistic behavior.

Composition of Word Representations Improves Semantic Role Labelling

Michael Roth and **Kristian Woodsend**

School of Informatics, University of Edinburgh
{mroth,kwoodsen}@inf.ed.ac.uk

Abstract

State-of-the-art semantic role labelling systems require large annotated corpora to achieve full performance. Unfortunately, such corpora are expensive to produce and often do not generalize well across domains. Even in domain, errors are often made where syntactic information does not provide sufficient cues. In this paper, we mitigate both of these problems by employing distributional word representations gathered from unlabelled data. While straight-forward word representations of predicates and arguments improve performance, we show that further gains are achieved by composing representations that model the interaction between predicate and argument, and capture full argument spans.

1 Introduction

The goal of *semantic role labelling* (SRL) is to discover the relations that hold between a predicate and its arguments in a given input sentence (e.g., "who" did "what" to "whom", "when", "where", and "how"). This semantic knowledge at the predicate-argument level is required by inference-based NLP tasks in order to identify meaning-preserving transformations, such as active/passive, verb alternations and nominalizations. Several manually-build semantic resources, including FrameNet (Ruppenhofer et al., 2010) and PropBank (Palmer et al., 2005), have been developed with the goal of documenting and providing examples of such transformations and how they preserve semantic role information. Given that labelled corpora are inevitably restricted in size and coverage, and that syntactic cues are not by themselves unambiguous or sufficient, the success of systems that automatically provide corresponding analyses has been limited in practice.

Recent work on SRL has explored approaches that can leverage unlabelled data, following a semi-supervised (Fürstenau and Lapata, 2012; Titov and Klementiev, 2012) or unsupervised learning paradigm (Abend et al., 2009; Titov and Klementiev, 2011). Unlabelled data provides additional statistical strength and can lead to more consistent models. For instance, latent representations of words can be computed, based on distributional similarity or language modelling, which can be used as additional features during traditional supervised learning. Although we would expect that extra features would improve classifier performance, this seems in part counter-intuitive. Just because one word has a specific representation does not mean that it should be assigned a specific argument label. Instead, one would expect a more complex interplay between predicate, argument and the context they appear in.

In this paper, we investigate the impact of distributional word representations for SRL. Initially, we augment the feature space with word representations for a predicate and its argument head. Furthermore, we use a compositional approach to model a representation of the full argument, by composing a joint representation of all words in the argument span, and we also investigate the interaction between predicate and argument, using a compositional representation of the dependency path. We demonstrate the benefits of these compositional features using a state-of-the-art semantic role labeller, which we evaluate on the English part of the CoNLL-2009 data set.

2 Related Work

Research into using distributional information in SRL dates back to Gildea and Jurafsky (2002), who used distributions over verb-object co-occurrence clusters to improve coverage in argument classification. The distribution of a word over these soft clusters assignments was added as

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 407–413,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

features to their classifier. The SRL system by Croce et al. (2010) combines argument clustering based on co-occurrence frequencies with a language model. Collobert et al. (2011) used distributional word representations in a neural network model that can update representations during training. Zapirain et al. (2013) suggested distributional information as a basis for a selectional preference model that can be used as a single additional feature for classifying potential arguments. Most recently, Hermann et al. (2014) used distributional word representations within pre-defined syntactic contexts as input to a classifier which learns to distinguish different predicate senses.

A complementary line of research explores the representation of sequence information. Prominent examples are the works by Deschacht and Moens (2009) and Huang and Yates (2010) who learned and applied Hidden Markov Models to assign state variables to words and word spans, which serve as supplementary features for classification. One drawback of this approach is that state variables are discrete and the number of states (i.e., their granularity) has to be chosen in advance.

The popularity of distributional methods for word representation has been a motivation for developing representations of larger constructions such as phrases and sentences, and there have been several proposals for computing the meaning of word combinations in vector spaces. Mitchell and Lapata (2010) introduced a general framework where composition is formulated as a function f of two vectors u and v. Depending on how f is chosen, different composition models arise, the simplest being an additive model where $f(u, v) = u + v$. To capture relational functions, Baroni and Zamparelli (2010) expanded on this approach by representing verbs, adjectives and adverbs by matrices which can modify the properties of nouns (represented by vectors). Socher et al. (2012) combined word representations with syntactic structure information, through a recursive neural network that learns vector space representations for multi-word phrases and sentences. An empirical comparison of these composition methods was provided in (Blacoe and Lapata, 2012).

In this work, we use type-based continuous representations of words to compose representations of multiple word sequences and spans, which can then be incorporated directly as features into SRL systems.

Distributional Feature	Computation
Argument a	$\vec{a}$
Predicate p	$\vec{p}$
Predicate-argument **Interaction**	$\vec{a} + \vec{p}$
Argument **Span** $w_1 \dots w_n$	$\Sigma_i \vec{w_i}$
Dependency **Path** from a to p	$\Sigma_{w \in \text{path}(a,p)} \vec{w}$

Table 1: Features based on distributional word representations and additive composition. Vector $\vec{w}$ denotes the representation of word w.

3 Method

Following the set-up of the CoNLL shared task in 2009, we consider predicate-argument structures that consist of a verbal or nominal predicate p and PropBank-labelled arguments $a_i \in \{a_1 \dots a_n\}$, where each a_i corresponds to the head word of the phrase that constitutes the respective argument. Traditional semantic role labelling approaches compute a set of applicable features on each pair $\langle p, a_i \rangle$, such as the observed lemma type of a word and the grammatical relation to its head, that serve as indicators for a particular role label.

The disadvantage of this approach lies in the fact that indicator features such as word and lemma type are often sparse in training data and hence do not generalize well across domains. In contrast, features based on distributional representations (e.g., raw co-occurrence frequencies) can be computed for every word, given that it occurs in some unlabelled corpus. In addition to this obvious advantage for out-of-domain settings, distributional representations can provide a more robust input signal to the classifier, for instance by projecting a matrix of co-occurrence frequencies to a lower-dimensional space. We hence hypothesize that such features enable the model to become more robust out-of-domain, while providing higher precision in-domain.

Although simply including the components of a word representation as features to a classifier can lead to immediate improvements in SRL performance, this observation seems in part counter-intuitive. Just because one word has a specific representation does not mean that it should be assigned a specific argument label. In fact, one would expect a more complex interplay between the representation of an argument a_i and the context it appears in. To model aspects of this interplay, we define an extended set of features that

further includes representations for the combination of p and a_i, the set of words in the dependency path between p and a_i, and the set of words in the full span of a_i. We compute additive compositional representations of multiple words, using the simplest method of Mitchell and Lapata (2010) where the composed representation is the uniformly weighted sum of each single representation. Our full set of feature types based on distributional word representations is listed in Table 1.

4 Experimental Setup

We evaluate the impact of different types of features by performing experiments on a benchmark dataset for semantic role labelling. To assess the gains of distributional representations realistically, we incorporate the features described in Section 3 into a state-of-the-art SRL system. The following paragraphs summarize the details of our experimental setup.

Semantic Role Labeller. In all our experiments, we use the publicly available system by Björkelund et al. (2010).[1] This system combines the first-ranked SRL system and the first-ranked syntactic parser in the CoNLL 2009 shared task for English (Björkelund et al., 2009; Bohnet, 2010). To the best of our knowledge, this combination represents the current state-of-the-art for semantic role labelling following the PropBank/NomBank paradigm (Palmer et al., 2005; Meyers et al., 2004). To re-train and evaluate models with different feature sets, we use the same training, development and test sets as provided in the CoNLL shared task (Hajič et al., 2009). Although the employed system features a full syntactic-semantic parsing pipeline, we only modify the feature sets of the two components directly related to the actual role labelling task, namely argument identification and argument classification.

Word Representations. As a baseline, we simply added as features the word representations of the predicate and argument head involved in a classification decision (first two lines in Table 1). We experimented with a range of publicly available sets of word representations, including embeddings from various neural language models (Mnih and Hinton, 2009; Collobert et al., 2011; Huang et al., 2012), eigenvectors (Dhillon et al., 2011), Brown clusters (Brown et al., 1992), and post-processed co-occurrence counts (Lebret and Collobert, 2014). Results on the development set for various off-the-shelf representations are shown in Table 2. The numbers reveal that any kind of word representation can be employed to improve results. We choose to perform all follow-up experiments using the 50-dimensional embeddings induced by Turian et al. (2010), using the method by Collobert et al., as they led to slightly better results in F_1-score than other representations. No significant differences were observed, however, using other types of representations or vector sizes.

Table 2: Results on the CoNLL-2009 development set, using off-the-shelf word representations for predicates and argument as additional features. Performance numbers in percent.

5 Results

We evaluate our proposed set of additional features on the CoNLL-2009 in-domain and out-of-domain test sets, using the aforementioned SRL system and word representations. All results are computed using the system's built-in preprocessing pipeline and re-trained models for argument identification and classification. We report labelled precision, recall and semantic F1-score as computed by the official scorer.

The upper part of Table 3 shows SRL performance on the in-domain CoNLL-2009 test set, with and without (**Original**) additional features based on distributional representations. The results reveal that any type of additional feature helps to improve precision and recall in this setting (from 85.2% F_1-score up to 85.5%), with significant gains for 4 of the 5 additional features (computed using a randomization test; cf. Yeh, 2000). Interestingly, we find that the features do not seem

to have a cumulative effect here, as indicated by the results with all features (**+All**, 85.5% F_1). We conjecture that this is due to the high volume of existing in-domain training data, which renders our full feature set redundant. To test this conjecture, we further assess performance on the out-of-domain test set of the CoNLL-2009 shared task.

The results for the out-of-domain experiment are summarized in the lower part of Table 3. We again observe that each single feature type improves classification, with absolute gains being slightly higher than in the in-domain setting. More interestingly though, we find that the complete feature set boosts performance even further, achieving an overall gain in precision and recall of 0.6 and 1.3 percentage points, respectively. The resulting F_1-score of 75.2 lies even higher than the top score for this particular data set reported in the CoNLL shared task (Zhao et al., 2009; 74.6 F_1).

We next investigate the benefits of compositional representations over features for single words by assessing their impact on the overall result in an ablation study. Table 4 shows results of ablation tests performed for the three compositional feature types **Interaction**, **Span** and **Path** on the out-of-domain test set. The results reveal

Out-of-domain	P	R	F_1
Original	76.9	71.7	74.2

Full −Path	77.6	72.3	74.8

Table 4: Results of an ablation study over features based on compositional representations. All numbers in percent.

a considerable loss in recall, indicating the importance of including compositional word representations and confirming our intuition that they can provide additional gains over simple type-level representations. In the next section, we discuss this result in more detail and provide examples of improved classification decisions.

6 Discussion

As a more detailed qualitative analysis, we examined the impact of word representations on SRL performance with respect to different argument labels and predicate types. Results on the in-domain data set, shown in the upper part of Table 5, suggest that most improvements in terms of precision are gained for verbal predicates, while nominal predicates primarily benefit from higher recall. One reason for the latter observation might be that arguments of nominal predicates are generally much harder to identify for the **Original** model, as the cues provided by indicator features on words and syntax are often inconclusive. For verbal predicates, the word representations mainly provide reinforcing signals to the classifier, improving its precision at a slight cost of recall.

The results on the out-of-domain data set provide more insights regarding the suitability of word representations for generalization. As shown in the lower half of Table 5, the additional features on average have a positive impact on precision and recall. For verbal predicates, we observe only one case, namely A0, in which improvements in recall came with a decline in precision. Regarding nominal predicates, the trend is similar to what we have seen in the in-domain setting, with most gains being achieved in terms of recall.

Apart from assessing quantitative effects, we further examined cases that directly show the qualitative gains of the compositional features defined

in Section 3. Table 6 lists examples from the out-of-domain data set that were misclassified by the **Original** model but could be correctly predicted using our enhanced feature set. As illustrated by Examples (1) and (2), the **Interaction** feature seems to help recall by guiding classification decisions towards more meaningful and complete structures.

Improvements using the **Path** feature can be observed in cases where nested syntactic structures need to be processed, as required in Example (2). In another instance, Example (3), the following path is predicted between argument and predicate: *He* $\xrightarrow{\text{SBJ}}$ *rose* $\xleftarrow{\text{COORD}}$ *and* $\xleftarrow{\text{CONJ}}$ *went* $\xleftarrow{\text{OPRD}}$ *to* $\xleftarrow{\text{IM}}$ *have*. Such cases are particularly problematic for the **Original** model because long and potentially erroneous paths are sparse in the training data.

Further gains in performance are achieved using the **Span** feature, which enables the model to better handle infrequent and out-of-vocabulary words occurring in an argument span, including "hours" and "softly" in Example (4) and (5), respectively.

7 Conclusions

In this paper, we proposed to enhance the feature space of a state-of-the-art semantic role labeller by applying and composing distributional word representations. Our results indicate that combining such features with standard syntactic cues leads to more precise and more robust models, with significant improvements both in-domain and out-of-domain. Ablation tests on an out-of-domain data set have shown that gains in recall are mostly due to features based on composed representations. Given the novelty of these features for SRL, we believe that this insight is remarkable and deserves further investigation. In future work, we plan to apply more sophisticated models of compositionality to better represent predicate-argument structures and to guide classification decisions towards outcomes that are semantically more plausible. We anticipate that this line of research will also be of interest for a range of related tasks beyond traditional SRL, including predicate-argument structure alignment (Roth and Frank, 2012) and implicit argument linking (Gerber and Chai, 2012).

Abstract

This paper reports on the development of a hybrid and simple method based on a machine learning classifier (Naive Bayes), Word Sense Disambiguation and rules, for the automatic assignment of WordNet Domains to nominal entries of a lexicographic dictionary, the Senso Comune De Mauro Lexicon. The system obtained an F1 score of 0.58, with a Precision of 0.70. We further used the automatically assigned domains to filter out word sense alignments between MultiWordNet and Senso Comune. This has led to an improvement in the quality of the sense alignments showing the validity of the approach for domain assignment and the importance of domain information for achieving good sense alignments.

1 Introduction and Problem Statement

Lexical knowledge, i.e. how words are used and express meaning, plays a key role in Natural Language Processing. Lexical knowledge is available in many different forms, ranging from unstructured terminologies (i.e. word list), to full fledged computational lexica and ontologies (e.g. WordNet (Fellbaum, 1998)). The process of creation of lexical resources is costly both in terms of money and time. To overcome these limits, semi-automatic approaches have been developed (e.g. MultiWordNet (Pianta et al., 2002)) with different levels of success. Furthermore, important information is scattered in different resources and difficult to use. Semantic interoperability between resources could represent a viable solution to allow reusability and develop more robust and powerful resources. Word sense alignment (WSA) qualifies as the preliminary requirement for achieving this goal (Matuschek and Gurevych, 2013).

WSA aims at creating lists of pairs of senses from two, or more, (lexical-semantic) resources which denote the same meaning. Different approaches to WSA have been proposed and they all share some common elements, namely: i.) the extensive use of sense descriptions of the words (e.g. WordNet glosses); and ii.) the extension of the basic sense descriptions with additional information such as hypernyms, synonyms and domain or category labels.

The purpose of this work is two folded: first, we experiment on the automatic assignment of domain labels to sense descriptions, and then, evaluate the impact of this information for improving an existing sense aligned dataset for nouns. Previous works has demonstrated that domain labels are a good feature for obtaining high quality alignments of entries (Navigli, 2006; Toral et al., 2009; Navigli and Ponzetto, 2012). The WordNet (WN) Domains (Magnini and Cavaglia, 2000; Bentivogli et al., 2004) have been selected as reference domain labels. We will use as candidate lexico-semantic resources to be aligned two Italian lexica, namely, MultiWordNet (MWN) and the Senso Comune De Mauro Lexicon (SCDM) (Vetere et al., 2011).

The two resources differ in terms of modelization: the former, MWN, is an Italian version of WN obtained through the "expand model" (Vossen, 1996) and perfectly aligned to Princeton WN 1.6, while the latter, SCDM, is a machine readable dictionary obtained from a paper-based reference lexicographic dictionary, De Mauro GRADIT. Major issues for WSA of the lexica concern the following aspects:

- SCMD has no structure of word senses (i.e. no taxonomy, no synonymy relations, no distinction between core senses and subsenses for polysemous entries) unlike MWN;
- SCDM has no domain or category labels associated to senses (with the exception of specific terminological entries) unlike MWN;
- the Italian section of MWN has only 2,481 glosses in Italian over 28,517 synsets for nouns (i.e. 8.7%).

The remainder of this paper is organized as follows: Section 2 will report on the methodology and experiments implemented for the automatic assignment of the WN Domains to the SCDM entries. Section 3 will describe the dataset used for the evaluation of the WSA experiments and the use of the WN Domains for filtering the sense alignments. Finally, Section 4 illustrates conclusion and future work.

2 Methodology and Experiments

The WN Domains consist of a set of 166 hierarchically organized labels which have been associated to each

synset[1] and express a subject field label (e.g. SPORT, MEDICINE). A special label, FACTOTUM, has been used for those synsets which can appear in almost all subject fields.

The identification of a domain label to the nominal entries in the SCDM Lexicon is based the "One Domain per Discourse" (ODD) hypothesis applied to the sense descriptions. We have used a reduced set of domains labels (45 normalized domains) following (Magnini et al., 2001).

To assign the WN domain label to the SCDM entries, we have developed a hybrid method: first a binary classifier is applied to the SCDM sense descriptions to discriminate between two domain values, FACTOTUM and OTHER, where the OTHER value includes all remaining 44 normalized domains. After this, all entries classified with the OTHER value are analyzed by a rule based system and associated with a specific domain label (i.e. SPORT, MEDICINE, FOOD ...).

2.1 Classifier and feature selection

We have developed a training set by manually aligning noun senses between the two lexica. The sense alignment allows us to associate all the information of a synset to a corresponding entry in the SCDM lexicon, including the WN Domain label. Concerning the test set, we have used an existing dataset of aligned noun pairs as in (Caselli et al., 2014). We report in Table 1 the figures for the training and test sets. Multiple alignments with the same domain label have been excluded from the training set.

Characteristics	Training Set	Test Set
# lemmas	131	46
# of aligned pairs	369	166
# of SCDM senses	747	216
# of MWN synsets	675	229
# SCDM with WN Domain label	350	118

Table 1: Training and test sets for the classifier.

In order for the classifier to predict the binary domain labels (FACTOTUM and OTHER), each sense description of the SCDM Lexicon has been represented by means of a two-dimensional feature vector (e.g. for training data: BINARY_DOMAIN_LABEL GENERIC:val SPECIFIC:val). Feature values have been obtained through two strategies:

- lemma label: we extract all normalized domain labels associated to each sense of each lemma in the sense description from MWN. The value of the feature GENERIC corresponds to the sum of the FACTOTUM labels. The value of the feature SPECIFIC corresponds to the sum of all other specific domain labels (e.g. MEDICINE, SPORT etc.) after they have been collapsed into a single value (i.e. NOT-FACTOTUM).

- word sense label: for each sense description, we have first performed Word Sense Disambiguation by means of an adapted version to Italian of the UKB package[2] (Agirre et al., 2010; Agirre et al., 2014)[3]. Only the highest ranked synset, and associated WN Domain(s), was retained as good. Similarly to the lemma label strategy, the sum of the domain label FACTOTUM is assigned to the feature GENERIC, while the sum of all other domain labels collapsed into the single value NOT-FACTOTUM is assigned to the feature SPECIFIC.

We experimented with two classifiers: Naive Bayes and Maximum Entropy as implemented in the MALLET package (McCallum, 2002). We illustrate the results in Table 2. The classifiers have been evaluated with respect to standard Precision (P), Recall (R) and F1 against the test set. Ten-fold cross validation has been performed on the training set as well. Classifiers trained with the first strategy will be associated with the label *lemma*, while those trained with the second strategy with the label *wsd*.

Both classifiers obtains good results with respect to the test data in terms of Precision and Recall. The Naive Bayes classifier outperforms the Maximum Entropy one in both training approaches, suggesting better generalization capabilities even in presence of a small training set and basic features. The role of WSD has a positive impact, namely for the Maximum Entropy classifier (Precision +4 points, Recall +5 points with respect to the lemma label). Although such a positive effect of the WSD does not emerge for the Naive Bayes classifier with respect to the test set, we can still observe an improvement over the ten-fold cross validation (F1= 0.69 *vs*. F1=0.66). We finally selected the

[1]The full set of labels and hierarchy is available at http://wndomains.fbk.eu/hierarchy.html

[2]Available at http://ixa2.si.ehu.es/ukb/

[3]We used the WN Multilingual Central Repository as knowledge base and the MWN entries as dictionary

predictions of Naive Bayes$_{wsd}$ classifier as input to the rule-based system as it provides the highest scores.

2.2 Rules for WN Domain assignment

The rule based classifier for final WN Domain assignment works as follows:

- lemmatized and word sense disambiguated lemmas in the sense descriptions are associated with the corresponding WN Domains from MWN;
- frequency counts on the WN Domain labels is applied; the most frequent WN Domain is assigned as the correct WN Domain of the nominal entry;
- in case two or more WN Domains have same frequency, the following assignment strategy is applied: if the frequency scores of the WN Domains is equal to 1, the value FACTOTUM is selected; on the contrary, if the frequency score is higher than 1, all WN Domain labels are retained as good.

We report the results on final domain assignment in Table 3. The final system, NaiveBayes+Rules, has been compared to two baselines. Both baselines apply frequency counts over the WN Domains labels of the lemmas of the sense descriptions for the entire set of the 45 normalized domain values, including the FACTOTUM label, as explained in Section2. The Baseline$_{lemma}$ assigns the domain by taking into account every WN Domain associated to each lemma. On the other hand, the Baseline$_{wsd}$ selects only the WN Domain of sense disambiguated lemmas. WSD for the second baseline has been performed by applying the same method described in Section 2.1. The results of both baselines have high values for Precision (0.58 for Baseline$_{lemma}$, 0.70 for Baseline$_{wsd}$). We consider this as a further support to the validity of the ODD hypothesis which seems to hold even for text descriptions like dictionary glosses which normally use generic lexical items to illustrate word senses. It is also interesting to notice that WSD on its own has a positive impact in Baseline$_{wsd}$ system for the assignment of specific domain labels (F1=0.53).

The hybrid system performs better than both baselines in terms of F1 scores (F1=0.58 *vs.* F1=0.45 for Baseline$_{lemma}$ *vs.* F1=0.53 for Baseline$_{wsd}$). However, both the hybrid system and the Baseline$_{wsd}$ obtain the same Precision. To better evaluate the performance of our hybrid approach, we computed the paired t-test. The results of the hybrid system are statistically significant with respect to the Baseline$_{lemma}$ ($p < 0.05$) and for Recall only when compared to the Baseline$_{wsd}$.

To further analyze the difference between the hybrid system and the Baseline$_{wsd}$, we performed an error analysis on their outputs. We have identified that the hybrid system is more accurate in the prediction of the FACTOTUM class with respect to the baseline. In particular, the accuracy of the hybrid system on this class is 79% while that of the baseline is only 65%. In addition to this, the hybrid system provides better results in terms of Recall (R=0.50 *vs.* R=0.43). Although comparable, the hybrid system provides more accurate results with respect to the baseline.

System	P	R	F1
NaiveBayes$_{wsd}$+Rules	0.70†	0.50†∗	0.58†
Baseline$_{lemma}$	0.58	0.36	0.45
Baseline$_{wsd}$	0.70	0.43	0.53

Table 3: Results of WN Domain Assignment over the SDCM entries. Statistical significance of the NaiveBayes+Rules system has been marked with a † for the Baseline$_{lemma}$ and with a ∗ for the Baseline$_{wsd}$

3 Domain Filtering for WSA

This section reports on the experiments for improving existing WSA for nouns between SDCM and MWN. In this work we have used the same dataset and alignment methods as in (Caselli et al., 2014), shortly described here:

- Lexical Match: for each word *w* and for each sense *s* in the given resources $R \in \{$MWN, SCDM$\}$, we constructed a sense descriptions d_R(s) as a bag of words in Italian. The alignment is based on counting the number of overlapping tokens between the two strings, normalized by the length of the strings;
- Cosine Similarity: we used the Personalized Page Rank (PPR) algorithm (Agirre et al., 2010) with WN 3.0 as knowledge base extended with the "Princeton Annotated Gloss Corpus". Once the PPR vector pairs are obtained, the alignment is obtained on the basis of the cosine score for each pair[4].

The dataset consists of 166 pairs of aligned senses from MWN and SCDM for 46 nominal lemmas (see also column "*Test set*" in Table 1). Overall, SCDM covers 53.71The main difference with respect to (Caselli et al., 2014) is that the proposed alignments have been additionally filtered on the basis of the output of the WN domain system (NaiveBayes$_{wsd}$+Rules). In particular, for each aligned pair which was considered as good in (Caselli et al., 2014), we have applied a further filtering based on the WN domain system results as follows: if two senses are aligned but do not have the same domain, they are excluded from the WSA results, otherwise they are retained. Table 4 illustrates

[4]The vectors for the SCDM entries were obtained by, first, applying Google Translate API to get the English translations and, then, PPR over WN 3.0.

System	P	R	F1
LexicalMatch	0.76 (0.69)	0.27 (0.44)	0.40 (0.55)
Cosine_noThreshold	0.27 (0.12)	**0.47 (0.94)**	0.35 (0.21)
Cosine > 0.1	0.77 (0.52)	0.21 (0.32)	0.33 (0.40)
Cosine > 0.2	**0.87 (0.77)**	0.14 (0.21)	0.24 (0.33)
LexicalMatch+Cosine > 0.1	0.73 (na)	0.40 (na)	**0.51 (na)**
LexicalMatch+Cosine > 0.2	**0.77 (0.67)**	0.37 (0.61)	0.50 (0.64)

Table 4: Results for WSA of nouns with domain filtering.

the results of the WSA approaches with domain filters. We report in brackets the results from (Caselli et al., 2014). The filtering based on WN Domains has a big impact on Precision and contributes to increase the quality of the aligned senses. Although, in general, we have a downgrading of the performance with respect to Recall, the increase in Precision will reduce the manual post-processing effort to fully aligned the two resources[5]. Furthermore, it is interesting to notice that, when merging together the results of the pre-filtered alignments from the two alignment approaches (LexicalMatch+Cosine > 0.1 and LexicalMatch+Cosine > 0.2), we still have a very high Precision (> 0.70) and an increase in Recall (> 0.40) with respect to the results of each approach. Finally, we want to point out that what was reported as the best alignment results in (Caselli et al., 2014), namely LexicalMatch+Cosine > 0.2, can be obtained, at least for Precision, with a lower filtering cut-off threshold on the Cosine Similarity approach (i.e cut-off threshold at or higher than 0.1)

4 Conclusions and Future Work

This work describes a hybrid approach based on a Naive Bayes classifier, Word Sense Disambiguation and rules for assigning WN Domains to nominal sense descriptions of a lexicographic dictionary, the Senso Comune De Mauro Lexicon. The assignment of domain labels has been used to improve WSA results on nouns between the Senso Comune Lexicon and MultiWordNet. The results support some observations, namely: i.) domain filtering plays an important role in WSA, namely as a strategy to exclude wrong alignments (false positives) and improve the quality of the aligned pairs; ii.) the method we have proposed is a viable approach for automatically enriching existing lexical resources in a reliable way; and iii.) the ODD hypothesis also apply to sense descriptions.

An advantage of our approach is its simplicity. We have used features based on frequency counts and obtained good results, with a Precision of 0.70 for automatic WN Domain assignment. Nevertheless, an important role is played by Word Sense Disambiguation. The use of domain labels obtained from sense disambiguated lemmas improves both the results of the classifier and those of the rules. The absence of statistical significance with respect to the Baseline$_{wsd}$ is not to be considered as a negative result. As the error analysis has showed, the classifier mostly contributes to the identification of the FACTOTUM value, which tends to be overestimated even with sense disambiguated lemmas, and to Recall. We are planning to extend this work to include domain clusters to improve the domain assignment results, namely in terms of Recall.

[5]The F1 of 0.64 in (Caselli et al., 2014) is obtained with a Precision of 0.67, suggesting that some alignments are false positives

Abstract

Much attention has been given to the impact of informativeness and similarity measures on distributional thesauri. We investigate the effects of context filters on thesaurus quality and propose the use of cooccurrence frequency as a simple and inexpensive criterion. For evaluation, we measure thesaurus agreement with WordNet and performance in answering TOEFL-like questions. Results illustrate the sensitivity of distributional thesauri to filters.

1 Introduction

Large-scale *distributional thesauri* created automatically from corpora (Grefenstette, 1994; Lin, 1998; Weeds et al., 2004; Ferret, 2012) are an inexpensive and fast alternative for representing semantic relatedness between words, when manually constructed resources like WordNet (Fellbaum, 1998) are unavailable or lack coverage. To construct a distributional thesaurus, the (collocational or syntactic) contexts in which a target word occurs are used as the basis for calculating its similarity with other words. That is, two words are similar if they share a large proportion of contexts.

Much attention has been devoted to refining thesaurus quality, improving informativeness and similarity measures (Lin, 1998; Curran and Moens, 2002; Ferret, 2010), identifying and demoting bad neighbors (Ferret, 2013), or using more relevant contexts (Broda et al., 2009; Biemann and Riedl, 2013). For the latter in particular, as words vary in their collocational tendencies, it is difficult to determine how informative a given context is. To remove uninformative and noisy contexts, filters have often been applied like pointwise mutual information (PMI), lexicographer's mutual information (LMI) (Biemann and Riedl, 2013), t-score (Piasecki et al., 2007) and z-score (Broda et al., 2009). However, the selection of a measure and of a threshold value for these filters is generally empirically determined. We argue that these filtering parameters have a great influence on the quality of the generated thesauri.

The goal of this paper is to quantify the impact of context filters on distributional thesauri. We experiment with different filter methods and measures to assess context significance. We propose the use of simple cooccurrence frequency as a filter and show that it leads to better results than more expensive measures such as LMI or PMI. Thus we propose a cheap and effective way of filtering contexts while maintaining quality.

This paper is organized as follows: in §2 we discuss evaluation of distributional thesauri. The methodology adopted in the work and the results are discussed in §3 and §4. We finish with some conclusions and discussion of future work.

2 Related Work

In a nutshell, the standard approach to build a distributional thesaurus consists of: (i) the *extraction of contexts* for the target words from corpora, (ii) the application of an *informativeness measure* to represent these contexts and (iii) the application of a *similarity measure* to compare sets of contexts. The contexts in which a target word appears can be extracted in terms of a window of cooccurring (content) words surrounding the target (Freitag et al., 2005; Ferret, 2012; Erk and Pado, 2010) or in terms of the syntactic dependencies in which the target appears (Lin, 1998; McCarthy et al., 2003; Weeds et al., 2004). The informativeness of each context is calculated using measures like PMI, and t-test while the similarity between contexts is calculated using measures like Lin's (1998), cosine, Jensen-Shannon divergence, Dice or Jaccard.

Evaluation of the quality of distributional thesauri is a well know problem in the area (Lin,

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 419–424,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

1998; Curran and Moens, 2002). For instance, for intrinsic evaluation, the agreement between thesauri has been examined, looking at the average similarity of a word in the thesauri (Lin, 1998), and at the overlap and rank agreement between the thesauri for target words like nouns (Weeds et al., 2004). Although much attention has been given to the evaluation of various informativeness and similarity measures, a careful assessment of the effects of filtering on the resulting thesauri is also needed. For instance, Biemann and Riedl (2013) found that filtering a subset of contexts based on LMI increased the similarity of a thesaurus with WordNet. In this work, we compare the impact of using different types of filters in terms of thesaurus agreement with WordNet, focusing on a distributional thesaurus of English verbs. We also propose a frequency-based saliency measure to rank and filter contexts and compare it with PMI and LMI.

Extrinsic evaluation of distributional thesauri has been carried out for tasks such as English lexical substitution (McCarthy and Navigli, 2009), phrasal verb compositionality detection (McCarthy et al., 2003) and the WordNet-based synonymy test (WBST) (Freitag et al., 2005). For comparative purposes in this work we adopt the latter.

3 Methodology

We focus on thesauri of *English verbs* constructed from the BNC (Burnard, 2007)[1]. Contexts are extracted from syntactic dependencies generated by RASP (Briscoe et al., 2006), using nouns (heads of NPs) which have subject and direct object relations with the target verb. Thus, each target verb is represented by a set of *triples* containing (i) the verb itself, (ii) a context noun and (iii) a syntactic relation (object, subject). The thesauri were constructed using Lin's (1998) method. Lin's version of the distributional hypothesis states that two words (verbs v_1 and v_2 in our case) are similar if they share a large proportion of contexts weighted by their information content, assessed with PMI (Bansal et al., 2012; Turney, 2013).

In the literature, little attention is paid to context filters. To investigate their impact, we compare two kinds of filters, and before calculating similarity using Lin's measure, we apply them to remove potentially noisy triples:

- **Threshold (th):** we remove triples that occur less than a threshold th. Threshold values vary from 1 to 50 counts per triple.
- **Relevance (p):** we keep only the top p most relevant contexts for each verb, were relevance is defined according to the following measures: (a) frequency, (b) PMI, and (c) LMI (Biemann and Riedl, 2013). Values of p vary between 10 and 1000.

In this work, we want to answer two questions: (a) Do more selective filters improve *intrinsic evaluation* of thesaurus? and (b) Do they also help in *extrinsic evaluation*?

For *intrinsic evaluation*, we determine agreement between a distributional thesaurus and WordNet as the path similarities for the first k distributional neighbors of a verb. A single score is obtained by averaging the similarities of all verbs with their k first neighbors. The higher this score is, the closer the neighbors are to the target in WordNet, and the better the thesaurus. Several values of k were tested and the results showed exactly the same curve shapes for all values, with WordNet similarity decreasing linearly with k. For the remainder of the paper we adopt $k = 10$, as it is widely used in the literature.

For *extrinsic evaluation*, we use the WBST set for verbs (Freitag et al., 2005) with 7,398 questions and an average polysemy of 10.4. The task consists of choosing the most suitable synonym for a word among a set of four options. The thesaurus is used to rank the candidate answers by similarity scores, and select the first one as the correct synonym. As discussed by Freitag et al. (2005), the upper bound reached by English native speakers is 88.4% accuracy, and simple lower bounds are 25% (random choice) and 34.5% (always choosing the most frequent option).

4 Results

Figure 1 shows average WordNet similarities for thesauri built filtering by frequency threshold th and by p most frequent contexts. Table 1 summarizes the parametrization leading to the best WordNet similarity for each kind of filter. In all cases we show the results obtained for different frequency ranges[2] as well as the results when averaging over all verbs.

[1] Even though larger corpora are available, we use a traditional carefully constructed corpus with representative samples of written English to control the quality of the thesaurus.

[2] In order to study the influence of verb frequency on the results, we divide the verbs in three groups: high-frequency

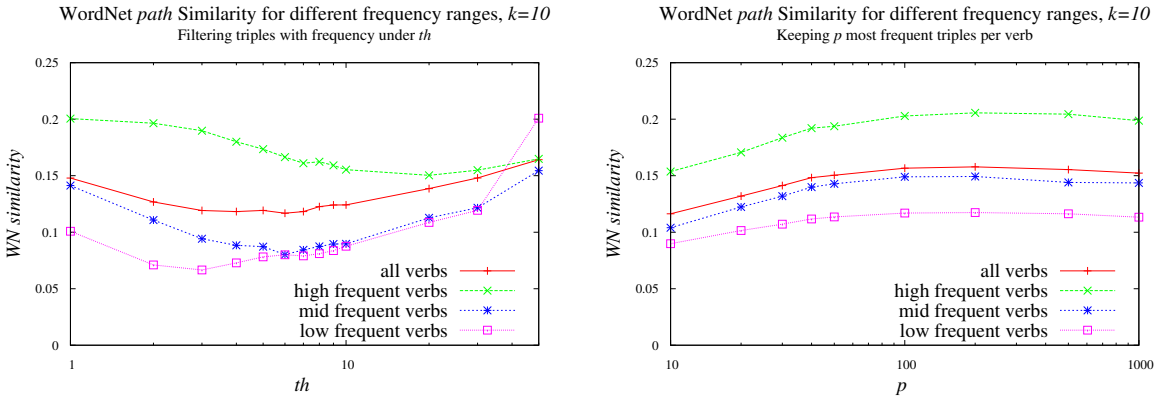

Figure 1: WordNet scores for verb frequency ranges, filtering by frequency threshold th (left) and p most frequent contexts (right).

Filter	All verbs		Frequency range Low		Mid		High	
No filter	-	0.148	-	0.101	-	0.144	-	0.198
Filter low freq. contexts	$th = 50$	**0.164**	$th = 50$	0.202	$th = 50$	0.154	$th = 1$	0.200
Keep p contexts (freq.)	$p = 200$	**0.158**	$p = 500$	0.138	$p = 200$	0.149	$p = 200$	0.206
Keep p contexts (PMI)	$p = 1000$	0.139	$p = 1000$	0.101	$p = 1000$	0.136	$p = 1000$	0.181
Keep p contexts (LMI)	$p = 200$	0.155	$p = 100$	0.112	$p = 200$	0.147	$p = 200$	0.208

Table 1: Best scores obtained for each filter for all verbs and frequency ranges. Scores are given in terms of WordNet path. Confidence interval is arround $\pm$ 0.002 in all cases.

When using a threshold filter (Figure 1 left), high values lead to better performance for mid- and low-frequency verbs. This is because, for high th values, there are few low and mid-frequency verbs left, since a verb that occurs less has less chances to be seen often in the same context. The similarity for verbs with no contexts over the frequency threshold cannot be assessed and as a consequence those verbs are not included in the final thesaurus. As Figure 2 shows, the number of verbs decreases much faster for low and mid frequency verbs when th increases.[3] For example, for $th = 50$, there are only 7 remaining low-frequency verbs in the thesaurus and these tend to be idiosyncratic multiword expressions. One example is *wreak*, and the only triple containing this verb that appeared more than 50 times is *wreak havoc* (71 occurrences). The neighbors of this verb are *cause* and *play*, which yield a good similarity score in WordNet. Therefore, although higher thresholds result in higher similarities for low and mid-frequency verbs, this comes at a cost, as the number of verbs included in the thesaurus decreases considerably.

($||v|| \geq 500$), mid-frequency ($150 \leq ||v|| < 500$) and low-frequency ($||v|| < 150$).

[3]For p most salient contexts, the number of verbs does not vary and is the same shown in Figure 2 for $th = 1$ (no filter).

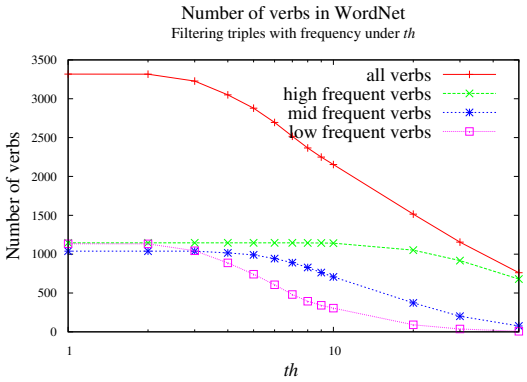

Figure 2: Number of verbs per frequency ranges when filtering by context frequency threshold th

As expected, the best performance is obtained for high-frequency verbs and no filter, since it results in more context information per verb. Increasing th decreases similarity due to the removal of some of these contexts. In average, higher th values lead to better overall similarity among the frequency ranges (from 0.148 with $th = 1$ to 0.164 with $th = 50$). The higher the threshold, the more high-frequency verbs will prevail in the thesauri, for which the WordNet path similarities are higher.

On the other hand, when adopting a relevance

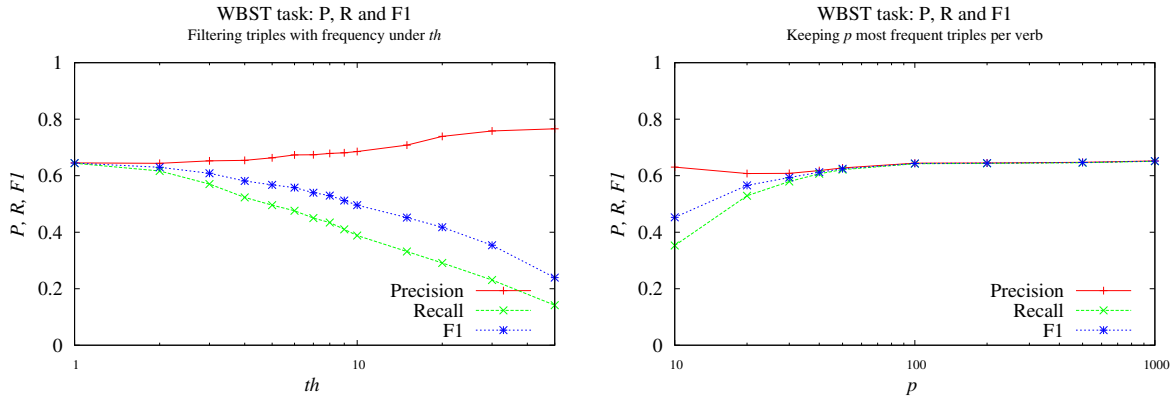

Figure 3: WBST task scores filtering by frequency threshold th (left) and p most frequent contexts (right).

filter of keeping the p most relevant contexts for each verb (Figure 1 right), we obtain similar results, but more stable thesauri. The number of verbs remains constant, since we keep a fixed number of contexts for each verb and verbs are not removed when the threshold is modified. WordNet similarity increases as more contexts are taken into account, for all frequency ranges. There is a maximum around $p = 200$, though larger values do not lead to a drastic drop in quality. This suggests that the noise introduced by low-frequency contexts is compensated by the increase of informativeness for other contexts. An ideal balance is reached by the lowest possible p that maintains high WordNet similarity, since the lower the p the faster the thesaurus construction.

In terms of saliency measure, when keeping only the p most relevant contexts, sorting them with PMI leads to much worse results than LMI or frequency, as PMI gives too much weight to infrequent combinations. This is consistent with results of Biemann and Riedl (2013). Regarding LMI versus frequency, the results using the latter are slightly better (or with no significant difference, depending on the frequency range). The advantage of using frequency instead of LMI is that it makes the process simpler and faster while leading to equal or better performance in all frequency ranges. Therefore for the extrinsic evaluation using WBST task, we use frequency to select the p most relevant contexts and then compute Lin's similarity using only those contexts.

Figure 3 shows the performance of the thesauri in the WBST task in terms of precision, recall and F1.[4] For precision, the best filter is to remove contexts occurring less than th times, but, this also leads to poor recall, since many verbs are left out of the thesauri and their WSBT questions cannot be answered. On the other hand, keeping the most relevant p contexts leads to more stable results and when p is high (right plot), they are similar to those shown in the left plot of Figure 3.

4.1 Discussion

The answer to our questions in Section 3 is *yes*, more selective filters improve intrinsic and extrinsic thesaurus quality. The use of both filtering methods results in thesauri in which the neighbors of target verbs are closer in WordNet and get better scores in TOEFL-like tests. However, the fact that filtering contexts with frequency under th removes verbs in the final thesaurus is a drawback, as highlighted in the extrinsic evaluation on the WBST task.

Furthermore, we demonstrated that competitive results can be obtained keeping only the p most relevant contexts per verb. On the one hand, this method leads to much more stable thesauri, with the same verbs for all values of p. On the other hand, it is important to highlight that the best results to assess the relevance of the contexts are obtained using frequency while more sophisticated filters such as LMI do not improve thesaurus quality. Although an LMI filter is relatively fast compared to dimensionality reduction techniques such as singular value decomposition (Landauer and Dumais, 1997), it is still considerably more expensive than a simple frequency filter.

In short, our experiments indicate that a reason-

[4]Filters based on LMI and PMI were also tested with the same results as intrinsic evaluation: sorting contexts by frequency leads to better results.

able trade-off between noise, coverage and computational efficiency is obtained for $p = 200$ most frequent contexts, as confirmed by intrinsic and extrinsic evaluation. Frequency threshold th is not recommended: it degrades recall because the contexts for many verbs are not frequent enough. This result is useful for extracting distributional thesauri from very large corpora like the UKWaC (Ferraresi et al., 2008) by proposing an alternative that minimizes the required computational resources while efficiently removing a significant amount of noise.

5 Conclusions and Future Work

In this paper we addressed the impact of filters on the quality of distributional thesauri, evaluating a set of standard thesauri and different filtering methods. The results suggest that the use of filters and their parameters greatly affect the thesauri generated. We show that it is better to use a filter that selects the most relevant contexts for a verb than to simply remove rare contexts. Furthermore, the best performance was obtained with the simplest method: frequency was found to be a simple and inexpensive measure of context salience. This is especially important when dealing with large amounts of data, since computing LMI for all contexts would be computationally costly. With our proposal to keep just the p most frequent contexts per verb, a great deal of contexts are cheaply removed and thus the computational power required for assessing similarity is drastically reduced.

As future work, we plan to use these filters to build thesauri from larger corpora. We would like to generalize our findings to other syntactic configurations (e.g. noun-adjective) as well as to other similarity and informativeness measures. For instance, ongoing experiments indicate that the same parameters apply when Lin's similarity is replaced by cosine. Finally, we would like to compare the proposed heuristics with more sophisticated filtering strategies like singular value decomposition (Landauer and Dumais, 1997) and non-negative matrix factorization (Van de Cruys, 2009).

Abstract

We align pairs of English sentences and corresponding Abstract Meaning Representations (AMR), at the token level. Such alignments will be useful for downstream extraction of semantic interpretation and generation rules. Our method involves linearizing AMR structures and performing symmetrized EM training. We obtain 86.5% and 83.1% alignment F score on development and test sets.

1 Introduction

Banarescu et al. (2013) describe a semantics bank of English sentences paired with their logical meanings, written in Abstract Meaning Representation (AMR). The designers of AMR leave open the question of how meanings are derived from English sentences (and vice-versa), so there are no manually-annotated alignment links between English words and AMR concepts. This paper studies how to build such links automatically, using co-occurrence and other information. Automatic alignments may be useful for downstream extraction of semantic interpretation and generation rules.

AMRs are directed, acyclic graphs with labeled edges, e.g., the sentence *The boy wants to go* is represented as:

```
(w / want-01
  :arg0 (b / boy)
  :arg1 (g / go-01
           :arg0 b))
```

We have hand-aligned a subset of the 13,050 available AMR/English pairs. We evaluate our automatic alignments against this gold standard. A sample hand-aligned AMR is here ("~n" specifies a link to the nth English word):

```
the boy wants to go
(w / want-01~3
  :arg0 (b / boy~2)
  :arg1 (g / go-01~5
           :arg0 b))
```

This alignment problem resembles that of statistical machine translation (SMT). It is easier in some ways, because AMR and English are highly cognate. It is harder in other ways, as AMR is graph-structured, and children of an AMR node are unordered. There are also fewer available training pairs than in SMT.

One approach is to define a generative model from AMR graphs to strings. We can then use EM to uncover hidden derivations, which alignments weakly reflect. This approach is used in string/string SMT (Brown et al., 1993). However, we do not yet have such a generative graph-to-string model, and even if we did, there might not be an efficient EM solution. For example, in syntax-based SMT systems (Galley et al., 2004), the generative tree/string transduction story is clear, but in the absence of alignment constraints, there are too many derivations and rules for EM to efficiently consider.

We therefore follow syntax-based SMT custom and use string/string alignment models in aligning our graph/string pairs. However, while it is straightforward to convert syntax trees into strings data (by taking yields), it is not obvious how to do this for unordered AMR graph elements. The example above also shows that gold alignment links reach into the internal nodes of AMR.

Prior SMT work (Jones et al., 2012) describes alignment of semantic graphs and strings, though their experiments are limited to the GeoQuery domain, and their methods are not described in detail. Flanigan et al (2014) describe a heuristic AMR/English aligner. While heuristic aligners can achieve good accuracy, they will not automatically improve as more AMR/English data comes

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 425–429,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

online.

The contributions of this paper are:

- A set of gold, manually-aligned AMR/English pairs.
- An algorithm for automatically aligning AMR/English pairs.
- An empirical study establishing alignment accuracy of 86.5% and 83.1% F score for development and test sets respectively.

2 Method

We divide the description of our method into three parts: preprocessing, training, and postprocessing. In the preprocessing phase, we linearize the AMR graphs to change them into strings, clean both the AMR and English sides by removing stop words and simple stemming, and add a set of corresponding AMR/English token pairs to the corpus to help the training phase. The training phase is based on IBM models, but we modify the learning algorithm to learn the parameters symmetrically. Finally, in the postprocessing stage we rebuild the aligned AMR graph. These components are described in more detail below.

2.1 Preprocessing

The first step of the preprocessing component is to linearize the AMR structure into a string. In this step we record the original structure of nodes in the graph for later reconstruction of AMR. AMR has a rooted graph structure. To linearize this graph we run a depth first search from the root and print each node as soon as it it visited. We print but not expand the nodes that are seen previously. For example the AMR:

```
(w / want-01
  :arg0 (b / boy)
  :arg1 (g / go-01
           :arg0 b))
```

is linearized into this order: *w / want-01 :arg0 b / boy :arg1 g / go-01 :arg0 b*.

Note that semantically related nodes often stay close together after linearization.

After linearizing the AMR graph into a string, we perform a series of preprocessing steps including lowercasing the letters, removing stop words, and stemming.

The AMR and English stop word lists are generated based on our knowledge of AMR design. We know that tokens like *an*, *the* or *to be* verbs will very rarely align to any AMR token; similarly, AMR role tokens like *:arg0*, *:quant*, *:opt1* etc. as well as the *instance-of* token /, and tokens like *temporal-quantity* or *date-entity* rarely align to any English token. We remove these tokens from the parallel corpus, but remember their position to be able to convert the resulting string/string alignment back into a full AMR graph/English string alignment. Although some stopwords participate in gold alignments, by removing them we will buy a large precision gain for some recall cost.

We remove the word sense indicator and quotation marks for AMR concepts. For instance we will change *want-01* to *want* and *"ohio"* to *ohio*. Then we stem AMR and English tokens into their first four letters, except for role tokens in AMR. The purpose of stemming is to normalize English morphological variants so that they are easier to match to AMR tokens. For example English tokens *wants*, *wanting*, *wanted*, and *want* as well as the AMR token *want-01* will all convert to *want* after removing the AMR word sense indicator and stemming.

In the last step of preprocessing, we benefit from the fact that AMR concepts and their corresponding English ones are frequently cognates. Hence, after stemming, an AMR token often can be translated to a token spelled similarly in English. This is the case for English token *want* and AMR token *want* in the previous paragraph. To help the training model learn from this fact, we extend our sentence pair corpus with the set of AMR/English token pairs that are spelled identically after preprocessing. Also, for English tokens that can be translated into multiple AMR tokens, like *higher* and *high :degree more* we add the corresponding string/string pairs to the corpus. This set is extracted from existing lexical resources, including lists of comparative/superlative adjectives, negative words, etc.

After preprocessing, the AMR at the start of this section will change into: *want boy go* and the sentence *The boy wants to go* changes into *boy want to go*, and we will also add the identity pairs *want/want*, *boy/boy*, and *go/go* to the corpus.

2.2 Training

Our training method is based on IBM word alignment models (Brown et al., 1993). We modify the objective functions of the IBM models to en-

courage agreement between learning parameters in English-to-AMR and AMR-to-English directions of EM. The solution of this objective function can be approximated in an extremely simple way that requires almost no extra coding effort.

Assume that we have a set of sentence pairs $\{(E, A)\}$, where each E is an English sentence and each A is a linearized AMR. According to IBM models, A is generated from E through a generative story based on some parameters.

For example, in IBM Model 2, given E we first decide the length of A based on some probability $l = p(len(A)|len(E))$, then we decide the distortions based on a distortion table: $d = p(i|j, len(A), len(E))$. Finally, we translate English tokens into AMR ones based on a translation table $t = p(a|e)$ where a and e are AMR and English tokens respectively.

IBM models estimate these parameters to maximize the conditional likelihood of the data: $\theta_{A|E} = argmax L_{\theta_{A|E}}(A|E)$ or $\theta_{E|A} = argmax L_{\theta_{E|A}}(E|A)$ where θ denotes the set of parameters. The conditional likelihood is intrinsic to the generative story of IBM models. However, word alignment is a symmetric problem. Hence it is more reasonable to estimate the parameters in a more symmetric manner.

Our objective function in the training phase is:

$$\theta_{A|E}, \theta_{E|A} = argmax L_{\theta_{A|E}}(A|E) + L_{\theta_{E|A}}(E|A)$$
$$\text{subject to} \quad \theta_{A|E}\theta_E = \theta_{E|A}\theta_A = \theta_{A,E}$$

We approximate the solution of this objective function with almost no change to the existing implementation of the IBM models. We relax the constraint to $\theta_{A|E} = \theta_{E|A}$, then apply the following iterative process:

1. Optimize the first part of the objective function: $\theta_{A|E} = argmax L_{\theta_{A|E}}(A|E)$ using EM
2. Satisfy the constraint: set $\theta_{E|A} \propto \theta_{A|E}$
3. Optimize the second part of the objective function: $\theta_{E|A} = argmax L_{\theta_{E|A}}(E|A)$ using EM
4. Satisfy the constraint: set $\theta_{A|E} \propto \theta_{E|A}$
5. Iterate

Note that steps 1 and 3 are nothing more than running the IBM models, and steps 2 and 4 are just initialization of the EM parameters, using tables from the previous iteration. The initialization steps only make sense for the parameters that involve both sides of the alignment (i.e., the translation table and the distortion table). For the translation table we set $t_{E|A}(e|a) = t_{A|E}(a|e)$ for English and AMR tokens e and a and then normalize the t table. The distortion table can also be initialized in a similar manner. We initialize the fertility table with its value in the previous iteration.

Previously Liang et al. (2006) also presented a symmetric method for training alignment parameters. Similar to our work, their objective function involves summation of conditional likelihoods in both directions; however, their constraint is on agreement between predicted alignments while we directly focus on agreement between the parameters themselves. Moreover their method involves a modification of the E step of EM algorithm which is very hard to implement for IBM Model 3 and above.

After learning the parameters, alignments are computed using the Viterbi algorithm in both directions of the IBM models. We tried merging the alignments of the two directions using methods like grow-diag-final heuristic or taking intersection of the alignments and adding some high probability links in their union. But these methods did not help the alignment accuracy.

2.3 Postprocessing

The main goal of the postprocessing component is to rebuild the aligned AMR graph. We first insert words removed as stop words into their positions, then rebuild the graph using the recorded original structure of the nodes in the AMR graph.

We also apply a last modification to the alignments in the postprocessing. Observing that pairs like *worker* and *person :arg0-of work-01* appear frequently, and in all such cases, all the AMR tokens align to the English one, whenever we see any of AMR tokens *person*, *product*, *thing* or *company* is followed by *arg0-of*, *arg1-of* or *arg2-of* followed by an AMR concept, we align the two former tokens to what the concept is aligned to.

3 Experiments

3.1 Data Description

Our data consists of 13,050 publicly available AMR/English sentence pairs[1]. We have hand

[1]LDC AMR release 1.0, Release date: June 16, 2014 https://catalog.ldc.upenn.edu/LDC2014T12

aligned 200 of these pairs to be used as development and test sets[2]. We train the parameters on the whole data. Table 1 presents a description of the data. We do not count parenthesis, slash and AMR variables as AMR tokens. Role tokens are those AMR tokens that start with a colon. They do not represent any concept, but provide a link between concepts. For example in:

```
(w / want-01
  :arg0 (b / boy)
  :arg1 (g / go-01
           :arg0 b))
```

the first *:arg0* states that the first argument of the concept *wanting* is the *boy* and the second argument is *going*.

	train	dev	test
Sent. pairs	13050	100	100
AMR tokens	465 K	3.8 K (52%)	2.3 K (%55)
AMR role tokens	226 K	1.9 K (23%)	1.1 K (%22)
ENG tokens	248 K	2.3 K (76%)	1.7 K (%74)

Table 1: AMR/English corpus. The number in parentheses is the percent of the tokens aligned in gold annotation. Almost half of AMR tokens are role tokens, and less than a quarter of role tokens are aligned.

3.2 Experiment Results

We use MGIZA++ (Gao and Vogel, 2008) as the implementation of the IBM models. We run Model 1 and HMM for 5 iterations each, then run our training algorithm on Model 4 for 4 iterations, at which point the alignments become stable. As alignments are usually many to one from AMR to English, we compute the alignments from AMR to English in the final step.

Table 2 shows the alignment accuracy for Model 1, HMM, Model 4, and Model 4 plus the modification described in section 2.2 (Model 4+).

The alignment accuracy on the test set is lower than the development set mainly because it is intrinsically a harder set, as we only made small modifications to the system based on the development set. Recall error due to stop words is one difference.

[2]The development and test AMR/English pairs can be found in /data/split/dev/amr-release-1.0-dev-consensus.txt and /data/split/test/amr-release-1.0-test-consensus.txt, respectively. The gold alignments are not included in these files but are available separately.

	model	precision	recall	F score
Dev	Model 1	70.9	71.1	71.0
	HMM	87.6	80.1	83.7
	Model 4	89.7	80.4	84.8
	Model 4+	94.1	80.0	86.5
Test	Model 1	74.8	71.8	73.2
	HMM	83.8	73.8	78.5
	Model 4	85.8	74.9	80.0
	Model 4+	92.4	75.6	83.1

Table 2: Results on different models. Our training method (Model 4+) increases the F score by 1.7 and 3.1 points on dev and test sets respectively.

Table 3 breaks down precision, recall, and F score for role and non-role AMR tokens, and also shows in parentheses the amount of recall error that was caused by removing either side of the alignment as a stop word.

	token type	precision	recall	F score
Dev	role	77.1	48.7	59.7
	non-role	97.2	88.2	92.5
	all	94.1	80.0 (34%)	86.5
Test	role	71.0	37.8	49.3
	non-role	95.5	84.7	89.8
	all	92.4	75.6 (36%)	83.1

Table 3: Results breakdown into role and non-role AMR tokens. The numbers in the parentheses show the percent of recall errors caused by removing aligned tokens as stop words.

While the alignment method works very well on non-role tokens, it works poorly on the role tokens. Role tokens are sometimes matched with a word or part of a word in the English sentence. For example *:polarity* is matched with the *un* part of the word *unpopular*, *:manner* is matched with most adverbs, or even in the pair:

```
thanks
(t / thank-01
    :arg0 (i / i)
    :arg1 (y / you))
```

all AMR tokens including *:arg0* and *:arg1* are matched to the only English word *thanks*. Inconsistency in aligning role tokens has made this a hard problem even for human experts.

4 Conclusions and Future Work

In this paper we present the first set of manually aligned English/AMR pairs, as well as the first published system for learning the alignments between English sentences and AMR graphs that provides a strong baseline for future research in this area. As the proposed system learns the alignments automatically using very little domain knowledge, it can be applied in any domain and for any language with minor adaptations.

Computing the alignments between English sentences and AMR graphs is a first step for extraction of semantic interpretation and generation rules. Hence, a natural extension to this work will be automatically parsing English sentences into AMR and generating English sentences from AMR.

Abstract

We introduce a Semantic Role Labeling (SRL) parser that finds semantic roles for a predicate together with the syntactic paths linking predicates and arguments. Our main contribution is to formulate SRL in terms of shortest-path inference, on the assumption that the SRL model is restricted to arc-factored features of the syntactic paths behind semantic roles. Overall, our method for SRL is a novel way to exploit larger variability in the syntactic realizations of predicate-argument relations, moving away from pipeline architectures. Experiments show that our approach improves the robustness of the predictions, producing arc-factored models that perform closely to methods using unrestricted features from the syntax.

1 Introduction

Semantic role labeling (SRL) consists of finding the arguments of a predicate and labeling them with semantic roles (Gildea and Jurafsky, 2002; Màrquez et al., 2008). The arguments fill roles that answer questions of the type "who" did "what" to "whom", "how", and "why" for a given sentence predicate. Most approaches to SRL are based on a pipeline strategy, first parsing the sentence to obtain a syntactic tree and then identifying and classifying arguments (Gildea and Jurafsky, 2002; Carreras and Màrquez, 2005).

SRL methods critically depend on features of the syntactic structure, and consequently parsing mistakes can harm the quality of semantic role predictions (Gildea and Palmer, 2002). To alleviate this dependence, previous work has explored k-best parsers (Johansson and Nugues, 2008), combination systems (Surdeanu et al., 2007) or joint syntactic-semantic models (Johansson, 2009; Henderson et al., 2008; Lluís et al., 2013).

In this paper we take a different approach. In our scenario SRL is the end goal, and we assume that syntactic parsing is only an intermediate step to extract features to support SRL predictions. In this setting we define a model that, given a predicate, identifies each of the semantic roles together with the syntactic path that links the predicate with the argument. Thus, following previous work (Moschitti, 2004; Johansson, 2009), we take the syntactic path as the main source of syntactic features, but instead of just conditioning on it, we predict it together with the semantic role. The main contribution of this paper is a formulation of SRL parsing in terms of efficient shortest-path inference, under the assumption that the SRL model is restricted to arc-factored features of the syntactic path linking the argument with the predicate.

Our assumption —that features of an SRL model should factor over dependency arcs— is supported by some empirical frequencies. Table 1 shows the most frequent path patterns on CoNLL-2009 (Hajič et al., 2009) data for several languages, where a path pattern is a sequence of ascending arcs from the predicate to some ancestor, followed by descending arcs to the argument. For English the distribution of path patterns is rather simple: the majority of paths consists of a number of ascending arcs followed by zero or one descending arc. Thus a common strategy in SRL systems, formulated by Xue and Palmer (2004), is to look for arguments in the ancestors of the predicate and their direct descendants. However, in Czech and Japanese data we observe a large portion of paths with two or more descending arcs, which makes it difficult to characterize the syntactic scope in which arguments are found. Also, in the datasets for German, Czech and Chinese the three most frequent patterns cover over the 90% of all arguments. In contrast, Japanese exhibits much more variability and a long tail of infrequent types

Table 1: Summary of the most frequent paths on the CoNLL-2009 Shared Task datasets. ↑ indicates that we traverse a syntactic dependency upwards from a modifier to a head. ↓ is for dependencies following a descending head to modifier edge. The symbol ∘ represents that the argument is the predicate itself. We exclude from this table Catalan and Spanish as predicates and arguments are always trivially related by a single syntactic dependency that descends.

of patterns. In general it is not feasible to capture path patterns manually, and it is not desirable that a statistical system depends on rather sparse non-factored path features. For this reason in this paper we explore arc-factored models for SRL.

Our method might be specially useful in applications were we are interested in some target semantic role, i.e. retrieving agent relations for some verb, since it processes semantic roles independently of each other. Our method might also be generalizable to other kinds of semantic relations which strongly depend on syntactic patterns such as relation extraction in information extraction or discourse parsing.

2 Arc-factored SRL

We define an SRL parsing model that retrieves predicate-argument relations based on arc-factored syntactic representations of paths connecting predicates with their arguments. Throughout the paper we assume a fixed sentence $\mathbf{x} = x_1, \ldots, x_n$ and a fixed predicate index p. The SRL output is an indicator vector $\mathbf{z}$, where $\mathbf{z}_{r,a} = 1$ indicates that token a is filling role r for predicate p. Our SRL parser performs $\operatorname{argmax}_{\mathbf{z} \in \mathcal{Z}(\mathbf{x},p)} s(\mathbf{x}, p, \mathbf{z})$, where $\mathcal{Z}(\mathbf{x}, p)$ defines the set of valid argument structures for p, and $s(\mathbf{x}, p, \mathbf{z})$ computes a plausibility score for $\mathbf{z}$ given $\mathbf{x}$ and p. Our first assumption is that the score function factors over role-argument pairs:

$$s(\mathbf{x}, p, \mathbf{z}) = \sum_{z_{r,a}=1} s(\mathbf{x}, p, r, a) \quad . \qquad (1)$$

Then we assume two components in the model, one that scores the role-argument pair alone, and another that considers the best ($\max$) syntactic dependency path $\boldsymbol{\pi}$ that connects the predicate p with the argument a:

$$s(\mathbf{x}, p, r, a) = s_0(\mathbf{x}, p, r, a) + \max_{\boldsymbol{\pi}} s_{\text{syn}}(\mathbf{x}, p, r, a, \boldsymbol{\pi}) \quad . \qquad (2)$$

The model does not assume access to the syntactic structure of $\mathbf{x}$, hence in Eq. (2) we locally retrieve the maximum-scoring path for an argument-role pair. A path $\boldsymbol{\pi}$ is a sequence of dependencies $\langle h, m, l \rangle$ where h is the head, m the modifier and l the syntactic label. We further assume that the syntactic component factors over the dependencies in the path:

$$s_{\text{syn}}(\mathbf{x}, p, r, a, \boldsymbol{\pi}) = \sum_{\langle h,m,l \rangle \in \boldsymbol{\pi}} s_{\text{syn}}(\mathbf{x}, p, r, a, \langle h, m, l \rangle) \; . \qquad (3)$$

This will allow to employ efficient shortest-path inference, which is the main contribution of this paper and is described in the next section. Note that since paths are locally retrieved per role-argument pair, there is no guarantee that the set of paths across roles forms a (sub)tree.

As a final note, in this paper we follow Lluís et al. (2013) and consider a constrained space of valid argument structures $\mathcal{Z}(\mathbf{x}, p)$: (a) each role is realized at most once, and (b) each token fills at most one role. As shown by Lluís et al. (2013), this can be efficiently solved as a linear assign-

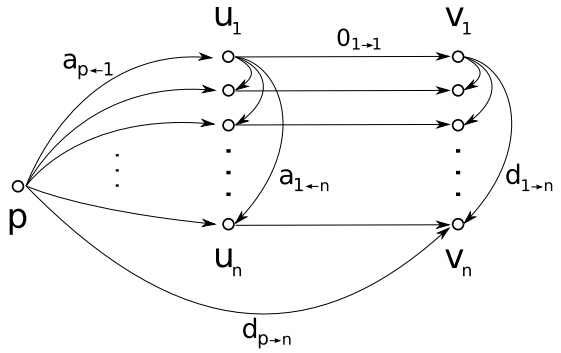

Figure 1: Graph representing all possible syntactic paths from a single predicate to their arguments. We find in this graph the best SRL using a shortest-path algorithm. Note that many edges are omitted for clarity reasons. We labeled the nodes and arcs as follows: p is the predicate and source vertex; $u_1, \ldots, u_n$ are tokens reachable by an ascending path; $v_1, \ldots, v_n$ are tokens reachable by a ascending path (possibly empty) followed by a descending path (possibly empty); $a_{i \leftarrow j}$ is an edge related to an *ascending* dependency from node u_i to node u_j; $d_{i \rightarrow j}$ is a *descending* dependency from node v_i to node v_j; $0_{i \rightarrow i}$ is a 0-weighted arc that connects the ascending portion of the path ending at u_i with the descending portion of the path starting at v_i.

ment problem as long as the SRL model factors over role-argument pairs, as in Eq. (1).

3 SRL as a Shortest-path Problem

We now focus on solving the maximization over syntactic paths in Eq. (2). We will turn it into a minimization problem which can be solved with a polynomial-cost algorithm, in our case a shortest-path method. Assume a fixed argument and role, and define $\theta_{\langle h,m,l \rangle}$ to be a *non-negative penalty* for the syntactic dependency $\langle h, m, l \rangle$ to appear in the predicate-argument path. We describe a shortest-path method that finds the path of arcs with the smaller penalty:

$$\min_{\boldsymbol{\pi}} \sum_{\langle h,m,l \rangle \in \boldsymbol{\pi}} \theta_{\langle h,m,l \rangle} \quad . \tag{4}$$

We find these paths by appropriately constructing a weighted graph $G = (V, E)$ that represents the problem. Later we show how to adapt the arc-factored model scores to be non-negative penalties, such that the solution to Eq. (4) will be the negative of the maximizer of Eq. (2).

It remains only to define the graph construction where paths correspond to arc-factored edges weighted by θ penalties. We start by noting that any path from a predicate p to an argument v_i is formed by a number of *ascending* syntactic arcs followed by a number of *descending* arcs. The ascending segment connects p to some ancestor q (q might be p itself, which implies an empty ascending segment); the descending segment connects q with v_i (which again might be empty). To compactly represent all these possible paths we define the graph as follows (see Figure 1):

1. Add node p as the *source* node of the graph.
2. Add nodes $u_1, \ldots, u_n$ for every token of the sentence except p.
3. Link every pair of these nodes u_i, u_j with a directed edge $a_{i \leftarrow j}$ weighted by the corresponding ascending arc, namely $\min_l \theta_{\langle j,i,l \rangle}$. Also add ascending edges from p to any u_i weighted by $\min_l \theta_{\langle i,p,l \rangle}$. So far we have a connected component representing all ascending path segments.
4. Add nodes $v_1, \ldots, v_n$ for every token of the sentence except p, and add edges $d_{i \rightarrow j}$ between them weighted by descending arcs, namely $\min_l \theta_{\langle i,j,l \rangle}$. This adds a second strongly-connected component representing descending path segments.
5. For each i, add an edge from u_i to v_i with weight 0. This ensures that ascending and descending path segments are connected consistently.
6. Add direct descending edges from p to all the v_i nodes to allow for only-descending paths, weighted by $\min_l \theta_{\langle p,i,l \rangle}$.

Dijkstra's algorithm (Dijkstra, 1959) will find the optimal path from predicate p to all tokens in time $O(V^2)$ (see Cormen et al. (2009) for an in-depth description). Thus, our method runs this algorithm for each possible role of the predicate, obtaining the best paths to all arguments at each run.

4 Adapting and Training Model Scores

The shortest-path problem is undefined if a negative cycle is found in the graph as we may indefinitely decrease the cost of a path by looping over this cycle. Furthermore, Dijkstra's algorithm requires all arc scores to be non-negative penalties. However, the model in Eq. (3) computes plausibility scores for dependencies, not penalties. And, if we set this model to be a standard feature-based linear predictor, it will predict unrestricted real-valued scores.

One approach to map plausibility scores to penalties is to assume a log-linear form for our

model. Let us denote by $\bar{x}$ the tuple $\langle \mathbf{x}, p, r, a \rangle$, which we assume fixed in this section. The log-linear model predicts:

$$\Pr(\langle h, m, l \rangle \mid \bar{x}) = \frac{\exp\{\mathbf{w} \cdot \mathbf{f}(\bar{x}, \langle h, m, l \rangle)\}}{Z(\bar{x})}\,, \tag{5}$$

where $\mathbf{f}(\bar{x}, \langle h, m, l \rangle)$ is a feature vector for an arc in the path, $\mathbf{w}$ are the parameters, and $Z(\bar{x})$ is the normalizer. We can turn predictions into non-negative penalties by setting $\theta_{\langle h,m,l \rangle}$ to be the negative log-probability of $\langle h, m, l \rangle$; namely $\theta_{\langle h,m,l \rangle} = -\mathbf{w} \cdot \mathbf{f}(\bar{x}, \langle h, m, l \rangle) + \log Z(\bar{x})$. Note that $\log Z(\bar{x})$ shifts all values to the non-negative side.

However, log-linear estimation of $\mathbf{w}$ is typically expensive since it requires to repeatedly compute feature expectations. Furthermore, our model as defined in Eq. (2) combines arc-factored path scores with path-independent scores, and it is desirable to train these two components jointly. We opt for a mistake-driven training strategy based on the Structured Averaged Perceptron (Collins, 2002), which directly employs shortest-path inference as part of the training process.

To do so we predict plausibility scores for a dependency directly as $\mathbf{w} \cdot \mathbf{f}(\bar{x}, \langle h, m, l \rangle)$. To map scores to penalties, we define

$$\theta_0 = \max_{\langle h,m,l \rangle} \mathbf{w} \cdot \mathbf{f}(\bar{x}, \langle h, m, l \rangle)$$

and we set

$$\theta_{\langle h,m,l \rangle} = -\mathbf{w} \cdot \mathbf{f}(\bar{x}, \langle h, m, l \rangle) + \theta_0 \quad .$$

Thus, θ_0 has a similar purpose as the log-normalizer $Z(\bar{x})$ in a log-linear model, i.e., it shifts the negated scores to the positive side; but in our version the normalizer is based on the max value, not the sum of exponentiated predictions as in log-linear models. If we set our model function to be

$$s_{\text{syn}}(\bar{x}, \langle h, m, l \rangle) = \mathbf{w} \cdot \mathbf{f}(\bar{x}, \langle h, m, l \rangle) - \theta_0$$

then the shortest-path method is exact.

5 Experiments

We present experiments using the CoNLL-2009 Shared Task datasets (Hajič et al., 2009), for the verbal predicates of English. Evaluation is based on precision, recall and F_1 over correct predicate-argument relations[1]. Our system uses the feature set of the state-of-the-art system by Johansson (2009), but ignoring the features that do not factor over single arcs in the path.

The focus of these experiments is to see the performance of the shortest-path method with respect to the syntactic variability. Rather than running the method with the full set of possible dependency arcs in a sentence, i.e. $O(n^2)$, we only consider a fraction of the most likely dependencies. To do so employ a probabilistic dependency-based model, following Koo et al. (2007), that computes the distribution over head-label pairs for a given modifier, $\Pr(h, l \mid \mathbf{x}, m)$. Specifically, for each modifier token we only consider the dependencies or heads whose probability is above a factor γ of the most likely dependency for the given modifier. Thus, $\gamma = 1$ selects only the most likely dependency (similar to a pipeline system, but without enforcing tree constraints), and as γ decreases more dependencies are considered, to the point where $\gamma = 0$ would select all possible dependencies. Table 2 shows the ratio of dependencies included with respect to a pipeline system for the development set. As an example, if we set $\gamma = 0.5$, for a given modifier we consider the most likely dependency and also the dependencies with probability larger than 1/2 of the probability of the most likely one. In this case the total number of dependencies is 10.3% larger than only considering the most likely one.

Table 3 shows results of the method on development data, when training and testing with different γ values. The general trend is that testing with the most restricted syntactic graph results in the best performance. However, we observe that as we allow for more syntactic variability during training, the results largely improve. Setting $\gamma = 1$ for both training and testing gives a semantic F_1 of 75.9. This configuration is similar to a pipeline approach but considering only factored features. If we allow to train with $\gamma = 0.1$ and we test with $\gamma = 1$ the results improve by 1.96 points to a semantic F_1 of 77.8 points. When syntactic variability is too large, e.g., $\gamma = 0.01$, no improvements are observed.

Finally, table 4 shows results on the verbal English WSJ test set using our best configuration

[1] Unlike in the official CoNLL-2009 evaluation, in this work we exclude the predicate sense from the features and the evaluation.

0.01	74.12	65.92	69.78

Table 3: Results of our shortest-path system for different number of allowed dependencies showing precision, recall and F_1 on development set for the verbal predicates of the *English* language.

from the development set. We compare to the state-of-the art system by Zhao et al. (2009) that was the top-performing system for the English language in SRL at the CoNLL-2009 Shared Task. We also show the results for a shortest-path system trained and tested with $\gamma = 1$. In addition we include an equivalent pipeline system using all features, both factored and non-factored, as defined in Johansson (2009). We observe that by not being able to capture non-factored features the final performance drops by 1.6 F_1 points.

6 Conclusions

We have formulated SRL in terms of shortest-path inference. Our model predicts semantic roles together with associated syntactic paths, and assumes an arc-factored representation of the path. This property allows for efficient shortest-path algorithms that, given a predicate and a role, retrieve the most likely argument and its path.

System	**prec(%)**	**rec(%)**	$\mathbf{F_1}$
Zhao et al. 2009	86.91	81.22	83.97
Non-factored	86.96	75.92	81.06
Factored $\gamma = 1$	79.88	76.12	77.96
Factored best	85.26	74.41	79.46

Table 4: Test set results for verbal predicates of the in-domain *English* dataset. The configurations are labeled as follows. *Factored* $\gamma = 1$: our shortest-path system trained and tested with $\gamma = 1$, similar to a pipeline system but without enforcing tree constraints and restricted to arc-factored features. *Factored best*: our shortest-path system with the best results from table 3. *Non-factored*: an equivalent pipeline system that includes both factored and non-factored features.

In the experimental section we prove the feasibility of the approach. We observe that arc-factored models are in fact more restricted, with a drop in accuracy with respect to unrestricted models. However, we also observe that our method largely improves the robustness of the arc-factored method when training with a degree of syntactic variability. Overall, ours is a simple strategy to bring arc-factored models close to the performance of unrestricted models. Future work should explore further approaches to parse partial syntactic structure specific to some target semantic relations.

Abstract

We present an empirical study on the use of semantic information for Concept Segmentation and Labeling (CSL), which is an important step for semantic parsing. We represent the alternative analyses output by a state-of-the-art CSL parser with tree structures, which we rerank with a classifier trained on two types of semantic tree kernels: one processing structures built with words, concepts and Brown clusters, and another one using semantic similarity among the words composing the structure. The results on a corpus from the restaurant domain show that our semantic kernels exploiting similarity measures outperform state-of-the-art rerankers.

1 Introduction

Spoken Language Understanding aims to interpret user utterances and to convert them to logical forms or, equivalently, to database queries, which can then be used to satisfy the user's information needs. This process is known as Concept Segmentation and Labeling (CSL), also called *semantic parsing* in the speech community: it maps utterances into meaning representations based on semantic constituents. The latter are basically word sequences, often referred to as concepts, attributes or semantic tags. CSL makes it easy to convert spoken questions such as "cheap lebanese restaurants in doha with take out" into database queries.

First, a language-specific semantic parser tokenizes, segments and labels the question:

[*Price* cheap] [*Cuisine* lebanese] [*Other* restaurants in] [*City* doha] [*Other* with] [*Amenity* take out]

Then, label-specific normalizers are applied to the segments, with the option to possibly relabel mislabeled segments:

[*Price* low] [*Cuisine* lebanese] [*City* doha] [*Amenity* carry out]

Finally, a database query is formed from the list of labels and values, and is then executed against the database, e.g., MongoDB; a backoff mechanism may be used if the query has not succeeded.

```
{$and [{cuisine:"lebanese"},{city:"doha"},
  {price:"low"},{amenity:"carry out"}]}
```

The state-of-the-art of CSL is represented by conditional models for sequence labeling such as Conditional Random Fields (CRFs) (Lafferty et al., 2001) trained with simple morphological and lexical features. The basic CRF model was improved by means of reranking (Moschitti et al., 2006; Dinarelli et al., 2012) using structural kernels (Moschitti, 2006). Although these methods exploited sentence structure, they did not use syntax at all. More recently, we applied shallow syntactic structures and discourse parsing with slightly better results (Saleh et al., 2014). However, the most obvious models for semantic parsing, i.e., rerankers based on semantic structural kernels (Bloehdorn and Moschitti, 2007b), had not been applied to semantic structures yet.

In this paper, we study the impact of semantic information conveyed by Brown Clusters (BCs) (Brown et al., 1992) and semantic similarity, while also combining them with innovative features. We use reranking, similarly to (Saleh et al., 2014), to select the best hypothesis annotated with concepts predicted by a local model. The competing hypotheses are represented as innovative trees enriched with the semantic concepts and BC labels. The trees can capture dependencies between sentence constituents, concepts and BCs. However, extracting explicit features from them is rather difficult as their number is exponentially large. Thus, we rely on (*i*) Support Vector Machines (Joachims, 1999) to train the reranking functions and on (*ii*) structural kernels (Moschitti, 2010; Moschitti, 2012; Moschitti, 2013) to automatically encode tree fragments that represent syntactic and semantic dependencies from words and concepts.

(a) Semantic Kernel Structure (SKS)

(b) SKS with Brown Clusters

Figure 1: CSL structures: standard and with Brown Clusters.

We further apply a semantic kernel (SK), namely the Smoothed Partial Tree Kernel (Croce et al., 2011), which uses the lexical similarity between the tree nodes, while computing the substructure space. This is the first time that SKs are applied to reranking hypotheses. This (*i*) makes the global sentence structure along with concepts available to the learning algorithm, and (*ii*) enables computing the similarity between lexicals in syntactic patterns that are enriched by concepts.

We tested our models on the *Restaurant* domain. Our results show that: *(i)* The basic CRF parser, which uses semi-Markov CRF, or semi-CRF (Sarawagi and Cohen, 2004), is already very accurate; it achieves F_1 scores over 83%, making any further improvement very hard. (*ii*) The upper-bound performance of the reranker is very high as well, i.e., the correct annotation is generated in the list of the first 100 hypotheses in 98.72% of the cases. (*iii*) SKs significantly improve over the semi-CRF baseline and our previous state-of-the-art reranker exploiting shallow syntactic patterns (Saleh et al., 2014), as shown by extensive comparisons using several systems. (*iv*) Making BCs effective requires a deeper study.

2 Related Work

One of the early approaches to CSL was that of Pieraccini et al. (1991), where the word sequences and *concepts* were modeled using Hidden Markov Models (HMMs) as observations and hidden states, respectively. Generative models were exploited by Seneff (1989) and Miller et al. (1994), who used stochastic grammars for CSL. Other discriminative models followed such preliminary work, e.g., (Rubinstein and Hastie, 1997; Santafé et al., 2007; Raymond and Riccardi, 2007). CRF-based models are considered to be the state of the art in CSL (De Mori et al., 2008).

Another relevant line of research are the semantic kernels, i.e., kernels that use lexical similarity between features. One of the first that applyed LSA was (Cristianini et al., 2002), whereas (Bloehdorn et al., 2006; Basili et al., 2006) used WordNet. Semantic structural kernels of the type we use in this paper were first introduced in (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b). The most advanced model based on tree kernels, which we also use in this paper, is the Smoothed PTK (Croce et al., 2011).

3 Reranking for CSL

Reranking is applied to a list of N annotation hypotheses, which are generated and sorted by the probability to be globally correct as estimated using local classifiers or global classifiers that only use local features. Then, a reranker, typically a meta-classifier, tries to select the best hypothesis from the list. The reranker can exploit global information, and specifically, the dependencies between the different concepts, which are made available by the local model. We use semi-CRFs for the local model as they yield the highest accuracy in CSL (when using a single model) and preference reranking for the global reranker.

3.1 Preference Reranking (PR)

PR uses a classifier $\mathcal{C}$, which takes a pair of hypotheses $\langle H_i, H_j \rangle$ and decides whether H_i is better than H_j. Given a training question Q, positive and negative examples are built for training the classifier. Let H_1 be the hypothesis with the lowest error rate with respect to the gold standard among all hypotheses generated for question Q. We adopt the following approach for example generation: the pairs $\langle H_1, H_i \rangle$ $(i = 2, 3, \ldots, N)$ are positive examples, while $\langle H_i, H_1 \rangle$ are considered negative.

At testing time, given a new question Q′, $\mathcal{C}$ classifies all pairs $\langle H_i, H_j \rangle$ generated from the annotation hypotheses of Q′: a positive classification is a vote for H_i, otherwise the vote is for H_j, where the classifier score can be used as a weighted vote. H_k are then ranked according to the number (sum) of the votes (weighted by score) they receive.

We build our reranker with SVMs using the following kernel: $K(\langle H_1, H_2 \rangle, \langle H'_1, H'_2 \rangle) = \phi(\langle H_1, H_2 \rangle) \cdot \phi(\langle H'_1, H'_2 \rangle) \triangleq \big(\phi(H_1) - \phi(H_2)\big) \cdot \big(\phi(H'_1) - \phi(H'_2)\big) = \phi(H_1)\phi(H'_1) + \phi(H_2)\phi(H'_2) - \phi(H_1)\phi(H'_2) - \phi(H_2)\phi(H'_1) = S(H_1, H'_1) + S(H_2, H'_2) - S(H_1, H'_2) - S(H_2, H'_1)$. We consider H as a tuple $\langle T, \vec{v} \rangle$ composed of a tree T and a feature vector $\vec{v}$. Then, we define $S(H, H') = S_{\text{TK}}(T, T') + S_{\text{v}}(\vec{v}, \vec{v}')$, where S_{TK} computes one of the tree kernel functions defined in 3.2 and 3.3; and S_{v} is a kernel (see 3.4), e.g., linear, polynomial, Gaussian, etc.

3.2 Tree kernels (TKs)

TKs measure the similarity between two structures in terms of the number of substructures they share. We use two types of tree kernels: (*i*) Partial Tree Kernel (PTK), which can be effectively applied to both constituency and dependency parse trees (Moschitti, 2006). It generates all possible connected tree fragments, e.g., sibling nodes can be also separated and can be part of different tree fragments: a fragment is any possible tree path, and other tree paths are allowed to depart from its nodes. Thus, it can generate a very rich feature space. (*ii*) The smoothed PTK or semantic kernel (SK) (Croce et al., 2011), which extends PTK by allowing soft matching (i.e., via similarity computation) between nodes associated with different but related lexical items. The node similarity can be derived from manually annotated resources, e.g., WordNet or Wikipedia, as well as using corpus-based clustering approaches, e.g., latent semantic analysis (LSA), as we do in this paper.

3.3 Semantic structures

Tree kernels allow us to compute structural similarities between two trees; thus, we engineered a special structure for the CSL task. In order to capture the structural dependencies between the semantic tags,[1] we use a basic tree (see for example Figure 1a), where the words of a sentence are tagged with their semantic tags.

More specifically, the words in the sentence constitute the leaves of the tree, which are in turn connected to the pre-terminals containing the semantic tags in BIO notation ('B'=*begin*, 'I'=*inside*, 'O'=*outside*). The BIO tags are then generalized in the upper level, and joined to the Root node. Additionally, part-of-speech (POS) tags[2] are added to each word by concatenating it with the string "::L", where L is the first letter of the POS-tags of the words, e.g., *along*, *my* and *route*, receive i, p and n, which are the first letters of the POS-tags IN, PRN and NN, respectively. SK applied to the above structure can generate powerful semantic patterns such as [Root [4-Cuisine [similar_to(*stake house*)]][7-Loc [similar_to(*within a mile*)]]], e.g., for correctly labeling new clauses like *Pizza Parlor in three kilometers*. The BC labels, represented as cluster IDs, are simply added as siblings of words as shown in Fig. 1b.

3.4 Feature Vectors

For the sake of comparison, we also devoted some effort towards engineering a set of features to be used in a flat feature-vector representation. These features can be used in isolation to learn the reranking function, or in combination with the kernel-based approach (as a composite kernel using a linear combination). They belong to the following four categories: (*i*) CRF-based: these include the basic features used to train the initial semi-CRF model; (*ii*) n-gram based: we collected 3- and 4-grams of the output label sequence at the level of concepts, with artificial tags inserted to identify the start ('S') and end ('E') of the sequence.[3] (*iii*) Probability-based, computing the probability of the label sequence as an average of the probabilities at the word level in the N-best list; and (*iv*) DB-based: a single feature encoding the number of results returned from the database when constructing a query using the conjunction of all semantic segments in the hypothesis.

4 Experiments

The experiments aim at investigating the role of feature vectors, PTK, SK and BCs in reranking. We first describe the experimental setting and then we move into the analysis of the results.

[1] They are associated with the following IDs: 0-Other, 1-Rating, 2-Restaurant, 3-Amenity, 4-Cuisine, 5-Dish, 6-Hours, 7-Location, and 8-Price.

[2] We use the Stanford tagger (Toutanova et al., 2003).

[3] For instance, if the output sequence is *Other-Rating-Other-Amenity* the 3-gram patterns would be: S-*Other-Rating, Other-Rating-Other, Rating-Other-Amenity*, and *Other-Amenity*-E.

	Train	Devel.	Test	Total
semi-CRF	6,922	739	1,521	9,182
Reranker	7,000	3,695	7,605	39,782

Table 1: Number of instances and pairs used to train the semi-CRF and rerankers, respectively.

4.1 Experimental setup

Dataset. In our experiments, we used questions annotated with semantic tags, which were collected through crowdsourcing on Amazon Mechanical Turk and made available[4] by McGraw et al. (2012). We split the dataset into training, development and test sets. Table 1 shows the number of examples and example pairs we used for the semi-CRF and the reranker, respectively. We subsequently split the training data randomly into 10 folds. We used cross-validation, i.e., iteratively training with 9 folds and annotating the remaining fold, in order to generate the N-best lists of hypotheses for the entire training dataset. We computed the 100-best hypotheses for each example. We then used the development dataset to test and tune the hyper-parameters of our reranking model. The results on the development set, which we will present in Section 4.2 below, were obtained using semi-CRF and reranking models trained on the training set.

Data representation. Each hypothesis is represented by a semantic tree, a feature vector (explained in Section 3), and two extra features: (*i*) the semi-CRF probability of the hypothesis, and (*ii*) its reciprocal rank in the N-best list.

Learning algorithm. We used the SVM-Light-TK[5] to train the reranker with a combination of tree kernels and feature vectors (Moschitti, 2006; Joachims, 1999). We used the default parameters and a linear kernel for the feature vectors. As a baseline, we picked the best-scoring hypothesis in the list, i.e., the output by the regular semi-CRF parser. The setting is exactly the same as that described in (Saleh et al., 2014).

Evaluation measure. In all experiments, we used the harmonic mean of precision and recall (F_1) (van Rijsbergen, 1979), computed at the token level and micro-averaged across the different semantic types.[6]

[4]http://groups.csail.mit.edu/sls/downloads/restaurant/

[5]http://disi.unitn.it/moschitti/Tree-Kernel.htm

[6]We do not consider 'Other' to be a semantic type; thus, we did not include it in the F_1 calculation.

N	1	2	**5**	10	100
F_1	83.03	87.76	**92.63**	95.23	98.72

Table 2: Oracle F_1 score for N-best lists.

Brown Clusters. Clustering groups of similar words together provides a way of generalizing them. In this work, we explore the use of Brown clusters (Brown et al., 1992) in both feature vectors and tree kernels. The Brown clustering algorithm uses an n-gram class model. It first assigns each word to a distinct cluster, and then it merges different clusters in a bottom-up fashion. The merge step is done in a way that minimizes the loss in average mutual information between clusters. The outcome is hierarchical clustering, which we use in our reranking algorithm. To create the Brown clusters, we used the Yelp dataset of reviews.[7] It contains 335,022 reviews about 15,585 businesses; 5,575 of the businesses and 233,839 of the reviews are restaurant-related. This dataset is very similar to the dataset of queries about restaurants we use in our experiments.

Similarity matrix for SK. We compute the lexical similarity for SK by applying LSA (Furnas et al., 1988) to Tripadvisor data. The dataset and the exact procedure for creating the LSA matrix are described in (Castellucci et al., 2013; Croce and Previtali, 2010).

4.2 Results

Oracle accuracy. Table 2 shows the oracle F_1 score for N-best lists of different lengths, i.e., the F_1 that is achieved by picking the best candidate in the N-best list for various values of N. Considering 5-best lists yields an increase in oracle F_1 of almost ten absolute points. Going up to 10-best lists only adds 2.5 extra F_1 points. The complete 100-best lists add 3.5 extra F_1 points, for a total of 98.72. This very high value is explained by the fact that often the total number of different annotations for a given question is smaller than 100. In our experiments, we will focus on 5-best lists.

Baseline accuracy. We computed F_1 for the semi-CRF model on both the development and the test sets, obtaining 83.86 and 83.03, respectively.

Learning Curves. The semantic information in terms of BCs or semantic similarity derived by LSA can have a major impact in case of data scarcity. Therefore, we trained our reranking models with increasing sizes of training data.

[7]http://www.yelp.com/dataset_challenge/

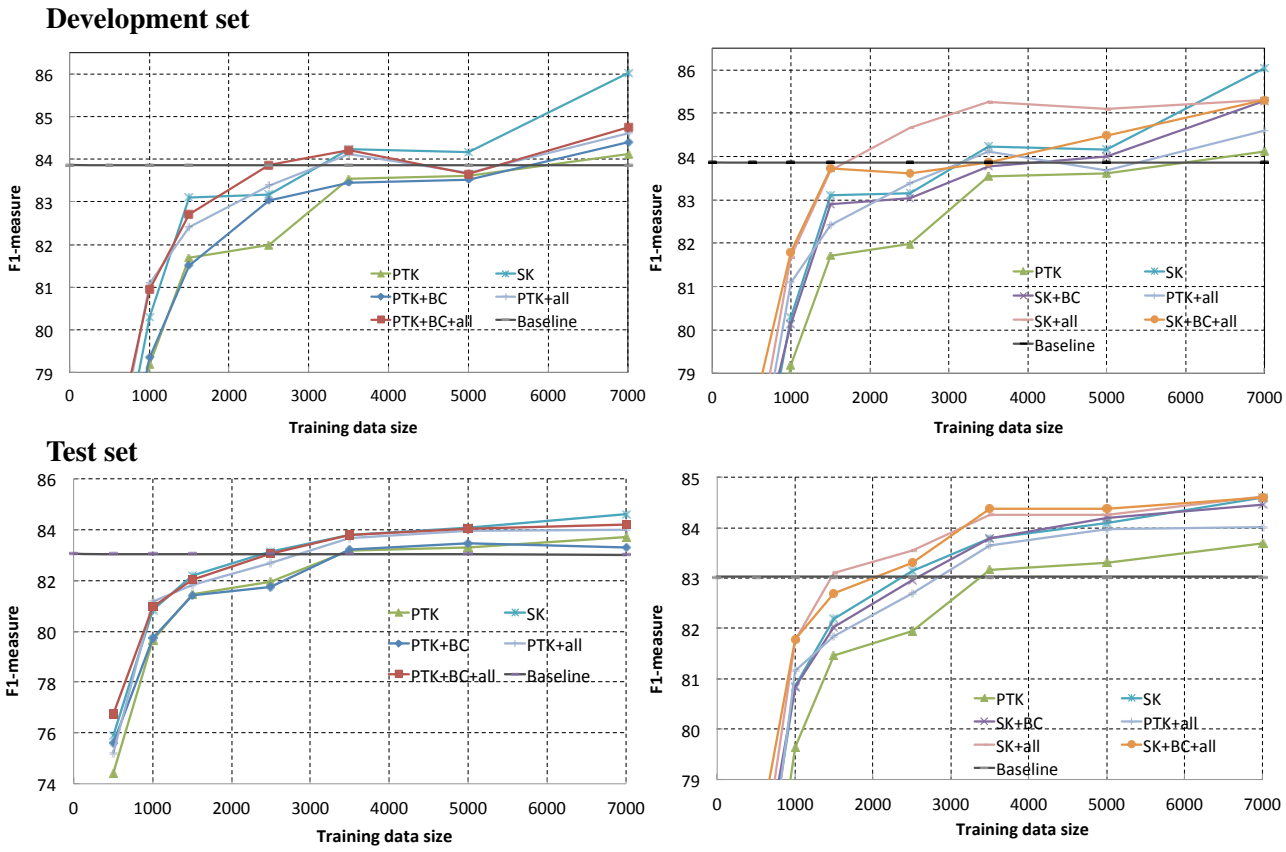

Figure 2: Learning curves for different reranking models on the development and on the testing sets.

The first two graphs in Fig. 2 show the plots on the development set whereas the last two are computed on the test set. The reranking models reported are Baseline, PTK, PTK+BC, PTK+all (features), PTK+BC+all, SK, SK+BC, SK+all and SK+BC+all.[8] We can see that: (*i*) PTK alone, i.e., without semantic information, has the lowest accuracy; (*ii*) BCs do not improve significantly any model; (*iii*) SK almost always achieves the highest accuracy; (*iv*) PTK+all (i.e., the model also using features) improves on PTK, but its accuracy is lower than for any model using SK, i.e., using semantic similarity; and (*v*) all features provide an initial boost to SK, but as soon as the data increases, their impact decreases.

5 Conclusion and Future Work

In summary, the learning curves clearly show the good generalization ability of SK, which improve the CRF baseline using little data (∼3,000). The semantic kernel significantly improves over the semi-CRF baseline and our previous state-of-the-art reranker exploiting shallow syntactic patterns (Saleh et al., 2014), which corresponds to PTK+all in the above comparison.

[8]Models are split between 2 plots in order to ease reading.

The improvement falls between 1-2 absolute percent points. This is remarkable as (*i*) it corresponds to ∼10% relative error reduction, and (*ii*) the state-of-the-art baseline system is very difficult to beat, as confirmed by the low impact of traditional features and BCs. Although the latter can generalize over concepts and words, their use is not straightforward, resulting in no improvement.

In the future, we plan to investigate the use of semantic similarity from distributional and other sources (Mihalcea et al., 2006; Padó and Lapata, 2007), e.g., Wikipedia (Strube and Ponzetto, 2006; Mihalcea and Csomai, 2007), Wiktionary (Zesch et al., 2008), WordNet (Pedersen et al., 2004; Agirre et al., 2009), FrameNet, VerbNet (Shi and Mihalcea, 2005), BabelNet (Navigli and Ponzetto, 2010), and LSA, and for different domains.

Acknowledgments

This research is part of the Interactive sYstems for Answer Search (Iyas) project, conducted by the Arabic Language Technologies (ALT) group at Qatar Computing Research Institute (QCRI) within the Qatar Foundation. We would like to thank Danilo Croce, Roberto Basili and Giuseppe Castellucci for helping and providing us with the similarity matrix for the semantic kernels.

Abstract

Various studies highlighted that topic-based approaches give a powerful spoken content representation of documents. Nonetheless, these documents may contain more than one main theme, and their automatic transcription inevitably contains errors. In this study, we propose an original and promising framework based on a compact representation of a textual document, to solve issues related to topic space granularity. Firstly, various topic spaces are estimated with different numbers of classes from a Latent Dirichlet Allocation. Then, this multiple topic space representation is compacted into an elementary segment, called c-vector, originally developed in the context of speaker recognition. Experiments are conducted on the DECODA corpus of conversations. Results show the effectiveness of the proposed multi-view compact representation paradigm. Our identification system reaches an accuracy of 85%, with a significant gain of 9 points compared to the baseline (best single topic space configuration).

1 Introduction

Automatic Speech Recognition (ASR) systems frequently fail on noisy conditions and high Word Error Rates (WER) make the analysis of the automatic transcriptions difficult. Speech analytics suffer from these transcription issues that may be overcome by improving the ASR robustness and/or the tolerance of speech analytic systems to ASR errors. This paper proposes a new method to improve the robustness of speech analytics by combining a semantic multi-model approach and a noise reduction technique based on the i-vector paradigm.

This method is evaluated in the application framework of the RATP call centre (Paris Public Transportation Authority), focusing on the theme identification task (Bechet et al., 2012).

Telephone conversations are a particular case of human-human interaction whose automatic processing raises problems, especially due to the speech recognition step required to obtain the transcription of the speech contents. First, the speaker's behavior may be unexpected and the training/test mismatch may be very large. Second, the speech signal may be strongly impacted by various sources of variability: environment and channel noises, acquisition devices, etc.

Telephone conversation issues

Topics are related to the reason why the customer called. Various classes corresponding to the main customer's requests are considered (*lost and founds, traffic state, timelines*, etc). In addition to classical issues in such adverse conditions, the topic-identification system should deal with problems related to class proximity. For example, a *lost & found* request is related to itinerary (*where was the object lost?*) or timeline (*when?*), that could appear in most of the classes. In fact, these conversations involve a relatively small set of basic concepts related to transportation issues. Figure 1 shows an example of a dialogue which is manually labeled by the agent as an issue related to an *infraction*. However, words in bold suggest that this conversation could be related to a *transportation card*. Thus, we assume that a dialogue representation should be seen as a multi-view problem to substantiate the claims regarding the multi-theme representation of a given dialogue.

On the other hand, multi-view approaches introduce additional variability due to the diversity of the views. This variability is also due to the vocabulary used by both agent and customer

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 443–454,

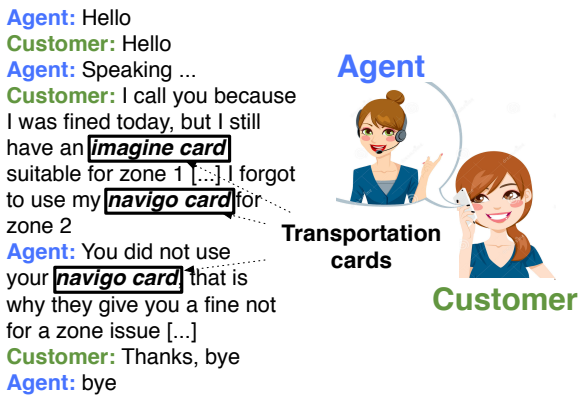

Figure 1: Example of a dialogue from the DECODA corpus labeled by the agent as an *infraction* issue which contains more than one theme (*infraction* + *transportation cards*).

during a telephone conversation. Indeed, an agent have to follow an predefined scenario of conversation. Thus, the agent can find the main reason for the call which corresponds to the theme.

Proposed solutions

An efficient way to tackle both ASR robustness and class ambiguity could be to map dialogues into a topic space abstracting the ASR outputs. Then, dialogue categorization is achieved in this topic space. Numerous unsupervised methods for topic-space estimation were proposed in the past. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) has been largely used for speech analytics; one of its main drawbacks is the tuning of the model, that involves various meta-parameters such as the number of classes (that determines the model granularity), word distribution methods, temporal spans... If the decision process is highly dependent on these features, the system's performance could be quite unstable.

Classically, this abstract representation involves selecting the right number of classes composing the topic space. This decision is crucial since topic model perplexity, which expresses its quality, is highly dependent on this feature. Furthermore, the multi-theme context of the study (see Figure 1) involves a more complex dialogue representation. In this paper, we propose to deal with these two drawbacks by using a compact representation from multiple topic spaces. This model is based on a robust multi-view representation of the textual documents.

A multi-view representation of a dialogue introduces both a *relevant* variability needed to represent different contexts of the dialogue, and a *noisy* variability related to topic space processing. Thus, a topic-based representation of a dialogue is built from the dialogue content itself. For this reason, the mapping process of a dialogue into several topic spaces generates a noisy variability related to the difference between the dialogue and the content of each class. In the same way, the relevant variability comes from the common content between the dialogue and the classes composing the topic space.

We propose to reduce the noisy variability by using a factor analysis technique, which was initially developed in the domain of speaker identification. In this field, the factor analysis paradigm is used as a decomposition model that enables to separate the representation space into two subspaces containing respectively useful and useless information. The general Joint Factor Analysis (JFA) paradigm (Kenny et al., 2008) considers multiple variabilities that may be cross-dependent. Therefore, JFA representation allows us to compensate the variability within sessions of a same speaker. This representation is an extension of the GMM-UBM (Gaussian Mixture Model-Universal Background Model) models (Reynolds and Rose, 1995). (Dehak et al., 2011) extract a compact super-vector (called an i-vector) from the GMM super-vector. The aim of the compression process (i-vector extraction) is to represent the super-vector variability in a low dimensional space. Although this compact representation is widely used in speaker recognition systems, this method has not been used yet in the field of text classification.

In this paper, we propose to apply factor analysis to compensate noisy variabilities due to the multiplication of LDA models. Furthermore, a normalization approach to condition dialogue representations (multi-model and i-vector) is presented. The two methods showed improvements for speaker verification: within Class Covariance Normalization (WCCN) (Dehak et al., 2011) and Eigen Factor Radial (EFR) (Bousquet et al., 2011). The latter includes length normalization (Garcia-Romero and Espy-Wilson, 2011). Both methods dilate the total variability space as a means of reducing the within-class variability. In our multi-model representation, the within class variability is redefined according to both dialogue content

(vocabulary) and topic space characteristics (word distributions among the topics). Thus, the speaker is represented by a theme, and the speaker session is a set of topic-based representations (frames) of a dialogue (session).

The paper is organized as follows. Section 2 presents previous related works. The dialogue representation is described in Section 3. Section 4 introduces the i-vector compact representation and presents its application to text documents. Sections 5 and 6 report experiments and results. The last section concludes and proposes some perspectives.

2 Related work

In the past, several approaches considered a text document as a mixture of latent topics. These methods, such as Latent Semantic Analysis (LSA) (Deerwester et al., 1990; Bellegarda, 1997), Probabilistic LSA (PLSA) (Hofmann, 1999) or Latent Dirichlet Allocation (LDA) (Blei et al., 2003), build a higher-level representation of the document in a topic space. ¿ Document is then considered as a bag-of-words (Salton, 1989) where the word order is not taken into account. These methods have demonstrated their performance on various tasks, such as sentence (Bellegarda, 2000) or keyword (Suzuki et al., 1998) extraction.

In opposition to a multinomial mixture model, LDA considers that a theme is associated to each occurrence of a word composing the document, rather than associate a topic to the complete document. Therefore, a document can change topics from a word to another one. However, word occurrences are connected by a latent variable which controls the global match of the distribution of the topics in the document. These latent topics are characterized by a distribution of associated word probabilities. PLSA and LDA models have been shown to generally outperform LSA on IR tasks (Hofmann, 2001). Moreover, LDA provides a direct estimate of the relevance of a topic given a word set. In this paper, probabilities of hidden topic features, estimated with LDA, are considered for possibly capturing word dependencies expressing the semantic contents of a given conversation.

Topic-based approaches involve defining a number of topics composing the topic space. The choice of the "right" number of topics is a crucial step, especially when the documents may contain multiple themes. Many studies have tried to find a relevant method to deal with this issue. (Arun et al., 2010) proposed to use a Singular Value Decomposition (SVD) to represent the separability between the words contained in the vocabulary. Then, if the singular values of the topic-word matrix $\mathbf{M}$ equal the norm of the rows of $\mathbf{M}$, this means that the vocabulary is well separated among the topics. This method has to be evaluated with the Kullback-Liebler divergence metric for each topic space. However, this process would be time consuming for thousands of representations of a dialogue.

(Teh et al., 2004) proposed the Hierarchical Dirichlet Process (HDP) method to find the "right" number of topics by assuming that the data has a hierarchical structure. The HDP models were then compared to the LDA ones on the same dataset. (Zavitsanos et al., 2008) presented a method to *learn* the right depth of an ontology depending of the number of topics of LDA models. The study presented by (Cao et al., 2009) is quite similar to (Teh et al., 2004). The authors consider the average correlation between pairs of topics at each stage as the right number of topics.

All these methods assume that a document can have only one representation since they consider that finding the optimal topic model is the best solution. Another solution would be to consider a set of topic models to represent a document. Nonetheless, a multi-topic-based representation of a dialogue can involve a noisy variability due to the mapping of a dialogue in each topic space. Indeed, a dialogue does not share its content (*i.e.* words) with each class composing the topic space. Thus, a variability is added during the mapping process. Another weakness of the multi-view representation is the relation between classes in a topic space. (Blei and Lafferty, 2006) show that classes into a LDA topic space are correlated. Moreover, (Li and McCallum, 2006) consider a class as a node of an acyclic graph and as a distribution over other classes contained in the same topic space.

3 Multi-view representation of automatic dialogue transcriptions in a homogeneous space

The purpose of the considered application is the identification of the major theme of a human-human telephone conversation in the customer

care service (CCS) of the RATP Paris transportation system. The approach considered in this paper focuses on modeling the variability between different dialogues expressing the same theme t. For this purpose, it is important to select relevant features that represent semantic contents for the theme of a dialogue. An attractive set of features for capturing possible semantically relevant word dependencies is obtained with Latent Dirichlet Allocation (LDA) (Blei et al., 2003), as described in section 2.

Given a training set of conversations D, a hidden topic space is derived and a conversation d is represented by its probability in each topic of the hidden space. Estimation of these probabilities is affected by a variability inherent to the estimation of the model parameters. If many hidden spaces are considered and features are computed for each hidden space, it is possible to model the estimation variability together with the variability of the linguistic expression of a theme by different speakers in different real-life situations. Even if the purpose of the application is theme identification and a training corpus annotated with themes is available, supervised LDA (Griffiths and Steyvers, 2004) is not suitable for the proposed approach. LDA is used only for producing different feature sets used involved in statistical variability models.

In order to estimate the parameters of different hidden spaces, a set of discriminative words V is constructed as described in (Morchid et al., 2014a). Each theme t contains a set of specific words. Note that the same word may appear in several discriminative word sets. All the selected words are then merged without repetition to form V.

Several techniques, such as Variational Methods (Blei et al., 2003), Expectation-propagation (Minka and Lafferty, 2002) or Gibbs Sampling (Griffiths and Steyvers, 2004), have been proposed for estimating the parameters describing a LDA hidden space. Gibbs Sampling is a special case of Markov-chain Monte Carlo (MCMC) (Geman and Geman, 1984) and gives a simple algorithm for approximate inference in high-dimensional models such as LDA (Heinrich, 2005). This overcomes the difficulty to directly and exactly estimate parameters that maximize the likelihood of the whole data collection defined as: $p(W|\overrightarrow{\alpha}, \overrightarrow{\beta}) = \prod_{w \in W} p(\overrightarrow{w}|\overrightarrow{\alpha}, \overrightarrow{\beta})$ for the whole data collection W knowing the Dirichlet parameters $\overrightarrow{\alpha}$ and $\overrightarrow{\beta}$.

Gibbs Sampling allows us both to estimate the LDA parameters in order to represent a new dialogue d with the r^{th} topic space of size n, and to obtain a feature vector $V_d^{z^r}$ of the topic representation of d. The j^{th} feature $V_d^{z_j^r} = P(z_j^r|d)$ (where $1 \leq j \leq n$) is the probability of topic z_j^r to be generated by the unseen dialogue d in the r^{th} topic space of size n (see Figure 2) and $V_{z_j^r}^w = P(w|z_j^r)$ is the vector representation of a word into r.

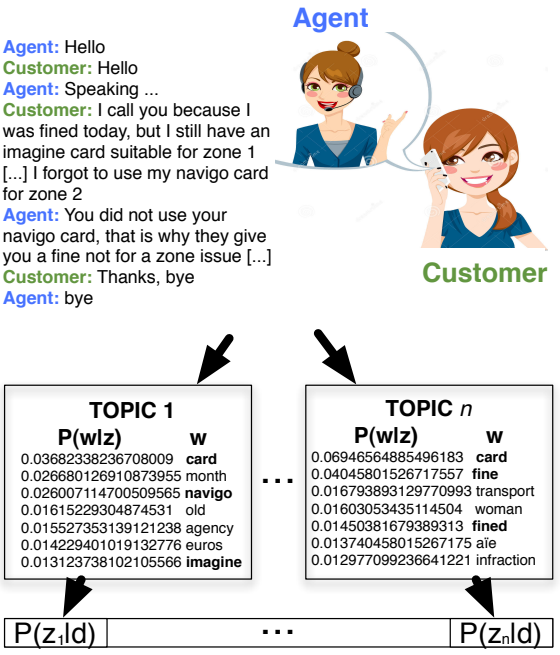

Figure 2: Example of a dialogue d mapped into a topic space of size n.

In the LDA technique, topic z_j, j is drawn from a multinomial over θ which is drawn from a Dirichlet distribution over $\overrightarrow{\alpha}$. Thus, a set of p topic spaces are learned using LDA by varying the number of topics n to obtain p topic spaces of size n. The number of topics n varies from 10 to $3,010$. Thus, a set of $3,000$ topic spaces is estimated. This is high enough to generate, for each dialogue, many feature sets for estimating the parameters of a variability model.

The next process allows us to obtain a homogeneous representation of transcription d for the r^{th} topic space r. The feature vector $V_d^{z^m}$ of d is mapped to the common vocabulary space V composed with a set of $|V|$ discriminative words (Morchid et al., 2014a) of size 166, to obtain a new feature vector $V_{d,r}^w = \{P(w|d)_r\}_{w \in V}$

of size $|V|$ for the r^{th} topic space r of size n where the i^{th} ($0 \leq i \leq |V|$) feature is:

$$\begin{aligned} V_{d,r}^{w_i} &= P(w_i|d) \\ &= \sum_{j=1}^{n} P(w_i|z_j^r)P(z_j^r|d) \\ &= \sum_{j=1}^{n} V_{z_j^r}^{w_i} \times V_d^{z_j^r} \\ &= \left\langle \overrightarrow{V_{z^r}^{w_i}}, \overrightarrow{V_d^{z^r}} \right\rangle \end{aligned}$$

where $\langle \cdot, \cdot \rangle$ is the inner product, δ being the frequency of the term w_i in d, $V_{z_j^r}^{w_i} = P(w_i|z_j)$ and $V_d^{z_j^r} = P(z_j|d)$ evaluated using Gibbs Sampling in the topic space r.

4 Compact multi-view representation

In this section, an i-vector-based method to represent automatic transcriptions is presented. Initially introduced for speaker recognition, i-vectors (Kenny et al., 2008) have become very popular in the field of speech processing and recent publications show that they are also reliable for language recognition (Martınez et al., 2011) and speaker diarization (Franco-Pedroso et al., 2010). I-vectors are an elegant way of reducing the imput space dimensionality while retaining most of the relevant information. The technique was originally inspired by the Joint Factor Analysis framework (Kenny et al., 2007). Hence, i-vectors convey the speaker characteristics among other information such as transmission channel, acoustic environment or phonetic content of speech segments. The next sections describe the i-vector extraction process, the application of this compact representation to textual documents (called c-vector), and the vector transformation with the EFR method and the Mahalanobis metric.

4.1 Total variability space definition

I-vector extraction could be seen as a probabilistic compression process that reduces the dimensionality of speech super-vectors according to a linear-Gaussian model. The speech (of a given speech recording) super-vector $\mathbf{m}_s$ of concatenated GMM means is projected in a low dimensionality space, named Total Variability space, with:

$$\mathbf{m}_{(h,s)} = m + \mathbf{T}\mathbf{x}_{(h,s)} \ , \qquad (1)$$

where m is the mean super-vector of the UBM[1]. $\mathbf{T}$ is a low rank matrix ($MD \times R$), where M is the number of Gaussians in the UBM and D is the cepstral feature size, which represents a basis of the reduced total variability space. $\mathbf{T}$ is named *Total Variability matrix*; the components of $\mathbf{x}_{(h,s)}$ are the total factors which represent the coordinates of the speech recording in the reduced total variability space called i-vector (i for $i$dentification).

4.2 From i-vector speaker identification to c-vector textual document classification

The proposed approach uses i-vectors to model transcription representation through each topic space in a homogeneous vocabulary space. These short segments are considered as basic semantic-based representation units. Indeed, vector V_d^w represents a segment or a session of a transcription d. In the following, (d, r) will indicate the dialogue representation d in the topic space r. In our model, the segment super-vector $\mathbf{m}_{(d,r)}$ of a transcription d knowing a topic space r is modeled:

$$\mathbf{m}_{(d,r)} = m + \mathbf{T}\mathbf{x}_{(d,r)} \qquad (2)$$

where $\mathbf{x}_{(d,r)}$ contains the coordinates of the topic-based representation of the dialogue in the reduced total variability space called c-vector (c for $c$lassification).

Let $\mathbf{N}_{(d,r)}$ and $\mathbf{X}_{(d,r)}$ be two vectors containing the zero order and first order dialogue statistics respectively. The statistics are estimated against the UBM:

$$\mathbf{N}_r[g] = \sum_{t \in r} \gamma_g(t); \ \{\mathbf{X}_{(d,r)}\}_{[g]} = \sum_{t \in (d,r)} \gamma_g(t) \cdot t \qquad (3)$$

where $\gamma_g(t)$ is the *a posteriori* probability of Gaussian g for the observation t. In the equation, $\sum_{t \in (d,r)}$ represents the sum over all the frames belonging to the dialogue d.

Let $\overline{\mathbf{X}}_{(d,r)}$ be the state dependent statistics defined as follows:

$$\{\overline{\mathbf{X}}_{(d,r)}\}_{[g]} = \{\mathbf{X}_{(d,r)}\}_{[g]} - \mathbf{m}_{[g]} \cdot \sum_{(d,r)} \mathbf{N}_{(d,r)}[g] \qquad (4)$$

Let $\mathbf{L}_{(d,r)}$ be a $R \times R$ matrix, and $\mathbf{B}_{(d,r)}$ a vector

[1]The UBM is a GMM that represents all the possible observations.

Algorithm 1: Estimation algorithm of **T** and latent variable **x**.

For each dialogue d mapped into the topic space r: $x_{(d,r)} \leftarrow 0$, $\mathbf{T} \leftarrow random$;
Estimate statistics: $\mathbf{N}_{(d,r)}$, $\mathbf{X}_{(d,r)}$ (eq.3);
for $i = 1$ *to* $nb\_iterations$ **do**
  for *all* d *and* r **do**
    Center statistics: $\overline{\mathbf{X}}_{(d,r)}$ (eq.4);
    Estimate $\mathbf{L}_{(d,r)}$ and $\mathbf{B}_{(d,r)}$ (eq.5);
    Estimate $\mathbf{x}_{(d,r)}$ (eq.6);
  end
  Estimate matrix **T** (eq. 7 and 8) ;
end

of dimension R, both defined as:

$$\mathbf{L}_{(d,r)} = \mathbf{I} + \sum_{g \in \text{UBM}} \mathbf{N}_{(d,r)}[g] \cdot \{\mathbf{T}\}^t_{[g]} \cdot \mathbf{\Sigma}^{-1}_{[g]} \cdot \{\mathbf{T}\}_{[g]}$$
$$\mathbf{B}_{(d,r)} = \sum_{g \in \text{UBM}} \{\mathbf{T}\}^t_{[g]} \cdot \mathbf{\Sigma}^{-1}_{g} \cdot \{\overline{\mathbf{X}}_{(d,r)}\}_{[g]}, \tag{5}$$

By using $\mathbf{L}_{(d,r)}$ and $\mathbf{B}_{(d,r)}$, $\mathbf{x}_{(d,r)}$ can be obtained using the following equation:

$$\mathbf{x}_{(d,r)} = \mathbf{L}^{-1}_{(d,r)} \cdot \mathbf{B}_{(d,r)} \tag{6}$$

The matrix **T** can be estimated line by line, with $\{\mathbf{T}\}^i_{[g]}$ being the i^{th} line of $\{\mathbf{T}\}_{[g]}$ then:

$$\mathbf{T}^i_{[g]} = \mathbf{L}\mathbf{U}^{-1}_g \cdot \mathbf{R}\mathbf{U}^i_g, \tag{7}$$

where $\mathbf{R}\mathbf{U}^i_g$ and $\mathbf{L}\mathbf{U}_g$ are given by:

$$\mathbf{L}\mathbf{U}_g = \sum_{(d,r)} \mathbf{L}^{-1}_{(d,r)} + \mathbf{x}_{(d,r)}\mathbf{x}^t_{(d,r)} \cdot \mathbf{N}_{(d,r)}[g]$$
$$\mathbf{R}\mathbf{U}^i_g = \sum_{(d,r)} \{\overline{\mathbf{X}}_{(d,r)}\}^{[i]}_{[g]} \cdot \mathbf{x}_{(d,r)} \tag{8}$$

Algorithm 1 presents the method adopted to estimate the multi-view variability dialogue matrix with the above developments where the standard likelihood function can be used to assess the convergence. One can refer to (Matrouf et al., 2007) to find out more about the implementation of the factor analysis.

C-vector representation suffers from 3 raised c-vector issues: (i) the c-vectors x of equation 2 have to be theoretically distributed among the normal distribution $\mathcal{N}(0, I)$, (ii) the "radial" effect should be removed, and (iii) the full rank total factor space should be used to apply discriminant transformations. The next section presents a solution to these 3 problems.

4.3 C-vector standardization

A solution to standardize c-vectors has been developed in (Bousquet et al., 2011). The authors proposed to apply transformations for training and test transcription representations. The first step is to evaluate the empirical mean $\overline{\mathbf{x}}$ and covariance matrix **V** of the training c-vector. Covariance matrix **V** is decomposed by diagonalization into:

$$\mathbf{P}\mathbf{D}\mathbf{P}^T \tag{9}$$

where **P** is the eigenvector matrix of **V** and **D** is the diagonal version of **V**. A training i-vector $\mathbf{x}_{(d,r)}$ is transformed in $\mathbf{x}'_{(d,r)}$ as follows:

$$\mathbf{x}'_{(d,r)} = \frac{\mathbf{D}^{-\frac{1}{2}}\mathbf{P}^T(\mathbf{x}_{(d,r)} - \overline{\mathbf{x}})}{\sqrt{(\mathbf{x}_{(d,r)} - \overline{\mathbf{x}})^T\mathbf{V}^{-1}(\mathbf{x}_{(d,r)} - \overline{\mathbf{x}})}} \tag{10}$$

The numerator is equivalent by rotation to $\mathbf{V}^{-\frac{1}{2}}(\mathbf{x}_{(d,r)} - \overline{\mathbf{x}})$ and the Euclidean norm of $\mathbf{x}'_{(d,r)}$ is equal to 1. The same transformation is applied to the test c-vectors, using the training set parameters $\overline{\mathbf{x}}$ and mean covariance **V**as estimations of the test set of parameters.

Figure 3 shows the transformation steps: Figure 3-(a) is the original training set; Figure 3-(b) shows the rotation applied to the initial training set around the principal axes of the total variability when $\mathbf{P}^T$ is applied; Figure 3-(c) shows the standardization of c-vectors when $\mathbf{D}^{-\frac{1}{2}}$ is applied; and finally, Figure 3-(d) shows the c-vector $\mathbf{x}'_{(d,r)}$ on the surface area of the unit hypersphere after a length normalization by a division of $\sqrt{(\mathbf{x}_{(d,r)} - \overline{\mathbf{x}})^T\mathbf{V}^{-1}(\mathbf{x}_{(d,r)} - \overline{\mathbf{x}})}$.

5 Experimental Protocol

The proposed c-vector representation of automatic transcriptions is evaluated in the context of the theme identification of a human-human telephone conversation in the customer care service (CCS) of the RATP Paris transportation system. The metric used to identify of the best theme is the Mahalanobis metric.

5.1 Theme identification task

The DECODA project corpus (Bechet et al., 2012) was designed to perform experiments on the identification of conversation themes. It is composed of 1,514 telephone conversations, corresponding to about 74 hours of signal, split into a training

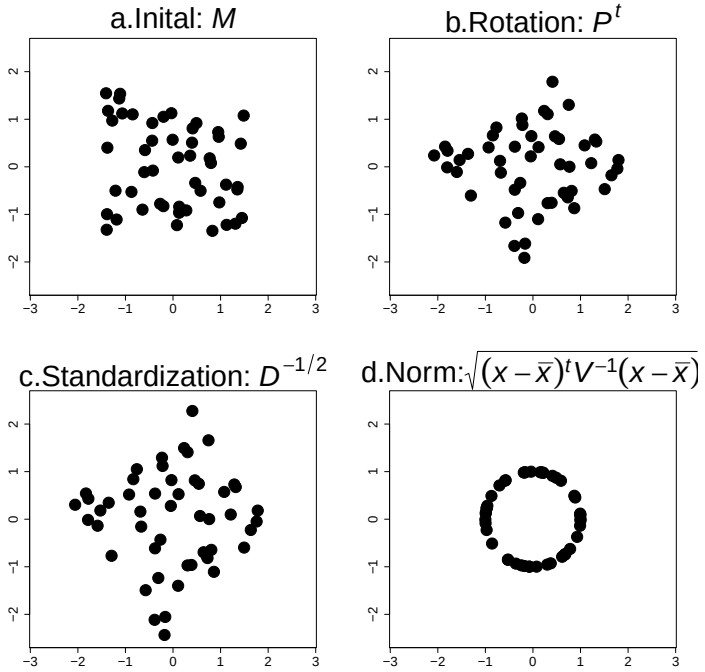

Figure 3: Effect of the standardization with the EFR algorithm.

set (740 dialogues), a development set (175 dialogues) and a test set (327 dialogues), and manually annotated with 8 conversation themes: *problems of itinerary*, *lost and found*, *time schedules*, *transportation cards*, *state of the traffic*, *fares*, *infractions* and *special offers*.

An LDA model allowed us to elaborate 3,000 topics spaces by varying the number of topics from 10 to 3,010. A topic space having less than 10 topics is not suitable for a corpus of more than 700 dialogues (training set). For each theme $\{C_i\}_{i=1}^{8}$, a set of 50 specific words is identified. All the selected words are then merged without repetition to compose V, which is made of 166 words. The topic spaces are made with the LDA Mallet Java implementation[2].

The LIA-Speeral ASR system (Linarès et al., 2007) is used for the experiments. Acoustic model parameters were estimated from 150 hours of speech in telephone conditions. The vocabulary contains 5,782 words. A 3-gram language model (LM) was obtained by adapting a basic LM with the training set transcriptions. A "stop list" of 126 words[3] was used to remove unnecessary words (mainly function words), which results in a Word Error Rate (WER) of 33.8% on the training, 45.2% on the development, and 49.5% on the test. These high WER are mainly due to speech disfluencies and to adverse acoustic environments (for example, calls from noisy streets with mobile phones).

[2]http://mallet.cs.umass.edu/

[3]http://code.google.com/p/stop-words/

5.2 Mahalanobis metric

Given a new observation x, the goal of the task is to identify the theme belonging to x. Probabilistic approaches ignore the process by which c-vectors were extracted and they pretend instead they were generated by a prescribed generative model. Once a c-vector is obtained from a dialogue, its representation mechanism is ignored and it is regarded as an observation from a probabilistic generative model. The Mahalanobis scoring metric assigns a dialogue d with the most likely theme C. Given a training dataset of dialogues, let $\mathbf{W}$ denote the within dialogue covariance matrix defined by:

$$\begin{aligned}\mathbf{W} &= \sum_{k=1}^{K} \frac{n_t}{n} \mathbf{W_k} \\ &= \frac{1}{n} \sum_{k=1}^{K} \sum_{i=0}^{n_t} \left(x_i^k - \overline{x_k}\right) \left(x_i^k - \overline{x_k}\right)^t \end{aligned} \quad (11)$$

where $\mathbf{W_k}$ is the covariance matrix of the k^{th} theme C_k, n_t is the number of utterances for the theme C_k, n is the total number of dialogues, and $\overline{x_k}$ is the centroid (mean) of all dialogues x_i^k of C_k.

Each dialogue does not contribute to the covariance in an equivalent way. For this reason, the term $\frac{n_t}{n}$ is introduced in equation 11. If homoscedasticity (equality of the class covariances) and Gaussian conditional density models are assumed, a new observation x from the test dataset can be assigned to the most likely theme $C_{k_{\text{Bayes}}}$ using the classifier based on the Bayes decision rule:

$$C_{k_{\text{Bayes}}} = \arg\max_k \{\mathcal{N}(x \mid \overline{x_k}, \mathbf{W})\}$$
$$= \arg\max_k \left\{ -\frac{1}{2} (x - \overline{x_k})^t \mathbf{W}^{-1} (x - \overline{x_k}) + a_k \right\}$$

where $\mathbf{W}$ is the within theme covariance matrix defined in eq. 11; $\mathcal{N}$ denotes the normal distribution and $a_k = \log(P(C_k))$. It is noted that, with these assumptions, the Bayesian approach is similar to Fisher's geometric approach: x is assigned to the class of the nearest centroid, according to the Mahalanobis metric (Xing et al., 2002) of $\mathbf{W}^{-1}$:

$$C_{k_{\text{Bayes}}} = \arg\max_k \left\{ -\frac{1}{2} ||x - \overline{x_k}||^2_{\mathbf{W}^{-1}} + a_k \right\}$$

6 Experiments and results

The proposed c-vector approach is applied to the same classification task and corpus proposed in (Morchid et al., 2014a; Morchid et al., 2014b; Morchid et al., 2013) (state-of-the-art in text classification in (Morchid et al., 2014a)). Experiments are conducted using the multiple topic spaces estimated with an LDA approach. From these multiple topic spaces, a classical way is to find the one that reaches the best performance. Figure 4 presents the theme classification performance obtained on the development and test sets using various topic-based representation configurations with the EFR normalization algorithm (*baseline*).

For sake of comparison, experiments are conducted using the automatic transcriptions only (ASR) only. The conditions indicated by the abbreviations between parentheses are considered for the development (Dev) and the test (Test) sets.

Only homogenous conditions (ASR for both training and validations sets) are considered in this study. Authors in (Morchid et al., 2014a) notice that results collapse dramatically when heterogenous conditions are employed (TRS or TRS+ASR for training set and ASR for validation set).

First of all, we can see that this baseline approach reached a classification accuracy of 83% and 76%, respectively on the development and the test sets. However, we note that the classification performance is rather unstable, and may completely change from a topic space configuration to another. The gap between the lower and the higher classification results is also important, with a difference of 25 points on the development set (the same trend is observed on the test set). As a result, finding the best topic space size seems crucial for this classification task, particularly in the context of highly imperfect automatic dialogue transcriptions containing more than one theme.

The topic space that yields the best accuracy with the baseline method ($n = 15$ topics) is presented in Figure 5. This figure presents each of the 15 topics and their 10 most representative words (highest $P(w|z)$). Several topics contain more or less the same representative words, such as topics 3, 6 and 9. This figure points out some interesting topics that allow us to distinguish a theme from the others. For example:

- topics 2, 10 and 15 represent some words related to *itinerary problems*,
- the *transportation cards* theme is mostly represented in topic 4 and 15 (*Imagine* and *Navigo* are names of transportation cards),
- the words which represent the *time schedules* theme are contained in topic 5,6,7 and less in topic 9,
- *state of the traffic* could be discussed with words such as: *departure, line, service, day*. These words and others are contained in topic 13,
- topics 4 and 12 are related to the *infractions* theme with to words *fine*, *pass*, *zone* or *ticket*,
- but topic 12 could be related to theme *fares* or *special offers* as well .

Table 1 presents results obtained with the proposed c-vector approach coupled with the EFR algorithm. We can firstly note that this compact representation allows it to outperform the best topic space configuration (*baseline*), with a gain of 9.4 points on the development data and of 9 points on the test data. Moreover, if we consider the different c-vector configurations with the development

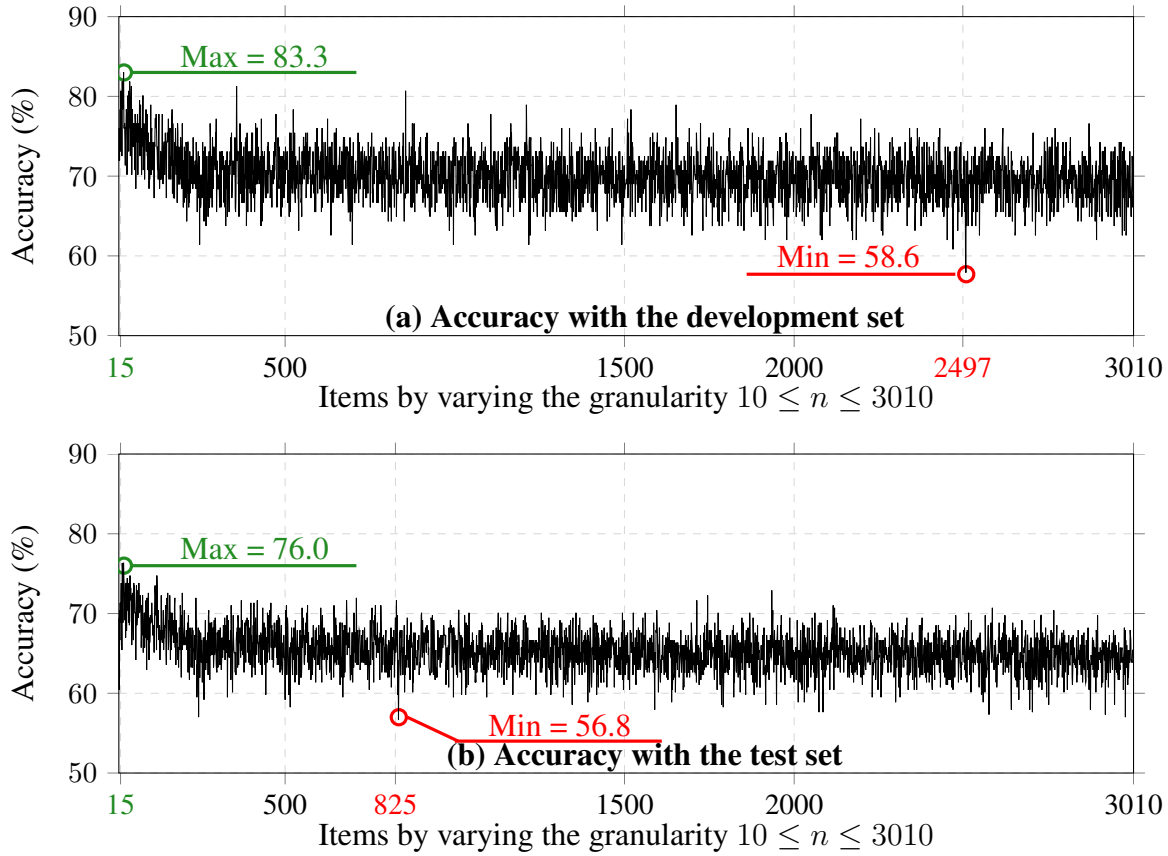

Figure 4: Theme classification accuracies using various topic-based representations with EFR normalization (baseline) on the development and test sets (X-coordinates start at 10 indeed, but to show the best configuration point (15), the origine (10) has been removed).

Table 1: Theme classification accuracy (%) with different c-vectors and GMM-UBM sizes.

	DEV				*TEST*			
c-vector size	**Number of Gaussians in GMM-UBM**							
	32	*64*	*128*	*256*	*32*	*64*	*128*	*256*
60	88.8	*86.5*	91.2	90.6	85.0	*82.6*	83.5	84.7
100	91.2	**92.4**	92.4	87.7	86.0	**85.0**	83.5	84.7
120	89.5	92.2	89.5	87.7	85.0	83.5	85.4	84.1

Table 2: Maximum (Max), minimum (Min) and Difference ($Max - Min$) theme classification accuracies (%) using the baseline and the proposed c-vector approaches.

	Max		**Min**		**Difference**	
Method	*DEV*	*TEST*	*DEV*	*TEST*	*DEV*	*TEST*
baseline	83.3	76.0	58.6	56.8	14.7	20.8
c-vector	**92.4**	**85.0**	86.5	82.6	5.9	2.4

and test sets, the gap between accuracies is much smaller: classification accuracy does not go below 82.6%, while it reached 56% for the worst topic-based configuration. Indeed, as shown in Table 2, the difference between the maximum and the minimum theme classification accuracies is of 20% using the baseline approach while it is only of 2.4% using the c-vector method.

We can conclude that this original c-vector approach allows one to better handle the variabilities

contained in dialogue conversations: in a classification context, better accuracy can be obtained and the results can be more consistent when varying the c-vector size and the number of Gaussians.

7 Conclusions

This paper presents an original multi-view representation of automatic speech dialogue transcriptions, and a fusion process with the use of a factor analysis method called i-vector. The first step of the proposed method is to represent a dialogue in multiple topic spaces of different sizes (*i.e.* number of topics). Then, a compact representation of the dialogue from the multiple views is processed to compensate the vocabulary and the variability of the topic-based representations. The effectiveness of the proposed approach is evaluated in a classification task of theme dialogue identification. Thus, the architecture of the system identifies conversation themes using the i-vector approach. This compact representation was initially developed for speaker recognition and we showed that it can be successfully applied to a text classification task. Indeed, this solution allowed the system to obtain better classification accuracy than with the use of the classical best topic space configuration. In fact, we highlighted that this original compact version of all topic-based representations of dialogues, called c-vector in this work, coupled with the EFR normalization algorithm, is a better solution to deal with dialogue variabilities (high word error rates, bad acoustic conditions, unusual word vocabulary, etc). This promising compact representation allows us to effectively solve both the difficult choice of the right number of topics and the multi-theme representation issue of particular textual documents. Finally, the classification accuracy reached 85% with a gain of 9 points compared to usual baseline (best topic space configuration). In a future work, we plan to evaluate this new representation of textual documents in other information retrieval tasks, such as keyword extraction or automatic summarization systems.

Abstract

This paper introduces a model of multiple-instance learning applied to the prediction of aspect ratings or judgments of specific properties of an item from user-contributed texts such as product reviews. Each variable-length text is represented by several independent feature vectors; one word vector per sentence or paragraph. For learning from texts with known aspect ratings, the model performs multiple-instance regression (MIR) and assigns importance weights to each of the sentences or paragraphs of a text, uncovering their contribution to the aspect ratings. Next, the model is used to predict aspect ratings in previously unseen texts, demonstrating interpretability and explanatory power for its predictions. We evaluate the model on seven multi-aspect sentiment analysis data sets, improving over four MIR baselines and two strong bag-of-words linear models, namely SVR and Lasso, by more than 10% relative in terms of MSE.

1 Introduction

Sentiment analysis of texts provides a coarse-grained view of their overall attitude towards an item, either positive or negative. The recent abundance of user texts accompanied by real-valued labels e.g. on a 5-star scale has contributed to the development of automatic sentiment analysis of reviews of items such as movies, books, music or other products, with applications in social computing, user modeling, and recommender systems. The overall sentiment of a text towards an item often results from the ratings of several specific aspects of the item. For instance, the author of a review might have a rather positive sentiment about a movie, having particularly liked the plot and the music, but not too much the actors. Determining the ratings of each aspect automatically is a challenging task, which may seem to require the engineering of a large number of features designed to capture each aspect. Our goal is to put forward a new feature-agnostic solution for analyzing aspect-related ratings expressed in a text, thus aiming for a finer-grained, deeper analysis of text meaning than overall sentiment analysis.

Current state-of-the-art approaches to sentiment analysis and aspect-based sentiment analysis, attempt to go beyond word-level features either by using higher-level linguistic features such as POS tagging, parsing, and knowledge infusion, or by learning features that capture syntactic and semantic dependencies between words. Once an appropriate feature space is found, the ratings are typically modeled using a linear model, such as Support Vector Regression (SVR) with ℓ_2 norm for regularization or Lasso Regression with ℓ_1 norm. By treating a text globally, these models ignore the fact that the sentences of a text have diverse contributions to the overall sentiment or to the attitude towards a specific aspect of an item.

In this paper, we propose a new learning model which answers the following question: "To what extent does each part of a text contribute to the prediction of its overall sentiment or the rating of a particular aspect?" The model uses multiple-instance regression (MIR), based on the assumption that not all the parts of a text have the same contribution to the prediction of the rating. Specifically, a text is seen as a bag of sentences (instances), each of them modeled as a word vector. The overall challenge is to learn which sentences refer to a given aspect, and how they contribute to the text's attitude towards it, but the model applies to overall sentiment analysis as well. For instance, Figure 1 displays a positive global comment on a TED talk and the weights assigned to two of its sentences by MIR.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 455–466,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

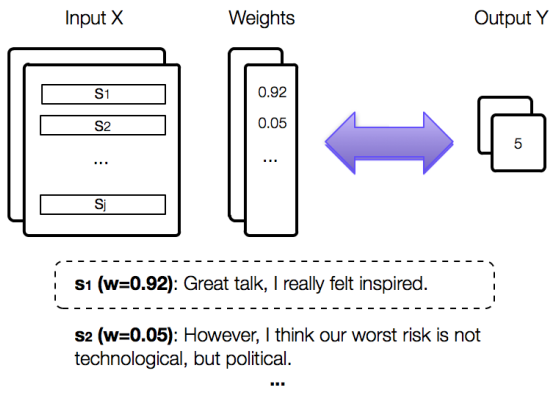

Figure 1: Analysis of a comment (bag of sentences $\{s_1, ..., s_j\}$) annotated by humans with the maximal positive sentiment score (5 stars). The weights assigned by MIR reveal that s_1 has the greatest relevance to the overall sentiment.

Using regularized least squares, we formulate an optimization objective to jointly assign instance weights and regression hyperplane weights. Then, an instance relevance estimation method is used to predict aspect ratings, or global ones, in previously unseen texts. The parameters of the model are learned using an alternating optimization procedure inspired by Wagstaff and Lane (2007). Our model requires only text with ratings for training, with no particular assumption on the word features to be extracted, and provides interpretable explanations of the predicted ratings through the relevance weights assigned to sentences. We also show that the model has reasonable computational demands. The model is evaluated on aspect and sentiment rating prediction over seven datasets: five of them contain reviews with aspect labels about beers, audiobooks and toys (McAuley et al., 2012), and two contain TED talks with emotion labels, and comments on them with sentiment labels (Pappas and Popescu-Belis, 2013). Our model outperforms previous MIR models and two strong linear models for rating prediction, namely SVR and Lasso by more than 10% relative in terms of MSE. The improvement is observed even when the sophistication of the feature space increases.

The paper is organized as follows. Section 2 shows how our model innovates with respect to previous work on MIR and rating prediction. Section 3 formulates the problem while Section 4 describes previous MIR models. Section 5 presents our MIR model and learning procedure. Section 6 presents the datasets and evaluation methods. Section 7 reports our results on rating prediction tasks, and provides examples of rating explanation.

2 Related Work

2.1 Multiple-Instance Regression

Multiple-instance regression (MIR) belongs to the class of multiple-instance learning (MIL) problems for real-valued output, and it is a variant of multiple regression where each data point may be described by more than one vectors of values. Many MIL studies focused on classification (Andrews et al., 2003; Bunescu and Mooney, 2007; Settles et al., 2008; Foulds and Frank, 2010; Wang et al., 2011) while fewer focused on regression (Ray and Page, 2001; Davis and others, 2007; Wagstaff et al., 2008; Wagstaff and Lane, 2007). Related to document analysis, several MIR studies have focused on news categorization (Zhang and Zhou, 2008; Zhou et al., 2009) or web-index recommendation (Zhou et al., 2005) but, to our knowledge, no study has attempted to use MIR for aspect rating prediction or sentiment analysis with real-valued labels.

MIR was firstly introduced by Ray et al. (2001), proposing an EM algorithm which assumes that one primary instance per bag is responsible for its label. Wagstaff and Lane (2007) proposed to simultaneously learn a regression model and estimate instance weights per bag for crop yield modeling (not applicable to prediction). A similar method which learns the internal structure of bags using clustering was proposed by Wagstaff et al. (2008) for crop yield prediction, and we will use it for comparison in the present study. Later, the method was adapted to map bags into a single-instance feature space by Zhang et al. (2009). Wang et al. (2008) assumed that each bag is generated by random noise around a primary instance, while Wang et al. (2012) represented bag labels with a probabilistic mixture model. Foulds et al. (2010) concluded that various assumptions are differently suited to different tasks, and should be stated clearly when describing an MIR model.

2.2 Rating Prediction from Text

Sentiment analysis aims at analyzing the polarity of a given text, either with classification (for discrete labels) or regression (for real-valued labels). Early studies introduced machine learning techniques for sentiment classification, e.g. Pang et al. (2002), including unsupervised techniques based on the notion of semantic orientation of phrases, e.g. Turney et al. (2002). Other studies focused on subjectivity detection, i.e. whether a

text span expresses opinions or not (Wiebe et al., 2004). Rating inference was defined by Pang et al. (2005) as multi-class classification or regression with respect to rating scales. Pang and Lee (2008) discusses the large range of features engineered for this task, though several recent studies focus on feature learning (Maas et al., 2011; Socher et al., 2011), including the use of a deep neural network (Socher et al., 2013). In contrast, we do not make any assumption about the nature or dimensionality of the feature space.

The fine-grained analysis of opinions regarding specific aspects or features of items is known as *multi-aspect sentiment analysis*. This task usually requires aspect-related text segmentation, followed by prediction or summarization (Hu and Liu, 2004; Zhuang et al., 2006). Most attempts to perform this task have engineered various feature sets, augmenting words with topic or content models (Mei et al., 2007; Titov and McDonald, 2008; Sauper et al., 2010; Lu et al., 2011), or with linguistic features (Pang and Lee, 2005; Baccianella et al., 2009; Qu et al., 2010; Zhu et al., 2012). Other studies have advocated joint modeling of multiple aspects (Snyder and Barzilay, 2007) or multiple reviews for the same product (Li et al., 2011). McAuley et al. (2012) introduced new corpora of multi-aspect reviews, which we also partly use here, and proposed models for aspect detection, sentiment summarization and rating prediction. Lastly, joint aspect identification and sentiment classification have been used for aggregating product review snippets by Sauper at al. (2013). None of the above studies considers the multiple-instance property of text in their modeling.

3 MIR Definition

Let us consider a set B of m bags with numerical labels Y as input data $D = \{(\{b_{1j}\}_{n_1}^d, y_1), ..., (\{b_{mj}\}_{n_m}^d, y_m)\}$, where $b_{ij} \in \mathbb{R}^d$ (for $1 \leq j \leq n_i$) and $y_i \in \mathbb{R}$. Each bag B_i consists of n_i data points (called 'instances'), hence it is a matrix of n_i d-dimensional vectors, e.g. word vectors. The challenge is to infer the label of the bag given a variable number of instances n_i. This requires finding a set of bag representations $X = \{x_1, \ldots, x_m\}$ of size m where $x_i \in \mathbb{R}^d$, from which the class labels can be computed. The goal is then to find a mapping from this representation, noted $\Phi : \mathbb{R}^d \rightarrow \mathbb{R}$, which is able to predict the label of a given bag. Ideally, assuming that X is the best bag representation for our task, we look for the optimal regression hyperplane Φ which minimizes a loss function $\mathcal{L}$ plus a regularization term Ω as follows:

$$\Phi = \underset{\Phi}{arg\,min} \left(\underbrace{\mathcal{L}(Y, X, \Phi)}_{\text{loss}} + \underbrace{\Omega(\Phi)}_{\text{reg.}} \right) \quad (1)$$

Since the best set of representations X for a task is generally unknown, one has to make assumptions to define it or compute it jointly with the regression hyperplane Φ. Thus, the main difficulty lies in finding a good assumption for X, as we will now discuss.

4 Previous MIR Assumptions

We describe here three assumptions frequently made in past MIR studies, to which we will later compare our model: aggregating all instances, keeping them as separate examples, or choosing the most representative one (Wang et al., 2012). For each assumption, we will experiment with two state-of-the-art regression models (noted abstractly as f), namely SVR (Drucker et al., 1996) and Lasso (Tibshirani, 1996) with respectively the ℓ_2 and ℓ_1 norms for regularization.

The *Aggregated* algorithm assumes that each bag is represented as a single d-dimensional vector, which is the average of its instances (hence $x_i \in \mathbb{R}^d$). Then, a regression model f is trained on pairs of vectors and class labels, $D_{agg} = \{(x_i, y_i) \mid i = 1, \ldots, m\}$, and the predicted class of an unlabeled bag $B_i = \{b_{ij} \mid j = 1, \ldots, n_i\}$ is computed as follows:

$$\hat{y}(B_i) = f(mean(\{b_{ij} \mid j = 1, \ldots, n_i\})) \quad (2)$$

In fact, a simple sum can also be used instead of the mean, and we observed in practice that with an appropriate regularization there is no difference on the prediction performance between these options. This baseline corresponds to the typical approach for text regression tasks, where each text sample is represented by a single vector in the feature space (e.g. BOW with counts or TF-IDF weights).

The *Instance* algorithm considers each of the instances in a bag as separate examples, by labeling each of them with the bag's label. A regression model f is learned over the training set made of all vectors of all bags, $D_{ins} = \{(b_{ij}, y_i) \mid j = 1, \ldots, n_i; i = 1, \ldots, m\}$, assuming that there are m labeled bags. To label a new bag B_i, given that

there is no representation x_i, the method simply averages the predicted labels of its instances:

$$\hat{y}(B_i) = mean(\{f(b_{ij}) \mid j = 1, \ldots, n_i\}) \quad (3)$$

Instead of the average, the median value can also be used, which is more appropriate when the bags contain outlying instances.

The *Prime* algorithm assumes that a single instance in each bag is responsible for its label (Ray and Page, 2001). This instance is called the primary or prime one. The method is similar to the previous one, except that only one instance per bag is used as training data: $D_{pri} = \{(b_i^p, y_i) \mid i = 1, \ldots, m\}$, where b_i^p is the prime instance of the i^{th} bag B_i and m is the number of bags. The prime instances are discovered through an iterative algorithm which refines the regression model f. Given an initial model f, in each iteration the algorithm selects from each bag a prime candidate which is the instance with the lowest prediction error. Then, a new model is trained over the selected prime candidates, until convergence. For a new bag, the target class is computed as in Eq. 3.

5 Proposed MIR Model

We propose a new MIR model which assigns individual relevance values (weights) to each instance of a bag, thus making fewer simplifying assumptions than previous models. We extend instance-relevance algorithms such as (Wagstaff and Lane, 2007) by supporting high-dimensional feature spaces, as required for text regression, and by predicting both the class label and the content structure of previously unseen (hence unlabeled) bags. The former is achieved by minimizing a regularized least squares loss (RLS) instead of solving normal equations, which is prohibitive in large spaces. The latter represents a significant improvement over *Aggregated* and *Instance* algorithms, which are unable to pinpoint the most relevant instances with respect to the label of each bag, being thus applicable only to bag label prediction. Similarly, *Prime* only identifies the prime instance when the bag is already labeled. Instead, our model learns an optimal method to aggregate instances, rather than a pre-defined one, and allows more degrees of freedom in the regression model than previous ones. Moreover, the weight of an instance is interpreted as its relevance both in training and prediction.

5.1 Instance Relevance Assumption

Each bag defines a bounded region of a hyperplane orthogonal to the y-axis (the envelope of all its points). The goal is to find a regression hyperplane that passes through each bag B_i and to predict its label by using at least one data point x_i within that bounded region. Thus, the point x_i is a convex combination of the points in the bag, in other words B_i is represented by the weighted average of its instances b_{ij}:

$$x_i = \sum_{j=1}^{n_i} \psi_{ij} b_{ij}, \psi_{ij} \geq 0 \text{ and } \sum_{j=1}^{n_i} \psi_{ij} = 1 \quad (4)$$

where ψ_{ij} is the weight of the j^{th} instance of the i^{th} bag. Each weight ψ_{ij} indicates the relevance of an instance j to the prediction of the class y_i of the i^{th} bag. The constraint forces x_i to fall within the bounded region of the points in bag i and guarantees that the i^{th} bag will influence the regressor.

5.2 Modeling Bag Structure and Labels

Let us consider a set of m bags, where each bag B_i is represented by its n_i d-dimensional instances, i.e. $B_i = \{b_{ij}\}_{n_i}^d$ along with the set of target class labels for each bag, $Y = \{y_i\}_N, y_i \in \mathbb{R}$. The representation set of all B_i in the feature space, $X = \{x_1, \ldots, x_m\}, x_i \in \mathbb{R}^d$, is obtained using the n_i instance weights associated to each bag B_i, $\psi_i = \{\psi_{ij}\}_{n_i}$, $\psi_{ij} \in [0, 1]$ which are initially unknown. Thus, we look for a linear regression model f that is able to model the target values using the regression coefficients $\Phi \in \mathbb{R}^d$, where X and Y are respectively the sets of training bags and their labels: $Y = f(X) = \Phi^T X$. We define a loss function according to the least squares objective dependent on X, Y, Φ and the set of weight vectors $\Psi = \{\psi_1, \ldots, \psi_m\}$ using Eq. 4 as follows:

$$\begin{aligned}\mathcal{L}(Y, X, \Psi, \Phi) &= ||Y - \Phi^T X||_2^2 \\ &\overset{(4)}{=} \sum_{i=1}^{N} \Big(y_i - \Phi^T \big(\sum_{j=1}^{n_i} \psi_{ij} b_{ij}\big)\Big)^2 \\ &= \sum_{i=1}^{N} \Big(y_i - \Phi^T (B_i \psi_i)\Big)^2 \end{aligned} \quad (5)$$

Using the above loss function, accounting for the constraints of our assumption in Eq. 4 and assuming ℓ_2-norm for regularization with ϵ_1 and ϵ_2 terms for each $\psi_i \in \Psi$ and Φ respectively, we obtain the

following least squares objective from Eq. 1:

$$\underset{\psi_1,\ldots,\psi_m,\Phi}{arg\,min} \underbrace{\sum_{i=1}^{m}\Big(\underbrace{\Delta_i^2}_{f_1 \text{ loss}} + \underbrace{\epsilon_1||\psi_i||}_{f_1 \text{ reg.}}\Big)}_{f_2 \text{ loss}} + \underbrace{\epsilon_2||\Phi||^2}_{f_2 \text{ reg.}}$$

$$\text{where } \Delta_i^2 = \Big(y_i - \Phi^T(B_i\psi_i)\Big)^2, \qquad (6)$$

subject to $\psi_{ij} \geq 0\ \forall i,j$ and $\sum_{j=1}^{n_i}\psi_{ij} = 1\ \forall i$. The selection of the ℓ_2-norm was based on preliminary results showing that it outperforms ℓ_1-norm. Other combinations of p-norm regularization can be explored for f_1 and f_2, e.g. to learn sparser instance weights and denser regression coefficients or vice versa.

The above objective is non-convex and difficult to optimize because the minimization is with respect to all $\psi_1,\ldots,\psi_m$ and Φ at the same time. As indicated in Eq. 6 above, we will note f_1 a model that is learned from the minimization only with respect to $\psi_1,\ldots,\psi_m$ and f_2 a model obtained from the minimization with respect to Φ only. In Eq. 6, we can observe that if one of the two is known or held fixed, then the other one is convex and can be learned with the well-known least squares solving techniques. In Section 5.3, we will describe an algorithm that is able to exploit this observation.

Having computed $\psi_1,\ldots,\psi_m$ and Φ, we could predict a label for an unlabeled bag using Eq. 3, but would not be able to compute the weights of the instances. Moreover, information that has been learned about the instances during the training phase would not be used during prediction. For these reasons, we introduce a third regression model f_3 with regression coefficients $O \in \mathbb{R}^d$ assuming a ℓ_2-norm for the regularization with ϵ_3 term, which is trained on the relevance weights obtained from the Eq. 6, $D_w = \{(b_{ij},\psi_{ij}) \mid i = 1,...,m; j = 1,...,n_i\}$. The optimization objective for the f_3 model is the following:

$$\underset{O}{arg\,min} \underbrace{\sum_{i=1}^{N}\sum_{j=1}^{n_i}\big(\psi_{ij} - O^T b_{ij}\big)^2}_{f_3 \text{ loss function}} + \underbrace{\epsilon_3||O||^2}_{f_3 \text{ reg.}} \qquad (7)$$

This minimization can be easily performed with the well-known least squares solving techniques. The learned model is able to estimate the weights of the instances of an unlabeled bag during prediction time as: $\hat{\psi}_i = f_3(B_i) = \Omega^T B_i$. The $\hat{\psi}_i$ weights are estimations which are influenced by the relevance weights learned in our minimization objective of Eq. 6 but they are not constrained at prediction time. To obtain interpretable weights, we can convert the estimated scores to the $[0,1]$ interval as follows: $\hat{\psi}_i = \hat{\psi}_i / sum(\hat{\psi}_i)$. Finally, the prediction of the label for the i^{th} bag using the estimated instance weights $\hat{\psi}_i$ is done as follows:

$$\hat{y} = f_2(B_i) = \Phi^T B_i \hat{\psi}_i \qquad (8)$$

5.3 Learning with Alternating Projections

Algorithm 1 solves the non-convex optimization problem of Eq. 6 by using a powerful class of methods for finding the intersection of convex sets, namely alternating projections (AP). The problem is firstly divided into two convex problems, namely f_1 loss function and f_2 loss function, which are then solved in an alternating fashion. Like EM algorithms, AP algorithms do not have general guarantees on their convergence rate, although, in practice, we found it acceptable at generally fewer than 20 iterations.

Algorithm 1 APWeights(B, Y, ϵ_1, ϵ_2, ϵ_3)

```
Initialize(ψ_1, ..., ψ_N, Φ, X)
while not converged do
    for B_i in B do
        ψ_i = cRLS(Φ^T Bi, Y_i, ε_1) # f_1 model
        x_i = B_i ψ_i^T
    end for
    Φ = RLS(X, Y, ε_2) # f_2 model
end while
Ω = RLS({b_ij ∀i,j}, {ψ_ij ∀i,j}, ε_3) # f_3 model
```

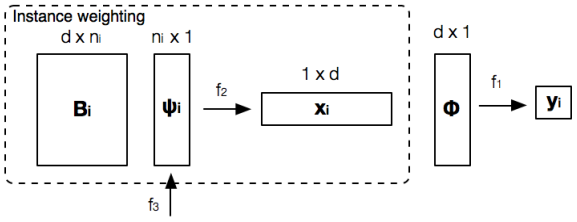

Figure 2: Visual representation for the training and testing procedure of Algorithm 1.

The algorithm takes as input the bags B_i, their target class labels Y and the regularization terms $\epsilon_1, \epsilon_2, \epsilon_3$ and proceeds as follows. First, under a fixed regression model (f_2), it proceeds with f_1 to the optimal assignment of weights to the instances of each bag (projection of Φ vectors on the ψ_i space which is a n_i-simplex) and computes its new representation set X. Second, given the fixed instance weights, it trains a new regression model (f_2) using X (projection back to the Φ

Table 1: Description of the seven datasets used for aspect, sentiment and emotion rating prediction.

space). This procedure repeats until convergence, i.e. when there is no more decrease on the training error, or until a maximum number of iterations has been reached. The regression model f_3 is trained on the weights learned from the previous steps.

5.4 Complexity Analysis

The overall time complexity T of Algorithm 1 in terms of the input variables, noted $h = \{m, \hat{n}, d\}$, with m being the number of bags, $\hat{n}$ the average size of the bags, and d the dimensionality of the feature space (here, the size of word vectors), is derived as follows:

$$\begin{aligned} T(h) &= T_{ap}(h) + T_{f_3}(h) \\ &= \mathrm{O}\big(m(\hat{n}^2 + d^2)\big) + \mathrm{O}\big(m\hat{n}d^2\big) \\ &= \mathrm{O}\big(m(\hat{n}^2 + d^2 + \hat{n}d^2)\big), \end{aligned} \tag{9}$$

where T_{ap} and T_{f_3} are respectively the time complexity of the AP procedure and of training the f_3 model. Eq. 9 shows that when $\hat{n} \ll m$, the model complexity is linear with the input bags m and always quadratic with the number of features d.

Previous works on relevance assignment for MIR have prohibitive complexity for high-dimensional feature spaces or numerous bags and hence they are not most appropriate for text regression tasks. Wagstaff and Lane (2007) have cubic time complexity with the average bag size $\hat{n}$ and number of features d; Zhou et al. (2009) use kernels, thus their complexity is quadratic with the number of bags m; and Wang et al. (2011) have cubic time wrt. d. Our formulation is thus competitive in terms of complexity.

6 Data, Protocol and Metrics

6.1 Aspect Rating Datasets

We use seven datasets summarized in Table 1. Five publicly available datasets were built for aspect prediction by McAuley et al. (2012) – BeerAdvocate, Ratebeer (ES), RateBeer (FR), Audiobooks and Toys & Games – and have aspect ratings assigned by their creators on the respective websites. On the set of comments on TED talks from Pappas and Popescu-Belis (2013), we aim to predict two things: talk-level emotion dimensions assigned by viewers through voting, and comment polarity scores assigned by crowdsourcing. The distributions of aspect ratings per dataset are shown in Figure 3. Five datasets are in English, one in Spanish (Ratebeer) and one in French (RateBeer), so our results will also demonstrate the language-independence of our method.

From every dataset we kept 1,200 texts as bags of sentences, but we also used three *full-size* datasets, namely Ratebeer ES (1,259 labeled reviews), Ratebeer FR (17,998) and Audiobooks (10,989). The features for each of them are word vectors with binary attributes signaling word presence or absence, in a traditional bag-of-words model (BOW). The word vectors are provided with the first five datasets and we generated them for the latter two, after lowercasing and stopword removal. Moreover, for TED comments, we computed TF-IDF scores using the same dimensionality as with BOW to experiment with a different feature space. The target class labels were normalized by the maximum rating in their scale, except for TED talks where the votes were normalized by the maximum number of votes over all the emotion classes for each talk, and two emotions, 'informative' and 'ok', were excluded as they are neutral ones.

6.2 Evaluation Protocol

We compare the proposed model, noted *AP-Weights*, with four baseline ones – *Aggregated*, *Instance*, *Prime* (Section 4) and *Clus-*

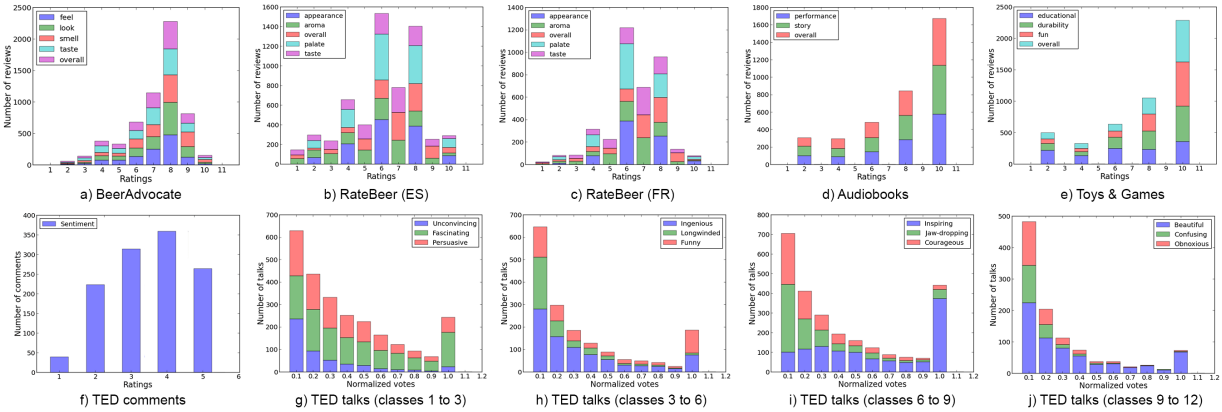

Figure 3: Distributions of rating values per aspect rating class for the seven datasets.

tering (from `github.com/garydoranjr/mcr`), which is an instance relevance method proposed by Wagstaff et al. (2008) for aspect rating prediction. First, for each aspect class, we optimize all methods on a development set of 25% of the data (300 randomly selected bags). Then, we perform 5-fold cross-validation for every aspect on each entire data set and report the average error scores using the optimal hyper-parameters per method. In addition, we report for comparison the scores of *AverageRating*, which always predicts the average rating over the training set.

We report standard error metrics for regression, namely the Mean Absolute Error (MAE) and the Mean Squared Error (MSE). The former measures the average magnitude of errors in a set of predictions while the latter measures the average of their squares, which are defined over the test set of bags B_i respectively as $\text{MAE} = (\sum_{i=1}^{k} |f(B_i) - y_i|)/k$ and $\text{MSE} = (\sum_{i=1}^{k} (f(B_i) - y_i)^2)/k$. The cross-validation scores are obtained by averaging the MAE and MSE scores on each fold.

To find the optimal hyper-parameters for each model, we perform 3-fold cross-validation on the development set using exhaustive grid-search over a fine-grained range of possible values and select the ones that perform best in terms of MAE. The hyper-parameters to be optimized for the baselines (except AverageRating) are the regularization terms λ_2, λ_1 of their possible regression model f, namely SVR which uses the ℓ_2 norm and Lasso which uses the ℓ_1 norm. As for APWeights, it relies on three regularization terms, namely $\epsilon_1, \epsilon_2, \epsilon_3$ of the ℓ_2-norm for f_1, f_2 and f_3 regression models. Lastly, for the Clustering baseline, we use the f_2 regression model, which relies on ϵ_2 and the number of clusters k, optimized over $\{5, ..., 50\}$ with step 5, for its clustering algorithm, here k-Means. All the regularization terms are optimized over the same range of possible values, noted $a \cdot 10^b$ with $a \in \{1, \ldots, 9\}$ and $b \in \{-4, \ldots, +4\}$, hence 81 values per term. For the regression models and evaluation protocol, we use the *scikit-learn* machine learning library (Pedregosa et al., 2012). Our code and data are available in the first author's website.

7 Experimental Results

7.1 Aspect Rating Prediction

The results for aspect rating prediction are given in Table 2. The proposed APWeights method outperforms Aggregated (ℓ_2) and Aggregated (ℓ_1) i.e. SVR and Lasso along with all other baselines on each case. The SVR baseline has on average 11% lower performance than APWeights in terms of MSE and about 6% in terms of MAE. Similarly, the Lasso baseline has on average 13% lower MSE and 8% MAE than APWeights. As shown in Figure 4, APWeights also outperforms them for each aspect in the five review datasets. The Instance method with ℓ_1 performed well on BeerAdvocate and Toys & Games (for MSE), and with ℓ_2 performed well on Ratebeer (ES), RateBeer (FR) and Toys & Games (for MAE). Therefore, the instance-as-example assumption is quite appropriate for this task, however both options score below APWeights – by about 5% MAE, and 8%/9% MSE, respectively. The Prime method with ℓ_1 performed well only on the BeerAdvocate dataset and Prime with ℓ_2 only on the Toys & Games dataset, always with lower scores than APWeights, namely about 9% MAE for both and 15%/18% MSE respectively. This suggests that the primary-instance

Table 2: Performance of aspect rating prediction (the lower the better) in terms of MAE and MSE ($\times$ 100) with 5-fold cross-validation. All scores are averaged over all aspects in each dataset. The scores of the best method are in **bold** and the second best ones are underlined. Significant improvements (paired t-test, $p < 0.05$) are in *italics*. Fig. 4 shows MSE scores per aspect for three methods on five datasets.

assumption is not the most appropriate for this task. Lastly, even though Clustering is an instance relevance method, it has similar scores to Prime, presumably because the relevances are assigned according to the computed clusters and they are not directly influenced by the task's objective.

To compare with the state-of-the-art results obtained by McAuley et al. (2012), we experimented with three of their *full-size* datasets. Splitting each dataset in half for training vs. testing, and using the optimal settings from our experiments above, we measured the average MSE over all aspects. APWeights improved over Lasso by 10%, 26% and 17% MSE respectively on each dataset – the absolute MSE scores are .038 for Lasso vs. .034 for APWeights on Ratebeer SP; .023 vs. .017 on Ratebeer FR; .063 vs. .052 on Audiobooks. Similarly, when compared to the best SVM baseline provided by the McAuley et al., our method improved by 32%, 43% and 35% respectively on each dataset, though it did not use their rating model. Moreover, the best model proposed by McAuley et al., which uses a joint rating model and an aspect-specific text segmenter trained on hand-labeled data, reaches MSE scores of .03, .02 and .03, which is comparable to our model that does not use these features (.034, .017, .052), though it could benefit from them in the future. Lastly, as mentioned by the same authors, predictors which use segmented text, for example with topic models as in (Lu et al., 2011), do not necessarly outperform SVR baselines; instead they have marginal or even no improvements, therefore, we did not further experiment with them. Interestingly, multiple-instance learning algorithms under several assumptions go beyond SVR baselines with BOW and even more sophisticated features such as TF-IDF (see below).

Table 3: MAE and MSE ($\times$ 100) on sentiment and emotion prediction with 5-fold c.-v. Scores on TED talks are averaged over the 12 emotions. The scores of the best method are in **bold** and the second best ones are underlined. Significant improvements (paired t-test, $p < 0.05$) are in *italics*.

7.2 Sentiment and Emotion Prediction

Our method is also competitive for sentiment prediction over comments on TED talks, as well as for talk-level emotion prediction with 12 dimensions from subsets of 10 comments on each talk (see Table 3). APWeights outperforms SVR and Lasso, as well as all other methods for each task. For sentiment prediction, SVR is outperformed by 11% MSE and Lasso by 5%. For emotion pre-

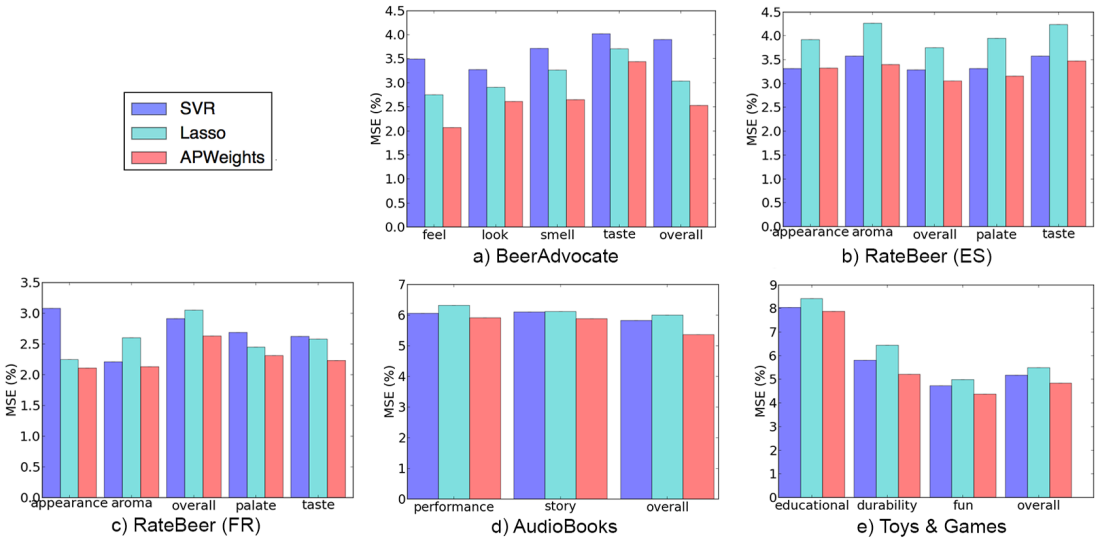

Figure 4: MSE scores of SVR, Lasso and APWeights for each aspect over the five review datasets.

diction (averaged over all 12 aspects), differences are smaller, at 1.6% and 2.9% respectively. These smaller differences could be explained by the fact that among the 10 most recent comments for each talk, many are not related to the emotion that the system tries to predict.

As mentioned earlier, the proposed model does not make any assumption about the feature space. Thus, we examined whether the improvements it brings remain present even with a different feature space, for instance based on TF-IDF instead of BOW with counts. For sentiment prediction on TED comments, we found that by changing the feature space to TF-IDF, strong baselines such as Aggregated (ℓ_1) and (ℓ_2), i.e. SVR and Lasso, improve their performance (16.25 and 16.59 MAE; 4.16 and 3.97 MSE respectively). However, APWeights still outperforms them on both MAE and MSE scores (15.35 and 3.63), improving over SVR by 5.5% on MAE and 12.5% on MSE, and over Lasso by 7.4% on MAE and 8.5% on MSE. These promising results suggest that improvements with APWeights could be observed also on more sophisticated feature spaces.

7.3 Interpreting the Relevance Weights

Apart from predicting ratings, the MIR scores assigned by our model reflect the contribution of each sentence to these predictions.

To illustrate the explanatory power of our model (until a dataset for quantitative analysis becomes available), we provide examples of predictions on test data taken from the cross-validation folds above. Table 5 displays the most relevant comment for two correctly predicted emotions on two TED talks, based on the $\hat{\psi}_i$ relevance scores, along with the $\hat{\psi}_i$ scores of the other comments, for two emotion classes: 'beautiful' and 'courageous'. These comments appear to reflect correctly the fact that the respective emotion is the majority one in each of the comments. As noted earlier, this task is quite challenging since we use only the ten most recent comments for each talk.

Table 4 displays four TED comments selected

Sentences per comment	$\hat{\psi}_i$	$\hat{y}_i$	y_i
"Very brilliant and witty, as well as great improvisation."	0.64	5.0	5.0
"I enjoyed this one a lot."	0.36		
"That's great idea, I really like it!"	0.56	4.2	4.0
"I can't wait to try it, but first thing, I need a house with big windows, next year, maybe I can do that."	0.44		
"Unfortunately countries are not led by gifted children."	0.48	2.4	2.0
"They are either dictated by the most extreme personalities who crave nothing but power or managed by politicians who are voted in by a far from gifted population."	0.52		
"I am very disappointed by this, smug, cliched and missing so much information as to be almost (...)"'	0.43	1.8	1.0
"No mention of ship transport lets say 50% of all material transport, no mention of rail transport, (...)"	0.29		
"I am sorry to be so negative, this just sounds like a sales pitch that he has given too many times (...)."	0.28		

Table 4: Predicted sentiment for TED comments: y_i is the actual sentiment, $\hat{y}_i$ the predicted one, and $\hat{\psi}_i$ the estimated relevance of each sentence.

Class	Top comment per talk (according to weights ψ_i)	$\hat{\psi}_i$ distribution
inspiring	"It seems to me that the idea worth spreading of this TED Talk is inspiring and key for a full life. 'No-one else is the authority on your potential. You're the only person that decides how far you go and what you're capable of.' It seems to me that teens actually think that. As a child one is all knowing and all capable. How did we get to the (...)"	beautiful	"The beauty of the nature. It would be more interesting just integrates his thought and idea into a mobile device, like a mobile, so we can just turn on the nature gallery in any time. The paintings don't look incidental but genuinely thought out, random perhaps, but with a clear grand design behind the randomness. Drawing is an art where it doesn't (...)"	funny	"Funny story, but not as funny as a good 'knock, knock' joke. My favorite knock-knock joke of all time is Cheech & Chong's 'Dave's Not Here' gag from the early 1970s. I'm still waiting for someone to top it after all these years. [Knock, knock] 'Who is it?' the voice of an obviously stoned male answers from the other side of a door, (...)"	courageous	"I was a soldier in Iraq and part of the unit represented in this documentary. I would question anyone that told you we went over there to kill Iraqi people. I spent the better part of my time in Iraq protecting the Iraqi people from insurgents who came from countries outside of Iraq to kill Iraqi people. We protected families men, women, and (...)"	
Table 5: Two examples of top comments (according to weights ψ_i) for correctly predicted emotions in four TED talks (score 1.0) and the distribution of weights over the 10 most recent comments in each talk.

Figure 5: Top words based on Φ for predicting four emotions from comments on TED talks.

from the test set of a given fold, for the comment-level sentiment prediction task. The table also shows the $\hat{\psi}_i$ relevance scores assigned to each of the composing sentences, the predicted polarity scores $\hat{y}_i$ and the actual ones y_i. We observe that the sentences that convey the most sentiment are assigned higher scores than sentences with less sentiment, always with respect to the global polarity level. These examples suggest that, given that APWeights has more degrees of freedom for interpretation, it is able to assign relevance to parts of a text (here, sentences) and even to words, while other models can only consider words. Hence, the assigned weights might be useful for other NLP tasks mentioned below.

8 Conclusion and Future Work

This paper introduced a novel MIR model for aspect rating prediction from text, which learns instance relevance together with target labels. To the best of our knowledge, this has not been considered before. Compared to previous work on MIR, the proposed model is competitive and more efficient in terms of complexity. Moreover, it is not only able to assign instance relevances on labeled bags, but also to predict them on unseen bags.

Compared to previous work on aspect rating prediction, our model performs significantly better than BOW regression baselines (SVR, Lasso) without using additional knowledge or features. The improvements persist even when the sophistication of the features increases, suggesting that our contribution may be orthogonal to feature engineering or learning. Lastly, the qualitative evaluation on test examples demonstrates that the parameters learned by the model are not only useful for prediction, but they are also interpretable.

In the future, we intend to test our model on sentiment classification at the sentence-level, based only on document-level supervision (Täckström and McDonald, 2011). Moreover, we will experiment with other model settings, such as regularization norms other than ℓ_2 and feature spaces other than BOW or TF-IDF. In the longer term, we plan to investigate new methods to estimate instance weights at prediction time, and to evaluate the impact of assigned weights on sentence ranking, segmentation or summarization.
