Abstract

We propose a semi-supervised bootstrapping algorithm for analyzing China's foreign relations from the People's Daily. Our approach addresses sentiment target clustering, subjective lexicons extraction and sentiment prediction in a unified framework. Different from existing algorithms in the literature, time information is considered in our algorithm through a hierarchical bayesian model to guide the bootstrapping approach. We are hopeful that our approach can facilitate quantitative political analysis conducted by social scientists and politicians.

1 Introduction

"We have no permanent allies, no permanent friends, but only permanent interests."

-Lord Palmerston

Newspapers, especially those owned by official governments, e.g., *Pravda* from Soviet Union, or *People's Daily* from P.R. China, usually provide direct information about policies and viewpoints of government. As national policies change over time, the tone that newspapers adopt, especially sentiment, changes along with the policies. For example, there is a stark contrast between the American newspapers' attitudes towards Afghanistan before and after 911. Similarly, consider the following examples extracted from the People's Daily[1]:

- People' Daily, Aug 29th, 1963
  All those who are being oppressed and exploited, Unite !! Beat US Imperialism and its lackeys.
- People's Daily, Oct, 20th, 2002
  A healthy, steady and developmental relationship between China and US, conforms to the fundamental interests of people in both countries, and the trend of historical development.

[1]Due to the space constraints, we only show the translated version in most of this paper.

Automatic opinion extraction from newspapers such as people's daily can facilitate sociologists 'or political scientists' research or help political pundits in their decision making process. While our approach applies to any newspaper in principle, we focus here on the People's Daily[2] (Renmin Ribao), a daily official newspaper in the People's Republic of China.

While massive number of works have been introduced in sentiment analysis or opinion target extraction literature (for details, see Section 2), a few challenges limit previous efforts in this specific task: First, the heavy use of linguistic phenomenon in the People's Daily including rhetoric, metaphor, proverb, or even nicknames, makes existing approaches less effective for sentiment inference as identifying these expressions is a hard NLP problem in nature.

Second, as we are more interested in the degree of sentiment rather than binary classification (i.e., positive versus negative) towards an entity (e.g. country or individual) in the news article, straightforward algorithms to apply would be document-level sentiment analysis approaches such as vector machine/regression (Pang et al., 2002) or supervised LDA (Blei and McAuliffe, 2010). A single news article, usually contains different attitudes towards multiple countries or individuals simultaneously (say praising "friends" and criticizing "enemies"), as shown in the following example from the People's Daily of Mar. 17th, 1966:

US imperialism set up a puppet regime in Vietnam and sent expeditionary force... People of Vietnam prevailed over the modern-equipped US troops with a vengeance... The result of Johnson Government's intensifying invasion is that.... There will be the day, when people from all over the world execute the heinous US imperialism by hanging on a gibbet.... The heroic people of Vietnam, obtained great victory in the struggle against the USA imperialism...

The switching of praising of Vietnam and criticizing of the USA would make aforemen-

October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

tioned document-level machine learning algorithms based on bags of words significantly less effective if not separating attitudes towards Vietnam from toward the USA in the first place. Meanwhile, the separating task is by no means trivial in news articles. While *US imperialism, US troops, Johnson Government, invaders, Ngo Dinh Diem*[3] all point to the USA or its allies, *People of Vietnam, the Workers' party*[4]*, Ho Chi Minh*[5]*, Vietnam People's Army* point to North Vietnam side. Clustering entities according to sentiment, especially in Chinese, is fundamentally a difficult task. And our goal, trying to identify entities towards whom an article holds the same attitudes, is different from standard coreference resolution, since for us the co-referent group may include several distinct entities.

To address the aforementioned problems, in this paper, we propose a sentiment analysis approach based on the following assumptions:

1. *In a single news article, sentiment towards an entity is consistent.*
2. *Over a certain period of time, sentiments towards an entity are inter-related.*

The assumptions will facilitate opinion analysis: (1) if we can identify the attitude towards an entity (e.g., Vietnam) in a news article as positive, then negative attitudes expressed in the article are about other entities. (2) The assumption enables sentiment inference for unseen words in a bootstrapping way without having to employ sophisticated NLP algorithms. For example, from 1950s to 1960s, USA is usually referred to as "a tiger made of paper" in translated version. It is a metaphor indicating things that appear powerful (tiger) but weak in nature (made of paper). If it is first identified that during the designated time period, China held a pretty negative attitude towards the USA based on clues such as common negative expressions (e.g., "evil" or "reactionary"), we can easily induce that "a tiger made of paper", is a negative word.

Based on aforementioned two assumptions, we formulate our approach as a semi-supervised model, which simultaneously bootstrap sentiment target lists, extracts subjective vocabularies and performs sentiment analysis. Time information is considered through a hierarchical bayesian model to guide time-, document-, sentence- and term-level sentiment inference. A small seed set of subjective words constitutes our only source of supervision.

The main contributions of this paper can be summarized as follows:

1. We propose a semi-supervised bootstrapping algorithm tailored for sentiment analysis in the People's daily where time information is incorporated. We are hopeful that sentiment cues can shed insights on other NLP tasks such as coreference or metaphor recognition.

2. In Analytical Political Science, the quantitative evaluation of diplomatic relations is usually a manual task (Robinson and Shambaugh, 1995). We are hopeful that our algorithm can enable automated political analysis and facilitate political scientists' and historians' work.

2 Related Works

Significant research efforts have been invested into sentiment analysis and opinion extraction. In one direction, researchers look into predicting overall sentiment polarity at document-level (Pang and Lee, 2008), aspect-level (Wang et al., 2010; Jo and Oh, 2011), sentence-level (Yang and Cardie, 2014) or tweet-level (Agarwal et al., 2011; Go et al., 2009), which can be treated as a classification/regression problem by employing standard machine-learning techniques, such as Naive Bayesian, SVM (Pang et al., 2002) or supervised-LDA (Blei and McAuliffe, 2010) with different types of features (i.e., unigram, bigram, POS).

Other efforts are focused on targeted sentiment extraction (Choi et al., 2006; Kim and Hovy, 2006; Jin et al., 2009; Kim and Hovy, 2006). Usually, sequence labeling models such as CRF (Lafferty et al., 2001) or HMM (LIU et al., 2004) are employed for identifying opinion holders (Choi et al., 2005), topics of opinions (Stoyanov and Cardie, 2008) or opinion expressions (e.g. (Breck et al., 2007; Johansson and Moschitti, 2010; Yang and Cardie, 2012)). Kim and Hovy (2004; 2006) identified opinion holders and targets by exploring their semantics rules related to the opinion words. Choi et al. (2006) jointly extracted opinion expressions, holders and their *is-from* relations using an ILP approach. Yang and Cardie (2013) introduced a sequence tagging model based on CRF to jointly identify opinion holders, opinion targets, and expressions.

Methods that relate to our approach include semi-supervised approaches such as pipeline or

[3]Leader of South Vietnam

[4]Ruling political party of Vietnam.

[5]One of Founders of Democratic Republic of Vietnam (North Vietnam) and Vietnam Workers' party.

propagation algorithms (Qiu et al., 2011; Qiu et al., 2009; Zhang et al., 2010; Duyu et al., 2013). Concretely, Qiu et al. (2011) proposed a rule-based semi-supervised framework called *double propagation* for jointly extracting opinion words and targets. Compared to existing bootstrapping approaches, our framework is more general one with less restrictions[6]. In addition, our approach harness global information (e.g. document-level, time-level) to guide the bootstrapping algorithm. Another related work is the approach introduced by O'Connor et al. (O'Connor et al., 2013) that extracts international relations from political contexts.

3 the People's Daily

The People's Daily[7] (Renmin Ribao), established on 15 June 1946, is a daily official newspaper in the People's Republic of China, with a approximate circulation of 2.5 million worldwide. It is widely recognized as the mouthpiece of the Central Committee of the Communist Party of China (CPC) (Wu, 1994). Editorials and commentaries are usually regarded both by foreign observers and Chinese readers as authoritative statements of government policy[8]. According to incomplete statistics, there have benn at least 13 major redesigns (face-liftings) for the People's Daily in history, the most recent in 2013.

4 Model

In this section, we present our model in detail.

4.1 Target and Expression extraction

We first extract *expressions* (attitude or sentiment related terms or phrases) and *target* (entities toward whom the opinion holder (e.g., the People's Daily) holds an attitude). See the following examples:

1. *[Albania Workers' party][T] is the [glorious][E] [party][T] of [Marxism and Leninism][E].*
2. *The [heroic][E] [people of Vietnam][T] obtained [great][E] [victory][E] against [the U.S. imperialism][T,E].*
3. *We strongly [warn][E] Soviet Revisionism][E,T].*

While the majority of subjective sentences omit the opinion holder, as in Examples 1 and 2, there are still a few circumstances where opinion holders (e.g., "we", "Chinese people", "Chinese government") are retained (Example 3). Some words (i.e. U.S. imperialism) can be both target and expression, and there can be multiple targets (Example 2) within one sentence.

We use a semi-Markov Conditional Random Fields (semi-CRFs) (Sarawagi and Cohen, 2004; Okanohara et al., 2006) algorithm for target and expression extraction. Semi-CRF are CRFs that relax the Markovian assumptions and allow for sequence labeling at the segment level. It has been demonstrated more powerful that CRFs in multiple sequence labeling applications including NER (Okanohara et al., 2006), Chinese word segmentation (Andrew, 2006) and opinion expression identification (Yang and Cardie, 2012). Our approach is an extension of Yang and Cardie (2012)'s system[9]. Features we adopted included:

- word, part of speech tag, word length.
- left and right context words within a window of 2 and the correspondent POS tags.
- NER feature.
- subjectivity lexicon features from dictionary[10]. The lexicon consists of a set of Chinese words that can act as strong or weak cues to subjectivity.
- segment-level syntactic features defined in (Yang and Cardie, 2012).

Most existing NER systems can barely recognize entities such as [Vietnamese People's Army] as a unified name entity in that Chinese parser usually divides them into a series of separate words, namely [Vietnamese/People's Army]. To handle this problem, we first employ the Stanford NER engine[11] and then iteratively 'chunk' consecutive words, at least one of which is labeled as a name entity by the NER engine, before checking whether the chunked entity matches a bag of words contained in Chinese encyclopedia, e.g., Baidu Encyclopedia[12] and Chinese Wikipedia[13].

[6] Qiu et al.'s rule base approach makes strong assumptions that consider opinion word to adjectives and targets to be nouns/noun, thus only capable of capturing sentences with simple patterns.

[7] paper.people.com.cn/rmrb/

[8] http://en.wikipedia.org/wiki/People's_Daily

[9] Yang and Cardie's system focuses on expression extraction (not target) and identifies *direct subjective expression (DSE)* and *expressive subjective expression (ESE)*.

[12] http://baike.baidu.com/

[13] http://zh.wikipedia.org/wiki/Wikipedia

4.2 Notation

Here we describe the key variables in our model. Let C_i denote the name entity of country i, G_i denote its corresponding collection of news articles. G_i is divided into 60*4=240 time spans (one for each quarter of the year, 60 years in total), $G_i = \{G_{i,t}\}$. $G_{i,t}$ is composed of a series of documents $\{d\}$, and d is composed of a series of sentences $\{S\}$, which is represented as a tuple $S = \{E_S, T_S\}$, where E_S is the expression and T_S is the target of current sentence.

Sentiment Score m**:** As we are interested in the degree of positiveness or negativeness, we divided international relations into 7 categories: *Antagonism* (score 1), *Tension* (score 2), *Disharmony* (score 3), *Neutrality* (score 4), *Goodness* (score 5), *Friendliness* (score 6), *Brotherhood (Comradeship)* (score 7) based on researches in political science literature[14]. Each of $G_{i,t}$, document d, sentence S and expression term w is associated with a sentiment score $m_{i,t}$, m_d, m_S and m_w, respectively. M denotes the list of subjective terms, $M = \{w, m_w\}$

Document Target List T_i^d**:** We use T_i^d to denote the collection of entity targets in document $d \in G_i$ which the People's daily holds similar attribute towards. For example, suppose document d belongs to Vietnam article collection ($C_i = Vietnam$), T_i^d can be {Vietnam, Workers' party, People's Army, Ho Chi Minh}. While U.S., U.S. troops and Lyndon Johnson are also entity targets found in d, they are not supposed to be included in T_i^d since the author holds opposite attributes.

Sentence List d_i**:** We further use d_i denotes the subset of sentences in d talking about entities from target list T_i^d. Similarly, in a Vietnam related article, sentences talking about the U.S. are not supposed to be included in d_i.

4.3 Hierarchical Bayesian Markov Model

In our approach, time information is incorporated through a hierarchical Bayesian Markov framework where $m_{i,t}$ is modeled as a first-order Poisson Process given the coherence assumption in time-dependent political news streams.

$$m_{i,t} \sim Poisson(m_{i,t}, m_{i,t-1}) \quad (1)$$

[14] http://www.imir.tsinghua.edu.cn/publish/iis/7522/20120522140122561915769

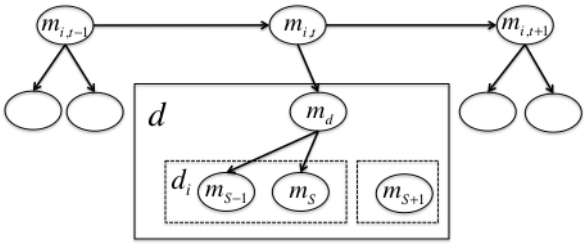

Figure 1: Hierarchical Bayesian Model for Inference

For each document $d \in G_{i,t}$, m_d is sampled from a Poisson distribution with mean value of $m_{i,t}$.

$$m_d \sim Poisson(m_d, m_{i,t}) \quad (2)$$

For sentence $S \in d_i$, m_S is sampled from m_d from a Poisson distribution based on m_d.

$$m_S \sim Poisson(m_S, m_d) \quad (3)$$

4.4 Intialization

Given a labeled subjective list M, for article $d \in G_i$, we initialize T_i^d with the name of entity C_i, d_i with sentences satisfying $T_S = C_i$ and $E_S \in M$. m_S for $S \in d_i$, is initialized as the average score of its containing expression E_s based on M. Then the MCMC algorithm is applied by iteratively updating m_d and $m_{i,t}$ according to the posterior distribution. Let $P(m|\cdot)$ denotes the probability of parameter m given all other parameters and the posterior distributions are given by:

$$\begin{aligned} &P(m_d = \lambda|\cdot) \propto Poisson(\lambda, m_{i,t}) \prod_{S \in d_i} Poisson(\lambda, m_S) \\ &P(m_{i,t} = \lambda|\cdot) \propto Poisson(\lambda, m_{i,t-1}) \\ &\times Poisson(m_{i,t+1}, \lambda) \cdot \times \prod_{d \in G_{i,t}} Poisson(m_d, \lambda) \end{aligned} \quad (4)$$

4.5 Semi-supervised Bootstrapping

Our semi-supervised learning algorithm updates M, T_i^d, d_i, S_d and S_i^d iteratively. A brief interpretation is shown in Figure 2 and the details are shown in Figure 4. Concretely, for each sentence $S \in d - d_i$, **step 1** means, if its expression E_S exists in subjective list M, we added its target T_S to T_i^d and S to d_i. **step 2** means if the target T_S exists in T_i^d, its expression, E_s, is added to subjective list M with score m_d. As M and T_i^d change in the iteration, in **step 3**, we again go over all unconsidered sentences with new M and T_i^d. m_d and $m_{i,t}$ are then updated based on new m_S using MCMC in Equ. 4. Note that sentences with pronoun target are not involved in the bootstrapping procedure.

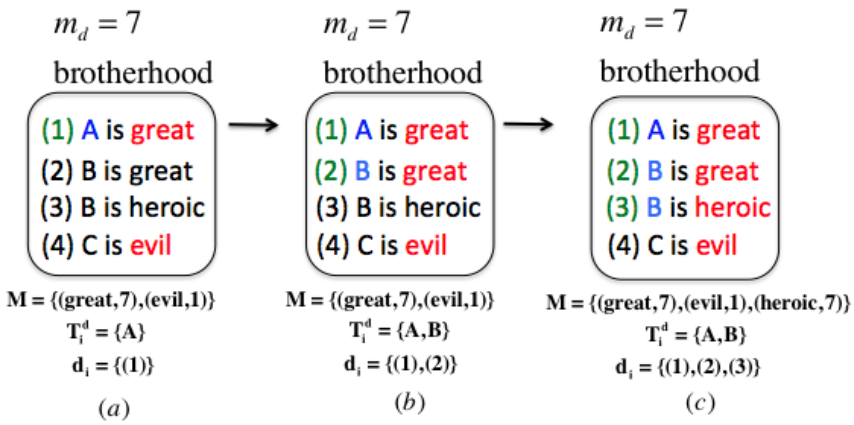

Figure 2: A brief demonstration of the adopted semi-supervised algorithm. (a)→(b): Sentence (2) is added to d_i due to the presence of already known subjective term "great" . Target B is added to target list T_i^d. (b)→(c): term "heroic" is added to subjective word list M with score 7 since it modifies target B.

Input: Entity C_i, G_i, subjective term list M
- for each entity i, each document d
  $T_i^d = \{C_i\}$, $d_i = \{S | S \in d, C_i = T_S, E_s \in M\}$
  for each sentence $S \in d_i$:
  . $m_s = \frac{1}{|E_S \in M|} \sum m_{E_s}$
- Iteratively update $m_{i,t}$, m_d using MCMC based on posterior probability shown in Equ.4.

Output: $\{d_i\}$, $\{T_i^d\}$, $\{m_{i,t}\}$ and $\{m_d\}$

Figure 3: Initialization Algorithm.

Input: Entity $\{C_i\}$, Articles Collections $\{G_i\}$, subjective term list M, sentiment score $\{m_d\}$, $\{m_{i,t}\}$, target list for each document $\{T_i^d\}$
Algorithm:
while not convergence:
• for each entity C_i, document d:
for each sentence $S \in d - d_i$
1. if $E_S \in M, T_s \notin T_i^d$
$T_i^d = T_i^d \bigcup T_s, d_i = d_i \bigcup S, m_S = m_d$
2. if $T_s \in T_i^t, E_s \notin M$
$M = M \bigcup (E_s, S_d), d_i = d_i \bigcup S, m_s = m_d$
3. if $E_S \in M, T_S \in T_i^d$
$d_i = d_i \bigcup S, m_S = m_{E_s}$
•Iteratively update $m_{i,t}$, m_d using MCMC based on posterior probability shown in Equ.4 .
end while:
Output: subjective term list M, score $\{m_{i,t}\}$

Figure 4: Semi-supervised learning algorithm.

4.6 Error Prevention in Bootstrapping

Error propagation is highly influential and damaging in bootstrapping algorithms, especially when extending very limited data to huge corpora. To avoid the collapse of the algorithm, we select candidates for opinion analysis in a extremely strict manner, at the sacrifice of many subjective sentences[15]. Concretely, we only consider sentences with exactly one target and at least one expression. Sentences with multiple targets (e.g., Example 2 in Section 4.1) or no expressions, or no targets are discarded.

In addition to the strict sentence selection approach, we adopt the following methods for self-correction in the boot-strapping procedure:

1. For $T_1, T_2 \in T_i^d$, $(E_1, T_1) \in S_1$, $(E_2, T_2) \in S_2$, $E_1, E_2 \in M$, if $|m_{E_1} - m_{E_2}| > 1$: Expel E_1 and E_2 from M, expel T_1 and T_2 from T_i^d, with the exception of original labeled data.
   Explanation: If sentiment scores for two expressions, whose correspondent targets both belong to the target list T_i^d, diverge enough, we discard both expressions and targets based according to Assumption 1: sentiments towards one entity (or its allies) in an article should be consistent.
2. $\exists S \in d$, $T_S \in T_i^d, |m_{E_S} - m_d| > 1$, T_S is expelled from T_i^d.
   Explanation: If target T_S for sentence S belongs to T_i^d, but its corresponding expression E_s is not consistent with article-level sentiment m_d, T_S is expelled from T_i^d.

[15]Negative effect of strict sentence selection can be partly compensated by the consideration of time-level information

5 Experiment

5.1 Data and Preprocessing

Our data set is composed of the People's daily from 1950 to 2010, across a 60-year time span.

antagonism (m=1)	残暴(extremely cruel), 敌人(enemy)
tension (m=2)	愤慨(indignation), 侵犯(offend)
disharmony (m=3)	失望(disappointed), 遗憾(regret)
neutrality (m=4)	关切, 关注(concern)
goodness (m=5)	发展的(developmental), 尊重(respect)
friendship (m=6)	友谊(friendship), 朋友(friend)
brotherhood (m=7)	伟大(firmly), 兄弟(brother)

Table 1: Illustration of subjective list M

News articles are first segmented using ICTCLAS Chinese segmentation word system[16] (Zhang et al., 2003). Articles with fewer than 200 Chinese words are discarded. News articles are clustered by the presence of a country's name more than 2 times based on a country name list from Wikipedia[17]. Articles mentioning more than 5 different countries are discarded since they usually talk about international conferences. Note that one article can appear in different collections (example in Section 1 will appear in both Vietnam and the U.S. collection).

Compound sentences are segmented into clauses based on dependency parse tree. Then those containing more than 50 characters or less than 4 characters are discarded. To avoid complicated inference, sentences with negation indicators are discarded.

5.2 Obtaining Subjectivity Word List

Since there are few Chinese subjectivity lexicons (with degrees) available and those exist may not serve our specific purpose, we manually label a small number of Chinese subjective terms as seed corpus. We divided the labeling process into 2 steps rather than directly labeling vocabularies[18]. We first selected 100 news articles and assigned each of them (as well as the appropriate country entity C_i) to 2 students majoring in *International Studies*, asking them to give a label sentiment score (1 to 7) according to the rules described in Section 4.2. 20 students participated in the procedure. Since annotators have plenty of background knowledge, they agreed on 98 out of 100. Second, we selected out subjectivity lexicons by matching to a comprehensive subjectivity lexicons list[19]. and ask 2 students select the candidates that signal the document-level label from the first step. According to whether a word a selected or not, the value of $Cohen's\ \kappa$ is 0.78, showing substantial agreement. For the small amount of labels on which the judges disagree, we recruited an extra judge and to serve as a tie breaker. Table 1 shows some labeled examples.

[16]http://ictclas.org/

[17]http://zh.wikipedia.org/wiki/ 国家列表-(按洲排列)

[18]We tried direct vocabulary labeling in the first place, but got low score for inter agreement, where value of $Cohen's\ \kappa$ is only 0.43.

CRF	0.73	0.66	0.68
	Single		
semi-CRF	**0.87**	**0.92**	**0.90**
CRF	0.80	0.87	0.83

Table 2: Results for Expressions/Targets extraction.

5.3 Targets and Expressions Extraction

As the good performance of *semi-CRF* in opinion extraction has been demonstrated in previous work (Yang and Cardie, 2012), we briefly go over model evaluation in this subsection for brevity. We manually labeled 600 sentences and performed 5-fold cross validation for evaluation. We compare *semi-CRF* to *Standard CRF*. We report performances on two settings in Table 2. The first setting, *Total*, corresponds to performance on the whole dataset, while second one *Single*, denotes the performance on the set of sentences with only one target, which we are more interested in because multiple-target sentences are discarded in our algorithm. It turned out that *semi-CRF* significantly outputs standard CRF, approaching 0.90 F-1 score on *Single* setting.

5.4 Foreign Relation Evaluation

Gold-standard foreign relations are taken from Political Science research at the Institute of Modern International Relations, Tsinghua University, extracted from monthly quantitative China foreign relations reports with 7 countries (U.S., Japan, Russia/Soviet, England, France, India, and Germany) from 1950 to 2012[20].

We consider several baselines. For fair comparison, we use identical processing techniques for each approach. Some baselines make article-level predictions, for which we obtain time-period level relation prediction by averaging the documents.

Coreference+Bootstrap (CB): We first implemented Ngai and Wang's Chinese coreference sys-

[20]Details found here http://www.imir.tsinghua.edu.cn/publish/iisen/7523/index.html.

Model	Ours	CB	No-time
Pearson	0.895	0.753	0.808
Model	SVR-d	SLDA	SVR-S
Pearson	0.482	0.427	0.688

Table 3: Pearson Correlation with Gold Standard.

tem (2007). We then bootstrap sentiment terms and score based on entity coreference.

No-time: A simplified version of our approach where each article is considered as an independent unit and no time-level information is considered. m_d is obtained by averaging its containing sentences and used for later bootstrapping.

SVR-d: Uses SVM^{light}(Joachims, 1999) to train a linear SVR (Pang and Lee, 2008) for document-level sentiment prediction using the unigram feature. The 100 labeled documents are used as training data.

SLDA: supervised-LDA (Blei and McAuliffe, 2010) for document-level label prediction. Topic number is set to 10, 20, 50, 100 respectively and we report the best result.

SVR-S: Sentence-level SVR to sentences with presence of entity C_i[21]. We obtain document-level prediction by averaging its containing sentences and then time-period level prediction by averaging its containing documents.

We report the Pearson Correlation with gold standards in table 3. As we can observe, simple document-level regression models, i.e., **SVR** and **SLDA** do not fit this task. The reason is simple: one article d can appear in different collections. Recall the Vietnam example in Section 1, it appears in both $G_{Vietnam}$ and $G_{the\ U.S.}$. Sentiment prediction for d should be totally opposite in the two document collections: very positive in $G_{Vietnam}$ and very negative in G_{USA}. But document level prediction would treat them equally. Our approach outperforms **No-Time**, illustrating the meaningfulness of exploiting time-level information in our task. Our system approaches around 0.9 correlation with the gold standards. The reason why **No-Time** is better than **CB** is also simple: **CB** includes only coreferent entities in the target list (e.g., America for the USA article collection), and therefore overlooks rich information provided by non-coreferent entities (e.g., President Nixon or Nixon Government). **No-Time** instead groups entities according to attitude, thereby enabling more information to be harnessed. For **SVR-S**, as the regression model trained from limited labeled data can hardly cover unseen terms during testing, the performance is just OK. **SVR-S** also suffers from overlooking rich sources of information since it only considers sentences with exact mention of the name entity of the corresponding country.

[21]Features we explore include word entities in current sentence, POS, a window of $k \in \{1, 2\}$ words from the target and the expression and corresponding POS, and the dependency path between target and expression.

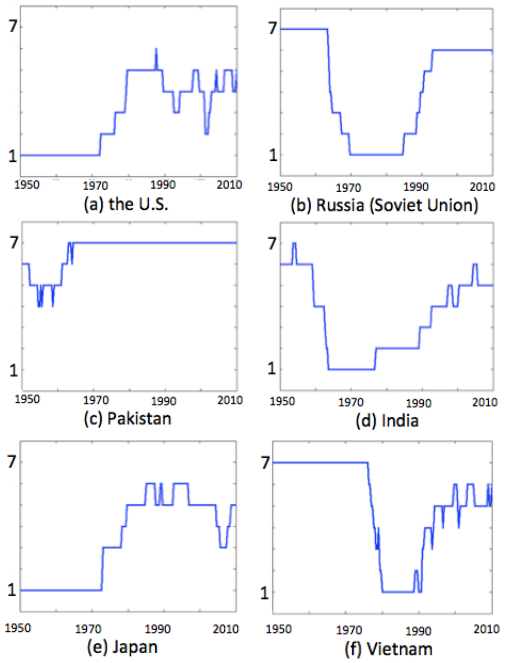

Figure 5: Examples of China's Foreign Relations.

6 Diplomatic Relations

"The enemy of my enemy is my friend"
—Arabic proverb

A central characteristic of post-World War Second international system with which China had to deal would be overwhelming preeminence of the USA and USSR as each of the superpowers stood at the center of a broad alliance system who was engaged in an intense and protracted global conflict with the other. We choose 6 countries and report results in Figure 5. One of interesting things we can observe from Figure 5 is that foreign attitudes are usually divergent towards two opposing forces: Sino-American relation (see Figure 5(a)) began to improve when the Sino-Soviet relation (see Figure 5(b)) reached its bottom at the beginning of 1970s. Similar patterns appear for Sino-Pakistan (see Figure 5(c)), Sino-India relations (see Figure 5(d))

Figure 6: Top coreference terms Towards USA and Soviet Union/Russia versus time. Blue denotes words that are both Target and positive words in M. Red denotes words that are both Target and negative words in M

in early 1960s[22], and Sino-Vietnam 5(f)), Sino-American relations in late 1970s. On the contrast, attitudes are usually consistent toward allied forces: Sino-Japan relations with Sino-USA relations before 1990s, and Sino-Vietnam relations with Sino-Soviet relations in late 1970s and 1980s.

Figure 6 presents top clustering target (T_i^d) in the USA and Soviet Union/Russia article collection. As some of vocabulary terms can be both target and expression, we use blue to label terms with positive sentiment, red to label negative ones. As we can see from Figure 6, targets(T) extracted by our model show a very clear pattern where allies and co-referent entities are grouped. Another interesting thing is, the subjectivity of target words from different times is generally in accord with the relation curves shown in Figure 5.

7 Conclusion and Discussion

In this paper, we propose a sentiment analysis algorithm to track China's foreign relations from the People's Daily. Our semi-supervised algorithm harnesses higher level information (i.e., document-level, time-level) by incorporating a hierarchical Bayesian approach into the framework, to resolve sentiment target clustering, create subjective lexicons, and perform sentiment prediction simultaneously. While we focus here on the People's Daily for diplomatic relation extraction, the idea of our approach is general and can be extended broadly. Another contribution of this work is the creation a comprehensive Chinese subjective lexicon list. We are hopeful that our approach can not only facilitate quantitative research by political scientists, but also shed light on NLP applications such as coreference and metaphor, where sentiment clues can be helpful.

It is worth noting that, while harnessing time-level information can indeed facilitate opinion analysis, especially when labeled data is limited in our specific task, it is not a permanent-perfect assumption, especially considering the diversity and treacherous currents at the international political stage.

At algorithm-level, to avoid error propagation due to limitations of current sentiment analysis tools (even though semi-CRF produces state-of-art performance in target and expression extraction task, a performance of 0.8 F-value, when applied to the whole corpus, can by no means satisfy our requirements), we discard a great number of sentences, among which is contained much useful information. How to resolve these problems and improve opinion extraction performance is our long-term goal in sentiment analysis/opinion extraction literature.

Abstract

In this paper, we propose a joint segmentation and classification framework for sentiment analysis. Existing sentiment classification algorithms typically split a sentence as a word sequence, which does not effectively handle the inconsistent sentiment polarity between a phrase and the words it contains, such as "*not bad*" and "*a great deal of*". We address this issue by developing a joint segmentation and classification framework (**JSC**), which simultaneously conducts sentence segmentation and sentence-level sentiment classification. Specifically, we use a log-linear model to score each segmentation candidate, and exploit the phrasal information of top-ranked segmentations as features to build the sentiment classifier. A marginal log-likelihood objective function is devised for the segmentation model, which is optimized for enhancing the sentiment classification performance. The joint model is trained only based on the annotated sentiment polarity of sentences, without any segmentation annotations. Experiments on a benchmark Twitter sentiment classification dataset in SemEval 2013 show that, our joint model performs comparably with the state-of-the-art methods.

1 Introduction

Sentiment classification, which classifies the sentiment polarity of a sentence (or document) as positive or negative, is a major research direction in the field of sentiment analysis (Pang and Lee, 2008; Liu, 2012; Feldman, 2013). Majority of existing approaches follow Pang et al. (2002) and treat sentiment classification as a special case of text categorization task. Under this perspective, previous studies typically use pipelined methods with two steps. They first produce sentence segmentations with separate text analyzers (Choi and Cardie, 2008; Nakagawa et al., 2010; Socher et al., 2013b) or bag-of-words (Paltoglou and Thelwall, 2010; Maas et al., 2011). Then, feature learning and sentiment classification algorithms take the segmentation results as inputs to build the sentiment classifier (Socher et al., 2011; Kalchbrenner et al., 2014; Dong et al., 2014).

The major disadvantage of a pipelined method is the problem of error propagation, since sentence segmentation errors cannot be corrected by the sentiment classification model. A typical kind of error is caused by the *polarity inconsistency* between a phrase and the words it contains, such as ⟨*not bad*, *bad*⟩ and ⟨*a great deal of*, *great*⟩. The segmentations based on bag-of-words or syntactic chunkers are not effective enough to handle the *polarity inconsistency* phenomenons. The reason lies in that bag-of-words segmentations regard each word as a separate unit, which losses the word order and does not capture the phrasal information. The segmentations based on syntactic chunkers typically aim to identify noun groups, verb groups or named entities from a sentence. However, many sentiment indicators are phrases constituted of adjectives, negations, adverbs or idioms (Liu, 2012; Mohammad et al., 2013a), which are splitted by syntactic chunkers. Besides, a better approach would be to utilize the sentiment information to improve the segmentor. Accordingly, the sentiment-specific segmentor will enhance the performance of sentiment classification in turn.

In this paper, we propose a joint segmentation and classification framework (**JSC**) for sentiment analysis, which simultaneous conducts sentence segmentation and sentence-level sentiment classification. The framework is illustrated in Fig-

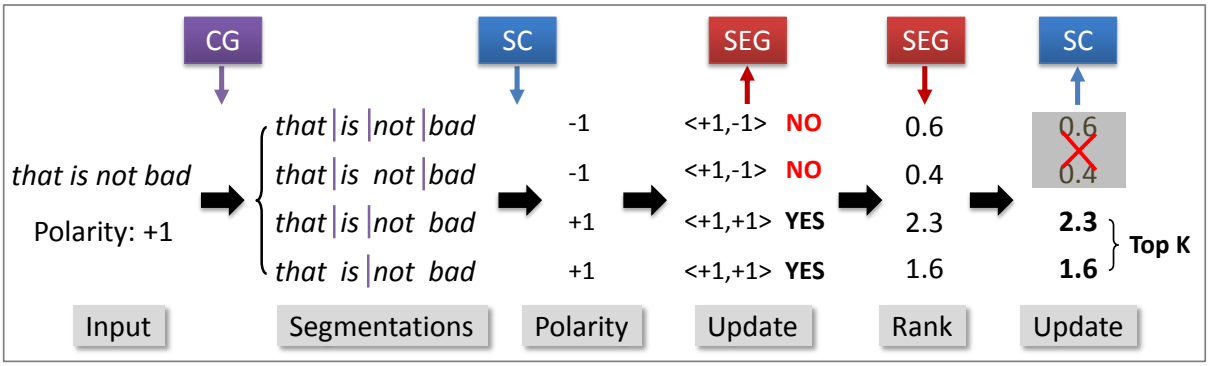

Figure 1: The joint segmentation and classification framework (**JSC**) for sentiment classification. **CG** represents the candidate generation model, **SC** means the sentiment classification model and **SEG** stands for the segmentation ranking model. **Down Arrow** means the use of a specified model, and **Up Arrow** indicates the update of a model.

ure 1. We develop (1) a candidate generation model to generate the segmentation candidates of a sentence, (2) a segmentation ranking model to score each segmentation candidate of a given sentence, and (3) a classification model to predict the sentiment polarity of each segmentation. The phrasal information of top-ranked candidates from the segmentation model are utilized as features to build the sentiment classifier. In turn, the predicted sentiment polarity of segmentation candidates from classification model are leveraged to update the segmentor. We score each segmentation candidate with a log-linear model, and optimize the segmentor with a marginal log-likelihood objective. We train the joint model from sentences annotated only with sentiment polarity, without any segmentation annotations.

We evaluate the effectiveness of our joint model on a benchmark Twitter sentiment classification dataset in SemEval 2013. Results show that the joint model performs comparably with state-of-the-art methods, and consistently outperforms pipeline methods in various experiment settings. The main contributions of the work presented in this paper are as follows.

- To our knowledge, this is the first work that automatically produces sentence segmentation for sentiment classification within a joint framework.

- We show that the joint model yields comparable performance with the state-of-the-art methods on the benchmark Twitter sentiment classification datasets in SemEval 2013.

2 Related Work

Existing approaches for sentiment classification are dominated by two mainstream directions. Lexicon-based approaches (Turney, 2002; Ding et al., 2008; Taboada et al., 2011; Thelwall et al., 2012) typically utilize a lexicon of sentiment words, each of which is annotated with the sentiment polarity or sentiment strength. Linguistic rules such as intensifications and negations are usually incorporated to aggregate the sentiment polarity of sentences (or documents). Corpus-based methods treat sentiment classification as a special case of text categorization task (Pang et al., 2002). They mostly build the sentiment classifier from sentences (or documents) with manually annotated sentiment polarity or distantly-supervised corpora collected by sentiment signals like emoticons (Go et al., 2009; Pak and Paroubek, 2010; Kouloumpis et al., 2011; Zhao et al., 2012).

Majority of existing approaches follow Pang et al. (2002) and employ corpus-based method for sentiment classification. Pang et al. (2002) pioneer to treat the sentiment classification of reviews as a special case of text categorization problem and first investigate machine learning methods. They employ Naive Bayes, Maximum Entropy and Support Vector Machines (SVM) with a diverse set of features. In their experiments, the best performance is achieved by SVM with bag-of-words feature. Under this perspective, many studies focus on designing or learning effective features to obtain better classification performance. On movie or product reviews, Wang and Manning (2012) present NBSVM, which trades-off

between Naive Bayes and NB-feature enhanced SVM. Kim and Zhai (2009) and Paltoglou and Thelwall (2010) learn the feature weights by investigating variants weighting functions from Information Retrieval. Nakagawa et al. (2010) utilize dependency trees, polarity-shifting rules and conditional random fields (Lafferty et al., 2001) with hidden variables to compute the document feature. On Twitter, Mohammad et al. (2013b) develop a state-of-the-art Twitter sentiment classifier in SemEval 2013, using a variety of sentiment lexicons and hand-crafted features.

With the revival of deep learning (representation learning (Hinton and Salakhutdinov, 2006; Bengio et al., 2013; Jones, 2014)), more recent studies focus on learning the low-dimensional, dense and real-valued vector as text features for sentiment classification. Glorot et al. (2011) investigate Stacked Denoising Autoencoders to learn document vector for domain adaptation in sentiment classification. Yessenalina and Cardie (2011) represent each word as a matrix and compose words using iterated matrix multiplication. Socher et al. propose Recursive Autoencoder (RAE) (2011), Matrix-Vector Recursive Neural Network (MV-RNN) (2012) and Recursive Neural Tensor Network (RNTN) (2013b) to learn the composition of variable-length phrases based on the representation of its children. To learn the sentence representation, Kalchbrenner et al. (2014) exploit Dynamic Convolutional Neural Network and Le and Mikolov (2014) investigate Paragraph Vector. To learn word vectors for sentiment analysis, Maas et al. (2011) propose a probabilistic document model following Blei et al. (2003), Labutov and Lipson (2013) re-embed words from existing word embeddings and Tang et al. (2014b) develop three neural networks to learn word vectors from tweets containing positive/negative emoticons.

Unlike most previous corpus-based algorithms that build sentiment classifier based on splitting a sentence as a word sequence, we produce sentence segmentations automatically within a joint framework, and conduct sentiment classification based on the segmentation results.

3 The Proposed Approach

In this section, we first give the task definition of two tasks, namely sentiment classification and sentence segmentation. Then, we present the overview of the proposed joint segmentation and classification model (**JSC**) for sentiment analysis. The segmentation candidate generation model and the segmentation ranking model are described in Section 4. The details of the sentiment classification model are presented in Section 5.

3.1 Task Definition

The task of sentiment classification has been well formalized in previous studies (Pang and Lee, 2008; Liu, 2012). The objective is to identify the sentiment polarity of a sentence (or document) as positive or negative [1].

The task of sentence segmentation aims to split a sentence into a sequence of exclusive parts, each of which is a basic computational unit of the sentence. An example is illustrated in Table 1. The original text "*that is not bad*" is segmented as "*[that] [is] [not bad]*". The segmentation result is composed of three basic computational units, namely *[that]*, *[is]* and *[not bad]*.

Type	**Sample**
Sentence	that is not bad
Segmentation	[that] [is] [not bad]
Basic units	[that], [is], [not bad]

Table 1: Example for sentence segmentation.

3.2 Joint Model (JSC)

The overview of the proposed joint segmentation and classification model (**JSC**) for sentiment analysis is illustrated in Figure 1. The intuitions of the joint model are two-folds:

- The segmentation results have a strong influence on the sentiment classification performance, since they are the inputs of the sentiment classification model.
- The usefulness of a segmentation can be judged by whether the sentiment classifier can use it to predict the correct sentence polarity.

Based on the mutual influence observation, we formalize the joint model in Algorithm 1. The inputs contain two parts, training data and feature extractors. Each sentence s_i in the training data

[1] In this paper, the sentiment polarity of a sentence is not relevant to the target (or aspect) it contains (Hu and Liu, 2004; Jiang et al., 2011; Mitchell et al., 2013).

Algorithm 1 The joint segmentation and classification framework (**JSC**) for sentiment analysis

Input:

training data: $T = [s_i, pol_i^g]$, $1 \leq i \leq |T|$
segmentation feature extractor: $sfe(\cdot)$
classification feature extractor: $cfe(\cdot)$

Output:

sentiment classifier: ***SC***
segmentation ranking model: ***SEG***

1: Generate segmentation candidates Ω_i for each sentence s_i in T, $1 \leq i \leq |T|$
2: Initialize sentiment classifier $\boldsymbol{SC}^{(0)}$ based on $cfe(\Omega_{ij})$, *randomize* $j \in [1, |\Omega_i|]$, $1 \leq i \leq |T|$
3: Randomly initialize the segmentation ranking model $\boldsymbol{SEG}^{(0)}$
4: **for** $r \leftarrow 1 \ldots R$ **do**
5: Predict the sentiment polarity pol_i for Ω_i based on $\boldsymbol{SC}^{(r-1)}$ and $cfe(\Omega_{i\cdot})$
6: Update the segmentation model $\boldsymbol{SEG}^{(r)}$ with $\boldsymbol{SEG}^{(r-1)}$ and $[\Omega_i, sfe(\Omega_{i\cdot}), \text{pol}_{i\cdot}, pol_i^g]$, $1 \leq i \leq |T|$
7: **for** $i \leftarrow 1 \ldots |T|$ **do**
8: Calculate the segmentation score for $\Omega_{i\cdot}$ based on $\boldsymbol{SEG}^{(r)}$ and $sfe(\Omega_{i\cdot})$
9: Select the top-ranked K segmentation candidates Ω_{i*} from Ω_i
10: **end for**
11: Train the sentiment classifier $\boldsymbol{SC}^{(r)}$ with $cfe(\Omega_{i*})$, $1 \leq i \leq |T|$
12: **end for**
13: $\boldsymbol{SC} \leftarrow \boldsymbol{SC}^{(R)}$
14: $\boldsymbol{SEG} \leftarrow \boldsymbol{SEG}^{(R)}$

T is annotated only with its gold sentiment polarity pol_i^g, without any segmentation annotations. There are two feature extractors for the task of sentence segmentation ($sfe(\cdot)$) and sentiment classification ($cfe(\cdot)$), respectively. The outputs of the joint model are the segmentation ranking model ***SEG*** and the sentiment classifier ***SC***.

In Algorithm 1, we first generate segmentation candidates Ω_i for each sentence s_i in the training set (line 1). Each Ω_i contains no less than one segmentation candidates. We randomly select one segmentation result from each Ω_i and utilize their classification features to initialize the sentiment classifier $\boldsymbol{SC}^{(0)}$ (line 2). We randomly initialize the segmentation model $\boldsymbol{SEG}^{(0)}$ (line 3). Subsequently, we iteratively train the segmentation model $\boldsymbol{SEG}^{(r)}$ and sentiment classifier $\boldsymbol{SC}^{(r)}$ in a joint manner (line 4-12). At each iteration, we predict the sentiment polarity of each segmentation candidate $\Omega_{i\cdot}$ with the current sentiment classifier $\boldsymbol{SC}^{(r-1)}$ (line 5), and then leverage them to update the segmentation model $\boldsymbol{SEG}^{(r)}$ (line 6). Afterwards, we utilize the recently updated segmentation ranking model $\boldsymbol{SEG}^{(r)}$ to update the sentiment classifier $\boldsymbol{SC}^{(r)}$ (line 7-11). We extract the segmentation features for each segmentation candidate $\Omega_{i\cdot}$, and employ them to calculate the segmentation score (line 8). The top-ranked K segmentation results Ω_{i*} of each sentence s_i is selected (line 9), and further used to train the sentiment classifier $\boldsymbol{SC}^{(r)}$ (line 11). Finally, after training R iterations, we dump the segmentation ranking model $\boldsymbol{SEG}^{(R)}$ and sentiment classifier $\boldsymbol{SC}^{(R)}$ in the last iteration as outputs (line 13-14).

At training time, we train the segmentation model and classification model from sentences with manually annotated sentiment polarity. At prediction time, given a test sentence, we generate its segmentation candidates, and then calculate segmentation score for each candidate. Afterwards, we select the top-ranked K candidates and vote their predicted sentiment polarity from sentiment classifier as the final result.

4 Segmentation Model

In this section, we present details of the segmentation candidate generation model (Section 4.1), the segmentation ranking model (Section 4.2) and the feature description for segmentation ranking model (Section 4.3).

4.1 Segmentation Candidate Generation

In this subsection, we describe the strategy to generate segmentation candidates for each sentence. Since the segmentation results have an exponential search space in the number of words in a sentence, we approximate the computation using beam search with constrains on a phrase table, which is induced from massive corpora.

Many studies have been previously proposed to recognize phrases in the text. However, it is out of scope of this work to compare them. We exploit a data-driven approach given by Mikolov et al. (2013), which identifies phrases based on the occurrence frequency of unigrams and bigrams,

$$freq(w_i, w_j) = \frac{freq(w_i, w_j) - \delta}{freq(w_i) \times freq(w_j)} \quad (1)$$

where δ is a discounting coefficient that prevents too many phrases consisting of very infrequent words. We run 2-4 times over the corpora to get longer phrases containing more words. We empirically set δ as 10 in our experiment. We use the default frequency threshold (value=5) in the word2vec toolkit [2] to select bi-terms.

Given a sentence, we initialize the beam of each index with the current word, and sequentially add phrases into the beam if the new phrase is contained in the phrase table. At each index of a sentence, we rank the segmentation candidates by the inverted number of items within a segmentation, and save the top-ranked N segmentation candidates into the beam. An example of the generated segmentation candidates is given in Table 2.

Type	Sample
Sentence	that is not bad
Phrase Table	[is not], [not bad], [is not bad]
Segmentations	[that] [is not bad] [that] [is not] [bad] [that] [is] [not bad] [that] [is] [not] [bad]

Table 2: Example for segmentation candidate generation.

4.2 Segmentation Ranking Model

The objective of the segmentation ranking model is to assign a scalar to each segmentation candidate, which indicates the usefulness of the segmentation result for sentiment classification. In this subsection, we describe a log-linear model to calculate the segmentation score. To effectively train the segmentation ranking model, we devise a marginal log-likelihood as the optimization objective.

Given a segmentation candidate Ω_{ij} of the sentence s_i, we calculate the segmentation score for Ω_{ij} with a log-linear model, as given in Equation 2.

$$\phi_{ij} = exp(b + \sum_{k} sfe_{ijk} \cdot w_k) \qquad (2)$$

where ϕ_{ij} is the segmentation score of Ω_{ij}; sfe_{ijk} is the k-th segmentation feature of Ω_{ij}; w and b are the parameters of the segmentation ranking model.

During training, given a sentence s_i and its gold sentiment polarity pol_i^g, the optimization objective of the segmentation ranking model is to maximize the segmentation scores of the **hit candidates**, whose predicted sentiment polarity equals to the gold polarity of sentence pol_i^p. The loss function of the segmentation model is given in Equation 3.

$$loss = -\sum_{i=1}^{|T|} log(\frac{\sum_{j \in H_i} \phi_{ij}}{\sum_{j' \in A_i} \phi_{ij'}}) + \lambda ||w||_2^2 \qquad (3)$$

where T is the training data; A_i represents all the segmentation candidates of sentence s_i; H_i means the hit candidates of s_i; λ is the weight of the L2-norm regularization factor. We train the segmentation model with L-BFGS (Liu and Nocedal, 1989), running over the complete training data.

4.3 Feature

We design two kinds of features for sentence segmentation, namely the phrase-embedding feature and the segmentation-specific feature. The final feature representation of each segmentation is the concatenation of these two features. It is worth noting that, the phrase-embedding feature is used in both sentence segmentation and sentiment classification.

Segmentation-Specific Feature We empirically design four segmentation-specific features to reflect the information of each segmentation, as listed in Table 3.

Phrase-Embedding Feature We leverage phrase embedding to generate the features of segmentation candidates for both sentence segmentation and sentiment classification. The reason is that, in both tasks, the basic computational units of each segmentation candidate might be words or phrases of variable length. Under this scenario, phrase embedding is highly suitable as it is capable to represent phrases with different length into a consistent distributed vector space (Mikolov et al., 2013). For each phrase, phrase embedding is a dense, real-valued and continuous vector. After the phrase embedding is trained, the nearest neighbors in the embedding space are favored to have similar grammatical usages and semantic meanings. The effectiveness of phrase embedding has been verified for building large-scale sentiment lexicon (Tang et al., 2014a) and machine translation (Zhang et al., 2014).

We learn phrase embedding with Skip-Gram model (Mikolov et al., 2013), which is the state-of-

[2] Available at https://code.google.com/p/word2vec/

Feature	Feature Description
#unit	the number of basic computation units in the segmentation candidate
#unit / #word	the ratio of units' number in a candidate to the length of original sentence
#word − #unit	the difference between sentence length and the number of basic computational units
#unit > 2	the number of basic component units composed of more than two words

Table 3: Segmentation-specific features for segmentation ranking.

Feature	Feature Description
All-Caps	the number of words with all characters in upper case
Emoticon	the presence of positive (or negative) emoticons, whether the last unit is emoticon
Hashtag	the number of hashtag
Elongated units	the number of basic computational containing elongated words (with one character repeated more than two times), such as *gooood*
Sentiment lexicon	the number of sentiment words, the score of last sentiment words, the total sentiment score and the maximal sentiment score for each lexicon
Negation	the number of negations as individual units in a segmentation
Bag-of-Units	an extension of bag-of-word for a segmentation
Punctuation	the number of contiguous sequences of dot, question mark and exclamation mark.
Cluster	the presence of units from each of the 1,000 clusters from Twitter NLP tool (Gimpel et al., 2011)

Table 4: Classification-specific features for sentiment classification.

the-art phrase embedding learning algorithm. We compose the representation (or feature) of a segmentation candidate from the embedding of the basic computational units (words or phrases) it contains. In this paper, we explore min, max and $average$ convolution functions, which have been used as simple and effective methods for composition learning in vector-based semantics (Mitchell and Lapata, 2010; Collobert et al., 2011; Socher et al., 2013a; Shen et al., 2014; Tang et al., 2014b), to calculate the representation of a segmentation candidate. The final phrase-embedding feature is the concatenation of vectors derived from different convolutional functions, as given in Equation 4,

$$pf(seg) = [pf_{max}(seg), pf_{min}(seg), pf_{avg}(seg)] \quad (4)$$

where $pf(seg)$ is the representation of the given segmentation; $pf_x(seg)$ is the result of the convolutional function $x \in \{min, max, avg\}$. Each convolutional function $pf_x(\cdot)$ conducts the matrix-vector operation of x on the sequence represented by columns in the lookup table of phrase embedding. The output of $pf_x(\cdot)$ is calculated as

$$pf_x(seg) = \theta_x \langle L_{ph} \rangle_{seg} \quad (5)$$

where θ_x is the convolutional function of pf_x; $\langle L_{ph} \rangle_{seg}$ is the concatenated column vectors of the basic computational units in the segmentation; L_{ph} is the lookup table of phrase embedding.

5 Classification Model

For sentiment classification, we follow the supervised learning framework (Pang et al., 2002) and build the classifier from sentences with manually labelled sentiment polarity. We extend the state-of-the-art hand-crafted features in SemEval 2013 (Mohammad et al., 2013b), and design the classification-specific features for each segmentation. The detailed feature description is given in Table 4.

6 Experiment

In this section, we conduct experiments to evaluate the effectiveness of the joint model. We describe the experiment settings and the result analysis.

6.1 Dataset and Experiment Settings

We conduct sentiment classification of tweets on a benchmark Twitter sentiment classification dataset in SemEval 2013. We run 2-class (positive *vs* negative) classification as sentence segmentation has a great influence on the positive/negative polarity of tweets due to the *polarity inconsistency* between a phrase and its constitutes, such as ⟨*not bad*, *bad*⟩.

We leave 3-class classification (positive, negative, neutral) and fine-grained classification (very negative, negative, neutral, positive, very positive) in the future work.

	Positive	Negative	Total
Train	2,642	994	3,636
Dev	408	219	627
Test	1,570	601	2,171

Table 5: Statistics of the SemEval 2013 Twitter sentiment classification dataset (positive *vs* negative).

The statistics of our dataset crawled from SemEval 2013 are given in Table 5. The evaluation metric is the macro-F1 of sentiment classification. We train the joint model on the training set, tune parameters on the dev set and evaluate on the test set. We train the sentiment classifier with LibLinear (Fan et al., 2008) and utilize existing sentiment lexicons [3] to extract classification-specific features. We randomly crawl 100M tweets from February 1st, 2013 to April 30th, 2013 with Twitter API, and use them to learn the phrase embedding with Skip-Gram [4]. The vocabulary size of the phrase embedding is 926K, from unigram to 5-gram. The parameter -c in SVM is tuned on the dev-set in both baseline and our method. We run the L-BFGS for 50 iterations, and set the regularization factor λ as 0.003. The beam size N of the candidate generation model and the top-ranked segmentation number K are tuned on the dev-set.

6.2 Baseline Methods

We compare the proposed joint model with the following sentiment classification algorithms:

• *DistSuper*: We collect 10M balanced tweets selected by positive and negative emoticons [5] as training data, and build classifier using the LibLinear and ngram features (Go et al., 2009; Zhao et al., 2012).

• *SVM*: The n-gram features and Support Vector Machine are widely-used baseline methods to build sentiment classifiers (Pang et al., 2002). We use LibLinear to train the SVM classifier.

• *NBSVM*: NBSVM (Wang and Manning, 2012) trades-off between Naive Bayes and NB-features enhanced SVM. We use NBSVM-bi because it performs best on sentiment classification of reviews.

• *RAE*: Recursive Autoencoder (Socher et al., 2011) has been proven effective for sentiment classification by learning sentence representation. We train the RAE using the pre-trained phrase embedding learned from 100M tweets.

• *SentiStrength*: Thelwall et al. (2012) build a lexicon-based classifier which uses linguistic rules to detect the sentiment strength of tweets.

• *SSWE$_u$*: Tang et al. (2014b) propose to learn sentiment-specific word embedding (SSWE) from 10M tweets collected by emoticons. They apply SSWE as features for Twitter sentiment classification.

• *NRC*: NRC builds the state-of-the-art system in SemEval 2013 Twitter Sentiment Classification Track, incorporating diverse sentiment lexicons and hand-crafted features (Mohammad et al., 2013b). We re-implement this system because the codes are not publicly available. We do not directly report their results in the evaluation task, as our training and development sets are smaller than their dataset. In *NRC + PF*, We concatenate the NRC features and the phrase embeddings feature (*PF*), and build the sentiment classifier with LibLinear.

Except for *DistSuper*, other baseline methods are conducted in a supervised manner. We do not compare with *RNTN* (Socher et al., 2013b) because the tweets in our dataset do not have accurately parsed results. Another reason is that, due to the differences between domains, the performance of *RNTN* trained on movie reviews might be decreased if directly applied on the tweets (Xiao et al., 2013).

6.3 Results and Analysis

Table 6 shows the macro-F1 of the baseline systems as well as our joint model (**JSC**) on sentiment classification of tweets (positive *vs* negative).

As is shown in Table 6, distant supervision is relatively weak because the noisy-labeled tweets are treated as the gold standard, which decreases the performance of sentiment classifier. The result of bag-of-unigram feature (74.50%) is not satisfied as it losses the word order and does not well cap-

[3] In this work, we use *HL* (Hu and Liu, 2004), *MPQA* (Wilson et al., 2005), *NRC_Emotion_Lexicon* (Mohammad and Turney, 2012), *NRC_Hashtag_Lexicon* and *Sentiment140Lexicon* (Mohammad et al., 2013b).

[4] https://code.google.com/p/word2vec/

[5] We use the emoticons selected by Hu et al. (2013). The positive emoticons are :) :) :-) :D =), and the negative emoticons are :(: (:-(.

Method	Macro-F1
DistSuper + unigram	61.74
DistSuper + 5-gram	63.92
SVM + unigram	74.50
SVM + 5-gram	74.97
Recursive Autoencoder	75.42
NBSVM	75.28
SentiStrength	73.23
$SSWE_u$	84.98
NRC (Top System in SemEval 2013)	84.73
NRC + PF	84.75
JSC	**85.51**

Table 6: Macro-F1 for positive *vs* negative classification of tweets.

ture the semantic meaning of phrases. The integration of high-order n-ngram (up to 5-gram) does not achieve significant improvement (+0.47%). The reason is that, if a sentence contains a bigram "*not bad*", they will use "*bad*" and "*not bad*" as parallel features, which confuses the sentiment classification model. *NBSVM* and *Recursive Autoencoder* perform comparatively and have a big gap in comparison with *JSC*. In *RAE*, the representation of a sentence is composed from the representation of words it contains. Accordingly, "*great*" in "*a great deal of*" also contributes to the final sentence representation via composition function. *JSC* automatically conducts sentence segmentation by considering the sentiment polarity of sentence, and utilize the phrasal information from the segmentations. Ideally, *JSC* regards phrases like "*not bad*" and "*a great deal of*" as basic computational units, and yields better classification performance. *JSC* (85.51%) performs slightly better than the state-of-the-art systems (*$SSWE_u$*, 84.98%; *NRC+PF*, 84.75%), which verifies its effectiveness.

6.4 Comparing Joint and Pipelined Models

We compare the proposed joint model with pipelined methods on Twitter sentiment classification with different feature sets. Figure 2 gives the experiment results. The tick *[A, B]* on x-axis means the use of *A* as segmentation feature and the use of *B* as classification feature. *PF* represents the phrase-embedding feature; *SF* and *CF* stand for the segmentation-specific feature and classification-specific feature, respectively. We use the bag-of-word segmentation result to build sentiment classier in *Pipeline 1*, and use the segmentation candidate with maximum phrase number in *Pipeline 2*.

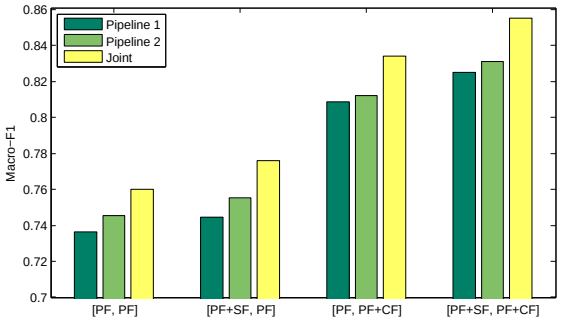

Figure 2: Macro-F1 for positive *vs* negative classification of tweets with joint and pipelined models.

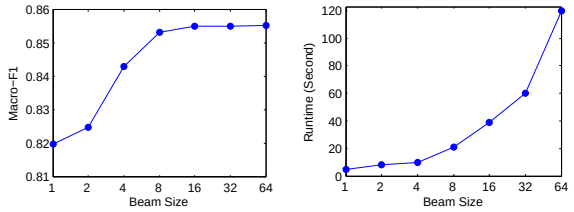
From Figure 2, we find that the joint model consistently outperforms pipelined baseline methods in all feature settings. The reason is that the pipelined methods suffer from error propagation, since the errors from linguistic-driven and bag-of-word segmentations cannot be corrected by the sentiment classification model. Besides, traditional segmentors do not update the segmentation model with the sentiment information of text. Unlike pipelined methods, the joint model is capable to address these problems by optimizing the segmentation model with the classification results in a joint framework, which yields better performance on sentiment classification. We also find that *Pipeline 2* always outperforms *Pipeline 1*, which indicates the usefulness of phrase-based segmentation for sentiment classification.

6.5 Effect of the beam size N

We investigate the influence of beam size N, which is the maximum number of segmentation candidates of a sentence. In this part, we clamp the feature set as [PF+SF, PF+CF], and vary the beam size N in [1,2,4,8,16,32,64]. The experiment results of macro-F1 on the development set are illustrated in Figure 3 (a). The time cost of each training iteration is given in Figure 3 (b).

From Figure 3 (a), we can see that when larger beam size is considered, the classification performance is improved. When beam size is 1, the model stands for the greedy search with the bag-of-words segmentation. When the beam size is small, such as 2, beam search losses many phrasal information of sentences and thus the improvement is not significant. The performance remains steady when beam size is larger than 16. From



(a) Macro-F1 score for sentiment classification.

(b) Time cost (seconds) of each training iteration.

Figure 3: Sentiment classification of tweets with different beam size N.

Figure 3 (b), we can find that the runtime of each training iteration increases with larger beam size. It is intuitive as the joint model with larger beam considers more segmentation results, which increases the training time of the segmentation model. We set beam size as 16 after parameter learning.

6.6 Effect of the top-ranked segmentation number K

We investigate how the top-ranked segmentation number K affects the performance of sentiment classification. In this part, we set the feature as [PF+SF, PF+CF], and the beam size as 16. The results of macro-F1 on the development set are illustrated in Figure 4.

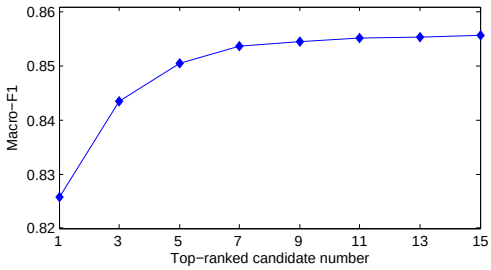


Figure 4: Sentiment classification of tweets with different top-ranked segmentation number K.

From Figure 4, we find that the classification performance increases with K being larger. The reason is that when a larger K is used, (1) at training time, the sentiment classifier is built by using more phrasal information from multiple segmentations, which benefits from the ensembles; (2) at test time, the joint model considers several top-ranked segmentations and get the final sentiment polarity through voting. The performance remains stable when K is larger than 7, as the phrasal information has been mostly covered.

7 Conclusion

In this paper, we develop a joint segmentation and classification framework (**JSC**) for sentiment analysis. Unlike existing sentiment classification algorithms that build sentiment classifier based on the segmentation results from bag-of-words or separate segmentors, the proposed joint model simultaneously conducts sentence segmentation and sentiment classification. We introduce a marginal log-likelihood function to optimize the segmentation model, and effectively train the joint model from sentences annotated only with sentiment polarity, without segmentation annotations of sentences. The effectiveness of the joint model has been verified by applying it on the benchmark dataset of Twitter sentiment classification in SemEval 2013. Results show that, the joint model performs comparably with state-of-the-art methods, and outperforms pipelined methods in various settings. In the future, we plan to apply the joint model on other domains, such as movie/product reviews.

Positive Unlabeled Learning for Deceptive Reviews Detection

Yafeng Ren **Donghong Ji** **Hongbin Zhang**
Computer School

Wuhan 430072, China
{renyafeng,dhji,zhanghongbin}@whu.edu.cn

Abstract

Deceptive reviews detection has attracted significant attention from both business and research communities. However, due to the difficulty of human labeling needed for supervised learning, the problem remains to be highly challenging. This paper proposed a novel angle to the problem by modeling PU (positive unlabeled) learning. A semi-supervised model, called mixing population and individual property PU learning (MPIPUL), is proposed. Firstly, some reliable negative examples are identified from the unlabeled dataset. Secondly, some representative positive examples and negative examples are generated based on LDA (Latent Dirichlet Allocation). Thirdly, for the remaining unlabeled examples (we call them *spy* examples), which can not be explicitly identified as positive and negative, two similarity weights are assigned, by which the probability of a *spy* example belonging to the positive class and the negative class are displayed. Finally, *spy* examples and their similarity weights are incorporated into SVM (Support Vector Machine) to build an accurate classifier. Experiments on gold-standard dataset demonstrate the effectiveness of MPIPUL which outperforms the state-of-the-art baselines.

1 Introduction

The Web has dramatically changed the way people express themselves and interact with others, people frequently write reviews on e-commerce sites, forums and blogs to achieve these purposes. For NLP (Natural Language Processing), these user-generated contents are of great value in that they contain abundant information related to people's opinions on certain topics. Currently, online reviews on products and services are used extensively by consumers and businesses to conduct decisive purchase, product design and marketing strategies. Hence, sentiment analysis and opinion mining based on product reviews have become a popular topic of NLP (Pang and Lee, 2008; Liu, 2012). However, since reviews information can guide people's purchase behavior, positive reviews can result in huge economic benefits and fame for organizations or individuals. This leaves room for promoting the generation of review spams. Through observations and studies of the predecessors (Jindal and Liu, 2008; Ott et al., 2011), review spams are divided into the following two classes:

- **Deceptive Reviews:** Those deliberately mislead readers by giving undeserving positive reviews to some target objects in order to promote the objects, or by giving unjust negative reviews to some target objects in order to damage their reputation.
- **Disruptive Reviews:** Those are non-reviews, which mainly include advertisements and other irrelevant reviews containing no opinion.

Disruptive reviews pose little threat to people, because human can easily identify and ignore them. In this paper, we focus on the more challenging ones: deceptive reviews. Generally, deceptive reviews detection is deemed to be a classification problem (Ott et al., 2011; Li et al., 2011; Feng et al., 2012). Based on the positive and negative examples annotated by people, supervised learning is utilized to build a classifier, and then an unlabeled review can be predicted as deceptive review or truthful one. But the work from Ott et al. (2011) shows that human cannot identify deceptive reviews from their prior knowledge, which indicates that human-annotated review datasets must

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 488–498,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

include some mislabeled examples. These examples will disturb the generation ability of the classifiers. So simple supervised learning is regarded as unsuitable for this task.

It is difficult to come by human labeling needed for supervised learning and evaluation, we cannot obtain the datasets containing deceptive reviews. However, we can get some truthful reviews with high confidence by heuristic rules and prior knowledge. Meanwhile, a lot of unlabeled reviews are available. The problem thus is this: based on some truthful reviews and a lot of unlabeled reviews, can we build an accurate classifier to identify deceptive reviews.

PU (positive unlabeled) learning can be utilized to deal with the above situation (Liu et al., 2002; Liu et al., 2003). Different from traditional supervised learning, PU learning can still build an accurate classifier even without the negative training examples. Several PU learning techniques have been applied successfully in document classification with promising results (Zhang, 2005; Elkan and Noto, 2008; Li et al., 2009; Xiao et al., 2011), while they have yet to be applied in detecting deceptive reviews. Here, we will study how to design PU learning to detect deceptive reviews.

An important challenge is how to deal with *spy* examples (easily mislabeled) of unlabeled reviews, which is not easily handled by the previous PU learning techniques. In this paper, we propose a novel approach, mixing population and individual property PU learning (MPIPUL), by assigning similarity weights and incorporating weights into SVM learning phase. This paper makes the following contributions:

- For the first time, PU learning is defined in the environment of identifying deceptive reviews.
- A novel PU learning is proposed based on LDA and SVM.
- Experimental results demonstrate that our proposed method outperforms the current baselines.

2 Related Work

2.1 Deceptive Reviews Detection

Spam has historically been investigated in the contexts of e-mail (Drucker et al., 1999; Gyongyi et al., 2004) and the Web (Ntoulas et al., 2006). In recent years, researchers have started to look at deceptive reviews.

Jindal and Liu (2008) found that opinion spam was widespread and different from e-mail and Web spam in essence (Jindal and Liu, 2008). They trained models using product review data, by defining features to distinguish duplicate opinion and non-duplicate based on the review text, reviewers and product information. Wu et al. (2010) proposed an alternative strategy of popularity rankings (Wu et al., 2010).

Ott et al. (2011) developed the first dataset containing gold-standard deceptive reviews by crowdsourcing (Ott et al., 2011), and presented three supervised learning methods to detect deceptive reviews by integrating knowledge from psycholinguistics and computational linguistics. This gold-standard dataset will be used in the paper. Li et al. (2011) manually built a review dataset from their crawled reviews (Li et al., 2011), and exploited semi-supervised co-training algorithm to identify deceptive reviews.

Feng et al. (2012) verified the connection between the deceptive reviews and the abnormal distributions (Feng et al., 2012a). Later, they (Feng et al., 2012b) demonstrated that features driven from CFG (Context Free Grammar) parsing trees consistently improve the detection performance.

Mukherjee et al. (2012) proposed detecting group spammers (a group of reviewers who work collaboratively to write deceptive reviews) in product reviews (Mukherjee et al., 2012). The proposed method first used frequent itemset mining to find a set of candidate groups. Then GSRank was presented which can consider relationships among groups, individual reviewers and products they reviewed to detect spammer groups. Later, they also proposed exploiting observed reviewing behaviors to detect opinion spammers in an unsupervised Bayesian inference framework (Mukherjee et al., 2013).

Ren et al. (2014) assumed that there must be some difference on language structure and sentiment polarity between deceptive reviews and truthful ones (Ren et al., 2014a), then they defined the features related to the review text and used genetic algorithm for feature selection, finally they combined two unsupervised clustering algorithm to identify deceptive reviews. Later, they (Ren et al., 2014b) present a new approach, from the viewpoint of correcting the mislabeled

examples, to find deceptive reviews. Firstly, they partition a dataset into several subsets.Then they construct a classifier set for each subset and select the best one to evaluate the whole dataset. Meanwhile, error variables are defined to compute the probability that the examples have been mislabeled. Finally, the mislabeled examples are corrected based on two threshold schemes, majority and non-objection.

Unlike previous studies, PU learning is implemented to identify deceptive reviews.

2.2 Positive Unlabeled Learning

According to the use of the unlabeled data, PU learning can be divided into two classes.

One family of methods built the final classifier by using positive examples dataset and some examples of the unlabeled dataset (Liu et al., 2002; Liu et al., 2003). The basic idea is to find a set of reliable negative examples from the unlabeled data firstly, and then to learn a classifier using EM (Expectation Maximization) or SVM. The performance is limited for neglecting the rest examples of unlabeled dataset.

Another family of methods learned the final classifier by using positive examples dataset and all examples of the unlabeled dataset. Li et al. (Li et al., 2009) studied PU learning in the data stream environment, they proposed a PU learning LELC (PU Learning by Extracting Likely positive and negative micro-Clusters) for document classification, they assume that the examples close together shared the same labels. Xiao et al. (Xiao et al., 2011) proposed a method, called SPUL (similarity-based PU learning), the local similarity-based and global similarity-based mechanisms are proposed to generate the similarity weights for the easily mislabeled examples, respectively. Experimental results show global SPUL generally performs better than local SPUL.

In this paper, a novel PU learning (MPIPUL) is proposed to identify deceptive reviews.

3 Preliminary

Before we introduce the proposed method, we briefly review SVM, which has proven to be an effective classification algorithm (Vapnik, 1998).

Let $T = \{(x^{(1)}, y^{(1)}), (x^{(2)}, y^{(2)}), \ldots, (x^{(|T|)}, y^{(|T|)})\}$ be a training set, where $x^{(i)} \in R^d$ and $y^{(i)} \in \{+1, -1\}$. SVM aims to seek an optimal separating hyperplane $w^T x^{(i)} + b = 0$, the hyperplane can be obtained by solving the following optimization problem:

$$\begin{aligned} min \quad & F(w, b, \epsilon_i) = \frac{1}{2}||w||^2 + C\sum_{i=1}^{|T|}\epsilon_i \\ s.t. \quad & y^{(i)}(w^T x^{(i)} + b) \geq 1 - \epsilon_i, i = 1, \ldots, |T| \\ & \epsilon_i \geq 0, i = 1, \ldots, |T| \end{aligned} \tag{1}$$

where w^T represents the transpose of w, C is a parameter to balance the classification errors and ϵ_i are variables to relax the margin constraints. The optimal classifier can be achieved by using the Lagrange function. For a test example x, if $w^T x + b < 0$, it is classified into the negative class; otherwise, it is positive.

In the following, SVM is extended to incorporate the *spy* examples and their weights, such that the *spy* examples can contribute differently to the classifier construction.

4 The Proposed Method

In this section, we will introduce the proposed approach in details. In our PU learning (MPIPUL), truthful reviews are named positive examples, and deceptive reviews are called negative examples. P is defined as a set which contains all positive examples. U is a set for all unlabeled examples. PU learning aims at building a classifier using P and U. MPIPUL adopts the following four steps:

- Step 1: Extract the reliable negative examples;
- Step 2: Compute the representative positive and negative examples;
- Step 3: Generate the similarity weights for the *spy* examples;
- Step 4: Build the final SVM classifier;

4.1 Extracting Reliable Negative Examples

Considering only positive and unlabeled examples are available in PU learning, some negative examples need to be extracted firstly. These examples will influence the performance of the following three steps. So high-quality negative examples must be guaranteed. Previous works solved the problem with the Spy technique (Liu et al., 2002) or the Rocchio technique (Liu et al., 2003), we integrate them in order to get reliable negative examples. Let subsets NS_1 and NS_2 contain the

corresponding reliable negative examples extracted by the two techniques, respectively. Examples are considered to be a reliable negative only if both techniques agree that they are negative. That is, $NS = NS_1 \cap NS_2$, where NS contains the reliable negative examples.

After reliable negative examples are extracted, there are still some unlabeled examples (we call *spy* examples) in set U, let subset $US = U - NS$, which stores all the *spy* examples. It is crucial to determine how to deal with these *spy* examples.

4.2 Computing Representative Positive and Negative Examples

Generally, a classifier can be constructed to predict deceptive reviews based on the positive examples set P and the reliable negative examples set NS. But the classifier is not accurate enough for lacking of making full use of unlabeled dataset U. In order to utilize *spy* examples in subset US, some representative positive and negative examples are calculated firstly. Since the examples have different styles in sentiment polarity and topic distribution, for every class, computing one representative example is not suitable. For the positive class or the negative class, to ensure there is a big difference between the different representative examples. This paper proposes clustering reliable negative examples into several groups based on LDA (Latent Dirichlet Allocation) topic model and K-means, and then multiple representative examples can be obtained.

LDA topic model is known as a parametric Bayesian clustering model (Blei et al., 2003), and assumes that each document can be represented as the distribution of several topics, each document is associated with common topics. LDA can well capture the relationship between internal documents.

In our experiments based on LDA model, we can get the topic distribution for the reliable negative examples, then some reliable negative examples which are similar in topic distribution will be clustered into a group by K-means. Finally, these reliable negative examples can be clustered into n micro-clusters $(NS_1, NS_2, \ldots, NS_n)$. Here,

$$n = 30 * |NS|/(|US| + |NS|) \quad (2)$$

Here, according to the suggestion of previous work (Xiao et al., 2011), we examine the impact of the different parameter (from 10 to 60) on overall performance, and select the best value 30.

Based on the modified Rocchio formula (Buckley et al., 1999), n representative positive examples (p_k) and n negative ones (n_k) can be obtained using the following formula:

$$p_k = \alpha \frac{1}{|P|} \sum_{i=1}^{|P|} \frac{x^{(i)}}{\| x^{(i)} \|} - \beta \frac{1}{|NS_k|} \sum_{i=1}^{|NS_k|} \frac{x^{(i)}}{\| x^{(i)} \|}$$

$$n_k = \alpha \frac{1}{|NS_k|} \sum_{i=1}^{|NS_k|} \frac{x^{(i)}}{\| x^{(i)} \|} - \beta \frac{1}{|P|} \sum_{i=1}^{|P|} \frac{x^{(i)}}{\| x^{(i)} \|}$$

$$k = 1, \ldots, n \quad (3)$$

According to previous works (Buckley et al., 1994), where the value of α and β are set to 16 and 4 respectively. The research from Buckley et al. demonstrate that this combination emphasizes occurrences in the relevant documents as opposed to non-relevant documents.

4.3 Generating Similarity Weights

For a *spy* example x, since we do not know which class it should belong to, enforcing x to the positive class or the negative class will lead to some mislabeled examples, which disturbs the performance of final classifier. We represent a *spy* example x using the following probability model:

$$\{x, (p^+(x), p^-(x))\}, \quad p^+(x) + p^-(x) = 1 \quad (4)$$

Where $p^+(x)$ and $p^-(x)$ are similarity weights which represent the probability of x belonging to the positive class and the negative class, respectively. For example, $\{x, (1, 0)\}$ means that x is positive, while $\{x, (0, 1)\}$ indicates that x is identified to be negative. For $\{x, (p^+(x), p^-(x))\}$, where $0 < p^+(x) < 1$ and $0 < p^-(x) < 1$, it implies that the probability of x belonging to the positive class and the negative class are both considered.

In this section, similarity weights are decided by mixing global information (population property) and local information (individual property). Then all *spy* examples and their similarity weights are incorporated into a SVM-based learning model.

4.3.1 Population Property

Population property means that the examples in each micro-cluster share the similarity in sentiment polarity and topic distribution, and they belong to the same category with a high possibility. In our framework, in order to compare with the representative examples, all *spy* examples are firstly clustered into n micro-clusters

$(US_1, US_2, \ldots, US_n)$ based on LDA and K-means. Then, for every *spy* example x in one micro-cluster US_i, we tags with temporary label by finding its most similar representative example. Finally, we can get the similarity weights for a *spy* example x in micro-cluster US_i, their probability pertaining to the positive class and negative class can be represented by the following formula:

$$\begin{aligned} p\_pop(x) &= \frac{|positive|}{|US_i|} \\ n\_pop(x) &= \frac{|negative|}{|US_i|} \end{aligned} \tag{5}$$

where $|US_i|$ represents the number of all examples in micro-cluster US_i, $|positive|$ means the number of the examples which is called temporary positive in US_i, and $|negative|$ means the number of the examples which is called temporary negative in US_i.

For example, Figure 1 shows the part (C1, C2, C3, C4) of the clustering results for the *spy* examples based on LDA and K-means, the examples x in C4 are assigned with weights $p\_pop(x) = \frac{4}{9}, n\_pop(x) = \frac{5}{9}$, the examples x in C1 are assigned with weights $p\_pop(x) = 1, n\_pop(x) = 0$.

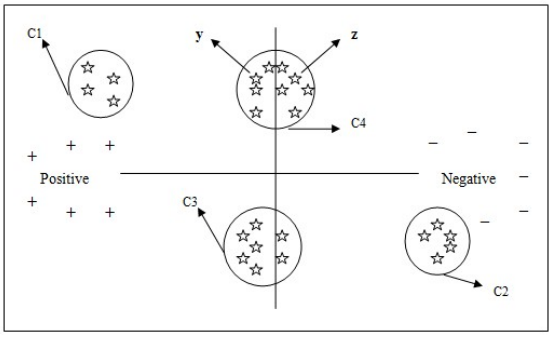

Figure 1: Illustration of population property

The advantage of population property lies in the fact that it considers the similar relationship between the examples, from which the same micro-cluster are assigned the same similarity weight. However, it cannot distinguish the difference of examples in one micro-cluster. In fact, the similarity weights of examples from the same micro-cluster can be different, since they are located physically different. For example, for the *spy* example y and z in micro-cluster C4, it is apparently unreasonable that we assign the same similarity weights to them. So we should join the local information (individual property) when we are computing the similarity weights for a *spy* example.

4.3.2 Individual Property

Individual property is taken into account to measure the relationship between every *spy* example and all representative ones. Specifically, for example x, we firstly compute its similarity to each of the representative examples, and then the probability of the example x belonging to the positive class and negative class can be calculated using the following formula:

$$\begin{aligned} p\_ind(x) &= \frac{\sum_{k=1}^{n} sim(x, p_k)}{\sum_{k=1}^{n}(sim(x, p_k) + sim(x, n_k))} \\ n\_ind(x) &= \frac{\sum_{k=1}^{n} sim(x, n_k)}{\sum_{k=1}^{n}(sim(x, p_k) + sim(x, n_k))} \end{aligned} \tag{6}$$

In the above formula,

$$sim(x, y) = \frac{x \cdot y}{||x|| \cdot ||y||}$$

4.3.3 Similarity Weights

A scheme mixing population and individual property is designed to generate the similarity weights of *spy* examples. Specifically, for *spy* example x, their similarity weights can be obtained by the following formula:

$$\begin{aligned} p^+(x) &= \lambda \cdot p\_pop(x) + (1 - \lambda) \cdot p\_ind(x) \\ p^-(x) &= \lambda \cdot n\_pop(x) + (1 - \lambda) \cdot n\_ind(x) \end{aligned} \tag{7}$$

Where λ is a parameter to balance the information from population property and individual property. In the remaining section, we will examine the impact of the parameter λ on overall performance. Meanwhile, it can be easily proved that $p^+(x) + p^-(x) = 1$.

4.4 Constructing SVM Classifier

After performing the third step, each *spy* example x is assigned two similarity weights: $p^+(x)$ and $p^-(x)$. In this section, we will extend the formulation of SVM by incorporating the examples in positive set P, reliable negative set NS, *spy* examples set US and their similarity weights into a SVM-based learning model.

4.4.1 Primal Problem

Since the similarity weights $p^+(x)$ and $p^-(x)$ indicate the probability for a *spy* example x belonging to the positive class and the negative class, respectively. The optimization formula (1) can be

rewritten as the following optimization problem:

$$
\begin{aligned}
min \quad & F(w,b,\epsilon) = \frac{1}{2}||w||^2 + C_1 \sum_{i=1}^{|P|} \epsilon_i + C_2 \cdot \\
& \sum_{j=1}^{|US|} p^+(x^{(j)})\epsilon_j + C_3 \sum_{m=1}^{|US|} p^-(x^{(m)})\epsilon_m \\
& + C_4 \sum_{n=1}^{|NS|} \epsilon_n \\
s.t. \quad & y^{(i)}(w^T x^{(i)} + b) \geq 1 - \epsilon_i, \quad x^{(i)} \in P \\
& y^{(j)}(w^T x^{(j)} + b) \geq 1 - \epsilon_j, \quad x^{(j)} \in US \\
& y^{(m)}(w^T x^{(m)} + b) \geq 1 - \epsilon_m, \quad x^{(m)} \in US \\
& y^{(n)}(w^T x^{(n)} + b) \geq 1 - \epsilon_n, \quad x^{(n)} \in NS \\
& \epsilon_i \geq 0, \quad \epsilon_j \geq 0, \quad \epsilon_m \geq 0, \quad \epsilon_n \geq 0
\end{aligned} \tag{8}
$$

Where C_1, C_2, C_3 and C_4 are penalty factors controlling the tradeoff between the hyperplane margin and the errors, $\epsilon_i, \epsilon_j, \epsilon_m$ and ϵ_n are the error terms. $p^+(x^{(j)})\epsilon_j$ and $p^-(x^{(m)})\epsilon_m$ can be considered as errors with different weights. Note that, a bigger value of $p^+(x^{(j)})$ can increase the effect of parameter ϵ_j, so that the corresponding example $x^{(j)}$ becomes more significant towards the positive class. In the following, we will find the dual form to address the above optimization problem.

4.4.2 Dual Problem

Assume α_i and α_j are Lagrange multipliers. To simplify the presentation, we redefine some notations as follows:

$$
C_i^+ = \begin{cases} C_1, & x^{(i)} \in P \\ C_2 p^+(x^{(j)}), & x^{(j)} \in US \end{cases}
$$

$$
C_j^- = \begin{cases} C_3 p^-(x^{(m)}), & x^{(m)} \in US \\ C_4, & x^{(n)} \in NS \end{cases}
$$

Based on the above definitions, we let $T^+ = P \cup US$, $T^- = US \cup NS$ and $T^* = T^+ \cup T^-$. The Wolfe dual of primal formulation can be obtained as follows (Appendix A for the calculation process):

$$
\begin{aligned}
max \quad & W(\alpha) = \sum_{i=1}^{|T^*|} \alpha_i - \frac{1}{2} \sum_{i=1,j=1}^{|T^*|} \alpha_i \alpha_j y^{(i)} \cdot \\
& y^{(j)} < x^{(i)}, x^{(j)} > \\
s.t. \quad & C_i^+ \geq \alpha_i \geq 0, \quad x^{(i)} \in T^+ \\
& C_j^- \geq \alpha_j \geq 0, \quad x^{(j)} \in T^- \\
& \sum_{i=1}^{|T^+|} \alpha_i - \sum_{j=1}^{|T^-|} \alpha_j = 0
\end{aligned} \tag{9}
$$

where $< x^{(i)}, x^{(j)} >$ is the inner product of $x^{(i)}$ and $x^{(j)}$. In order to get the better performance, we can replace them by using kernel function $\phi(x^{(i)})$ and $\phi(x^{(j)})$, respectively. The kernel track can convert the input space into a high-dimension feature space. It can solve the uneven distribution of dataset and complex problem from heterogeneous data sources, which allows data to get a better expression in the new space (Lanckriet et al., 2004; Lee et al., 2007).

After solving the above problem, w can be obtained, then b can also be obtained by using KKT (Karush-Kuhn-Tucker) conditions. For a test example x, if $w^T x + b > 0$, it belongs to the positive class. Otherwise, it is negative.

5 Experiments

We aim to evaluate whether our proposed PU learning can identify deceptive reviews properly. We firstly describe the gold-standard dataset, and then introduce the way to generate the positive examples P and unlabeled examples U. Finally we present human performance in gold-standard dataset.

5.1 Datasets

There is very little progress in detection of deceptive reviews, one reason is the lack of standard dataset for algorithm evaluation. The gold-standard dataset is created based on crowdsourcing platform (Ott et al., 2011), which is also adopted as the experimental dataset in this paper.

5.1.1 Deceptive Reviews

Crowdsourcing services can carry out massive data collection and annotation; it defines the task in the network platform, and paid for online anonymous workers to complete the task.

Humans cannot be precisely distinguish deceptive ones from existing reviews, but they can create deceptive reviews as one part of the dataset. Ott et al. (2011) accomplish this work by AMT (Amazon Mechanical Turk). They set 400 tasks for 20 hotels, in which each hotel gets 20 tasks. Specific task is: If you are a hotel market department employee, for each positive review you wrote for the benefit for hotel development, you may get one dollar. They collect 400 deceptive reviews.

5.1.2 Truthful Reviews

For the collection of truthful reviews, they get 6977 reviews from TripAdvisor[1] based on the same 20 Chicago hotels, and remove some reviews on the basis of the following constraints:

- Delete all non-five star reviews;
- Delete all non-English reviews;
- Delete all reviews which are less than 75 characters;
- Delete all reviews written by first-time authors;

2124 reviews are gathered after filtering. 400 of them are chosen as truthful ones for balancing the number of deceptive reviews, as well as maintaining consistent with the distribution of the length of deceptive reviews. 800 reviews constitute whole gold-standard dataset at last.

5.2 Experiment Setup

We conduct 10-fold cross-validation: the dataset is randomly split into ten folds, where nine folds are selected for training and the tenth fold for test. In training dataset, it contains 360 truthful reviews and 360 deceptive ones. This paper is intended to apply PU learning to identify deceptive reviews. We specially make the following setting: take 20% of the truthful reviews in training set as positive examples dataset P, all remaining truthful and deceptive reviews in training set as the unlabeled dataset U. Therefore, during one round of the algorithm, the training set contains 720 examples including 72 positive examples (set P) and 648 unlabeled examples (set U), and the test set contains 80 examples including 40 positive and 40 negative ones. In order to verify the stability of the proposed method, we also experiment another two different settings, which account for 30% and 40% of the truthful reviews in training set as positive examples dataset P respectively.

[1] http://www.tripadvisor.com

5.3 Human Performance

Human performance reflects the degree of difficulty to address this task. The rationality of PU learning is closely related to human performance.

We solicit the help of three volunteer students, who were asked to make judgments on test subset (corresponding to the tenth fold of our cross-validation experiments, contains 40 deceptive reviews and 40 truthful reviews). Additionally, to test the extent to which the individual human judges are biased, we evaluate the performance of two virtual meta-judges: one is the MAJORITY meta-judge when at last two out of three human judge believe the review to be deceptive, and the other is the SKEPTIC when any human judge believes the review to be deceptive. It is apparent from the results that human judges are not particularly effective at this task (Table 1). Inter-annotator agreement among the three judges, computed using Fleiss' kappa, is 0.09. Landis and Koch (Landis and Koch, 1977) suggest that scores in the range (0.00, 0.20) correspond to "slight agreemen" between annotators. The largest pairwise Cohen's kappa is 0.11 between JUDGE-1 and JUDGE-3, far below generally accepted pairwise agreement levels. We can infer that the dataset which are annotated by people will include a lot of mislabeled examples. Identifying deceptive reviews by simply using supervised learning methods is not appropriate. So we propose addressing this issue by using PU learning.

Table 1: Human performance

Methods		Accuracy (%)
Human	JUDGE-1	57.9
	JUDGE-2	55.4
	JUDGE-3	61.7
META	MAJORITY	58.3
	SKEPTIC	62.4

6 Results and Analysis

In order to verify the effectiveness of our proposed method, we perform two PU learning (LELC and SPUL) in the gold-standard dataset.

6.1 Experimental Results

Table 2 shows that the experimental results compared with different PU learning techniques. In Table 2, $P(20\%)$ means that we randomly select 20 percentages of truthful reviews to form the positive examples subset P. In our MPIPUL framework, we set $\lambda = 0.3$. We can see that our proposed method can obtain 83.91%, 85.43% and 86.69% in accuracy from different experimental settings, respectively. Compared to the current best method (SPUL-global), the accuracy can be improved 2.06% on average. MPUPUL can improve 3.21% on average than LELC. The above discussion shows our proposed methods consistently outperform the other PU baselines.

Table 2: Accuracy on the different PU learning

Baselines	P(20%)	P(30%)	P(40%)
LELC	81.12	82.08	83.21
SPUL-local	81.43	82.71	84.09
SPUL-global	81.89	83.24	84.73
MPIPUL (0.3)	83.91	85.43	86.69

PU learning framework in this paper can obtain the better performance. Two factors contribute to the improved performance. Firstly, LDA can capture the deeper information of the reviews in topic distribution. Secondly, strategies of mixing population and individual property can generate the similarity weights for *spy* examples, and these examples and their similarity weights are extended into SVM, which can build a more accurate classifier.

6.2 Parameter Sensitivity

For the *spy* examples, the similarity weights are generated by population property and individual property. Should we select the more population information or individual information? In MPIPUL, parameter λ is utilized to adjust this process. So we experiment with the different value of the parameter λ on MPUPUL performance (Figure 2).

As showed in Figure 2, for $P(20\%)$, if $\lambda < 0.3$, the performance increases linearly, if $\lambda > 0.3$, the performance will decrease linearly. Meanwhile, we can get the same trends for $P(30\%)$ and $P(40\%)$. Based on the above discussion, MPIPUL can get the best performance when $\lambda \approx 0.3$.

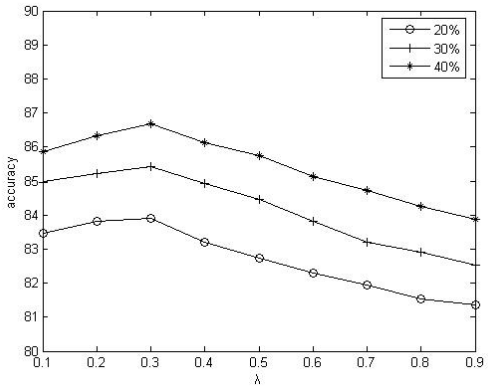

Figure 2: Algorithm performance on different parameter

7 Conclusions and Future Work

This paper proposes a novel PU learning (MPIPUL) technique to identify deceptive reviews based on LDA and SVM. Firstly, the *spy* examples are assigned similarity weights by integrating the information from the population property and individual property. Then the *spy* examples and their similarity weights are incorporated into SVM learning phase to build an accurate classifier. Experimental results on gold-standard dataset show the effectiveness of our method.

In future work, we will discuss the application of our proposed method in the massive dataset.

Appendix A

The optimization problem is as follows:

$$\begin{aligned} min \qquad & F(w,b,\epsilon) = \frac{1}{2}||w||^2 + C_1\sum_{i=1}^{|P|}\epsilon_i + C_2\cdot \\ & \sum_{j=1}^{|US|}p^+(x^{(j)})\epsilon_j + C_3\sum_{m=1}^{|US|}p^-(x^{(m)})\epsilon_m + \\ & C_4\sum_{n=1}^{|NS|}\epsilon_n \\ s.t. \quad & y^{(i)}(w^Tx^{(i)}+b) \geq 1-\epsilon_i, \quad x^{(i)} \in P \\ & y^{(j)}(w^Tx^{(j)}+b) \geq 1-\epsilon_j, \quad x^{(j)} \in US \\ & y^{(m)}(w^Tx^{(m)}+b) \geq 1-\epsilon_m, \quad x^{(m)} \in US \\ & y^{(n)}(w^Tx^{(n)}+b) \geq 1-\epsilon_n, \quad x^{(n)} \in NS \\ & \epsilon_i \geq 0, \quad \epsilon_j \geq 0, \quad \epsilon_m \geq 0, \quad \epsilon_n \geq 0 \end{aligned} \tag{10}$$

We construct the Lagrangian function for the above optimization problem, we have:

$$\begin{aligned} L(w,b,\epsilon,\alpha,\gamma) = & F(w,b,\epsilon) + \sum_{i=1}^{|P|}\alpha_i[-y^{(i)}\cdot \\ & (w^Tx^{(i)}+b)+1-\epsilon_i] + \sum_{j=1}^{|US|}\alpha_j[-y^{(j)}(w^Tx^{(j)}+ \\ & b)+1-\epsilon_j] + \sum_{m=1}^{|US|}\alpha_m[-y^{(m)}(w^Tx^{(m)}+b)+1 \\ & -\epsilon_m] + \sum_{n=1}^{|NS|}\alpha_n[-y^{(n)}(w^Tx^{(n)}+b)+1-\epsilon_n] - \\ & \sum_{i=1}^{|P|}\gamma_i\epsilon_i - \sum_{j=1}^{|US|}\gamma_j\epsilon_j - \sum_{m=1}^{|US|}\gamma_m\epsilon_m - \sum_{n=1}^{|NS|}\gamma_n\epsilon_n \end{aligned} \tag{11}$$

Here, the α and γ are Lagrange multipliers. To find the dual form of the problem, we need to first minimize $L(w,b,\epsilon,\alpha,\gamma)$ with respect to w and b, we will do by setting the derivatives of L with respect to w and b to zero, we have:

$$\begin{aligned} \frac{\partial L(w,b,\epsilon,\alpha,\gamma)}{\partial w} = & w - \sum_{i=1}^{|P|}\alpha_i y^{(i)}x^{(i)} - \sum_{j=1}^{|US|} \\ & \alpha_j y^{(j)}x^{(j)} - \sum_{m=1}^{|US|}\alpha_m y^{(m)}x^{(m)} - \sum_{n=1}^{|NS|}\alpha_n y^{(n)}\cdot \\ & x^{(n)} = 0 \end{aligned} \tag{12}$$

This implies that

$$\begin{aligned} w = & \sum_{i=1}^{|P|}\alpha_i y^{(i)}x^{(i)} + \sum_{j=1}^{|US|}\alpha_j y^{(j)}x^{(j)} + \sum_{m=1}^{|US|}\alpha_m\cdot \\ & y^{(m)}x^{(m)} + \sum_{n=1}^{|NS|}\alpha_n y^{(n)}x^{(n)} \end{aligned} \tag{13}$$

Here, to simplify the presentation, we redefine some notations in the following:

$$T^+ = P \cup US, T^- = US \cup NS, T^* = T^+ \cup T^-$$

$$C_i^+ = \begin{cases} C_1, & x^{(i)} \in P \\ C_2 p^+ x^{(j)}, & x^{(j)} \in US \end{cases}$$

$$C_j^- = \begin{cases} C_3 p^- x^{(m)}, & x^{(m)} \in US \\ C_4, & x^{(n)} \in NS \end{cases}$$

so we obtain

$$w = \sum_{i=1}^{|T^*|}\alpha_i y^{(i)}x^{(i)} \tag{14}$$

As for the derivative with respect to b, we obtain

$$\begin{aligned} \frac{\partial L(w,b,\epsilon,\alpha,\gamma)}{\partial b} = & -\sum_{i=1}^{|P|}\alpha_i y^{(i)} - \sum_{j=1}^{|US|}\alpha_j y^{(j)} \\ & - \sum_{m=1}^{|US|}\alpha_m y^{(m)} - \sum_{n=1}^{|NS|}\alpha_n y^{(n)} = 0 \end{aligned} \tag{15}$$

We get:

$$\sum_{i=1}^{|T^*|}\alpha_i y^{(i)} = 0 \tag{16}$$

If we take Equation (14) and (16) back into the Lagrangian function (Equation 11), and simplify, we get

$$L(w,b,\epsilon,\alpha,\gamma) = \sum_{i=1}^{|T^*|}\alpha_i - \frac{1}{2}\sum_{i,j=1}^{|T^*|} y^{(i)}y^{(j)}\alpha_i \cdot \alpha_j < x^{(i)}, x^{(j)} > \tag{17}$$

To the primal optimization formula (10), we can obtain the following dual optimization problem:

$$\begin{aligned} max \qquad W(\alpha) &= \sum_{i=1}^{|T^*|}\alpha_i - \frac{1}{2}\sum_{i=1,j=1}^{|T^*|} \alpha_i\alpha_j y^{(i)} \cdot y^{(j)} < x^{(i)}, x^{(j)} > \\ s.t. \quad & C_i^+ \geq \alpha_i \geq 0, \quad x^{(i)} \in T^+ \\ & C_j^- \geq \alpha_j \geq 0, \quad x^{(j)} \in T^- \\ & \sum_{i=1}^{|T^+|}\alpha_i - \sum_{j=1}^{|T^-|}\alpha_j = 0 \end{aligned} \tag{18}$$

where $< x^{(i)}, x^{(j)} >$ is the inner product of $x^{(i)}$ and $x^{(j)}$, we can replace them by using kernel function $\phi(x^{(i)})$ and $\phi(x^{(j)})$, respectively.

Resolving Shell Nouns

Abstract

Shell nouns, such as *fact* and *problem*, occur frequently in all kinds of texts. These nouns themselves are unspecific, and can only be interpreted together with the *shell content*. We propose a general approach to automatically identify shell content of shell nouns. Our approach exploits lexico-syntactic knowledge derived from the linguistics literature. We evaluate the approach on a variety of shell nouns with a variety of syntactic expectations, achieving accuracies in the range of 62% (baseline = 33%) to 83% (baseline = 74%) on crowd-annotated data.

1 Introduction

Shell nouns are abstract nouns, such as *fact*, *issue*, *idea*, and *problem*, which facilitate efficiency by avoiding repetition of long stretches of text. The *shell* metaphor comes from Schmid (2000), and it captures the various functions of these nouns in a discourse: containment, signalling, pointing, and encapsulating. Shell nouns themselves are unspecific, and can only be interpreted together with their *shell content*, i.e., the propositional content they encapsulate in the given context. The process of identifying this content in the given context is referred to as *shell noun resolution* or *interpretation*. Examples (1), (2), and (3) show usages of the shell nouns *fact* and *issue*. The shell noun phrases are resolved to the postnominal *that* clause, the complement *wh* clause, and the immediately preceding clause, respectively.[1,2]

(1) **The fact that a major label hadn't been at liberty to exploit and repackage the material on CD** meant that prices on the vintage LP market were soaring.

(2) **The issue** that this country and Congress must address is **how to provide optimal care for all without limiting access for the many**.

(3) **Living expenses are much lower in rural India than in New York**, but **this fact** is not fully captured if prices are converted with currency exchange rates.

Observe that the relation between shell noun phrases and their shell content is similar to the relation of abstract anaphora (or cataphora) (Asher, 1993) with backward- or forward-looking abstract-object antecedents. For anaphoric shell noun examples, the shell content precedes the shell noun phrase, and for cataphoric shell noun examples the shell content follows the shell noun phrase.[3]

Shell nouns as a group occur frequently in argumentative texts (Schmid, 2000; Flowerdew, 2003; Botley, 2006). They play an important role in organizing a discourse and maintaining its coherence (Schmid, 2000; Flowerdew, 2003), and resolving them is an important component of various computational linguistics tasks that rely on

[1] Note that the postnominal *that*-clause in (1) is not a relative clause: the fact in question is not an argument of *exploit and repackage*.

[2] All examples in this paper are from the New York Times corpus (`https://catalog.ldc.upenn.edu/LDC2008T19`)

[3] We use the terms cataphoric shell noun and anaphoric shell noun for lack of better alternatives.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 499–510,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

discourse structure. Accordingly, identifying shell content can be helpful in summarization, information retrieval, and ESL learning (Flowerdew, 2003; Hinkel, 2004).

Despite their importance in discourse, understanding of shell nouns from a computational linguistics perspective is only in the preliminary stage. Recently, we proposed an approach to annotate and resolve anaphoric cases of six typical shell nouns: *fact*, *reason*, *issue*, *decision*, *question*, and *possibility* (Kolhatkar et al., 2013b). This work drew on the observation that shell nouns following cataphoric constructions are easy to resolve. We manually developed rules to identify shell content for such cases. Later, we used these cataphoric examples and their shell content as training data to resolve harder anaphoric examples.

In this paper, we propose a general algorithm to resolve cataphoric shell noun examples. Our long-term goal is to build an end-to-end shell-noun resolution system. If we want to go beyond the six shell nouns from our previous work, and generalize our approach to other shell nouns, first we need to develop an approach to resolve cataphoric shell noun examples. A number of challenges are associated with this seemingly easy task. The primary challenges is that this resolution is in many crucial respects a semantic phenomenon. To obtain the required semantic knowledge, we exploit the properties of shell nouns and their categorization described in the linguistics literature. We evaluate our method using crowdsourcing, and demonstrate how far one can get with simple, deterministic shell content extraction.

2 Related work

Shell-nounhood is a well-established concept in linguistics (Vendler, 1968; Ivanic, 1991; Asher, 1993; Francis, 1994; Schmid, 2000, inter alia). However, understanding of shell nouns from a computational linguistics perspective is only in the preliminary stage.

Shell nouns take a number of semantic arguments. In this respect, they are similar to the general class of argument-taking nominals as given in the NomBank (Meyers et al., 2004). Similarly, there is a small body of literature that addresses nominal semantic role labelling (Gerber et al., 2009) and nominal subcategorization frames (Preiss et al., 2007). That said, the distinguishing property of shell nouns is that one of their semantic arguments is the shell content, but the literature in computational linguistics does not provide any method that is able to identify the shell content. The focus of our work is to rectify this.

Shell content represents complex and abstract objects. So traditional linguistic and psycholinguistic principles used in pronominal anaphora resolution (see the survey by Poesio et al. (2011)), such as gender and number agreement, are not applicable in resolving shell nouns. That said, there is a line of literature on annotating and resolving personal and demonstrative pronouns, which typically refer to similar kinds of non-nominal abstract entities (Passonneau, 1989; Eckert and Strube, 2000; Byron, 2003; Müller, 2008; Hedberg et al., 2007; Poesio and Artstein, 2008; Navarretta, 2011, inter alia). Also, there have been attempts at annotating the shell content of anaphoric occurrences of shell nouns (e.g., Botley (2006), Kolhatkar et al. (2013a)). However, none of these approaches attempt to annotate and resolve cataphoric examples such (1) and (2).

3 Challenges

A number of challenges are associated with the task of resolving cataphoric shell noun examples, especially when it comes to developing a holistic approach for a variety of shell nouns.

First, each shell noun has idiosyncrasies. Different shell nouns have different semantic and syntactic expectations, and hence they take different types of one or more semantic arguments: one introducing the shell content, and others expressing circumstantial information about the shell noun. For instance, *fact* typically takes a single factual clause as an argument, which is its shell content, as we saw in example (1), whereas *reason* expects two arguments: the cause and the effect, with the content introduced in the cause, as shown in example (4).[4] Similarly, *decision* takes an agent making the decision and the shell content is represented as an action or a proposition, as shown in (5).[5]

(4) **<u>One reason</u>** [that 60 percent of New York City public-school children read below grade level]$^{\text{effect}}$ is [**that many elementary schools don't have libraries**]$^{\text{cause}}$.

[4]Observe that the postnominal *that* clause in (4) is not a relative clause, and still it is not the shell content because it is not the cause argument of the shell noun *reason*.

[5]Observe that this aspect of shell nouns of taking different numbers and kinds of complement clauses is similar to verbs having different subcategorization frames.

(5) I applaud loudly the decision of [Greenburgh]^{agent} **to ban animal performances**.

Second, the relation between a shell noun and its content is in many crucial respects a semantic phenomenon. For instance, resolving the shell noun *reason* to its shell content involves identifying a) that *reason* generally expects two semantic arguments: cause and effect, b) that the cause argument (and not the effect argument) represents the shell content, and c) that a particular constituent in the given context represents the cause argument.

Third, at the conceptual level, once we know which semantic argument represents shell content, resolving examples such as (4) seems straightforward using syntactic structure, i.e., by extracting the complement clause. But at the implementation level, this is a non-trivial problem for two reasons. The first reason is that examples containing shell nouns often follow syntactically complex constructions, including embedded clauses, coordination, and sentential complements. An automatic parser is not always accurate for such examples. So the challenge is whether the available tools in computational linguistics such as syntactic parsers and discourse parsers are able to provide us with the information that is necessary to resolve these difficult cases. The second reason is that the shell content can occur in many different constructions, such as apposition (e.g., ***parental ownership of children***, ***a concept*** *that allows* ...), postnominal and complement clause constructions, as we saw in examples (1) and (2), and modifier constructions (e.g., ***the liberal trade policy*** *that* ...). Moreover, in some constructions, the content is indefinite (e.g., ***A bad idea*** *does not harm until someone acts upon it.*) or *None* because the example is a non-shell noun usage (e.g., ***this week's issue*** *of Sports Illustrated*), and the challenge is to identify such cases.

Finally, whether the postnominal clause introduces the shell content or not is dependent on the context of the shell noun phrase. The resolution can be complicated by complex syntactic constructions. For instance, when the shell noun follows verbs such as *expect*, it becomes difficult for an automatic system to identify whether the postnominal or the complement clause is of the verb or of the shell noun (e.g., *they did not expect* ***the decision*** *to reignite tension in Crown Heights* vs. *no one expected* ***the decision*** ***to call an election***). Similarly, shell noun phrases can be objects of prepositions, and whether the postnominal clause introduces the shell content or not is dependent on this preposition. For instance, for the pattern *reason that*, the postnominal *that* clause does not generally introduce the shell content, as we saw in (4); however, this does not hold when the shell noun phrase containing *reason* follows the preposition *for*, as shown in (6).

(6) Low tax rates give people an incentive to work, for **the simple reason that they get to keep more of what they earn**.

4 Linguistic framework

Linguists have studied a variety of shell nouns, their classification, different patterns they follow, and their semantic and syntactic properties in detail (Vendler, 1968; Ivanic, 1991; Asher, 1993; Francis, 1994; Schmid, 2000, inter alia). Schmid points out that being a shell noun is a property of a specific usage of the noun rather than an inherent property of the word. He provides a list of 670 English nouns that tend to occur as shell nouns. A few frequently occurring ones are: *problem*, *notion*, *concept*, *issue*, *fact*, *belief*, *decision*, *point*, *idea*, *event*, *possibility*, *reason*, *trouble*, *question*, *plan*, *theory*, *aim*, and *principle*.

4.1 Lexico-syntactic patterns

Precisely defining the notion of shell-nounhood is tricky. A necessary property of shell nouns is that they are capable of taking clausal arguments, primarily with two lexico-syntactic constructions: *Noun + postnominal clause* and *Noun + be + complement clause* (Vendler, 1968; Biber et al., 1999; Schmid, 2000; Huddleston and Pullum, 2002). Schmid exploits these lexico-syntactic constructions to identify shell noun usages. In particular, he provides a number of typical lexico-syntactic patterns that are indicative of either anaphoric or cataphoric shell noun occurrences. Table 1 shows these patterns with examples.

Cataphoric These patterns primarily follow two constructions.

N-be-clause In this construction, the shell noun phrase occurs as the subject in a subject-verb-clause construction, with the linking verb *be*, and the shell content embedded as a *wh* clause, *that* clause, or *to*-infinitive clause. The linking

	Cataphoric	
1	*N-be-to*	**Our plan is *to*** *hire and retain the best managers we can*.
2	*N-be-that*	**The major reason is *that*** *doctors are uncomfortable with uncertainty*.
3	*N-be-wh*	Of course, **the central, and probably insoluble, issue is *whether*** *animal testing is cruel*.
4	*N-to*	**The decision *to*** *disconnect the ventilator* came after doctors found no brain activity.
5	*N-that*	Mr. Shoval left open **the possibility *that*** *Israel would move into other West Bank cities*.
6	*N-wh*	If there ever is **any doubt *whether*** *a plant is a poppy or not*, break off a stem and squeeze it.
7	*N-of*	**The concept of** *having an outsider as Prime Minister* is outdated.
	Anaphoric	
8	*th-N*	*Living expenses are much lower in rural India than in New York*, but **this fact** is not fully captured if prices are converted with currency exchange rates.
9	*th-be-N*	*People change*. **This is a fact**.
10	*Sub-be-N*	If the money is available, however, ***cutting the sales tax* is a good idea**.

Table 1: Lexico-grammatical patterns of shell nouns (Schmid, 2000). Shell noun phrases are underlined, the pattern is marked in boldface, and the shell content is marked in italics.

	Proportion							
Noun	***N-be-to***	***N-be-that***	***N-be-wh***	***N-to***	***N-that***	***N-wh***	***N-of***	**total**
idea	7	2	-	5	23	10	53	91,277
issue	-	1	5	7	14	2	71	55,088
concept	1	-	-	6	12	-	79	14,301
decision	-	-	-	80	12	1	5	55,088
plan	5	-	-	72	17	-	4	67,344
policy	4	1	-	16	25	2	51	24,025

Table 2: Distribution of cataphoric patterns for six shell nouns in the New York Times corpus. Each column shows the percentage of instances following that pattern. The last column shows the total number of cataphoric instances of each noun in the corpus.

verb *be* indicates the semantic identity between the shell noun and its content in the given context. The construction follows the patterns in rows 1, 2, and 3 of Table 1.

N-clause This construction includes the cataphoric patterns 4–7 in Table 1. For these patterns the link between the shell noun and the content is much less straightforward: whether the postnominal clause expresses the shell content or not is dependent on the shell noun and the syntactic structure under consideration. For instance, for the shell noun *fact*, the shell content is embedded in the postnominal *that* clause, as shown in (1), but this does not hold for the shell noun *reason* in example (4). The *N-of* pattern is different from other patterns: it follows the construction *N-prepositional phrase* rather than *N-clause*, and since a prepositional phrase can take different kinds of embedded constituents such as a noun phrase, a sentential complement, and a verb phrase, the pattern offers flexibility in the syntactic type of the shell content.

Anaphoric For these patterns, the link between the shell noun and the content is created using linguistic elements such as *the*, *this*, *that*, *other*, *same*, and *such*. For the patterns 8 and 9 the shell content does not typically occur in the sentence containing the shell noun phrase. For the pattern 10, the shell content is the subject in a subject-verb-N construction.

Pattern preferences Different shell nouns have different pattern preferences. Table 2 shows the distribution of cataphoric patterns for six shell nouns in the New York Times corpus. The shell nouns *idea*, *issue*, and *concept* prefer *N-of* pattern, whereas *plan* and *decision* prefer the pattern *N-to*. Among all instances of the shell noun *decision* fol-

***Idea* family**
Semantic features: [mental], [conceptual]
Frame: mental; focus on propositional content of IDEA
Nouns: ***idea***, ***issue***, ***concept***, *point*, *notion*, *theory*, ...
Patterns: *N-be-that/of*, *N-that/of*

***Plan* family**
Semantic features: [mental], [volitional], [manner]
Frame: mental; focus on IDEA
Nouns: ***decision***, ***plan***, ***policy***, *idea*, ...
Patterns: *N-be-to/that*, *N-to/that*

***Trouble* family**
Semantic features: [eventive], [attitudinal], [manner], [deontic]
Frame: general eventive
Nouns: ***problem***, ***trouble***, ***difficulty***, *dilemma*, *snag*
Patterns: *N-be-to*

***Problem* family**
Semantic features: [factual], [attitudinal], [impeding]
Frame: general factual
Nouns: ***problem***, ***trouble***, ***difficulty***, *point*, *thing*, *snag*, *dilemma* , ...
Patterns: *N-be-that/of*

***Thing* family**
Semantic features: [factual]
Frame: general factual
Nouns: ***fact***, ***phenomenon***, *point*, *case*, *thing*, *business*
Patterns: *N-that*, *N-be-that*

***Reason* family**
Semantic features: [factual], [causal]
Frame: causal; attentional focus on CAUSE
Nouns: ***reason***, *cause*, *ground*, *thing*
Patterns: *N-be-that/why*, *N-that/why*

Table 3: Example families from Schmid (2000). The nouns in boldface are used to evaluate this work.

lowing Schmid's cataphoric patterns, 80% of the instances follow the pattern *N-to*.[6]

4.2 Categorization of shell nouns

Schmid classifies shell nouns at three levels. At the most abstract level, he classifies shell nouns into six semantic classes: *factual*, *linguistic*, *mental*, *modal*, *eventive*, and *circumstantial*. Each semantic class indicates the type of experience the shell noun is intended to describe. For instance, the *mental* class describes ideas and cognitive states, whereas the *linguistic* class describes utterances, linguistic acts, and products thereof.

The next level of classification includes more-detailed semantic features. Each broad semantic class is sub-categorized into a number of *groups*. A group of an abstract class tries to capture the semantic features associated with the fine-grained differences between different usages of shell nouns in that class. For instance, groups associated with the *mental* class are: *conceptual*, *creditive*, *dubiative*, *volitional*, and *emotive*.

The third level of classification consists of *families*. A family groups together shell nouns with similar semantic features. Schmid provides 79 distinct families of 670 shell nouns. Each family is named after the primary noun in that family. Table 3 shows six families: *Idea*, *Plan*, *Trouble*, *Problem*, *Thing*, and *Reason*. A shell noun can be a member of multiple families. The nouns subsumed in a family share semantic features. For instance, all nouns in the *Idea* family are *mental* and *conceptual*. They are mental because ideas are only accessible through thoughts, and conceptual because they represent reflection or an application of a concept. Each family activates a *semantic frame*. The idea of these semantic frames is similar to that of frames in Frame semantics (Fillmore, 1985) and in semantics of grammar (Talmy, 2000). In particular, Schmid follows Talmy's conception of frames. A semantic frame describes conceptual structures, its elements, and their interrelationships. For instance, the *Reason* family invokes the causal frame, which has cause and effect as its elements with the attentional focus on the cause. According to Schmid, the nouns in a family also share a number of lexico-syntactic features. The *patterns* attribute in Table 3 shows prototypical lexico-syntactic patterns, which *attract* the members of the family. Schmid defines *attraction* as the degree to which a lexico-grammatical pattern attracts a certain noun. For instance, the patterns *N-to* and *N-that* attract the shell nouns in the *Plan* family, whereas the *N-that* pattern attracts the nouns in the *Thing* family. The pattern *N-of* is restricted to a smaller group of nouns such as *concept*, *problem*, and *issue*.[7,8]

[6] Table 2 does not include anaphoric patterns, as this paper is focused on cataphoric shell noun examples. Anaphoric patterns are common for all shell nouns: among all instances of a shell noun, approximately 50 to 80% are anaphoric.

[7] Schmid used the British section of COBUILD'S *Bank of English* for his classification.

[8] Schmid's families could help enrich resources such as FrameNet (Baker et al., 1998) with the shell content information.

5 Resolution algorithm

With this exposition, the problem of shell noun resolution is identifying the appropriate semantic argument of the shell noun representing its shell content. This section describes our algorithm to resolve shell nouns following cataphoric patterns. The algorithm addresses the primary challenge of idiosyncrasies of shell nouns by exploiting Schmid's semantic families (see Section 4.2). The input of the algorithm is a shell noun instance following a cataphoric pattern, and the output is its shell content or *None* if the shell content is not present in the given sentence. The algorithm follows three steps. First, we parse the given sentence using the Stanford parser.[9] Second, we look for the noun phrase (NP), where the head of the NP is the shell noun to be resolved.[10] Finally, we extract the appropriate shell content, if it is present in the given sentence.

5.1 Identifying potentially anaphoric shell-noun constructions

Before starting the actual resolution, first we identify whether the shell content occurs in the given sentence or not. According to Schmid, the lexico-syntactic patterns signal the position of the shell content. For instance, if the pattern is of the form *N-be-clause*, the shell content is more likely to occur in the complement clause in the same sentence. That said, although on the surface level, the shell noun seems to follow a cataphoric pattern, it is possible that the shell content is not given in a postnominal or a complement clause, as shown in (7).

(7) Just as weekend hackers flock to the golf ball most used by PGA Tour players, **recreational skiers, and a legion of youth league racers, gravitate to the skis worn by Olympic champions**. It is **the reason** that top racers are so quick flash their skis for the cameras in the finish area.

Here, the shell noun and its content are linked via the pronoun *it*. For such constructions, the shell noun phrase and shell content do not occur in the same sentence. Shell content occurs in the preceding discourse, typically in the preceding sentence.

[9] `http://nlp.stanford.edu/software/lex-parser.shtml`

[10] We extract the head of an NP following the heuristics proposed by Collins (1999, p. 238).

We identify such cases, and other cases where the shell content is not likely to occur in the postnominal or complements clauses, by looking for the patterns below in the given order, returning the shell content when it occurs in the given sentence.

Sub-be-N This pattern corresponds to the lexico-grammatical pattern in Figure 1(a). If this pattern is found, there are three main possibilities for the *subject*. First, if an existential *there* occurs at the subject position, we move to the next pattern. Second, if the subject is *it* (example (7)), *this* or *that*, we return *None*, assuming that the content is not present in the given sentence. Finally, if the first two conditions are not satisfied, i.e., if the subject is neither a pronoun not an existential *there*, we assume that subject contains a valid shell content, and return it. An example is shown in (8). Note that in such cases, unlike other patterns, the shell content is expressed as a noun phrase.

(8) **Strict liability** is **the biggest issue** when considering what athletes put in their bodies.

Apposition Another case where shell content does not typically occur in the postnominal or complement clause is the case of apposition. Indefinite shell noun phrases often occur in apposition constructions, as shown in (9).

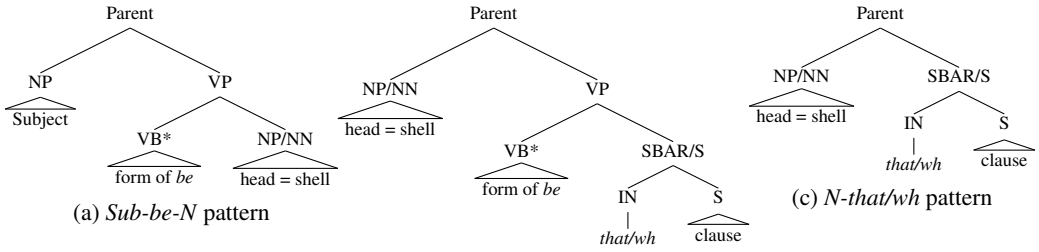
(9) The LH lineup, according to Gale, will feature **"cab-forward" design**, **a concept** that particularly pleases him.

In this step, we check for this construction and return the sentential, verbal, or nominal left sibling of the shell noun phrase.

Modifier For shell nouns such as *issue*, *phenomenon*, and *policy*, often the shell content is given in the modifier of the shell noun, as shown in (10).

(10) But in the 18th century, Leipzig's central location in German-speaking Europe and **the liberal trade policy** of the Saxon court fostered publishing.

We deal with such cases as follows. First, we extract the modifier phrases by concatenating the modifier words having noun, verb, or adjective part-of-speech tags. To exclude unlikely modifier phrases as shell content (e.g., *good idea*, *big*



(a) *Sub-be-N* pattern

(b) *N-be-clause* pattern

(c) *N-that/wh* pattern

Figure 1: Lexico-syntactic patterns for shell nouns

issue), we extract a list of modifiers for a number of shell nouns and create a stoplist of modifiers. If any of the words in the modifier phrases is a pronoun or occurs in the stoplist, we move to the next pattern. If the modifier phrase passes the stoplist test, to distinguish between non-shell content and shell content modifiers, we examine the hypernym paths of the words in the modifier phrase in WordNet (Fellbaum, 1998). If the synset *abstraction.n.06* occurs in the path, we consider the modifier phrase to be valid shell content, assuming that the shell content of shell nouns most typically represents an abstract entity.

5.2 Resolving remaining instances

At this stage we are assuming that the shell content occurs either in the postnominal clause or the complement clause. So we look for the patterns below, returning the shell content when found.

N-be-clause The lexico-grammatical pattern corresponding to the pattern *N-be-clause* is shown in Figure 1(b). This is one of the more reliable patterns for shell content extraction, as the *be* verb suggests the semantic identity between the shell noun and the complement clause. The *be*-verb does not necessarily have to immediately follow the shell noun. For instance, in example (2), the head of the NP *The issue that this country and Congress must address* is the shell noun *issue*, and hence it satisfies the construction in Figure 1(b).

N-clause Finally, we look for this pattern. An example of this pattern is shown in Figure 1(c). This is the most common (see Table 2) and trickiest pattern in terms of resolution, and whether the shell content is given in the postnominal clause or not is dependent on the properties of the shell noun under consideration and the syntactic construction of the example. For instance, for the shell noun *decision*, the postnominal *to*-infinitive clause typically represents shell content. But this did not hold for the shell noun *reason*, as shown in (11).

(11) **The reason** to resist becoming a participant is obvious.

Here, Schmid's semantic families come in the picture. We wanted to examine a) the extent to which the previous steps help in resolution, and b) whether knowledge extracted from Schmid's families add value to the resolution. So we employ two versions of this step.

Include Schmid's cues (+SC) This version exploits the knowledge encoded in Schmid's semantic families (Section 4.2), and extracts postnominal clauses only if Schmid's pattern cues are satisfied. In particular, given a shell noun, we determine the families in which it occurs and list all possible patterns of these families as shell content cues. The postnominal clause is a valid shell content only if it satisfies these cues. For instance, the shell noun *reason* occurs in only one family: *Reason*, with the allowed shell content patterns *N-that* and *N-why*. Schmid's patterns suggest that the postnominal *to*-infinitive clauses are not allowed as shell content for this shell noun, and thus this step will return *None*. This version helps correctly resolving examples such as (11) to *None*.

Exclude Schmid's cues (–SC) This version does not enforce Schmid's cues in extracting the postnominal clauses. For instance, the *Problem* family does not include *N-that/wh/to/of* patterns, but in this condition, we nonetheless allow these patterns in extracting the shell content of the nouns from this family.

6 Evaluation data

We claim that our algorithm is able to resolve a variety of shell nouns. That said, creating evaluation data for all of Schmid's 670 English shell

nouns is extremely time-consuming, and is therefore not pursued further in the current study. Instead we create a sample of representative evaluation data to examine how well the algorithm works a) on a variety of shell nouns, b) for shell nouns within a family, c) for shell nouns across families with completely different semantic and syntactic expectations, and d) for a variety of shell patterns from Table 1.

6.1 Selection of nouns

Recall that each shell noun has its idiosyncrasies. So in order to evaluate whether our algorithm is able to address these idiosyncrasies, the evaluation data must contain a variety of shell nouns with different semantic and syntactic expectations. To examine a), we consider the six families shown in Table 3. These families span three abstract categories: *mental*, *eventive*, and *factual*, and five distinct groups: *conceptual*, *volitional*, *factual*, *causal*, and *attitudinal*. Also, the families have considerably different syntactic expectations. For instance, the nouns in the *Idea* family can have their content in *that* or *of* clauses occurring in *N-clause* or *N-be-clause* constructions, whereas the *Trouble* and *Problem* families do not allow *N-clause* pattern. The shell content of the nouns in the *Plan* family is generally represented with *to*-infinitive clauses. To examine b) and c), we choose three nouns from each of the first four families from Table 3. To add diversity, we also include two shell nouns from the *Thing* family and a shell noun from the *Reason* family. So we selected a total of 12 shell nouns for evaluation: *idea*, *issue*, *concept*, *decision*, *plan*, *policy*, *problem*, *trouble*, *difficulty*, *reason*, *fact*, and *phenomenon*.

6.2 Selection of instances

Recall that the shell content varies based on the shell noun and the pattern it follows. Moreover, shell nouns have pattern preferences, as shown in Table 2. To examine d), we need shell noun examples following different patterns from Table 1. We consider the New York Times corpus as our base corpus, and from this corpus extract all sentences following the lexico-grammatical patterns in Table 1 for the twelve selected shell nouns. Then we arbitrarily pick 100 examples for each shell noun, making sure that the selection contains examples of each cataphoric pattern from Table 1. These examples consist of 70% examples of each of the seven cataphoric patterns, and the remaining 30% of the examples are picked randomly from the distribution of patterns for that shell noun.

6.3 Crowdsourcing annotation

We designed a crowdsourcing experiment to obtain the annotated data for evaluation. We parse each sentence using the Stanford parser, and extract all possible candidates, i.e., arguments of the shell noun from the parser's output. Since our examples include embedding clauses and sentential complements, the parser is often inaccurate. For instance, in example (12), the parser attaches only the first clause of the coordination (*that people were misled*) to the shell noun *fact*.

(12) **<u>The fact</u> that people were misled and information was denied**, that's the reason that you'd wind up suing.

To deal with such parsing errors, we consider the 30-best parses given by the parser. From these parses, we extract a list of eligible candidates. This list includes the arguments of the shell noun given in the appositional clauses, modifier phrases, postnominal *that*, *wh*, or *to*-infinitive clauses, complement clauses, objects of postnominal prepositions of the shell noun, and subject if the shell noun follows *subject-be-N* construction. On average, there were three candidates per instance.

After extracting the candidates, we present the annotators with the sentence, with the shell noun highlighted, and the extracted candidates. We ask the annotators to choose the option that provides the correct interpretation of the highlighted shell noun. We also provide them the option *None of the above*, and ask them to select it if the shell content is not present in the given sentence or the shell content is not listed in the list of candidates.

CrowdFlower We used CrowdFlower[11] as our crowdsourcing platform, which in turn uses various worker channels such as Amazon Mechanical Turk[12]. CrowdFlower offers a number of features. First, it provides a *quiz* mode which facilitates filtering out spammers by requiring an annotator to pass a certain number of test questions before starting the real annotation. Second, during annotation, it randomly presents test questions with known answers to the annotators to keep them on their toes. Based on annotators' responses to the test questions, each annotator is assigned a trust

score: an annotator performing well on the test questions gets a high trust score. Finally, CrowdFlower allows the user to select the permitted demographic areas and skills required.

Settings We asked for at least 5 annotations per instance by annotators from the English-speaking countries. The evaluation task contained a total of 1200 instances, 100 instances per shell noun. To maintain the annotation quality, we included 105 test questions, distributed among different answers. We paid 2.5 cents per instance and the annotation task was completed in less than 24 hours.

Results Table 4 shows the agreement of the crowd. In most cases, at least 3 out of 5 annotators agreed on a single answer. We took this answer as the gold standard in our evaluation, and discard the instances where fewer than three annotators agreed. The option *None of the above* was annotated for about 30% of the cases. We include these cases in the evaluation. In total we had 1,257 instances (1,152 instances where at least 3 annotators agreed + 105 test questions).

7 Evaluation results

Baseline We evaluate our algorithm against crowd-annotated data using a *lexico-syntactic clause* (LSC) baseline. Given a sentence containing a shell instance and its parse tree, this baseline extracts the postnominal or complement clause from the parse tree depending only upon the lexico-syntactic pattern of the shell noun. For instance, for the *N-that* and *N-be-to* patterns, it extracts the postnominal *that* clause and the complement *to*-infinitive clause, respectively.[13]

	Nouns	LSC	A–SC	A+SC
1	*idea*	74	82	**83**
2	*issue*	60	75	**77**
3	*concept*	51	67	**68**
4	*decision*	70	71	**73**
5	*plan*	51	**63**	62
6	*policy*	58	**70**	52
7	*problem*	66	**69**	59
8	*trouble*	63	**68**	50
9	*difficulty*	68	**75**	49
10	*reason*	43	53	**77**
11	*fact*	43	55	**68**
12	*phenomenon*	33	**62**	50
13	*all*	57	**69**	64

Table 5: Shell noun resolution results. Each column shows the percent accuracy of resolution with the respective method. Boldface is best in row.

Results Table 5 shows the evaluation results for the LSC baseline, the algorithm without Schmid's cues (A–SC), and the algorithm with Schmid's cues (A+SC). The A–SC condition in all cases and the A+SC condition in some cases outperform the LSC baseline, which proves to be rather low, especially for the shell nouns with strict syntactic expectations (e.g., *fact* and *reason*). Thus we see that our algorithm is adding value.

That said, we observe a wide range of performance for different shell nouns. On the up side, adding Schmid's cues helps resolving the shell nouns with strict syntactic expectations. The A+SC results for the shell nouns *idea*, *issue*, *concept*, *decision*, *reason*, and *fact* outperform the baseline and the A–SC results. In particular, the A+SC results for the shell nouns *fact* and *reason* are markedly better than the baseline results. These nouns have strict syntactic expectations for the shell content clauses they take: the families *Thing* and *Certainty* of the shell noun *fact* allow only a *that* clause, and the *Reason* family of the shell noun *reason* allows only *that* and *because* clauses for the shell content. These cues help in correctly resolving examples such as (11) to *None*, where the postnominal *to*-infinitive clause

[13]Note that we only extract subordinating clauses (e.g., (SBAR (IN *that*) (*clause*))) and *to*-infinitive clauses, and not relative clauses.

describes the purpose or the goal for the reason, but not the shell content itself.

On the down side, adding Schmid's cues hurts the performance of more versatile nouns, which can take a variety of clauses. Although the A–SC results for the shell nouns *plan*, *policy*, *problem*, *trouble*, *difficulty*, and *phenomenon* are well above the baseline, the A+SC results are markedly below it. That is, Schmid's cues were deleterious. Our error analysis revealed that these nouns are versatile in terms of the clauses they take as shell content, and Schmid's cues restrict these clauses to be selected as shell content. For instance, the shell noun *problem* occurs in two semantic families with *N-be-that/of* and *N-be-to* as pattern cues (Table 3), and postnominal clauses are not allowed for this noun. Although these cues help in filtering some unwanted cases, we observed a large number of cases where the shell content is given in postnominal clauses, as shown in (13).

(13) I was trying to address **the problem** of **unreliable testimony by experts** in capital cases.

Similarly, the *Plan* family does not allow the *N-of* pattern. This cue works well for the shell noun *decision* from the same family because often the postnominal *of* clause is the agent for this shell noun and not the shell content. However, it hurts the performance of the shell noun *policy*, as *N-of* is a common pattern for this shell noun (e.g., *. . . officials in Rwanda have established* ***a policy*** *of* ***refusing to protect refugees****. . . *). Other failures of the algorithm are due to parsing errors and lack of inclusion of context information.

8 Discussion and conclusion

In this paper, we proposed a general method to resolve shell nouns following cataphoric constructions. This is a first step towards end-to-end shell noun resolution. In particular, this method can be used to create training data for any given shell noun, which can later be used to resolve harder anaphoric cases of that noun using the method that we proposed earlier (Kolhatkar et al., 2013b).

The first goal of this work was to point out the difficulties associated with the resolution of cataphoric cases of shell nouns. The low resolution results of the LSC baseline demonstrate the difficulties of resolving such cases using syntax alone, suggesting the need for incorporating more linguistic knowledge in the resolution.

The second goal of this work was to examine to what extent knowledge derived from the linguistics literature helps in resolving shell nouns. We conclude that Schmid's pattern and clausal cues are useful for resolving nouns with strict syntactic expectations (e.g., *fact*, *reason*); however, these cues are defeasible: they miss a number of cases in our corpus. It is possible to improve on Schmid's cues using crowdsourcing annotation and by exploiting lexico-syntactic patterns associated with different shell nouns from a variety of corpora.

One limitation of our approach is that in our resolution framework, we do not consider the problem of ambiguity of nouns that might not be used as shell nouns. The occurrence of nouns with the lexical patterns in Table 1 does not always guarantee shell noun usage. For instance, in our data, we observed a number of instances of the noun *issue* with the publication sense (e.g., *this week's issue of Sports Illustrated*).

Our algorithm is able to deal with only a restricted number of shell noun usage constructions, but the shell content can be expressed in a variety of other constructions. A robust machine learning approach that incorporates context and deeper semantics of the sentence, along with Schmid's cues, could mitigate this limitation.

This work opens a number of new research directions. Our next planned task is clustering different shell nouns based on the kind of complements they take in different usages similar to verb clustering (Merlo and Stevenson, 2000; Schulte im Walde and Brew, 2002).

A Comparison of Selectional Preference Models for Automatic Verb Classification

Will Roberts and **Markus Egg**
Institut für Anglistik und Amerikanistik, Humboldt University
10099 Berlin, Germany
{will.roberts,markus.egg}@anglistik.hu-berlin.de

Abstract

We present a comparison of different selectional preference models and evaluate them on an automatic verb classification task in German. We find that all the models we compare are effective for verb clustering; the best-performing model uses syntactic information to induce nouns classes from unlabelled data in an unsupervised manner. A very simple model based on lexical preferences is also found to perform well.

1 Introduction

Selectional preferences (Katz and Fodor, 1963; Wilks, 1975; Resnik, 1993) are the tendency for a word to semantically select or constrain which other words may appear in a direct syntactic relation with it. Selectional preferences (SPs) have been a perennial knowledge source for NLP tasks such as word sense disambiguation (Resnik, 1997; Stevenson and Wilks, 2001; McCarthy and Carroll, 2003) and semantic role labelling (Erk, 2007); and recognising selectional violations is thought to play a role in identifying and interpreting metaphor (Wilks, 1978; Shutova et al., 2013). We focus on the SPs of verbs, since determining which arguments are typical of a given verb sheds light on the semantics of that verb.

In this study, we present the first empirical comparison of different SP models from the perspective of automatic verb classification (Schulte im Walde, 2009; Sun, 2012), the task of grouping verbs together based on shared syntactic and semantic properties.

We cluster German verbs using features capturing their *valency* or *subcategorisation*, following prior work (Schulte im Walde, 2000; Esteve Ferrer, 2004; Schulte im Walde, 2006; Sun et al., 2008; Korhonen et al., 2008; Li and Brew, 2008), and investigate the effect of adding information about verb argument preferences. SPs are represented by features capturing lexical information about the heads of arguments to the verbs; we restrict our focus here to nouns.

We operationalise a selectional preference model as a function which maps such an argument head to a concept label. We submit that the primary characteristic of such a model is its *granularity*. In our baseline condition, all nouns are mapped to the same label; this effectively captures no information about a verb's SPs (i.e., we cluster verbs using subcategorisation information only). On the other extreme, each noun is its own concept label; we term this condition *lexical preferences* (LP). Between the baseline and LP lie a spectrum of models, in which multiple concepts are distinguished, and each concept label can represent multiple nouns. Our main hypothesis is that verb clustering will work best using a model of such intermediate granularity. This follows the intuition that verbs would seem to select for classes of nouns; for instance, we suppose that *essen* 'eat' would tend to prefer as a direct object a noun from the abstract concept *Essen* ('food'). We assume that these concepts can be expressed independently of particular predicates; that is, there exist selectional preference models that will work for all verbs (and all grammatical relations). Further benefits of grouping nouns into classes include combating data sparsity, as well as deriving models which can generalise to nouns unseen in training data.

Another parameter of a selectional preference model is the methodology used to induce the conceptual classes; put another way, the success of an SP model hinges on how it represents concepts. In this paper, we investigate the choice of noun categorisation method through an empirical comparison of selectional preference models previously used in the literature.

We set out to investigate the following questions:

1. What classes of nouns are effective descriptors

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 511–522,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

of selectional preference concepts? For example, do they correspond to features such as ANIMATE?

2. What is the appropriate granularity of selectional preference concepts?

3. Which methods of classifying nouns into concepts are most effective at capturing selectional preferences for verb clustering?

This paper is structured as follows: In Section 2, we introduce our baseline method of clustering verbs using subcategorisation information and describe evaluation; Section 3 lists the models of selectional preferences that we compare in this work; Section 4 presents results and discussion; Section 5 summarises related work; and Section 6 concludes with directions for future research.

2 Automatic verb classification

Verb classifications such as VerbNet (Kipper-Schuler, 2005) allow generalisations about the syntax and semantics of verbs and have proven useful for a range of NLP tasks; however, creation of these resources is expensive and time-consuming. Automatic verb classification seeks to learn verb classes automatically from corpus data in a cheaper and faster way. This endeavour is possible due to the link between a verb's semantics and its syntactic behaviour (Levin, 1993). Recent research has found that even automatically-acquired classifications can be useful for NLP applications (Shutova et al., 2010; Guo et al., 2011). In this section, we introduce the verb classification method used by our baseline model, which clusters verbs based on subcategorisation information. Following this, Section 2.2 explains the gold standard verb clustering and cluster purity metric which we use for evaluation.

2.1 Baseline model

In this work, we take subcategorisation to mean the requirement of a verb for particular types of argument or concomitant. For example, the English verb *put* subcategorises for subject, direct object, and a prepositional phrase (PP) like *on the shelf*:

(1) *[$_{NP}$ Al] put [$_{NP}$ the book] [$_{PP}$ on the shelf].*

A *subcategorisation frame* (SCF) describes a combination of arguments required by a specific verb; a description of the set of SCFs which a verb may take is called its *subcategorisation preference*. We acquire descriptions of verbal SCF preferences on the basis of unannotated corpus data.

Our experiments use the SdeWaC corpus (Faaß and Eckart, 2013), containing 880 million words in 45 million sentences; this is a subset of deWaC (Baroni et al., 2009), a corpus of 10^9 words extracted from Web search results. SdeWaC is filtered to include only those sentences which are maximally parsable[1]. We parsed SdeWaC with the `mate-tools` dependency parser (Bohnet et al., 2013)[2], which performs joint POS and morphological tagging, as well as lemmatisation. Our subcategorisation analyses are delivered by the rule-based SCF tagger described by Roberts et al. (2014), which operates using the dependency parses and assigns each finite verb an SCF type. The SCF tags are taken from the SCF inventory proposed by Schulte im Walde (2002), which indicates combinations of nominal and verbal complement types, such as `nap:für.Acc` (transitive verb, with a PP headed by *für* 'for'). Examples of complements are `n` for nominative subject, and `a` for accusative direct object; in SCFs which include PPs (`p`), the SCF tag specifies the head of the PP and the case of the prepositional argument (`Acc` in our example indicates the accusative case of the prepositional argument). The SCF tagger undoes passivisation and analyses verbs embedded in modal and tense constructions. We record 673 SCF types in SdeWaC.

From SdeWaC, we extracted the first 3,000,000 verb instances assigned an SCF tag by the SCF tagger, where the verb lemma is one of the 168 listed in our gold standard clustering (this requires approximately 270 million words of parsed text, or 25% of SdeWaC). We refer to this as our **test set**. In this set, each verb is seen on average 17,857 times; the most common is *geben* ('give', 328,952 instances), and the least is *grinsen* ('grin', 50).

We represent verbs as vectors, where each dimension represents a different SCF type. Vector entries are initialised with SCF code counts over the test set, and each vector is then normalised to sum to 1, so that a vector represents a discrete probability distribution over the SCF inventory. We use the Jensen-Shannon divergence as a dissimilarity measure between pairs of verb vectors. The Jensen-Shannon divergence (Lin, 1991) is an information-theoretic, symmetric measure (Equation (2)) re-

[1] The filtering used a rule-based dependency parser to estimate a per-token parse error rate for each sentence, and removed those sentences with very high error rates.

[2] `https://code.google.com/p/mate-tools/`

lated to the Kullback-Leibler divergence (Equation (3)).

$$JS(p,q) = D(p||\frac{p+q}{2}) + D(q||\frac{p+q}{2}) \quad (2)$$

$$D(p||q) = \sum_i p_i \log \frac{p_i}{q_i} \quad (3)$$

With this dissimilarity measure, we use hierarchical clustering with Ward's criterion (Ward, Jr, 1963) to partition the verbs into K disjoint sets (i.e., hard clustering), where we match K to the number of classes in our gold standard (described below).

2.2 Evaluation paradigm

We evaluate the automatically induced verb clusterings against a manually-constructed gold standard, published by Schulte im Walde (2006, page 162ff.). This Levin-style classification groups 168 high- and low-frequency verbs into 43 semantic classes; examples include Aspect (e.g., *anfangen* 'begin'), Propositional Attitude (e.g., *denken* 'think'), and Weather (e.g., *regnen* 'rain'). Some of the classes are further sub-classified; for the purposes of our evaluation, we ignore the hierarchical structure of the classification and consider each class or subclass to be a separate entity. In this way, we obtain classes of fairly comparable size and sufficient semantic consistency.[3]

We evaluate a given verb clustering against the gold standard using the *pairwise F-score* (Hatzivassiloglou and McKeown, 1993). To calculate this statistic, we construct a contingency table over the $\binom{n}{2}$ pairs of verbs, the idea being that the gold standard provides binary judgements about whether two verbs should be clustered together or not. If a clustering agrees with the gold standard as to whether a pair of verbs belong together or not, this is a "correct" answer. Using the contingency table, the standard information retrieval measures of precision (P) and recall (R) can be computed; the F-score is then the harmonic mean of these: $F = 2PR/(P+R)$. The random baseline is 2.08 (calculated as the average score of 50 random partitions), and the optimal score is 95.81, calculated by evaluating the gold standard against itself. As the gold standard includes polysemous verbs, which belong to more than one cluster, the optimal score is calculated by randomly picking one of their senses; the average is then taken over 50 such trials.

The pairwise F-score is known to be somewhat nonlinear (Schulte im Walde, 2006), penalising early clustering "mistakes" more than later ones, but it has the advantage that we can easily determine statistical significance using the contingency table and McNemar's test.

We use only one clustering algorithm and one purity metric, because our prior work shows that the most important choices for verb clustering are the distance measure used, and how verbs are represented. These factors set, we expect similar performance trends from different algorithms, with predictable variation (e.g., spectral tends to outperform hierarchical clustering, which in turn outperforms k-means). Combining Ward's criterion and F-score is a trade-off at this point; the criterion is deterministic, giving reproducible results without computational complexity, but disallows estimates of density over our evaluation metric and is greedy (see discussion in Section 4.3).

3 Selectional preference models

In this section, we introduce the various SP models that we compare in this paper. In all cases, we hold the verb clustering procedure described in the previous section unchanged, with the exception that SCF tags for verbs are parameterised for selectional preferences. As an example, a verb instance observed in a simple transitive frame with a nominal subject and accusative object would receive the SCF tag `na`. Assuming that a given SP model places the subject noun in the SP concept `animate` and the object noun in the concept `concrete`, the parameterised SCF tag would be `na*subj-{animate}*obj-{concrete}`. This process captures argument co-occurrence information about verb instances, and has the effect of multiplying the SCF inventory size, making the verb vectors described in Section 2.1 both longer and sparser.

We evaluate various types of SP models: the simple lexical preferences model; three models which perform automatic unsupervised induction of noun concepts from unlabelled data; and one which uses a manually-built lexical resource. As far as we are aware, two of these, the word space and LDA models, have never been applied to verb classification before.

[3] In contrast, a top-level class like 'Transfer of Possession (Obtaining)', not only covers 25% of the gold standard, it also comprises the semantically very diverse subclasses 'Transfer of Possession (Giving)', 'Manner of Motion', and 'Emotion'.

N	Coverage of test set
100	12.08%
200	17.18%
500	26.11%
1,000	32.70%
5,000	45.31%
10,000	49.09%
50,000	55.69%
100,000	57.67%

Table 1: Fraction of verb instances in the test set parameterised by LP as a function of the number of nouns N included in the LP model.

3.1 Lexical preferences

The LP model is the simplest in our study after the baseline condition; it simply maps a noun to its own lemma. We include as a parameter of the LP model a maximum number of nouns N to admit as LP tags. In this way, the LP model parameterises SCFs using only the N most frequent nouns in SdeWaC; nouns beyond rank N are treated as if they were unseen. Table 1 indicates what fraction of the 3 million verb instances receive SCF tags specifying one or more LPs as a function of this parameter. Note that the coverage approaches an asymptote of around 60%. This is due to the fact that noun arguments are not observed for every verb instance; many verbs' arguments are pronominal or verbal and are not treated by our SP models. Setting N allows a simple way of tuning the LP model: With increasing N, the LP model should capture more data about verb instances, but after a point this benefit should be cancelled out by the increasing sparsity in the verb vectors.

3.2 Sun and Korhonen model

The SP model described in this section (SUN) was first used by Sun and Korhonen (2009) to deliver state-of-the-art verb classification performance for English; more recently, the technique was applied to successfully identify metaphor in free text (Shutova et al., 2010; Shutova et al., 2013). It uses co-occurrence counts that describe which nouns are found with which verbs in which grammatical relations; this information is used to sort the nouns into classes in a procedure almost identical to our verb clustering method described in Section 2.1.

We extract all verb instances in SdeWaC which are analysed by the SCF tagger, and count all (verb, grammatical relation, nominal argument head) triples, where the grammatical relation is subject, direct (accusative) object, indirect (dative) object, or prepositional object[4], and is listed in the verb instance's SCF tag; we undo passivisation, remove instances of auxiliary and modal verbs, and filter out those triples seen less than 10 times in the corpus.

These observations cover 60,870 noun types and 33,748,390 tokens, co-occurring with 6,705 verb types (11,426 verb-grammatical-relation types); an example is (*sprechen, obj, Wort*) ('speak' with direct object 'word', occurring 1,585 times)[5]. We represent each noun by a vector whose 11,426 dimensions are the different verb-grammatical-relation pairs; coordinates in the vector indicate the observed corpus counts. The vectors are then normalised to sum to 1, such that each represents some particular noun's discrete probability distribution over the set of verb-grammatical-relation pairs. The distance between two noun vectors is defined to be the Jensen-Shannon divergence between their probability distributions, and we partition the set of nouns into M groups using hierarchical Ward's clustering.

The SP model then maps a noun to an arbitrary label indicating which of the M disjoint sets that noun is to be found in (i.e., all nouns in the first noun class map to the concept label `concept1`); we employ the parameter M to model SP concept granularity. As with the LP model, we use the parameter N to indicate how many nouns are included in the SUN model; we search the parameter values $N = \{300, 500, 1000, 5000, 10000\}$ and $\frac{N}{M} = \{5, 10, 15, 20, 30, 50\}$.

3.3 Word space model

Word space models (WSMs, (Sahlgren, 2006; Turney and Pantel, 2010)) use word co-occurrence counts to represent the distributional semantics of a word. This strategy makes possible a clustering of nouns that does not depend on verbal dependencies in the first place.

[4]We have also experimented with adding features for each noun showing nominal modification features (e.g., (*schwarz, nmod, Haar*), 'hair' modified by 'black'), but these seem to hurt performance.

[5]Triples representing prepositional object relations are distinguished by preposition (e.g., the triple (*geben*, *prep-in*, *Auftrag*), 'give' with PP headed by 'in' with argument head 'contract', an idiomatic expression meaning 'to commission' something).

Dagan et al. (1999) address the problem of data sparseness for the automatic determination of word co-occurrence probabilities, which includes selectional preferences. They introduce the idea of estimating the probability of hitherto unseen word combinations using available information on words that are closest w.r.t. distributional word similarity. Following this idea, Erk (2007) and Padó et al. (2007) describe a memory-based SP model, using a WSM similarity measure to generalise the model to unseen data.

We build a WSM of German nouns and use it to partition nouns into disjoint sets, which we then employ as with the SUN model. We compute word co-occurrence counts across the whole SdeWaC corpus, using as features the 50,000 most common words in SdeWaC, skipping the first 50 most common words (i.e., we use words 50 through 50,050), with sentences as windows. We lemmatise the corpus and remove all punctuation; no other normalisation is performed. Co-occurrence counts between a word w_i and a feature c_j are weighted using the t-test scheme:

$$\text{ttest}(w_i, c_j) = \frac{p(w_i, c_j) - p(w_i)p(c_j)}{\sqrt{p(w_i)p(c_j)}}$$

We use a recent technique called *context selection* (Polajnar and Clark, 2014) to improve the word space model, whereby only the C most highly weighted features are kept for each word vector. We set C by optimising the correlation between the word space model's cosine similarity and a data set of human semantic relatedness judgements for 65 word pairs (Gurevych and Niederlich, 2005); at $C = 380$, we obtain Spearman $\rho = 0.813$ and Pearson $r = 0.707$ (human inter-annotator agreement for this data set is given as $r = 0.810$).

After this, we build a similarity matrix between all pairs of nouns using the cosine similarity, and then partition the set of N nouns into M disjoint classes using spectral clustering with the MNCut algorithm (Meilă and Shi, 2001). As with the SUN model, this SP model assigns labels to nouns indicating which noun class they belong to. We search the same parameter space for N and M as for the SUN model.

3.4 GermaNet

Statistical models of SPs have often used WordNet as a convenient and well-motivated inventory of concepts (e.g., Resnik (1997), Li and Abe (1998), Clark and Weir (2002)). Typically, such models make use of probabilistic treatments to determine an appropriate concept granularity separately for each predicate; we opt here for a simple model that allows more direct control over concept granularity. We take the set of concepts relevant to describing selectional preferences to be a *target set* of synsets in GermaNet (Hamp and Feldweg, 1997), and represent the target set as the set of synsets which are at some *depth* d or less in the GermaNet noun hierarchy: $\{s \mid \text{depth}(s) \leq d\}$ where $\text{depth}(s)$ counts the number of hypernym links separating s from the root of the hierarchy. We model concept granularity by varying $d = 1 \ldots 6$; at $d = 1$, the target set is of size 5, and at $d = 6$, it is of size 17,125. Nouns are attributed to concepts as follows: Given a noun belonging to a synset s, either s is in the target set, or we take s's lowest hypernym in the target set. For polysemous nouns, each synset listing a sense of the noun votes for a member of the target set; the noun observation is then spread over the target set using the votes as weights.

This procedure makes our GermaNet SP model a *soft clustering* over nouns (i.e., a noun can belong to more than one SP concept); a consequence of this is that a single verb occurrence in the corpus can contribute fractional counts to multiple SCF types.

3.5 LDA

Latent Dirichlet allocation (Blei et al., 2003) is a generative model that discovers similarities in data using latent variables; it is frequently used for topic modelling. LDA models of SPs have been proposed by Ó Séaghdha (2010) and Ritter et al. (2010); previous to this, Rooth et al. (1999) also described a latent variable model of SPs.

We implement the LDA model of selectional preferences described by Ó Séaghdha (2010). Generatively, the model produces nominal arguments to verbs as follows: For a given (verb, grammatical relation) pair (v, r), (1) Sample a noun class z from a from a multinomial distribution $\Phi_{v,r}$ with a Dirichlet prior parameterised by α; (2) Sample a noun n from a multinomial distribution Θ_z with a Dirichlet prior parameterised by β. Like Ó Séaghdha, we use an asymmetric Dirichlet prior for $\Phi_{v,r}$ (i.e., α can differ for each noun class) and a symmetric prior for Θ_z (β is the same for each Θ_z). We estimate the LDA model using the MALLET software (McCallum, 2002) using the same (verb, grammatical

relation, argument head) co-occurrence statistics used for the SUN model. We train for 1,000 iterations using the software's default parameters, allowing the LDA hyperparameters α and β to be re-estimated every 10 iterations. We build models with 50 or 100 topics as a proxy to concept granularity; models include number of nouns N of $\{500, 1000, 5000, 10000, 50000, 100000\}$.

As with the GermaNet-based model, the LDA model creates a soft clustering of nouns; the ability of a noun to have degrees of membership in multiple concepts might be a good way to model polysemy. We also experiment with a hard clustering version of the LDA model; to do this, we assign each noun n its most likely class label z using the model's estimate for $P(z|n)$.

4 Results

We experimented with applying the SP models to different combinations of grammatical relations (e.g., only subject, only object, subject+object, etc.), but generally obtained better results by parameterising SCF tags for all grammatical relations. Table 2 summarises the evaluation scores and parameter settings for the best-performing SP models, applied to verb arguments in all four grammatical relations (subject, direct, indirect and prepositional object)[6]. The table also indicates the number of SCF types constructed by each SP model (i.e., the number of dimensions of the vectors representing verbs).

All the SP models we compare help with automatic verb clustering. Using McNemar's test on the contingency tables underlying the F-scores, all models score better than the baseline at at least the $p < 0.01$ level. LDA-hard is better than the GermaNet, LDA-soft, WSM and LP models at at least the $p < 0.05$ level; SUN is better ($p \leq 0.05$) than all models except LDA-hard. All other performance differences are not statistically significant[7].

We can also demonstrate the effectiveness of the SP models with a regression analysis on the models' coverage of the test set. By varying the number of nouns N included in the SP models which use this parameter (LP, SUN, WSM, LDA), or by parameterising SCF tags with SP information only for particular combinations of grammatical relations, different numbers of the verb instances in the test data will end up with SP information in their SCF tags (this is the "coverage" statistic in Table 1); with the exception of the GermaNet model, all of the SP models we examine here show positive correlation between the number of verb instances tagged for SP information and verb clustering performance. This effect is independent of parameter settings, indicating the performance benefit conferred by the SP models is robust.

4.1 Comparison of SP models

The GermaNet model is the least successful in our study. It achieves its best performance with a depth of 5; after this, verb clustering performance drops off again. Verb clustering using the GermaNet SP model is only slightly better than the baseline condition.

Against our expectations, the hard clustering LDA models perform better than the soft clustering ones, achieving the second highest score in our evaluation; also, in contrast to the other SP models studied in this paper, LDA performs best with fewer, coarser-grained topics. We observe that the soft clustering models produce verb vectors more than an order of magnitude longer than the hard clustering models, and suggest that simple soft clustering may be causing problems with data sparsity that interfere with verb clustering. We have also observed that the topics found by LDA do not represent polysemy as we had hoped. While some of the topics discovered by the LDA models can be easily assigned labels (e.g., body parts, people, quantities, emotions, places, buildings, tools, etc.), others are less cohesive. We found that frequent words (e.g., time, person) are generated with high probability by multiple topics in ways that do not appear to reflect multiple word senses, and that the 100-topic models exhibit this property to a greater extent. For instance, *Zeit* 'time' is highly predictive of three topics in the 50-topic models, of which only the highest-weighted topic groups time expressions together; in the 100-topic models, *Zeit* is found in six topics. Again, of these six, only the topic with the highest α consists of time expressions. In the 50-topic models, we find 11 topics that we cannot assign a coherent label; in the 100-topic models, there are 38 of these mismatched topics. In our work to date, we have not found that LDA models with greater numbers of topics find more

[6] Due to space constraints, we do not present here a detailed per-model study of performance as a function of parameter settings; we feel a summary to be adequate, since the relative performances of the models reflect trends across a range of parameter settings.

[7] Using a significance criterion of $p < 0.05$.

SP model	Parameters	Granularity	F-score	Number of SCF types
SUN	10,000 nouns	1,000 noun classes	39.76	248,665
LDA (hard)	10,000 nouns	50 topics	39.10	78,409
LP	5,000 nouns		38.02	388,691
WSM	10,000 nouns	500 noun classes	36.95	149,797
LDA (soft)	10,000 nouns	50 topics	35.91	1,524,338
GermaNet	depth = 5	8,196 synsets	34.41	851,265
Baseline			33.47	673

Table 2: Evaluation of the best SP models.

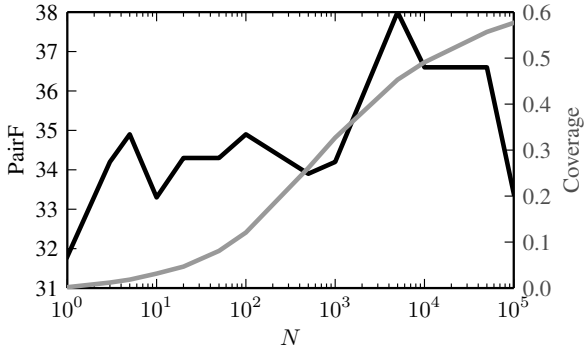

Figure 1: Verb clustering performance (black) and test set coverage (grey) of the LP model as a function of the number of nouns N included in the model.

specific concepts; it is possible that this problem might be alleviated by careful filtering of the (verb, grammatical relation, noun) triples, but we leave this question to future research.

The LP model is very effective, which is surprising given its simplicity. As expected, with increasing N, we do observe sparsity effects which hurt verb clustering performance (see Figure 1).

Our best performing model is SUN. Our best result is obtained with 10,000 nouns (the maximum value of N that we tried) in 1,000 classes, giving relatively fine-grained classes (on average 10 nouns per class). Table 3 shows some example noun classes learned by the SUN model. These include: groups with synonyms or near synonyms, often including alternate spellings of the same word (such as in the *truck* grouping); and groups of closely-related co-hyponyms, such as the body part grouping and the clothing grouping. In the latter, *bill*, *joint responsibility*, *complicity* and *inscription* are also included as things which can be *borne*, this is due to the fact that the SUN noun clustering is based on triples of verbs, grammatical relations, and nouns.

LKW (truck), *Lkw* (truck), *Lastwagen* (truck), *Castor* (container for highly radioactive material), *Laster* (truck), *Krankenwagen* (ambulance), *Transporter* (van), *Traktor* (tractor)
Hand (hand), *Kopf* (head), *Fuß* (foot), *Haar* (hair), *Bein* (leg), *Arm* (arm), *Zahn* (tooth), *Fell* (fur)
Leiche (corpse), *Leichnam* (body), *Schädel* (skull), *Skelett* (skeleton), *Wrack* (wreck), *Mumie* (mummy), *Trümmer* (debris)
Sauna (sauna), *Badezimmer* (bathroom), *Schwimmbad* (swimming pool), *Nachbildung* (replica), *Kamin* (fireplace), *Aufenthaltsraum* (common room), *Mensa* (cafeteria)
Rechnung (bill), *Kopftuch* (headscarf), *Uniform* (uniform), *Anzug* (suit), *Helm* (helmet), *Gewand* (garment), *Handschuh* (glove), *Mitverantwortung* (joint responsibility), *Bart* (beard), *Rüstung* (armour), *Mitschuld* (complicity), *Socke* (sock), *Jeans* (jeans), *Sonnenbrille* (sunglasses), *Aufschrift* (inscription), *Pullover* (sweater), *Weste* (vest), *Handschellen* (handcuffs), *Hörner* (horns), *Kennzeichen* (marking), *Tracht* (traditional costume), *Korsett* (corset), *Schuhwerk* (footwear), *Kopfbedeckung* (headgear), *Pelz* (fur), *Maulkorb* (muzzle)
Missionar (missionary), *Weihnachtsmann* (Santa Claus), *Selbstmordattentäter* (suicide bomber), *Bote* (messenger), *Nikolaus* (Nicholas), *Killer* (killer), *Bomber* (bomber), *Osterhase* (Easter bunny)

Table 3: Example noun clusters in the SUN SP model.

Furthermore, there are thematically related groups (*corpse*, *body*, etc., and *sauna*, *bathroom*, etc.). All months are placed together in one 12-word group.

Some classes can be easily subdivided into separate groups, and sometimes the source for this can be guessed: For example, sports (*football*, *golf*, *tennis*) are lumped together with musical instruments (*guitar*, *piano*, *violin*) and film roles (*starring role*, *supporting role*), these all being things that can be *played*. Many groups of personal roles (such as various kinds of government ministers) are distinguished, as are diseases and medications; other groupings contain proper names or geographical locations, sometimes of surprising specificity (e.g., authors, Biblical names, philosophers, NGOs, Eastern European countries, foreign currencies, German male first names, newspapers, television channels). The last group in Table 3 shows a grouping which appears to combine two of these semantically narrow categories, in which Santa Claus and the Easter bunny are united with killers and suicide bombers.

4.2 Noun classes as SP concepts

The WSM SP model is not as successful as SUN, but, due to the methodological similarity between these two (SP concepts modelled as hard partitions of nouns), it affords us an opportunity to investigate the question of what properties might make for an effective noun partition.

The WSM model partitions nouns based on paradigmatic information (which sentence contexts a noun appears in), rather than SUN's use of syntagmatic information (which grammatical contexts a noun appears in). Therefore, it is perhaps not surprising that the noun classes derived by the WSM are organised thematically, and the synonym/co-hyponym structure observed in the SUN noun classes is in many cases absent (e.g., {*Pferd* (horse), *Reiter* (rider), *Stall* (stable), *Sattel* (saddle), *Stute* (mare)}; these classes can easily conflate semantic roles (e.g., Agent for rider and Location for stable), which is presumably unhelpful for representing selectional preferences.

The distribution of noun classes also differs between SUN and WSM. The largest noun class in the WSM model contains 1,076 high-frequency nouns which are semantically unrelated (*day, question, case, part, reason, kind, form, week, person, month, ...*). We suppose that these nouns are thematically "neutral" and are classed together by virtue of their usage in a wide variety of sentences. This one noun class by itself subsumes 13.6% of all noun tokens in SdeWaC. WSM also includes 56 singleton noun classes; the variance in noun class size is 2800. For comparison, in SUN, the largest noun class has 73 words, and the smallest, 2 (there are 12 of these two-word classes); noun class size variance is 37. The 73-word class in SUN does indeed appear to be a grab bag (including *gas, taboo, pioneer, mustard, spy, mafia*, and *skinhead*), but these are uncommon words and account for only 0.1% of noun tokens in SdeWaC. The next two most common classes (with some 40 nouns each) are lists of names (politicians' surnames, and male first names). The noun class in the SUN model containing the largest number of high-frequency nouns (28 nouns: *human, child, woman, man, people, Mr., mother, father, ...*) only covers 3.6% of noun usages in SdeWaC and is both semantically cohesive and intuitively useful as a SP concept.

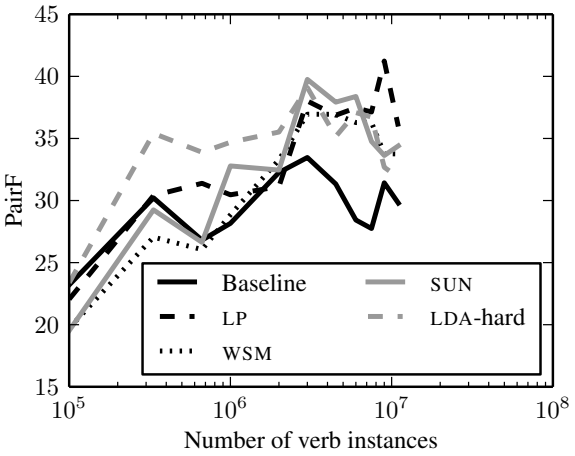

Figure 2: Verb clustering performance of SP models as a function of number of verb instances.

These issues raise the question of why the WSM model is effective at all for verb classification. We think that the larger less-related noun classes neither help nor hurt verb clustering, and we find that some of the thematic classes represent abstractions that should be useful for describing SPs. Examples include lists of body parts, countries (separate classes for Europe, Africa, Asia, etc.), diseases, human names, articles of clothing, and the group {*fruit, apple, banana, pear, strawberry*}.

4.3 Effects of test set size

We were curious if the success of the LP model might be due to the size of the test set preventing

sparsity from becoming a problem. To pursue this question, we take the four best performing SP models and run the verb clustering evaluation with the number of verb instances in the test set varying between 10,000 and the full SdeWaC corpus (11 million). The results are displayed in Figure 2. This graph indicates that below 3×10^5 verb instances, sparsity seems to become a problem for all models on this task, and the baseline delivers the best performance. Above this threshold, it seems that sparsity is not a major issue: LP performs fairly consistently, and is competitive with the SUN model. We attribute this to our use of the Jensen-Shannon divergence as a verb dissimilarity measure, which seems relatively robust to data sparsity. The LDA-hard model with its fewer topics seems to do quite well with fewer data; as the test set size increases, it drops off in the rankings. At the maximum number of verb instances, the best-performing models are SUN, WSM and the lexical preferences. The figure also shows that our evaluation metric is not smooth (note, e.g., the fluctuations in the baseline score). We believe that this reflects a degree of instability in the Ward's hierarchical clustering algorithm; this clustering method is greedy, and clustering errors can be expected to propagate, which might explain the jaggedness of the plot.

4.4 Conclusions

To conclude, we summarise the results of our analysis, using the questions formulated in the Introduction as guidelines.

First, we wanted to compare the efficiency of different classes of nouns as descriptors of selectional preference concepts. Our findings suggest that noun classes are most effective when they are semantically highly consistent, representing groups of strongly related nouns. It seems reasonable that SP concepts representing collections of synonyms would be useful for generalising observations, and should represent arguments better than simple LP. A classification of proper names (e.g., as human, corporation, country, medication) is also useful. This implies that we can expect features such as ANIMATE to be shared by all members of a noun cluster.

Second, we were interested in the appropriate granularity of selectional preference concepts. In our evaluation, we have observed a tendency for smaller, more specific noun classes to be superior; this holds because data sparsity is not a problem in our experiment. Beyond this finding, we would have liked to present a direct juxtaposition of different models on "granularity" but this is difficult: We have not yet identified a strong abstraction of granularity from the proxies we use (e.g., GermaNet depth, or SUN's N/M).

Finally, which methods of classifying nouns into concepts are most effective at capturing selectional preferences for verb clustering? In our experiments, the SUN and LDA-hard models proved to be more effective than lexical preferences, supporting our primary hypothesis that some level of SP concept granularity above the lexical level is desirable for verb clustering. On the other hand, the LP model is only slightly worse than SUN and LDA-hard, making it attractive because it is so simple. As we have shown, the potential data sparsity issues with LP can be alleviated by judiciously choosing the value of the N parameter that controls the number of nouns included in the model. In addition, comparing the SUN and WSM models, and observing the performance of the LDA-hard method, we conclude that inducing noun classes using syntagmatic information is more effective than using paradigmatic relations.

5 Related work

In this study, we have looked at the utility of selectional preferences for automatic verb classification. Some previous research has followed this line of inquiry, though prior studies have not compared alternative methods of modelling SPs. Schulte im Walde (2006) presented a detailed examination of parameters for k-means-based verb clustering in German, using the same gold standard that we employ here. She reports on the effects of adding SP information to a SCF-based verb clustering using 15 high-level GermaNet synsets as SP concepts; SP information for some combinations of grammatical relations improves clustering performance slightly, but neither are the effects consistent, nor is the improvement delivered by the SP model over the SCF-based baseline statistically significant. Schulte im Walde et al. (2008) used expectation maximisation to induce latent verb clusters from the British National Corpus while simultaneously building a tree cut model of SPs on the WordNet hierarchy using a minimum description length method; their evaluation focuses on the induced soft verb clusters, reporting the model's estimated perplexity of (verb, grammatical relation, argument head) triples. The

SPs are described qualitatively by presenting two example cases. Sun and Korhonen (2009) study the effect of adding selectional preferences to a subcategorisation-based verb clustering in English using the SUN model (see Section 3.2). They demonstrate that adding SPs to the SCF preference data leads to the best results on their two clustering evaluations; overall, their best results come from using SP information only for the subject grammatical relation. They employ coarse SP concepts (20 or 30 noun clusters) which capture general semantic categories (*Human, Building, Idea*, etc.).

Selectional preferences are usually evaluated either from a word sense disambiguation standpoint using pseudo-words (Chambers and Jurafsky, 2010), or in terms of how acceptable an argument is with a verb, via regression against human plausibility judgements. Several studies have compared SP methodologies from the latter perspective. These include Brockmann and Lapata (2003), who compared three GermaNet-based models of SP, showing that different models were most effective for describing different grammatical relations; Ó Séaghdha (2010), who compared different LDA-based models of SP, showing these to be effective for a variety of grammatical relations; and Ó Séaghdha and Korhonen (2012), who show that WordNet tree cut models, LDA, and a hybrid LDA-WordNet model are effective for describing verb-object relations.

6 Future work

Our GermaNet model delivered disappointing performance in this study; we would be interested in seeing whether a more sophisticated implementation such as the tree cut model of Li and Abe (1998) would be more competitive. We also would like to explore alternative noun clustering methods such as CBC (Pantel and Lin, 2002) and Brown clusters (Brown et al., 1992), which were not covered in this work; these would fit easily into our SP evaluation paradigm. More challenging would be a verb classification-based evaluation of the SP models of (Rooth et al., 1999) and (Schulte im Walde et al., 2008), which use expectation maximisation to simultaneously cluster verbs into verb classes and nominal arguments into noun classes; these approaches are not compatible with the evaluation framework we have used here. Finally, the SP model of Bergsma et al. (2008) has also achieved impressive results on a number of tasks, but has not been investigated for use in verb classification.

Our verb clustering evaluation in this work has matched K, the number of clusters found by Ward's method, to the number of classes in the gold standard. Since the number of clusters has an influence on the quality of the ensuing semantic classification (Schulte im Walde, 2006, page 180f.), we will also be running our experiments with different settings of K to explore whether this also influences the overall results of our evaluation.

Abstract

This paper presents a novel approach to learning to solve simple arithmetic word problems. Our system, ARIS, analyzes each of the sentences in the problem statement to identify the relevant variables and their values. ARIS then maps this information into an equation that represents the problem, and enables its (trivial) solution as shown in Figure 1. The paper analyzes the arithmetic-word problems "genre", identifying seven categories of verbs used in such problems. ARIS learns to categorize verbs with 81.2% accuracy, and is able to solve 77.7% of the problems in a corpus of standard primary school test questions. We report the first learning results on this task without reliance on predefined templates and make our data publicly available.[1]

1 Introduction

Designing algorithms to automatically solve math and science problems is a long-standing AI challenge (Feigenbaum and Feldman, 1963). For NLP, mathematical word problems are particularly attractive because the text is concise and relatively straightforward, while the semantics reduces to simple equations.

Arithmetic word problems begin by describing a partial world state, followed by simple updates or elaborations and end with a quantitative question. For a child, the language understanding part is trivial, but the reasoning may be challenging; for our system, the opposite is true. ARIS needs to make sense of multiple sentences, as shown in Figure 2, without *a priori* restrictions on the syntax or vocabulary used to describe the problem. Figure 1 shows an example where ARIS is asked to infer how many kittens Joan received based on facts and constraints expressed in the text, and represented by the state diagram and corresponding equation. While the equation is trivial, the text could have involved assembling toy aircraft, collecting coins, eating cookies, or just about any activity involving changes in the quantities of discrete objects.

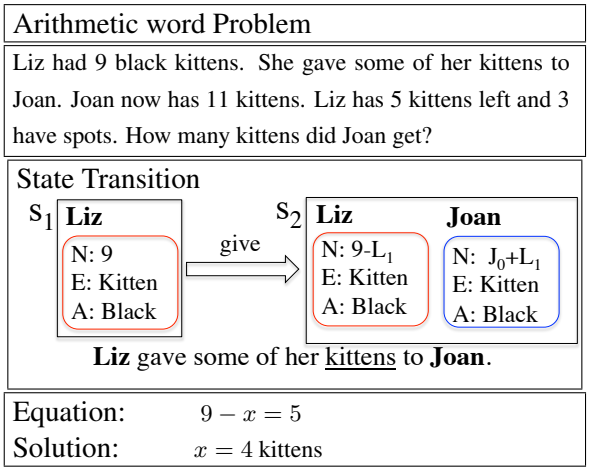

Figure 1: Example problem and solution.

This paper investigates the task of learning to solve such problems by mapping the verbs in the problem text into categories that describe their impact on the world state. While the verbs category is crucial (e.g., what happens if "give" is replaced by "receive" in Figure 1?), some elements of the problem are irrelevant. For instance, the fact that three kittens have spots is immaterial to the solution. Thus, ARIS has to determine what information is relevant to solving the problem.

To abstract from the problem text, ARIS maps the text to a state representation which consists of

a set of entities, their containers, attributes, quantities, and relations. A problem text is split into fragments where each fragment corresponds to an observation or an update of the quantity of an entity in one or two containers. For example in Figure 1, the sentence "Liz has 5 kittens left and 3 have spots" has two fragments of "Liz has 5 kittens left" and "3 have spots".

The verb in each sentence is associated with one or two containers, and ARIS has to classify each verb in a sentence into one of seven categories that describe the impact of the verb on the containers (Table 1). ARIS learns this classifier based on training data as described in section 4.2.

To evaluate ARIS, we compiled a corpus of about 400 arithmetic (addition and subtraction) word problems and utilized cross validation to both train ARIS and evaluate its performance over this corpus. We compare its performance to the template-based learning method developed independently and concurrently by Kushman et al. (2014). We find that our approach is much more robust to domain diversity between the training and test sets.

Our contributions are three-fold: (a) We present ARIS, a novel, fully automated method that learns to solve arithmetic word problems; (b) We introduce a method to automatically categorize verbs for sentences from simple, easy-to-obtain training data; our results refine verb senses in WordNet (Miller, 1995) for arithmetic word problems; (c) We introduce a corpus of arithmetic word problems, and report on a series of experiments showing high efficacy in solving addition and subtraction problems based on verb categorization.

2 Related Work

Understanding semantics of a natural language text has been the focus of many researchers in natural language processing (NLP). Recent work focus on learning to align text with meaning representations in specific, controlled domains. A few methods (Zettlemoyer and Collins, 2005; Ge and Mooney, 2006) use an expensive supervision in the form of manually annotated formal representations for every sentence in the training data. More recent work (Eisenstein et al., 2009; Kate and Mooney, 2007; Goldwasser and Roth, 2011; Poon and Domingos, 2009; Goldwasser et al., 2011; Kushman and Barzilay, 2013) reduce the amount of required supervision in mapping sentences to meaning representations while taking advantage of special properties of the domains. Our method, on the other hand, requires small, easy-to-obtain training data in the form of verb categories that are shared among many different problem types.

Our work is also closely related to the grounded language acquisition research (Snyder and Barzilay, 2007; Branavan et al., 2009; Branavan et al., 2012; Vogel and Jurafsky, 2010; Chen et al., 2010; Hajishirzi et al., 2011; Chambers and Jurafsky, 2009; Liang et al., 2009; Bordes et al., 2010) where the goal is to align a text into underlying entities and events of an environment. These methods interact with an environment to obtain supervision from the real events and entities in the environment. Our method, on the other hand, grounds the problem into world state transitions by learning to predict verb categories in sentences. In addition, our method combines the representations of individual sentences into a coherent whole to form the equations. This is in contrast with the previous work that study each sentence in isolation from the other sentences.

Previous work on studying math word and logic problems uses manually aligned meaning representations or domain knowledge where the semantics for all the words is provided (Lev, 2007; Lev et al., 2004). Most recently, Kushman et al. (2014) introduced an algorithm that learns to align algebra problems to equations through the use of templates. This method applies to broad range of math problems, including multiplication, division, and simultaneous equations, while ARIS only handles arithmetic problems (addition and subtraction). However, our empirical results show that for the problems it handles, ARIS is much more robust to diversity in the problem types between the training and test data.

3 Arithmetic Problem Representation

We address solving arithmetic word problems that include addition and subtraction. A problem text is split into fragments where each fragment is represented as a transition between two world states in which the quantities of entities are updated or observed (Figure 2). We refer to these fragments as sentences. We represent the world state as a tuple $\langle E, C, R \rangle$ consisting of entities E, containers C, and relations R among entities, containers, attributes, and quantities.

Entities: An *entity* is a mention in the text corre-

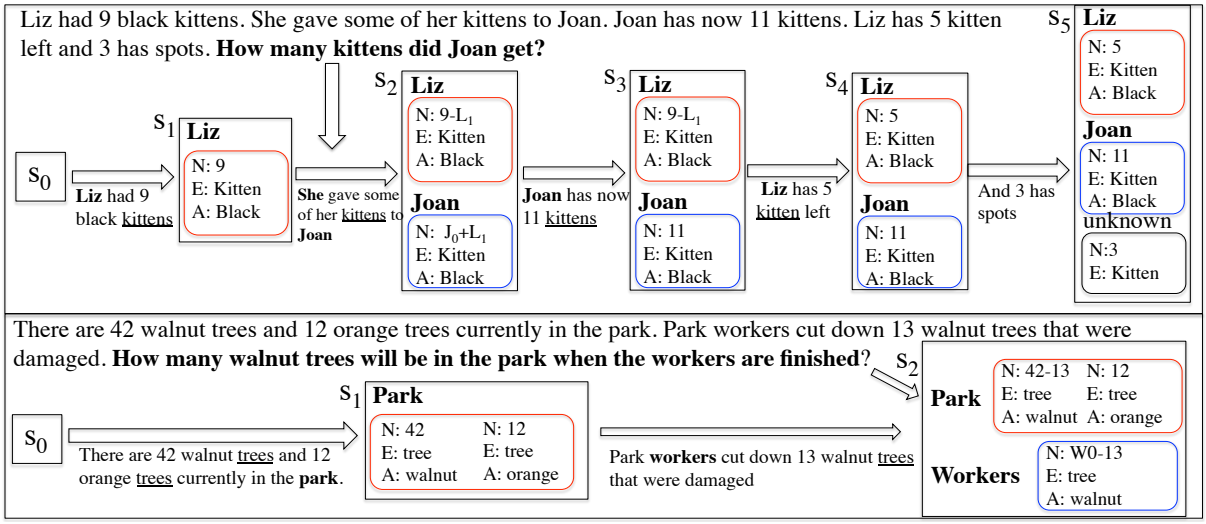

Figure 2: A figure sketching different steps of our method — a sequence of states.

sponding to an object whose quantity is observed or is changing throughout the problem. For instance, `kitten` and `tree` are entities in Figure 2. In addition, every entity has *attributes* that modify the entity. For instance, `black` is an attribute of `kittens`, and `walnut` is an attribute of `tree` (more details on attributes in section 4.1). Relations describing attributes are invariant to the state changes. For instance kittens stay `black` throughout the problem of Figure 1.

Containers: A *container* is a mention in the text representing a set of entities. For instance, `Liz`, `Joan`, `park`, and `workers` are containers in Figure 2. Containers usually correspond to the *person* possessing entities or a *location* containing entities. For example, in the sentence "There are 43 blue marbles in the basket. John found 32 marbles.", `basket` and `John` are containers of `marbles`.

Quantities: Containers include entities with their corresponding quantities in a particular world state. Quantities can be known numbers (e.g. 9), unknown variables (e.g. L_1), or numerical expressions over unknown quantities and numbers (e.g. $9-L_1$). For instance, in state 2 of Figure 2, the numerical expression corresponding to `Liz` is $9-L_1$ and corresponding to `Joan` is $J_0 + L_1$, where J_0 is a variable representing the number of `kittens` that `Joan` has started with.

Hereinafter, we will refer to a generic entity as e, container as c, number as num, attribute as a. We represent the relation between a container, an entity, and a number in the form of a quantity expression `N(c,e)`. Figure 2 shows the quantity relations in different world states.

Category	Example
Observation	There **were** 28 bales of hay in the *barn*.
Positive	*Joan* **went** to 4 football games this year.
Negative	*John* **lost** 3 of the violet balloons.
Positive Transfer	*Mike's dad* **borrowed** 7 nickels from *Mike*.
Negative Transfer	*Jason* **placed** 131 erasers in the *drawer*.
Construct	*Karen* **added** 1/4 of a cup of walnuts to a *batch* of trail mix.
Destroy	The *rabbits* **ate** 4 of *Dan's* potatoes.

Table 1: Examples for different verb categories in sentences. Entities are underlined; *containers* are italic, and **verbs** are bolded.

State transitions: Sentences depict progression of the world state (Figure 2) in the form of observations of updates of quantities. We assume that every sentence w consists of a verb v, an entity e, a quantity num (might be unknown), one or two containers c_1, c_2, and attributes a. The presence of the second container, c_2, will be dictated by the category of the verb, as we discuss below. Sentences abstract transitions $(s_t \rightarrow s_{t+1})$ between states in the form of an algebraic operation of addition or subtraction. For every sentence, we model the state transition according to the verb category and containers in the sentence. There are three verb categories for sentences with one container: *Observation*: the quantity is initialized in the container, *Positive*: the quantity is increased in the container, and *Negative*: the quantity is decreased in the container. Moreover, there are four categories for sentences with two containers: *Pos-*

itive transfer: the quantity is transferred from the second container to the first one, *Negative transfer*: the quantity is transferred from the first container to the second one, *Construct*: the quantity is increased for both containers, and *Destroy*: the quantity is decreased for both containers.

Figure 2 shows how the state transitions are determined by the verb categories. The sentence "Liz has 9 black kittens" initializes the quantity of `kittens` in the container `Liz` to `9`. In addition, the sentence "She gave some of her kittens to Joan." shows the negative transfer of L_1 kittens from `Liz` to `Joan` represented as `N(Liz,kitten)=9-`L_1 and `N(Joan,kitten)=`$J_0 + L_1$.

Given a math word problem, ARIS grounds the world state into entities (e.g., `kitten`), containers (e.g., `Liz`), attributes (e.g., `black`), and quantities (e.g., `9`) (Section 4.1). In addition, ARIS learns state transitions by classifying verb categories in sentences (Section 4.2). Finally, from the world state and transitions, it generates an arithmetic equation which can be solved to generate the numeric answer to the word problem.

4 Our Method

In this section we describe how ARIS maps an arithmetic word problem into an equation (Figure 2). ARIS consists of three main steps (Figure 3): (1) grounding the problem into entities and containers, (2) training a model to classify verb categories in sentences, and (3) solving the problem by updating the world states with the learned verb categories and forming equations.

4.1 Grounding into Entities and Containers

ARIS automatically identifies entities, attributes, containers, and quantities corresponding to every sentence fragment (details in Figure 3 step 1). For every problem, this module returns a sequence of sentence fragments $\langle w_1, \ldots, w_T, w_x \rangle$ where every w_t consists of a verb v_t, an entity e_t, its quantity num_t, its attributes a_t, and up to two containers c_{t_1}, c_{t_2}. w_x corresponds to the question sentence inquiring about an unknown entity. ARIS applies the Stanford dependency parser, named entity recognizer and coreference resolution system to the problem text (de Marneffe et al., 2006; Finkel et al., 2005; Raghunathan et al., 2010). It uses the predicted coreference relationships to replace pronouns (including possessive pronouns) with their coreferenent links. The named entity recognition output is used to identify numbers and people.

Entities: Entities are references to some object whose quantity is observed or changing throughout the problem. So to determine the set of entities, we define h as the set of noun types which have a dependent number (in the dependency parse) somewhere in the problem text. The set of entities is then defined as all noun phrases which are headed by a noun type in h. For instance `kitten` in the first sentence of Figure 1 is an entity because it is modified by the number `9`, while `kitten` in the second sentence of Figure 1 is an entity because `kitten` was modified by a number in the first sentence. Every number in the text is associated with one entity. Numbers which are dependents of a noun are associated with its entity. Bare numbers (not dependent on a noun) are associated with the previous entity in the text. The entity in the last sentence is identified as the question entity e_x . Finally, ARIS splits the problem text into $T + 1$ sentence fragments $\langle w_1, \ldots w_T, w_x \rangle$ such that each fragment contains a single entity and it's containers. For simplicity we refer to these fragments as a sentences.

Containers: Each entity is associated with one or two container noun phrases using the algorithm described in in Figure 3 step 1c. As we saw earlier with numbers, arithmetic problems often include sentences with missing information. For example in Figure 2, the second container in the the sentence "Park workers had to cut down 13 walnut trees that were damaged." is not explicitly mentioned. To handle this missing information, we use the *circumscription* assumption (McCarthy, 1980). The circumscription assumption formalizes the commonsense assumption that things are as expected unless otherwise specified. In this setting, we assume that the set of containers are fixed in a problem. Thus if the container(s) for a given entity cannot be identified they are set to the container(s) for the previous entity with the same head word. For example in Figure 2 we know from the previous sentence that `trees` were in the `park`. Therefore, we assume that the unmentioned container is the `park`.

Attributes: ARIS selects attributes A as modifiers for every entity from the dependency parser (details in Figure 3 step 1a). For example `black` is an attribute of the entity `kitten` and is an adjective modifier in the parser. These attributes are

1. **Grounding into entities and containers: for every problem p in dataset** (Section 4.1)
   (a) $\langle e_1, \ldots, e_T, e_x \rangle_p \leftarrow$ extract all entities and the question entity
      i. Extract all numbers and noun phrases (NP).
      ii. $h \leftarrow$ all noun types which appear with a number as a dependant (in the dependency parse tree) somewhere in the problem text.
      iii. $e_t \leftarrow$ all NPs which are headed by a noun type in h.
      iv. $num_t \leftarrow$ the dependant number of e_t if one exists. Bare numbers (not directly dependant on any noun phrase) are associated with the previous entity in the text. All other num_t are set to unknown.
      v. $e_x \leftarrow$ the last identified entity.
      vi. $a_t \leftarrow$ adjective and noun modifiers of e_t. Update implicit attributes using the previously observed attributes.
      vii. $v_t \leftarrow$ the verb with the shortest path to e_t in the dependency parse tree.
   (b) $\langle w_1, \ldots, w_T, w_x \rangle_p \leftarrow$ split the problem text into fragments based on the entities and verbs
   (c) $\langle c_{t_1}, c_{t_2}, \ldots, c_{T_1}, c_{T_2}, c_x \rangle_p \leftarrow$ the list of containers for each entity
      i. $c_{t_1} \leftarrow$ the subject of w_t.
      If w_t contains *There is/are*, c_{t_1} is the first adverb of place to the verb.
      ii. $c_{t_2} \leftarrow$ An NP that is direct object of the verb. If not found, c_{t_2} is the object of the first adverbial phrase of the verb.
      iii. Circumscription assumption: When c_{t_1} or c_{t_2} are not found, they are set to the previous containers.

2. **Training for sentence categorization** (Section 4.2)
   (a) $instances_1, instances_2 \leftarrow \emptyset$
   (b) for every sentence $w_t \in \langle w_1, \ldots, w_T, w_x \rangle_p$ in the training set:
      i. $features_t \leftarrow$ extract features (similarity based, WordNet based, structural) (Section 4.2.1)
      ii. $l_{t_1}, l_{t_2} \leftarrow$ determine labels for containers c_{t_1} and c_{t_2} based on the verb category of w_t.
      iii. append $\langle features_t, l_{t,1} \rangle$, $\langle features_t, l_{t,2} \rangle$ to $instances_1, instances_2$.
   (c) $M_1, M_2 \leftarrow$ train two SVMs for $instances_1, instances_2$

3. **Solving: for every problem p in the test set** (Section 4.3)
   (a) **Identifying verb categories in sentences**
      i. for every sentence $w_t \in \langle w_1, \ldots, w_T, w_x \rangle_p$:
         A. $features_t \leftarrow$ extract features (similarity based, WordNet based, structural).
         B. $l_{t_1}, l_{t_2} \leftarrow$ classify w_t for both containers c_{t_1} and c_{t_2} using models M_1, M_2.
   (b) **State progression**: Form $\langle s_0, \ldots, s_T \rangle$ (Section 4.3.1)
      i. $s_0 \leftarrow null$.
      ii. for $t \in \langle 1, \ldots, T \rangle$: $s_t \leftarrow progress(s_{t-1}, w_t)$.
         A. if $e_t = e_x$ and $a_t = a_x$:
            if w_t is an observation: $N_t(c_{t_1}, e_t) = num_t$.
            else: update $N_t(c_{t_1}, e_t)$ and $N_t(c_{t_2}, e_t)$ given verb categories l_{t_1}, l_{t_2}.
         B. copy $N_{t-1}(c, e)$ to $N_t(c, e)$ for all other (c, e) pairs.
   (c) **Forming equations and solution** (Section 4.3.2)
      i. Mark each w_t that matches with w_x if:
      a) c_{t_1} matches with c_x and verb categories are equal or verbs are similar.
      b) c_{t_2} matches with c_x and the verbs are in opposite categories.
      ii. $x \leftarrow$ the unknown quantity if w_x matches with a sentence introducing an unknown number
      iii. If the question asks about an unknown variable x or a start variable (w_x contains "begin" or "start"):
      For some container c, find two states s_t (quantity expression contains x) and s_{t+1} (quantity is a known number). Then, form an equation for x: $N_t(c, e_x) = N_{t+1}(c, e_x)$.
      iv. else: form equation as $x = N_t(c_x, e_x)$.
      v. Solve the equation and return the absolute value of x.

Figure 3: ARIS: a method for solving arithmetic word problems.

used to prune the irrelevant information in progressing world states.

Arithmetic problems usually include sentences with no attributes for the entities. For example, the attribute `black` has not been explicitly mentioned for the `kitten` in the second sentence. In particular, ARIS updates an implicit attribute using the previously observed attribute. For example, in "Joan went to 4 football games this year. She went to 9 games last year.", ARIS assigns `football` as an attribute of the `game` in both sentences.

4.2 Training for Verb Categories

This step involves training a model to identify verb categories for sentences. This entails predicting one label (increasing, decreasing) for each (verb, container) pair in the sentence. Each possible setting of these binary labels corresponds to one of the seven verb categories discussed earlier. For example, if c_1 is increasing and c_2 is decreasing this is a *positive transfer* verb.

Our dataset includes word problems from different domains (more details in Section 5.2). Each verb in our dataset is labeled with one of the 7 cat-

egories from Table 1.

For training, we compile a list of sentences from all the problems in the dataset and split sentences into training and test sets in two settings. In the first setting no instance from the same domain appears in the training and test sets in order to study the robustness of our method to new problem types. In the second setting no verb is repeated in the training and test sets in order to study how well our method predicts categories of unseen verbs.

For every sentence w_t in the problems, we build two data instances, (w_t, c_1) and (w_t, c_2), where c_1 and c_2 are containers extracted from the sentence. For every instance in the training data, we assign training labels using the verb categories of the sentences instead of labeling every sentence individually. The verb can be increasing or decreasing corresponding to every container in the sentence. For positive (negative) and construction (destruction) verbs, both instances are labeled positive (negative). For transfer positive (negative) verbs, the first instance is labeled positive (negative) and the second instance is labeled negative (positive). For observation verbs, both instances are labeled positive. We assume that the observation verbs are known (total of 5 verbs). Finally, we train Support Vector Machines given the extracted features and training labels explained above (Figure 3 step 2). In the following, we describe the features used for training.

4.2.1 Features

There are three sets of features: similarity based, Wordnet-based, and structural features. The first two sets of features focus on the verb and the third set focuses on the dependency structure of the sentence. All of our features are unlexicalized. This allows ARIS to handle verbs in the test questions which are completely different from those seen in the training data.

Similarity-based Features: For every instance (w, c), the feature vector includes similarity between the verb of the sentence w and a list of seed verbs. The list of seed verbs is automatically selected from a set $\mathcal{V}$ containing the 2000 most common English verbs using ℓ_1 regularized feature selection technique. We select a small set of seed verbs to avoid dominating the other feature types (structural and WordNet-based features).

The goal is to automatically select verbs from $\mathcal{V}$ that are most discriminative for each of the 7 verb categories in Table 1. We define 7 classification tasks: "Is a verb a member of each category?" Then, we select the three most representative verbs for each category. To do so, we randomly select a set of 65 verbs $\mathcal{V}_l$, from all the verbs in our dataset (118 in total) and manually annotate the verb categories. For every classification task, the feature vector $\mathbf{X}$ includes the similarity scores (Equation 1) between the verb v and all the verbs in the $\mathcal{V}$. We train an ℓ_1 regularized regression model (Park and Hastie, 2007) over the feature vector $\mathbf{X}$ to learn each category individually. The number of original (similarity based) features in $\mathbf{X}$ is relatively large, but ℓ_1 regularization provides a sparse weight vector. ARIS then selects the three most common verbs (without replacement) among the features (verbs) with non-zero weights. This accounts for 21 total seed verbs to be used for the main classification task. We find that in practice using this selection technique leads to better performance than using either all the verbs in $\mathcal{V}$ or using just the 65 randomly selected verbs.

Our method computes the similarity between two verbs v_1 and v_2 from the similarity between all the senses (from WordNet) of these verbs (Equation 1). We compute the similarity between two senses using linear similarity (Lin, 1998). The similarity between two synsets sv_1 and sv_2 are penalized according to the order of each sense for the corresponding verb. Intuitively, if a synset appears earlier in the set of synsets of a verb, it is more likely to be considered as the correct meaning. Therefore, later occurrences of a synset should result in reduced similarity scores. The similarity between two verbs v_1 and v_2 is the maximum similarity between two synsets of the verbs:

$$\text{sim}(v_1, v_2) = \max_{sv:\text{synsets}(v)} \frac{\text{lin-sim}(sv_1, sv_2)}{log(p_1 + p_2)} \quad (1)$$

where sv_1, sv_2 are two synsets, p_1, p_2 are the position of each synset match, and lin-sim is the linear similarity. Our experiments show better performance using linear similarity compared to other common similarity metrics (e.g., WordNet path similarity and Resnik similarity (Resnik, 1995)).

WordNet-based Features: We use WordNet verb categories in the feature vector. For each part of speech in WordNet, the synsets are organized into different categories. There are 15 categories for verbs. Some examples in-

clude "verb.communication", "verb.possession", and "verb.creation". In addition, WordNet includes the frequency measure $f_{c_{sv}}$ indicating how often the sense sv has appeared in a reference corpus. For each category i, we define the feature f_i as the ratio of the frequency of the sense sv_i over the total frequency of the verb i.e., $f_i = f_{c_{sv_i}}/f_{c_v}$.

Structural Features: For structural features, we use the dependency relations between the verb and the sentence elements since they can be a good proxy of the sentence structure. ARIS uses a binary vector including 35 dependency relations between the verb and other elements. For example, in the sentence "Joan picked 2 apples from the apple tree", the dependency between ('picked' and 'tree') and ('picked' and 'apples') are depicted as 'prep-from' and 'dobj' relations in the dependency parser, respectively. In addition, we include the length of the path in the dependency parse from the entity to the verb.

4.3 Solving the Problem

So far, ARIS grounds every problem into entities, containers, and attributes, and learns verb categories in sentences. Solving the problem consists of two main steps: (1) progressing states based on verb categories in sentences and (2) forming the equation.

4.3.1 State Progression with Verb Categories

This step (Figure 3 step 3b) involves forming states $\langle s_1, \ldots, s_T \rangle$ by updating quantities in every container using learned verb categories (Figure 3 step 3a). ARIS initializes s_0 to an empty state. It then iteratively updates the state s_t by progressing the state s_{t-1} given the sentence w_t with the verb v, entity e, number num, and containers c_1 and c_2.

For a given sentence t, ARIS attempts to match e_t and c_t to entities and categories in s_{t-1}. An entity/category is matched if has the same head word and same set of attributes as an existing entity/category. If an entity or category cannot be matching to one in s_{t-1}, then a new one is created in s_t.

The progress subroutine prunes the irrelevant sentences by checking if the entity e and its attributes a agree with the question entity e_x and its attributes a_x in the question. For example both `game` entities agree with the question entity in the problem "Joan went to 4 football games this year. She went to 9 games last year. How many football games did Joan go?". The first entity has an explicit `football` attribute, and the second entity has been assigned the same attribute (Section 4.1). Even if the question asks about `games` without mentioning `football`, the two sentences will match the question. Note that the second sentence would have not been matched if there was an explicit mention of the 'basketball game' in the second sentence.

For the matched entities, ARIS initializes or updates the values of the containers c_1, c_2 in the state s_t. ARIS uses the learned verb categories in sentences (Section 4.2) to update the values of containers. For an observation sentence w_t, the value of c_1 in the state s_t is assigned to the observed quantity num. For other sentence types, if the container c does not match to a container the previous state, its value is initialized with a start variable C_0. For example, the container `Joan` is initialized with J_0 at the state s_1 (Figure 2). Otherwise, the values of c_1 and c_2 are updated according to the verb category in the sentence. For instance, if the verb category in the sentence is a positive transfer then $N_t(c_1, e) = N_{t-1}(c_1, e) - num$ and $N_t(c_2, e) = N_{t-1}(c_2, e) + num$ where $N_t(c, e)$ represents the quantity of e in the container c at state s_t (Figure 2).

4.3.2 Forming Equations and Solution

The question entity e_x can match either to an entity in the final state, or to some unknown generated during the state progression. Concretely, the question sentence w_x asks about the quantity x of the entity e_x in a container c_x at a particular state s_u or a transition after the sentence w_u (Figure 3 step 3c).

To determine if e_x matches to an unknown variable, we define a matching subroutine between the question sentence w_x and every sentence w_t to check entities, containers, and verbs (Figure 3 step 3(c)i). We consider two cases. 1) When w_x contains the words "begin", or "start", the unknown variable is about the initial value of an entity, and it is set to the start variable of the container c_x (Figure 3 step 3(c)iii). For example, in "Bob had balloons. He gave 9 to his friends. He now has 4 balloons. How many balloons did he have to start with?", the unknown variable is set to the start variable B_0. 2) When the question verb is not one of the defined set of observation verbs, ARIS attempts to match e_x with an unknown introduced by one of the state transitions (Figure 3

step 3(c)iii). For example, the second sentence in Figure 1 introduces an unknown variable over `kittens`. The matching subroutine matches this entity with the question entity since the question container, i.e. `Joan`, matches with the second container and verb categories are complementary.

In order to solve for the unknown variable x, ARIS searches through consecutive states s_t and s_{t+1}, where in s_t, the quantity of e_x for a container c is an expression over x, and in s_{t+1}, the quantity is a known number for a container matched to c. It then forms an equation by comparing the quantities for containers matched between the two states. In the previous example, the equation will be $B_0 - 9 = 4$ by comparing states s_2 and s_3, where the numerical expression over `balloons` is $B_0 - 9$ in the state s_2, and the quantity is a known number in the state s_3.

When neither of the two above cases apply, ARIS matches e_x to an entity in the final state, s_T and returns its quantity, (Figure 3 step 3(c)iv). In the `football` example of the previous section, the equation will be $x = N_t(c_x, e_x)$, where $N_t(c_x, e_x)$ is the quantity in the final state.

Finally, the equation will be solved for the unknown variable x and the absolute value of the unknown variable is returned.

5 Experiments

To experimentally evaluate our method we build a dataset of arithmetic word problems along with their correct solutions. We test our method on the accuracy of solving arithmetic word problems and identifying verb categories in sentences.

5.1 Experimental Setup

Datasets: We compiled three diverse datasets MA1, MA2, IXL (Table 2) of Arithmetic word problems on addition and subtraction for third, fourth, and fifth graders. These datasets have similar problem types, but have different characteristics. Problem types include combinations of additions, subtractions, one unknown equations, and U.S. money word problems. Problems in MA2 include more irrelevant information compared to the other two datasets, and IXL includes more information gaps. In total, they include 395 problems, 13,632 words, 118 verbs, and 1,483 sentences.

Tasks and Baselines: We evaluate ARIS on two tasks: 1) solving arithmetic word problems in the three datasets and 2) classifying verb categories in sentences. We use the percentage of correct answers to the problems as the evaluation metric for the first task and accuracy as the evaluation metric for the second task. We use Weka's SVM (Witten et al., 1999) with default parameters for classification which is trained with verb categories in sentences (as described in Section 4.2).

	Source	#Tests	Avg.# Sentences
MA1	math-aids.com	134	3.5
IXL	ixl.com	140	3.36
MA2	math-aids.com	121	4.48

Table 2: Properties of the datasets.

	MA1	IXL	MA2	Total
3-fold Cross validation				
ARIS	83.6	**75.0**	**74.4**	**77.7**
ARIS$_2$	83.9	75.4$^+$	69.8$^+$	76.5$^+$
KAZB	**89.6**	51.1	51.2	64.0
Majority	45.5	71.4	23.7	48.9
Gold sentence categorization				
Gold ARIS	94.0	77.1	81.0	84.0

Table 3: Accuracy of solving arithmetic word problems in three datasets MA1, IXL, and MA2. This table compares our method, ARIS, ARIS$_2$ with the state-of-the-art KAZB. All methods are trained on two (out of three) datasets and tested on the other one. ARIS$_2$ is trained when no verb is repeated in the training and test sets. Gold ARIS uses gold verb categories. The improvement of ARIS (boldfaced) and ARIS$_2$ (denoted by $^+$) are significant over KAZB and the majority baseline with $p < 0.05$.

For the first task, we compare ARIS with KAZB (Kushman et al., 2014), majority baseline, ARIS$_2$, and Gold ARIS. KAZB requires training data in the form of equation systems and numerical answers to the problems. The majority baseline classifies every instance as increasing. In ARIS$_2$ (a variant of ARIS) the system is trained in a way that no verb is repeated in the training and test sets. Gold ARIS uses the ground-truth sentence categories instead of predicted ones. For the second task, we compare ARIS with a baseline that uses WordNet verb senses.

5.2 Results

We evaluate ARIS in solving arithmetic word problems in the three datasets and then evaluate its ability in classifying verb categories in sentences.

5.2.1 Solving Arithmetic Problems

Table 3 shows the accuracy of ARIS in solving problems in each dataset (when trained on the other two datasets).Table 3 shows that ARIS

significantly outperforms KAZB and the majority baseline. As expected, ARIS shows a larger gain on the two more complex datasets MA2 and IXL; our method shows promising results in dealing with irrelevant information (dataset MA2) and information gaps (dataset IXL). This is because ARIS learns to classify verb categories in sentences and does not require observing similar patterns/templates in the training data. Therefore, ARIS is more robust to differences between the training and test datasets and can generalize across different dataset types. As discussed in the experimental setup, the datasets have mathematically similar problems, but differ in the natural language properties such as in the sentence length and irrelevant information (Table 2).

Table 3 also shows that the sentence categorization is performed with high accuracy even if the problem types and also the verbs are different. In particular, there are a total of 118 verbs among which 64 verbs belong to MA datasets and 54 are new to IXL. To further study this, we train our method ARIS_2 in which no verb can be repeated in the training and test sets. ARIS_2 still significantly outperforms KAZB. In addition, we observe only a slight change in accuracy between ARIS and ARIS_2.

To further understand our method, we study the effect of verb categorization in sentences in solving problems. Table 3 shows the results of Gold ARIS in solving arithmetic word problems with gold sentence categorizations. In addition, comparing ARIS with Gold ARIS suggests that our method is able to reliably identify verb categories in sentences.

We also perform an experiment where we pool all of the problems in the three datasets and randomly choose 3 folds for the data (instead of putting each original dataset into it's own fold). We compare our method with KAZBin this scenario. In this setting, our method's accuracy is 79.5% while KAZB's accuracy is 81.8%. As expected, our method's performance has not changed significantly from the previous setting, while KAZB's performance significantly improves because of the reduced diversity between the training and test sets in this scenario.

5.2.2 Sentence Categorization

Table 4 compares accuracy scores of sentence categorization for our method with different features, a baseline that uses WordNet verb senses, and the majority baseline that assigns every (verb, container) pair as increasing. Similar to ARIS_2, we randomly split verbs into three equal folds and assign the corresponding sentences to each fold. No verb is shared between training and test sets. We then directly evaluate the accuracy of the SVM's verb categorization (explained in Section 4.2). This table shows that ARIS performs well in classifying sentence categories even with new verbs in the test set. This suggests that our method can generalize well to predict verb categories for unseen verbs.

Table 4 also details the performance of four variants of our method that ablate various features of ARIS. The table shows that similarity, contextual, and WordNet features are all important to the performance of ARIS in verb categorization, whereas the WordNet features are less important for solving the problems. In addition, it shows that similarity features play more important roles. We also performed another experiment to study the effect of the proposed feature selection method for similarity-based features. The accuracy of ARIS in classifying sentence categories is 69.7% when we use all the verbs in $\mathcal{V}$ in the similarity feature vector. This shows that our feature selection algorithm for selecting seed verbs is important towards categorizing verbs.

Finally, Table 4 shows that our method significantly outperforms the baseline that only uses WordNet verb sense. An interesting observation is that the majority baseline in fact outperforms WordNet verb senses in verb categorization, but is significantly worse in solving arithmetic word problems. In addition, we evaluate the accuracy of predicting only verb categories by assigning the verb label according to the majority of its labels in the sentence categories. The accuracy of verb categories is 78.2% confirming that ARIS is able to successfully categorize verbs.

5.2.3 Error Analysis

We analyzed all 63 errors of Gold ARIS and present our findings in Table 5. There are five major classes of errors. In the first category, some information is not mentioned explicitly and should be entailed. For example, 'washing cars' is the source of 'making money'. Despite the improvements that come from ARIS, a large portion of the errors can still be attributed to irrelevant information. For example, 'short' is not a 'toy'. The third category refers to errors that require knowledge

	Categorization	Solution
ARIS	**81.2**$^+$	**76.5**$^+$
No similarity features	68.8	65.4
No WordNet features	75.3	78.0$^+$
No structural features	75.5	72.4$^+$
Baseline (WordNet)	67.8	68.4
Majority Baseline	73.4	48.9

Table 4: Ablation study and baseline comparisons: this table reports the accuracy of verb categorization in sentences and solutions for ARIS with ablating features. It also provides comparisons to WordNet and majority baselines. The improvement of ARIS (boldfaced) and ablations denoted by $^+$ are statistically significant over the baselines (with $p < 0.05$) for both tasks.

Error type	Example
Entailment, Implicit Action (26%)	Last week Tom had $74. He **washed cars** over the weekend and now has $86. How much money did he make washing cars?
Irrelevant Information (19%)	Tom bought a skateboard for $9.46, and spent $9.56 on marbles. Tom also spent $14.50 on **shorts**. In total, how much did Tom spend on **toys**?
Set Completion (13%)	Sara's school **played** 12 games this year. They **won** 4 games. How many games did they **lose**?
Parsing Issues (21%)	Sally had 27 Pokemon cards. Dan gave **her** 41 new Pokemon cards. How many Pokemon cards does Sally have now?
Others (21%)	In March it rained 0.81 inches. It rained 0.35 inches **less** in April than in March. How much did it rain in April?

Table 5: Examples of different error categories and relative frequencies. The cause of error is **bolded**.

about set completions. For example, the 'played' games can be split into 'win' and 'lost' games. Finally, parsing and coreference mistakes are another source of errors for ARIS.

6 Discussions and Conclusion

In this paper we introduce ARIS, a method for solving arithmetic word problems. ARIS learns to predict verb categories in sentences using syntactic and (shallow) semantic features from small, easy-to-obtain training data. ARIS grounds the world state into entities, sets, quantities, attributes, and their relations and takes advantage of the circumscription assumption and successfully fills in the information gaps. Finally, ARIS makes use of attributes and discards irrelevant information in the problems. Together these provide a new representation and a learning algorithm for solving arithmetic word problems.

This paper is one step toward building a system that can solve any math and logic word problem. Our empirical evaluations show that our method outperforms a template-based learning method (developed recently by Kushman et al. (2014)) on solving addition and subtraction problems with diversity between the training and test sets. In particular, our method generalizes better to data from different domains because ARIS only relies on learning verb categories which alleviates the need for equation templates for arithmetic problems. In this paper, we have focused on addition and subtraction problems. However, KAZB can deal with more general types of problems such as multiplication, division, and simultaneous equations.

We have observed a complementary behavior between our method and that of Kushman et al. This suggests a hybrid approach that can benefit from the strengths of both methods while being applicable to more general problems while robust to the errors specific to each. In addition, we plan to focus on incrementally collecting domain knowledge to deal with missing information gaps. Another possible direction is to improve parsing and coreference resolution.

Acknowledgments

The research was supported by the Allen Institute for AI, and grants from the NSF (IIS-1352249) and UW-RRF (65-2775). We thank Ben Hixon and the anonymous reviewers for helpful comments and the feedback on the work.

Abstract

Common-sense reasoning is important for AI applications, both in NLP and many vision and robotics tasks. We propose NaturalLI: a Natural Logic inference system for inferring common sense facts – for instance, that *cats have tails* or *tomatoes are round* – from a very large database of known facts. In addition to being able to provide strictly valid derivations, the system is also able to produce derivations which are only *likely* valid, accompanied by an associated confidence. We both show that our system is able to capture strict Natural Logic inferences on the FraCaS test suite, and demonstrate its ability to predict common sense facts with 49% recall and 91% precision.

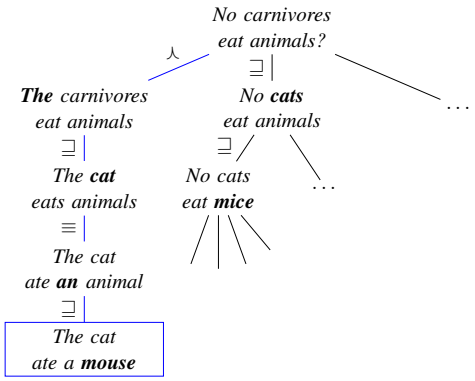

Figure 1: Natural Logic inference cast as search. The path to the boxed premise *the cat ate a mouse* disproves the query *no carnivores eat animals*, as it passes through the negation relation (人). This path is one of many candidates taken; the premise is one of many known facts in the database. The edge labels denote Natural Logic inference steps.

1 Introduction

We approach the task of *database completion*: given a database of true facts, we would like to predict whether an unseen fact is true and should belong in the database. This is intuitively cast as an inference problem from a collection of candidate premises to the truth of the query. For example, we would like to infer that *no carnivores eat animals* is false given a database containing *the cat ate a mouse* (see Figure 1).

These inferences are difficult to capture in a principled way while maintaining high recall, particularly for large scale open-domain tasks. Learned inference rules are difficult to generalize to arbitrary relations, and standard IR methods easily miss small but semantically important lexical differences. Furthermore, many methods require explicitly modeling either the database, the query, or both in a formal meaning representation (e.g., Freebase tuples).

Although projects like the Abstract Meaning Representation (Banarescu et al., 2013) have made headway in providing broad-coverage meaning representations, it remains appealing to use human language as the vessel for inference. Furthermore, OpenIE and similar projects have been very successful at collecting databases of natural language snippets from an ever-increasing corpus of unstructured text. These factors motivate our use of Natural Logic – a proof system built on the syntax of human language – for broad coverage database completion.

Prior work on Natural Logic has focused on inferences from a single relevant premise, making use of only formally valid inferences. We improve upon computational Natural Logic in three ways: (i) our approach operates over a very large set of candidate premises simultaneously; (ii) we do not require explicit alignment between a premise and the query; and (iii) we allow imprecise inferences at an associated cost learned from data.

Our approach casts inference as a single unified search problem from a query to any valid

supporting premise. Each transition along the search denotes a (reverse) inference step in Natural Logic, and incurs a cost reflecting the system's confidence in the validity of that step. This approach offers two contributions over prior work in database completion: (i) it allows for unstructured text as the input database without any assumptions about the schema or domain of the text, and (ii) it proposes Natural Logic for inference, rather than translating to a formal logic syntax. Moreover, the entire pipeline is implemented in a single elegant search framework, which scales easily to large databases.

2 MacCartney's Natural Logic

Natural Logic aims to capture common logical inferences by appealing directly to the structure of language, as opposed to running deduction on an abstract logical form. The logic builds upon traditional rather than first-order logic: to a first approximation, Natural Logic can be seen as an enhanced version of Aristotle's syllogistic system (van Benthem, 2008). A working understanding of the logic as syllogistic reasoning is sufficient for understanding the later contributions of the paper. While some inferences of first-order logic are not captured by Natural Logic, it nonetheless allows for a wide range of intuitive inferences in a computationally efficient and conceptually clean way.

We build upon the variant of the logic introduced by the NatLog system (MacCartney and Manning, 2007; 2008; 2009), based on earlier theoretical work on Natural Logic and Monotonicity Calculus (van Benthem, 1986; Valencia, 1991). Later work formalizes many aspects of the logic (Icard, 2012; Djalali, 2013); we adopt the formal semantics of Icard and Moss (2014), along with much of their notation.

At a high level, Natural Logic proofs operate by mutating spans of text to ensure that the mutated sentence follows from the original – each step is much like a syllogistic inference. We construct a complete proof system in three parts: we define MacCartney's atomic relations between lexical entries (Section 2.1), the effect these lexical mutations have on the validity of the sentence (Section 2.2), and a practical approach for executing these proofs. We review MacCartney's alignment-based approach in Section 2.3, and show that we can generalize and simplify this system in Section 3.

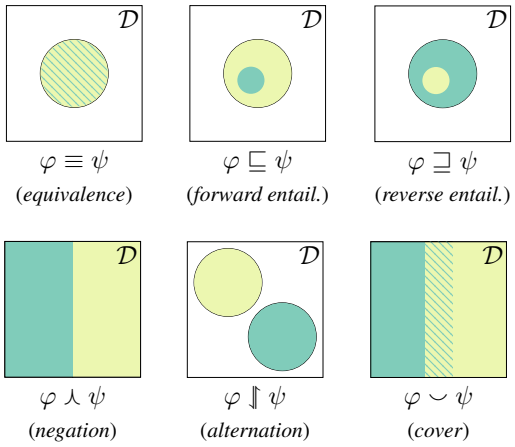

Figure 2: The model-theoretic interpretation of the MacCartney relations. The figure shows the relation between the denotation of φ (dark) and ψ (light). The universe is denoted by $\mathcal{D}$.

2.1 Lexical Relations

MacCartney and Manning (2007) introduce seven set-theoretic relations between the denotations of any two lexical items. The denotation of a lexical item is the set of objects in the domain of discourse $\mathcal{D}$ to which that lexical item refers. For instance, the denotation of *cat* would be the set of all cats. Two denotations can then be compared in terms of set algebra: if we define the set of cats to be φ and the set of animals to be ψ, we can state that $\varphi \subseteq \psi$.

The six informative relations are summarized in Figure 2; a seventh relation ($\#$) corresponds to to the completely uninformative relation. For instance, the example search path in Figure 1 makes use of the following relations:

$$\begin{array}{rcl} \textit{No } x\ y & \perp\!\!\!\perp & \textit{The } x\ y \\ \textit{cat} & \sqsubseteq & \textit{carnivore} \\ \textit{animal} & \equiv & \textit{a animal} \\ \textit{animal} & \sqsupseteq & \textit{mouse} \end{array}$$

Denotations are not required to be in the space of predicates (e.g., *cat*, *animal*). In the first example, the denotations of *No* and *The* are in the space of operators $p \to (p \to t)$: functions from predicates p to truth values t. The $\perp\!\!\!\perp$ relation becomes the conjunction of two claims: $\forall x \forall y\ \neg(\textit{no}\ x\ y \wedge \textit{the}\ x\ y)$ and $\forall x \forall y\ (\textit{no}\ x\ y \vee \textit{the}\ x\ y)$. This is analogous to the construction of the set-theoretic definition of $\perp\!\!\!\perp$ in Figure 2: $\varphi \cap \psi = \varnothing$ and $\varphi \cup \psi = \mathcal{D}$ (see Icard and Moss (2014)).

Examples of the last two relations ($\Rightarrow$ and $\smile$) and the complete independence relation ($\#$) include:

$$\begin{array}{rcl} \textit{cat} & \Rightarrow & \textit{dog} \\ \textit{animal} & \smile & \textit{nonhuman} \\ \textit{cat} & \# & \textit{friendly} \end{array}$$

2.2 Monotonicity and Polarity

The previous section details the relation between lexical items; however, we still need a theory for how to "project" the relation induced by a lexical mutation as a relation between the two containing sentences. For example, *cat* $\sqsubseteq$ *animal*, and *some cat meows* $\sqsubseteq$ *some animal meows*, but *no cat barks* $\not\sqsubseteq$ *no animal barks*. Despite differing by the same lexical relation, the first example describes a valid entailment, while the second does not.

We appeal to two important concepts: *monotonicity* as a property of arguments to natural language operators, and *polarity* as a property of lexical items in a sentence. Much like monotone functions in calculus, an [upwards] monotone operator has an output truth value which is non-decreasing (i.e., material implication) as the input "increases" (i.e., the subset relation). From the example above, *some* is upwards monotone in its first argument, and *no* is downwards monotone in its first argument.

Polarity is a property of lexical items in a sentence determined by the operators acting on it. All lexical items have *upward* polarity by default; upwards monotone operators preserve polarity, and downwards monotone operators reverse polarity. For example, *mice* in ***no*** *cats eat mice* has downward polarity, whereas *mice* in ***no*** *cats do**n't** eat mice* has upward polarity (it is in the scope of two downward monotone operators). The relation between two sentences differing by a single lexical relation is then given by the projection function ρ in Table 1.[1]

2.3 Proof By Alignment

MacCartney and Manning (2007) approach the inference task in the context of inferring whether a single relevant premise entails a query. Their approach first generates an alignment between the premise and the query, and then classifies each aligned segment into one of the lexical relations in Figure 2. Inference reduces to projecting each

r	$\equiv$	$\sqsubseteq$	$\sqsupseteq$	$\Rightarrow$	$\smile$	$\wedge$	$\#$
$\rho(r)$	$\equiv$	$\sqsupseteq$	$\sqsubseteq$	$\smile$	$\Rightarrow$	$\wedge$	$\#$

Table 1: The projection function ρ, shown for downward polarity contexts only. The input r is the lexical relation between two words in a sentence; the projected relation $\rho(r)$ is the relation between the two sentences differing only by that word. Note that ρ is the identity function in upward polarity contexts.

$\bowtie$	$\equiv$	$\sqsubseteq$	$\sqsupseteq$	$\wedge$	$\Rightarrow$	$\smile$	$\#$
$\equiv$	$\equiv$	$\sqsubseteq$	$\sqsupseteq$	$\wedge$	$\Rightarrow$	$\smile$	$\#$
$\sqsubseteq$	$\sqsubseteq$	$\sqsubseteq$	$\#$	$\Rightarrow$	$\Rightarrow$	$\#$	$\#$
$\sqsupseteq$	$\sqsupseteq$	$\#$	$\sqsupseteq$	$\smile$	$\#$	$\smile$	$\#$
$\wedge$	$\wedge$	$\smile$	$\Rightarrow$	$\equiv$	$\sqsupseteq$	$\sqsubseteq$	$\#$
$\Rightarrow$	$\Rightarrow$	$\#$	$\Rightarrow$	$\sqsubseteq$	$\#$	$\sqsubseteq$	$\#$
$\smile$	$\smile$	$\smile$	$\#$	$\sqsupseteq$	$\sqsupseteq$	$\#$	$\#$
$\#$	$\#$	$\#$	$\#$	$\#$	$\#$	$\#$	$\#$

Table 2: The join table as shown in Icard (2012). Entries in the table are the result of joining a row with a column.

of these relations according to the projection function ρ (Table 1) and iteratively *joining* two projected relations together to get the final entailment relation. This join relation, denoted as $\bowtie$, is given in Table 2.

To illustrate, we can consider MacCartney's example inference from *Stimpy is a cat* to *Stimpy is not a poodle*. An alignment of the two statements would provide three lexical mutations: $r_1 \coloneqq \textit{cat} \rightarrow \textit{dog}$, $r_2 \coloneqq \cdot \rightarrow \textit{not}$, and $r_3 \coloneqq \textit{dog} \rightarrow \textit{poodle}$. Each of these are then projected with the projection function ρ, and are joined using the join relation:

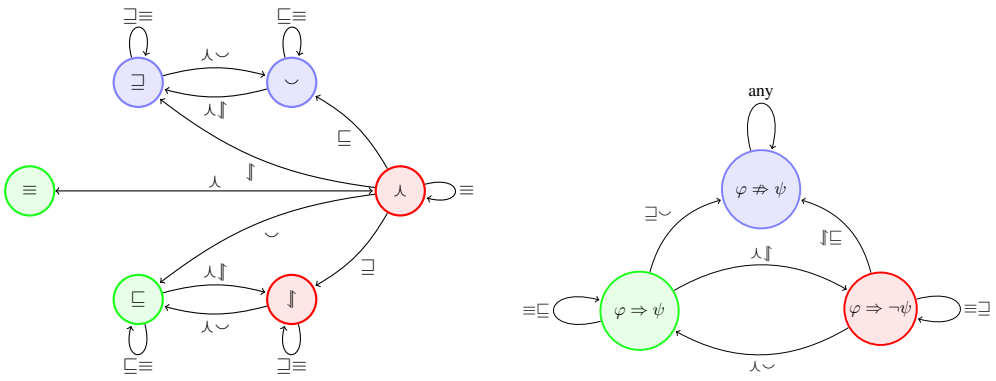
$$r_0 \bowtie \rho(r_1) \bowtie \rho(r_2) \bowtie \rho(r_3),$$

where the initial relation r_0 is axiomatically $\equiv$. In MacCartney's work this style of proof is presented as a table. The last column (s_i) is the relation between the premise and the i^{th} step in the proof, and is constructed inductively as $s_i \coloneqq s_{i-1} \bowtie \rho(r_i)$:

	Mutation	r_i	$\rho(r_i)$	s_i
r_1	*cat*$\rightarrow$*dog*	$\Rightarrow$	$\Rightarrow$	$\Rightarrow$
r_2	$\cdot \rightarrow$*not*	$\wedge$	$\wedge$	$\sqsubseteq$
r_3	*dog*$\rightarrow$*poodle*	$\sqsupseteq$	$\sqsubseteq$	$\sqsubseteq$

In our example, we would conclude that *Stimpy is a cat* $\sqsubseteq$ *Stimpy is not a poodle* since s_3 is $\sqsubseteq$; therefore the inference is valid.

[1] Note that this table optimistically assumes every operator is *additive* and *multiplicative*, as defined in Icard (2012).



(a) (b)

Figure 3: (a) Natural logic inference expressed as a finite state automaton. Omitted edges go to the unknown state (#), with the exception of omitted edges from ≡, which go to the state of the edge type. Green states (≡, ⊑) denote valid inferences; red states (⇂, ⅄) denote invalid inferences; blue states (⊒, ⌣) denote inferences of unknown validity. (b) The join table collapsed into the three meaningful states over truth values.

3 Inference as a Finite State Machine

We show that the tabular proof formulation from Section 2.3 can be viewed as a finite state machine, and present a novel observation that we can losslessly collapse this finite state machine into only three intuitive inference states. These observations allow us to formulate our search problem such that a search path corresponds to an input to (i.e., path through) this collapsed state machine.

Taking notation from Section 2.3, we construct a finite state machine over states $s \in \{\sqsubseteq, \sqsupseteq, \dots\}$. A machine in state s_i corresponds to relation s_i holding between the initial premise and the derived fact so far. States therefore correspond to states of *logical validity*. The start state is ≡. Outgoing transitions correspond to *inference steps*. Each transition is labeled with a projected relation $\rho(r) \in \{\sqsubseteq, \sqsupseteq, \dots\}$, and spans from a source state s to a target s' according to the join table. That is, the transition $s \xrightarrow{\rho(r)} s'$ exists iff $s' = s \bowtie \rho(r)$. For example, the path in Figure 1 yields the transitions $\equiv \xrightarrow{⅄} ⅄ \xrightarrow{\sqsupseteq} ⇂ \xrightarrow{\equiv} ⇂ \xrightarrow{\sqsupseteq} ⇂$. Figure 3a shows the automaton, with trivial edges omitted for clarity.

Our second contribution is collapsing this automaton into the three meaningful states we use as output: *valid* ($\varphi \Rightarrow \psi$), *invalid* ($\varphi \Rightarrow \neg\psi$), and *unknown validity* ($\varphi \nRightarrow \psi$). We can cluster states in Figure 3a into these three categories. The relations ≡ and ⊑ correspond to valid inferences; ⅄ and ⇂ correspond to invalid inferences; ⊒, ⌣ and # correspond to unknown validity. This clustering mirrors that used by MacCartney for his textual entailment experiments.

Collapsing the FSA into the form in Figure 3b becomes straightforward from observing the regularities in Figure 3a. Nodes in the valid cluster transition to invalid nodes always and only on the relations ⅄ and ⇂. Symmetrically, invalid nodes transition to valid nodes always and only on ⅄ and ⌣. A similar pattern holds for the other transitions.

Formally, for every relation r and nodes a_1 and a_2 in the same cluster, if we have transitions $a_1 \xrightarrow{r} b_1$ and $a_2 \xrightarrow{r} b_2$ then b_1 and b_2 are necessarily in the same cluster. As a concrete example, we can take $r = ⅄$ and the two states in the *invalid* cluster: $a_1 = ⅄$, $a_2 = ⇂$. Although $⅄ \xrightarrow{⅄} \equiv$ and $⇂ \xrightarrow{⅄} \sqsubseteq$, both ≡ and ⊑ are in the same cluster (*valid*). It is not trivial *a priori* that the join table should have this regularity, and it certainly simplifies the logic for inference tasks.

A few observations deserve passing remark. First, even though the states ⊒ and ⌣ appear meaningful, in fact there is no "escaping" these states to either a valid or invalid inference. Second, the hierarchy over relations presented in Icard (2012) becomes apparent – in particular, ⅄ always behaves as negation, whereas its two "weaker" versions (⇂ and ⌣) only behave as negation in certain contexts. Lastly, with probabilistic inference, transitioning to the unknown state can be replaced with staying in the current state at a (potentially arbitrarily large) cost to the confidence of validity. This allows us to make use of only two states: *valid* and *invalid*.

4 Inference As Search

Natural Logic allows us to formalize our approach elegantly as a single search problem. Given a query, we search over the space of possible facts for a valid premise in our database. The nodes in our search problem correspond to candidate facts (Section 4.1); the edges are mutations of these facts (Section 4.2); the costs over these edges encode the confidence that this edge maintains an informative inference (Section 4.5). This mirrors the automaton defined in Section 3, except importantly we are constructing a reversed derivation, and are therefore "traversing" the FSA backwards.

This approach is efficient over a large database of 270 million entries without making use of explicit queries over the database; nor does the approach make use of any sort of approximate matching against the database, beyond lemmatizing individual lexical items. The motivation in prior work for approximate matches – to improve the recall of candidate premises – is captured elegantly by relaxing Natural Logic itself. We show that allowing invalid transitions with appropriate costs generalizes JC distance (Jiang and Conrath, 1997) – a common thesaurus-based similarity metric (Section 4.3). Importantly, however, the entire inference pipeline is done within the framework of weighted lexical transitions in Natural Logic.

4.1 Nodes

The space of possible nodes in our search is the set of possible partial derivations. To a first approximation, this is a pair (w, s) of a surface form w tagged with word sense and polarity, and an inference state $s \in \{\text{valid}, \text{invalid}\}$ in our collapsed FSA (Figure 3b). For example, the search path in Figure 1 traverses the nodes:

(*No carnivores eat animals*,	valid)
(*The carnivores eat animals*,	invalid)
(*The cat eats animals*,	invalid)
(*The cat eats an animal*,	invalid)
(*The cat ate a mouse*,	invalid)

During search, we assume that the validity states s are reversible – if we know that *the cat ate a mouse* is true, we can infer that *no carnivores eat animals* is false. In addition, our search keeps track of some additional information:

Mutation Index Edges between sentences are most naturally defined to correspond to mutations of individual lexical items. We therefore maintain an index of the next item to mutate at each search state. Importantly, this enforces that each derivation orders mutations left-to-right; this is computationally efficient, at the expense of rare search errors. A similar observation is noted in MacCartney (2009), where prematurely collapsing to # occasionally misses inferences.

Polarity Mutating operators can change the polarity on a span in the fact. Since we do not have the full parse tree at our disposal at search time, we track a small amount of metadata to guess the scope of the mutated operator.

4.2 Transitions

We begin by introducing some terminology. A *transition template* is a broad class of transitions; for instance WordNet hypernymy. A *transition* (or *transition instance*) is a particular instantiation of a transition template. For example, the transition from *cat* to *feline*. Lastly, an *edge* in the search space connects two nodes, which are separated by a single transition instance. For example, an edge exists between *some felines have tails* and *some cats have tails*. Transition [instances] are stored statically in memory, whereas edges are constructed on demand.

Transition templates provide a means of defining transitions and subsequently edges in our search space using existing lexical resources (e.g., WordNet, distributional similarity, etc.). We can then define a mapping from these templates to Natural Logic lexical relations. This allows us to map every edge in our search graph back to the Natural Logic relation it instantiates. The full table of transition templates is given in Table 3, along with the Natural Logic relation that instances of the template introduce. We include most relations in WordNet as transitions, and parametrize insertions and deletions by the part of speech of the token being inserted/deleted.

Once we have an edge defining a lexical mutation with an associated Natural Logic relation r, we can construct the corresponding end node (w', s') such that w' is the sentence with the lexical mutation applied, and s' is the validity state obtained from the FSA in Section 3. For instance, if our edge begins at (w, s), and there exists a transition in the FSA from $s' \xrightarrow{r} s$, then we define the end point of the edge to be (w', s'). To illustrate concretely, suppose our search state is:

(*some felines have tails*, valid)

Transition Template	Relation
WordNet hypernym	$\sqsubseteq$
WordNet hyponym	$\sqsupseteq$
WordNet antonym†	$\Downarrow$
WordNet synonym/pertainym†	$\equiv$
Distributional nearest neighbor	$\equiv$
Delete word†	$\sqsubseteq$
Add word†	$\sqsupseteq$
Operator weaken	$\sqsubseteq$
Operator strengthen	$\sqsupseteq$
Operator negate	$\curlywedge$
Operator synonym	$\equiv$
Change word sense	$\equiv$

Table 3: The edges allowed during inference. Entries with a dagger (†) are parametrized by their part-of-speech tag, from the restricted list of {noun,adjective,verb,other}. The first column describes the type of the transition. The set-theoretic relation introduced by each relation is given in the second column.

The transition template for WordNet hypernymy gives us a transition instance from *feline* to *cat*, corresponding to the Natural Logic inference *cat* $\stackrel{\sqsubseteq}{\Longrightarrow}$ *feline*. Recall, we are constructing the inference in reverse, starting from the consequent (query). We then notice that the transition $valid \stackrel{\sqsubseteq}{\Longrightarrow} valid$ in the FSA ends in our current inference state (*valid*), and set our new inference state to be the start state of the FSA transition – in this case, we maintain validity.

Note that negation is somewhat subtle, as the transitions are not symmetric from valid to invalid and visa versa, and we do not know our true inference state with respect to the premise yet. In practice, the search procedure treats all three of $\{\curlywedge, \Downarrow, \smile\}$ as negation, and re-scores complete derivations once their inference states are known.

It should be noted that the mapping from transition templates to relation types is intentionally imprecise. For instance, clearly nearest neighbors do not preserve equivalence ($\equiv$); more subtly, while *all cats like milk* $\Downarrow$ *all cats hate milk*, it is not the case that *some cats like milk* $\Downarrow$ *some cats hate milk*.[2] We mitigate this imprecision by introducing a cost for each transition, and learning the appropriate value for this cost (see Section 5). The cost of an edge from fact (w, v) with surface form w and validity v to a new fact (w', v'), using a transition instance t_i of template t and mutating a word with polarity p, is given by $f_{t_i} \cdot \theta_{t,v,p}$. We define this as:

f_{t_i}: A value associated with every transition instance t_i, intuitively corresponding to how "far" the endpoints of the transition are.

$\theta_{t,v,p}$: A learned cost for taking a transition of template t, if the source of the edge is in a inference state of v and the word being mutated has polarity p.

The notation for f_{t_i} is chosen to evoke an analogy to features. We set f_{t_i} to be 1 in most cases; the exceptions are the edges over the WordNet hypernym tree and the nearest neighbors edges. In the first case, taking the hypernymy relation from w to w' to be $\uparrow_{w \to w'}$, we set:

$$f_{\uparrow_{w \to w'}} = \log \frac{p(w')}{p(w)} = \log p(w') - \log p(w).$$

The value $f_{\downarrow_{w \to w'}}$ is set analogously. We define $p(w)$ to be the "probability" of a concept – that is, the normalized frequency of a word w or any of its hyponyms in the Google N-Grams corpus (Brants and Franz, 2006). Intuitively, this ensures that relatively long paths through fine-grained sections of WordNet are not unduly penalized. For instance, the path from *cat* to *animal* traverses six intermediate nodes, naïvely yielding a prohibitive search depth of 6. However, many of these transitions have low weight: for instance $f_{\uparrow_{cat \to feline}}$ is only 0.37.

For nearest neighbors edges, we take Neural Network embeddings learned in Huang et al. (2012) corresponding to each vocabulary entry. We then define $f_{NN_{w \to w'}}$ to be the arc cosine of the cosine similarity (i.e., the angle) between word vectors associated with lexical items w and w':

$$f_{NN_{w \to w'}} = \arccos\left(\frac{w \cdot w'}{\|w\|\|w'\|}\right).$$

For instance, $f_{NN_{cat \to dog}} = 0.43$. In practice, we explore the 100 nearest neighbors of each word.

We can express f_{t_i} as a feature vector by representing it as a vector with value f_{t_i} at the index corresponding to (t, v, p) – the transition template, the validity of the inference, and the polarity of the mutated word. Note that the size of this vector mirrors the number of cost parameters $\theta_{t,v,p}$, and

[2] The latter example is actually a consequence of the projection function in Table 1 being overly optimistic.

is in general smaller than the number of transition instances.

A search path can then be parametrized by a sequence of feature vectors $f_1, f_2, \ldots, f_n$, which in turn can be collapsed into a single vector $\mathbf{f} = \sum_i f_i$. The cost of a path is defined as $\theta \cdot \mathbf{f}$, where θ is the vector of $\theta_{t,v,p}$ values. Both $\mathbf{f}$ and θ are constrained to be non-negative, or else the search problem is misspecified.

4.3 Generalizing Similarities

An elegant property of our definitions of f_{t_i} is its ability to generalize JC distance. Let us assume we have lexical items w_1 and w_2, with a least common subsumer lcs. The JC distance $\text{dist}_{\text{jc}}(w_1, w_2)$ is:

$$\text{dist}_{\text{jc}}(w_1, w_2) = \log \frac{p(\text{lcs})^2}{p(w_1) \cdot p(w_2)}. \quad (1)$$

For simplicity, we simplify $\theta_{\uparrow,v,p}$ and $\theta_{\downarrow,v,p}$ as simply $\theta_\uparrow$ and $\theta_\downarrow$. Without loss of generality, we also assume that a path in our search is only modifying a single lexical item w_1, eventually reaching a mutated form w_2.

We can factorize the cost of a path, $\theta \cdot \mathbf{f}$, along the path from w_1 to w_2 through its lowest common subsumer (lcs), $[w_1, w_1^{(1)}, \ldots, \text{lcs}, \ldots, w_2^{(1)}, w_2]$, as follows:

$$\begin{aligned}
\theta \cdot \phi &= \theta_\uparrow \left(\left[\log p(w_1^{(1)}) - \log p(w_1) \right] + \ldots \right) + \\
&\quad \theta_\downarrow \left(\left[\log p(\text{lcs}) - \log p(w_1^{(n)}) \right] + \ldots \right) \\
&= \theta_\uparrow \left(\log \frac{p(\text{lcs})}{p(w_1)} \right) + \theta_\downarrow \left(\log \frac{p(\text{lcs})}{p(w_2)} \right) \\
&= \log \frac{p(\text{lcs})^{\theta_\uparrow + \theta_\downarrow}}{p(w_1)^{\theta_\uparrow} \cdot p(w_2)^{\theta_\downarrow}}.
\end{aligned}$$

Note that setting both $\theta_\uparrow$ and $\theta_\downarrow$ to 1 exactly yields Formula (1) for JC distance. This, in addition to the inclusion of nearest neighbors as transitions, allows the search to capture the intuition that similar objects have similar properties (e.g., as used in Angeli and Manning (2013)).

4.4 Deletions in Inference

Although inserting lexical items in a derivation (deleting words from the reversed derivation) is trivial, the other direction is not. For brevity, we refer to a deletion in the derivation as an insertion, since from the perspective of search we are inserting lexical items.

Naïvely, at every node in our search we must consider every item in the vocabulary as a possible insertion. We can limit the number of items we consider by storing the database as a trie. Since the search mutates the fact left-to-right (as per Section 4.1), we can consider children of a trie node as candidate insertions. To illustrate, given a search state with fact $w_0\, w_1 \ldots w_n$ and mutation index i, we would look up completions w_{i+1} for $w_0\, w_1 \ldots w_i$ in our trie of known facts.

Although this approach works well when i is relatively large, there are too many candidate insertions for small i. We special case the most extreme example for this, where $i = 0$ – that is, when we are inserting into the beginning of the fact. In this case, rather than taking all possible lexical items that start any fact, we take all items which are followed by the first word of our current fact. To illustrate, given a search state with fact $w_0\, w_1 \ldots w_n$, we would propose candidate insertions w_{-1} such that $w_{-1}\, w_0\, w_1' \ldots w_k'$ is a known fact for some $w_1' \ldots w_k'$. More concretely, if we know that *fluffy cats have tails*, and are at a node corresponding to *cats like boxes*, we propose *fluffy* as a possible insertion: *fluffy cats like boxes*.

4.5 Confidence Estimation

The last component in inference is translating a search path into a probability of truth. We notice from Section 4.2 that the *cost* of a path can be represented as $\theta \cdot \mathbf{f}$. We can normalize this value by negating every element of the cost vector θ and passing it through a sigmoid:

$$\text{confidence} = \frac{1}{1 + e^{-(-\theta \cdot \mathbf{f})}}.$$

Importantly, note that the cost vector must be non-negative for the search to be well-defined, and therefore the confidence value will be constrained to be between 0 and $\frac{1}{2}$.

At this point, we have a confidence that the given path has not violated strict Natural Logic. However, to translate this value into a probability we need to incorporate whether the inference path is confidently valid, or confidently invalid. To illustrate, a fact with a low confidence should translate to a probability of $\frac{1}{2}$, rather than a probability of 0. We therefore define the probability of validity as follows: We take v to be 1 if the query is in the *valid* state with respect to the premise, and -1 if the query is in the *invalid* state. For completeness, if no path is given we can set $v = 0$. The

probability of validity becomes:

$$p(\text{valid}) = \frac{v}{2} + \frac{1}{1 + e^{v\theta \cdot \mathbf{f}}}. \quad (2)$$

Note that in the case where $v = -1$, the above expression reduces to $\frac{1}{2}$ − confidence; in the case where $v = 0$ it reduces to simply $\frac{1}{2}$. Furthermore, note that the probability of truth makes use of the same parameters as the cost in the search.

5 Learning Transition Costs

We describe our procedure for learning the transition costs θ. Our training data $\mathcal{D}$ consists of query facts q and their associated gold truth values y. Equation (2) gives us a probability that a particular inference is *valid*; we axiomatically consider a valid inference from a known premise to be justification for the truth of the query. This is at the expense of the (often incorrect) assumption that our database is clean and only contains true facts.

We optimize the likelihood of our gold annotations according to this probability, subject to the constraint that all elements in our cost vector θ be non-negative. We run the search algorithm described in Section 4 on every query $q_i \in \mathcal{D}$. This produces the highest confidence path x_1, along with its inference state v_i. We now have annotated tuples: $((x_i, v_i), y_i)$ for every element in our training set. Analogous to logistic regression, the log likelihood of our training data $\mathcal{D}$, subject to costs θ, is:

$$l_\theta(\mathcal{D}) = \sum_{0 \le i < |\mathcal{D}|} \Big[y_i \log \left(\frac{v_i}{2} + \frac{1}{1 + e^{v_i \theta \cdot \mathbf{f}(x_i)}} \right) + (1 - y_i) \log \left(\frac{-v_i}{2} + \frac{1}{1 + e^{-v_i \theta \cdot \mathbf{f}(x_i)}} \right) \Big],$$

where y_i is 1 if the example is annotated true and 0 otherwise, and $\mathbf{f}(x_i)$ are the features extracted for path x_i. The objective function is the negative log likelihood with an L_2 regularization term and a log barrier function to prohibit negative costs:

$$O(\mathcal{D}) = -l_\theta(\mathcal{D}) + \frac{1}{2\sigma^2} \|\theta\|_2^2 - \epsilon \log(\theta).$$

We optimize this objective using conjugate gradient descent. Although the objective is non-convex, in practice we can find a good initialization of weights to reduce the risk of arriving at local optima.

An elegant property of this formulation is that the weights we are optimizing correspond directly to the costs used during search. This creates a positive feedback loop – as better weights are learned, the search algorithm is more likely to find confident paths, and more data is available to train from. We therefore run this learning step for multiple epochs, re-running search after each epoch. The weights for the first epoch are initialized to an approximation of valid Natural Logic weights. Subsequent epochs initialize their weights to the output of the previous epoch.

Table 4: Results on the FraCaS textual entailment suite. N is this work; M07 refers to MacCartney and Manning (2007); M08 refers to MacCartney and Manning (2008). The relevant sections of the corpus intended to be handled by this system are sections 1, 5, and 6 (although not 2 and 9, which are also included in M08).

6 Experiments

We evaluate our system on two tasks: the FraCaS test suite, used by MacCartney and Manning (2007; 2008), evaluates the system's ability to capture Natural Logic inferences even without the explicit alignments of these previous systems. In addition, we evaluate the system's ability to predict common-sense facts from a large corpus of OpenIE extractions.

6.1 FraCaS Entailment Corpus

The FraCaS corpus (Cooper et al., 1996) is a small corpus of entailment problems, aimed at providing a comprehensive test of a system's handling of various entailment patterns. We process the corpus following MacCartney and Manning (2007). It should be noted that many of the sections of the corpus are not directly applicable to Natural Logic inferences; MacCartney and Manning (2007) identify three sections which are in the scope of their system, and consequently our system as well.

Results on the dataset are given in Table 4.

System	P	R	F_1	Accuracy
Lookup	100.0	12.1	21.6	56.0
NaturalLI Only	88.8	40.1	55.2	67.5
NaturalLI + Lookup	90.6	49.1	63.7	72.0

Table 5: Accuracy inferring common-sense facts on a balanced test set. *Lookup* queries the lemmatized lower-case fact directly in the 270M fact database. *NaturalLI Only* disallows such lookups, and infers every query from only distinct premises in the database. *NaturalLI + Lookup* takes the union of the two systems.

Since the corpus is not a blind test set, the results are presented less as a comparison of performance, but rather to validate the expressive power of our search-based approach against MacCartney's align-and-classify approach. For the experiments, costs were set to express valid Natural Logic inference as a hard constraint.

The results show that the system is able to capture Natural Logic inferences with similar accuracy to the state-of-the-art system of MacCartney and Manning (2008). Note that our system is comparatively crippled in this framework along at least two dimensions: It cannot appeal to the premise when constructing the search, leading to the introduction of a class of search errors which are entirely absent from prior work. Second, the derivation process itself does not have access to the full parse tree of the candidate fact.

Although precision is fairly high even on the non-applicable sections of FraCaS, recall is significantly lower than prior work. This is a direct consequence of not having alignments to appeal to. For instance, we can consider two inferences:

Jack saw Jill is playing $\overset{?}{\Rightarrow}$ *Jill is playing*
Jill saw Jack is playing $\overset{?}{\Rightarrow}$ *Jill is playing*

It is clear from the parse of the sentence that the first is valid and the second is not; however, from the perspective of the search algorithm both make the same two edits: inserting *Jack* and *saw*. In order to err on the side of safety, we disallow deleting the verb *saw*.

6.2 Common Sense Reasoning

We validate our system's ability to infer unseen common sense facts from a large database of such facts. Whereas evaluation on FraCaS shows that our search formulation captures applicable inferences as well as prior work, this evaluation presents a novel use-case for Natural Logic inference.

For our database of facts, we run the Ollie OpenIE system (Mausam et al., 2012) over Wikipedia,[3] Simple Wikipedia,[4] and a random 5% of CommonCrawl. Extractions with confidence below 0.25 or which contained pronouns were discarded. This yielded a total of 305 million unique extractions composed entirely of lexical items which mapped into our vocabulary (186 707 items). Each of these extracted triples (e_1, r, e_2) was then flattened into a plain-text fact $e_1\ r\ e_2$ and lemmatized. This yields 270 million unique lemmatized premises in our database. In general, each fact in the database could be arbitrary unstructured text; our use of Ollie extractions is motivated only by a desire to extract short, concise facts.

For our evaluation, we infer the top 689 most confident facts from the ConceptNet project (Tandon et al., 2011). To avoid redundancy with WordNet, we take facts from eight ConceptNet relations: MemberOf, HasA, UsedFor, CapableOf, Causes, HasProperty, Desires, and CreatedBy. We then treat the *surface text* field of these facts as our candidate query. This yields queries like the following:

not all birds can fly
noses are used to smell
nobody wants to die
music is used for pleasure

For negative examples, we take the 689 ReVerb extractions (Fader et al., 2011) judged as false by Mechanical Turk workers (Angeli and Manning, 2013). This provides a set of plausible but nonetheless incorrect examples, and ensures that our recall is not due to over-zealous search. Search costs are tuned from an additional set of 540 true ConceptNet and 540 false ReVerb extractions.

Results are shown in Table 5. We compare against the baseline of looking up each fact verbatim in the fact database. Note that both the query and the facts in the database are short snippets, already lemmatized and lower-cased; therefore, it is not in principle unreasonable to expect a database of 270 million extractions to contain these facts. Nonetheless, only 12% of facts were found via a direct lookup. We show that NaturalLI (allowing lookups) improves this recall four-fold, at only an 9.4% drop in precision.

7 Related Work

A large body of work is devoted to compiling open-domain knowledge bases. For instance, OpenIE systems (Yates et al., 2007; Fader et al., 2011) extract concise facts via surface or dependency patterns. In a similar vein, NELL (Carlson et al., 2010; Gardner et al., 2013) continuously learns new high-precision facts from the internet.

Many NLP applications query large knowledge bases. Prominent examples include question answering (Voorhees, 2001), semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2013; Berant and Liang, 2014), and information extraction systems (Hoffmann et al., 2011; Surdeanu et al., 2012). A goal of this work is to improve accuracy on these downstream tasks by providing a *probabilistic* knowledge base for likely true facts.

A natural alternative to the approach taken in this paper is to extend knowledge bases by inferring and adding new facts directly. For instance, Snow et al. (2006) present an approach to enriching the WordNet taxonomy; Tandon et al. (2011) extend ConceptNet with new facts; Soderland et al. (2010) use ReVerb extractions to enrich a domain-specific ontology. Chen et al. (2013) and Socher et al. (2013) use Neural Tensor Networks to predict unseen relation triples in WordNet and Freebase, following a line of work by Bordes et al. (2011) and Jenatton et al. (2012). Yao et al. (2012) and Riedel et al. (2013) present a related line of work, inferring new relations between Freebase entities via inference over both Freebase and OpenIE relations. In contrast, this work runs inference over arbitrary text, without restricting itself to a particular set of relations, or even entities.

The goal of tackling common-sense reasoning is by no means novel in itself. Work by Reiter and McCarthy (Reiter, 1980; McCarthy, 1980) attempts to reason about the truth of a consequent in the absence of strict logical entailment. Similarly, Pearl (1989) presents a framework for assigning confidences to inferences which can be reasonably assumed. Our approach differs from these attempts in part in its use of Natural Logic as the underlying inference engine, and more substantially in its attempt at creating a broad-coverage system. More recently, work by Schubert (2002) and Van Durme et al. (2009) approach common sense reasoning with *episodic logic*; we differ in our focus on inferring truth from an arbitrary query, and in making use of longer inferences.

This work is similar in many ways to work on recognizing textual entailment – e.g., Schoenmackers et al. (2010), Berant et al. (2011). Work by Lewis and Steedman (2013) is particularly relevant, as they likewise evaluate on the FraCaS suite (Section 1; 89% accuracy with gold trees). They approach entailment by constructing a CCG parse of the query, while mapping questions which are paraphrases of each other to the same logical form using distributional relation clustering. However, their system is unlikely to scale to either our large database of premises, or our breadth of relations.

Fader et al. (2014) propose a system for question answering based on a sequence of paraphrase rewrites followed by a fuzzy query to a structured knowledge base. This work can be thought of as an elegant framework for unifying this two-stage process, while explicitly tracking the "risk" taken with each paraphrase step. Furthermore, our system is able to explore mutations which are only valid in one direction, rather than the bidirectional entailment of paraphrases, and does not require a corpus of such paraphrases for training.

8 Conclusion

We have presented NaturalLI, an inference system over unstructured text intended to infer common sense facts. We have shown that we can run inference over a large set of premises while maintaining Natural Logic semantics, and that we can learn how to infer unseen common sense facts.

Future work will focus on enriching the class of inferences we can make with Natural Logic. For example, extending the approach to handle meronymy and relation entailments. Furthermore, we hope to learn richer lexicalized parameters, and use the syntactic structure of a fact during search.

Abstract

Term translation is of great importance for statistical machine translation (SMT), especially document-informed SMT. In this paper, we investigate three issues of term translation in the context of document-informed SMT and propose three corresponding models: (a) a term translation disambiguation model which selects desirable translations for terms in the source language with domain information, (b) a term translation consistency model that encourages consistent translations for terms with a high strength of translation consistency throughout a document, and (c) a term bracketing model that rewards translation hypotheses where bracketable source terms are translated as a whole unit. We integrate the three models into hierarchical phrase-based SMT and evaluate their effectiveness on NIST Chinese-English translation tasks with large-scale training data. Experiment results show that all three models can achieve significant improvements over the baseline. Additionally, we can obtain a further improvement when combining the three models.

1 Introduction

A term is a linguistic expression that is used as the designation of a defined concept in a language (ISO 1087). As terms convey concepts of a text, term translation becomes crucial when the text is translated from its original language to another language. The translations of terms are often affected by the domain in which terms are used and the context that surrounds terms (Vasconcellos et al., 2001). In this paper, we study domain-specific and context-sensitive term translation for SMT.

In order to achieve this goal, we focus on three issues of term translation: 1) translation ambiguity, 2) translation consistency and 3) bracketing. First, term translation ambiguity is related to translations of the same term in different domains. A source language term may have different translations when it occurs in different domains. Second, translation consistency is about consistent translations for terms that occur in the same document. Usually, it is undesirable to translate the same term in different ways as it occurs in different parts of a document. Finally, bracketing concerns whether a multi-word term is bracketable during translation. Normally, a multi-word term is translated as a whole unit into a contiguous target string.

We study these three issues in the context of document-informed SMT. We use document-informed information to disambiguate term translations in different documents and maintain consistent translations for terms that occur in the same document. We propose three different models for term translation that attempt to address the three issues mentioned above. In particular,

- *Term Translation Disambiguation Model:* In this model, we condition the translations of terms in different documents on corresponding per-document topic distributions. In doing so, we enable the decoder to favor translation hypotheses with domain-specific term translations.
- *Term Translation Consistency Model:* This model encourages the same terms with a high strength of translation consistency that occur in different parts of a document to be translated in a consistent fashion. We calculate the translation consistency strength of a term based on the topic distribution of the documents where the term occurs in this model.
- *Term Bracketing Model:* We use the bracketing model to reward translation hypothe-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 546–556,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ses where bracketable multi-word terms are translated as a whole unit.

We integrate the three models into hierarchical phrase-based SMT (Chiang, 2007). Large-scale experiment results show that they are all able to achieve significant improvements of up to 0.89 BLEU points over the baseline. When simultaneously integrating the three models into SMT, we can gain a further improvement, which outperforms the baseline by up to 1.16 BLEU points.

In the remainder of this paper, we begin with a brief overview of related work in Section 2, and bilingual term extraction in Section 3. We then elaborate the proposed three models for term translation in Section 4. Next, we conduct experiments to validate the effectiveness of the proposed models in Section 5. Finally, we conclude and provide directions for future work in Section 6.

2 Related Work

In this section, we briefly introduce related work and highlight the differences between our work and previous studies.

As we approach term translation disambiguation and consistency via topic modeling, our models are related to previous work that explores the topic model (Blei et al., 2003) for machine translation (Zhao and Xing, 2006; Su et al., 2012; Xiao et al., 2012; Eidelman et al., 2012). Zhao and Xing (2006) employ three models that enable word alignment process to leverage topical contents of document-pairs with topic model. Su et al. (2012) establish the relationship between out-of-domain bilingual corpus and in-domain monolingual corpora via topic mapping and phrase-topic distribution probability estimation for translation model adaptation. Xiao et al. (2012) propose a topic similarity model for rule selection. Eidelman et al. (2012) use topic models to adapt lexical weighting probabilities dynamically during translation. In these studies, the topic model is not used to address the issues of term translation mentioned in Section 1.

Our work is also related to document-level SMT in that we use document-informed information for term translation. Tiedemann (2010) propose cache-based language and translation models, which are built on recently translated sentences. Gong et al. (2011) extend this by further introducing two additional caches. They employ a static cache to store bilingual phrases extracted from documents in training data that are similar to the document being translated and a topic cache with target language topic words. Recently we have also witnessed efforts that model lexical cohesion (Hardmeier et al., 2012; Wong and Kit, 2012; Xiong et al., 2013a; Xiong et al., 2013b) as well as coherence (Xiong and Zhang, 2013) for document-level SMT. Hasler et al. (2014a) use topic models to learn document-level translation probabilities. Hasler et al. (2014b) use topic-adapted model to improve lexical selection. The significant difference between our work and these studies is that term translation has not been investigated in these document-level SMT models.

Itagaki and Aikawa (2008) employ bilingual term bank as a dictionary for machine-aided translation. Ren et al. (2009) propose a binary feature to indicate whether a bilingual phrase contains a term pair. Pinis and Skadins (2012) investigate that bilingual terms are important for domain adaptation of machine translation. These studies do not focus on the three issues of term translation as discussed in Section 1. Furthermore, domain and document-informed information is not used to assist term translation.

Itagaki et al. (2007) propose a statistical method to calculate translation consistency for terms with explicit domain information. Partially inspired by their study, we introduce a term translation consistency metric with document-informed information. Furthermore, we integrate the proposed term translation consistency model into an actual SMT system, which has not been done by Itagaki et al. (2007). Ture et al. (2012) use IR-inspired tf-idf scores to encourage consistent translation choice. Guillou (2013) investigates what kind of words should be translated consistently. Term translation consistency has not been investigated in these studies.

Our term bracketing model is also related to Xiong et al. (2009)'s syntax-driven bracketing model for phrase-based translation, which predicts whether a phrase is bracketable or not using rich syntactic constraints. The difference is that we construct the model with automatically created bilingual term bank and do not depend on any syntactic knowledge.

3 Bilingual Term Extraction

Bilingual term extraction is to extract terms from two languages with the purpose of creating or ex-

tending a bilingual term bank, which in turn can be used to improve other tasks such as information retrieval and machine translation. In this paper, we want to automatically build a bilingual term bank so that we can model term translation to improve translation quality of SMT. Our interest is to extract multi-word terms.

Currently, there are mainly two strategies to conduct bilingual term extraction from parallel corpora. One of them is to extract term candidates separately for each language according to monolingual term metrics, such as C-value/NC-value (Frantzi et al., 1998; Vu et al., 2008), or other common cooccurrence measures such as Log-Likelihood Ratio, Dice coefficient and Pointwise Mutual Information (Daille, 1996; Piao et al., 2006). The extracted monolingual terms are then paired together (Hjelm, 2007; Fan et al., 2009; Ren et al., 2009). The other strategy is to align words and word sequences that are translation equivalents in parallel corpora and then classify them into terms and non-terms (Merkel and Foo, 2007; Lefever et al., 2009; Bouamor et al., 2012). In this paper, we adopt the first strategy. In particular, for each sentence pair, we collect all source phrases which are terms and find aligned target phrases for them via word alignments. If the target side is also a term, we store the source and target term as a term pair.

We conduct monolingual term extraction using the C-value/NC-value metric and Log-Likelihood Ratio (LLR) measure respectively. We then combine terms extracted according to the two metrics mentioned above. For the C-value/NC-value metric based term extraction, we implement it in the same way as described in Frantzi et al. (1998). This extraction method recognizes linguistic patterns (mainly noun phrases) listed as follows.

$$((Adj|Noun)^{+}|((Adj|Noun)^{*}$$
$$(NounPrep)^{?})(Adj|Noun)^{*})Noun$$

It captures the linguistic structures of terms. For the LLR metric based term extraction, we implement it according to Daille (1996), who estimate the propensity of two words to appear together as a multi-word expression. We then adopt LLR-based hierarchical reducing algorithm proposed by Ren et al. (2009) to extract terms with arbitrary lengths. Since the C-value/NC-value metric based extraction method can obtain terms in strict linguistic patterns while the LLR measure based method extracts more flexible terms, these two methods are complementary to each other. Therefore, we use these two methods to extract monolingual multi-word terms and then combine the extracted terms.

4 Models

This section presents the three models of term translation. They are the term translation disambiguation model, term translation consistency model and term bracketing model respectively.

4.1 Term Translation Disambiguation Model

The most straightforward way to disambiguate term translations in different domains is to calculate the conditional translation probability of a term given domain information. We use the topic distribution of a document obtained by a topic model to represent the domain information of the document. Since Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is the most widely-used topic model, we exploit it for inferring topic distributions of documents. Xiao et al. (2012) proposed a topic similarity model for rule selection. Different from their work, we take an easier strategy that estimates topic-conditioned term translation probabilities rather than rule-topic distributions. This makes our model easily scalable on large training data.

With the bilingual term bank created from the training data, we calculate the source-to-target term translation probability for each term pair conditioned on the topic distribution of the source document where the source term occurs. We maintain a K-dimension (K is the number of topics) vector for each term pair. The k-th component $p(t_e|t_f, z = k)$ measures the conditional translation probability from source term t_f to target term t_e given the topic k.

We calculate $p(t_e|t_f, z = k)$ via maximum likelihood estimation with counts from training data. When the source part of a bilingual term pair occurs in a document D with topic distribution $p(z|D)$ estimated via LDA tool, we collect an instance $(t_f, t_e, p(z|D), c)$, where c is the fraction count of the instance as described in Chiang (2007). After collection, we get a set of instances $I = \{(t_f, t_e, p(z|D), c)\}$ with different document-topic distributions for each bilingual term pair. Using these instances, we calculate the probability

$p(t_e|t_f, z = k)$ as follows:

$$p(t_e|t_f, z = k) = \frac{\sum_{i \in I, i.t_f = t_f, i.t_e = t_e} i.c * p(z = k|D)}{\sum_{i \in I, i.t_f = t_f} i.c * p(z = k|D)} \quad (1)$$

We associate each extracted term pair in our bilingual term bank with its corresponding topic-conditioned translation probabilities estimated in the Eq. (1). When translating sentences of document $D^{'}$, we first get the topic distribution of $D^{'}$ using LDA tool. Given a sentence which contains T terms $\{t_{f_i}\}_1^T$ in $D^{'}$, our term translation disambiguation model $TermDis$ can be denoted as

$$TermDis = \prod_{i=1}^{T} P_d(t_{e_i}|t_{f_i}, D^{'}) \quad (2)$$

where the conditional source-to-target term translation probability $P_d(t_{e_i}|t_{f_i}, D^{'})$ given the document $D^{'}$ is formulated as follows:

$$P_d(t_{e_i}|t_{f_i}, D^{'}) = \sum_{k=1}^{K} p(t_{e_i}|t_{f_i}, z = k) * p(z = k|D^{'}) \quad (3)$$

Whenever a source term t_{f_i} is translated into t_{e_i}, we check whether the pair of t_{f_i} and its translation t_{e_i} can be found in our bilingual term bank. If it can be found, we calculate the conditional translation probability from t_{f_i} to t_{e_i} given the document $D^{'}$ according to Eq. (3).

The term translation disambiguation model is integrated into the log-linear model of SMT as a feature. Its weight is tuned via minimum error rate training (MERT) (Och, 2003). Through the feature, we can enable the decoder to favor translation hypotheses that contain target term translations appropriate for the domain represented by the topic distribution of the corresponding document.

4.2 Term Translation Consistency Model

The term translation disambiguation model helps the decoder select appropriate translations for terms that are in accord with their domains. Yet another translation issue related to the domain-specific term translation is to what extent a term should be translated consistently given the domain where it occurs. Term translation consistency indicates the translation stability that a source term is translated into the same target term (Itagaki et al., 2007). When translating a source term, if the translation consistency strength of the source term is high, we should take the corresponding target term as the translation for it. Otherwise, we may need to create a new translation for it according to its context. In particular, we want to enable the decoder to choose between: 1) translating a given source term into the extracted corresponding target term or 2) translating it in another way according to the strength of its translation consistency. In doing so, we can encourage consistent translations for terms with a high translation consistency strength throughout a document.

Our term translation consistency model can exactly measure the strength of term translation consistency in a document. Since the essential component of our term translation consistency model is the translation consistency strength of the source term estimated under the topic distribution, we describe how to calculate it before introducing the whole model.

With the bilingual term bank created from training data, we first group each source term and all its corresponding target terms into a 2-tuple $G\langle t_f, Set(t_e)\rangle$, where t_f is the source term and $Set(t_e)$ is the set of t_f's corresponding target terms. We maintain a K-dimension (K is the number of topics) vector for each 2-tuple $G\langle t_f, Set(t_e)\rangle$. The k-th component measures the translation consistency strength $cons(t_f, k)$ of the source term t_f given the topic k.

We calculate $cons(t_f, k)$ for each $G\langle t_f, Set(t_e)\rangle$ with counts from training data as follows:

$$cons(t_f, k) = \sum_{m=1}^{M} \sum_{n=1}^{N_m} (\frac{q_{mn} * p(k|m)}{Q_k})^2 \quad (4)$$

$$Q_k = \sum_{m=1}^{M} \sum_{n=1}^{N_m} q_{mn} * p(k|m) \quad (5)$$

where M is the number of documents in which the source term t_f occurs, N_m is the number of unique corresponding term translations of t_f in the mth document, q_{mn} is the frequency of the nth translation of t_f in the mth document, $p(k|m)$ is the conditional probability of the mth document over topic k, and Q_k is the normalization factor. All translations of t_f are from $Set(t_e)$. We adapt Itagaki et al. (2007)'s translation consistency metric for terms to our topic-based translation consistency measure in the Eq. (4). This equation calculates the translation consistency strength of the source term t_f given the topic k according to the distribution of t_f's translations in each document

where they occur. According to Eq. (4), the translation consistency strength is a score between 0 and 1. If a source term only occurs in a document and all its translations are the same, the translation consistency strength of this term is 1.

We reorganize our bilingual term bank into a list of 2-tuples $G\langle t_f, Set(t_e)\rangle$s, each of which is associated with a K-dimension vector storing the topic-conditioned translation consistency strength calculated in the Eq. (4). When translating sentences of document D, we first get the topic distribution of D via LDA tool. Given a sentence which contains T terms $\{t_{f_i}\}_1^T$ in D, our term translation consistency model $TermCons$ can be denoted as

$$TermCons = \prod_{i=1}^{T} exp(S_c(t_{f_i}|D)) \quad (6)$$

where the strength of translation consistency for t_{f_i} given the document D is formulated as follows:

$$S_c(t_{f_i}|D) = log(\sum_{k=1}^{K} cons(t_{f_i}, k) * p(k|D)) \quad (7)$$

During decoding, whenever a hypothesis just translates a source term t_{f_i} into t_e, we check whether the translation t_e can be found in $Set(t_e)$ of t_{f_i} from the reorganized bilingual term bank. If it can be found, we calculate the strength of translation consistency for t_{f_i} given the document D according to Eq. (7) and take it as a soft constraint. If the $S_c(t_{f_i}|D)$ of t_{f_i} is high, the decoder should translate t_{f_i} into the extracted corresponding target terms. Otherwise, the decoder will select translations from outside of $Set(t_e)$ for t_{f_i}. In doing so, we encourage terms to be translated in a topic-dependent consistency pattern in the test data similar to that in the training data so that we can control the translation consistency of terms in the test data.

The term translation consistency model is also integrated into the log-linear model of SMT as a feature. Through the feature, we can enable the decoder to translate terms with a high translation consistency in a document into corresponding target terms from our bilingual term bank rather than other translations in a consistent fashion.

4.3 Term Bracketing Model

The term translation disambiguation model and consistency model concern the term translation accuracy with domain information. We further propose a term bracketing model to guarantee the integrality of term translation. Xiong et al. (2009) proposed a syntax-driven bracketing model for phrase-based translation, which predicts whether a phrase is bracketable or not using rich syntactic constraints. If a source phrase remains contiguous after translation, they refer to this type of phrase as bracketable phrase, otherwise unbracketable phrase. For multi-word terms, it is also desirable to be bracketable since a source term should be translated as a whole unit and its translation should be contiguous.

In this paper, we adapt Xiong et al. (2009)'s bracketing approach to term translation and build a classifier to measure the probability that a source term should be translated in a bracketable manner. For all source parts of the extracted bilingual term bank, we find their target counterparts in the word-aligned training data. If the corresponding target counterpart remains contiguous, we take the source term as a bracketable instance, otherwise an unbracketable instance. With these bracketable and unbracketable instances, we train a maximum entropy binary classifier to predict bracketable (b) probability of a given source term t_f within particular contexts $c(t_f)$. The binary classifier is formulated as follows:

$$P_b(b|c(t_f)) = \frac{exp(\sum_j \theta_j h_j(b, c(t_f)))}{\sum_{b'} exp(\sum_j \theta_j h_j(b', c(t_f)))} \quad (8)$$

where $h_j \in \{0, 1\}$ is a binary feature function and θ_j is the weight of h_j. We use the following features: 1) the word sequence of the source term, 2) the first word of the source term, 3) the last word of the source term, 4) the preceding word of the first word of the source term, 5) the succeeding word of the last word of the source term, and 6) the number of words in the source term.

Given a source sentence which contains T terms $\{t_{f_i}\}_1^T$, our term bracketing model $TermBrack$ can be denoted as

$$TermBrack = \prod_{i=1}^{T} P_b(b|c(t_{f_i})) \quad (9)$$

Whenever a hypothesis just covers a source term t_{f_i}, we calculate the bracketable probability of t_{f_i} according to Eq. (8).

The term bracketing model is integrated into the log-linear model of SMT as a feature. Through the feature, we want the decoder to translate source terms with a high bracketable probability as a whole unit.

Source	Target	D	M
Fángyù Xìtǒng	defence mechanisms	470	56
Fángyù Xìtǒng	defence systems		
Fángyù Xìtǒng	defense programmes		
Fángyù Xìtǒng	prevention systems		
...	...		
Zhànluè Dǎodàn Fángyù Xìtǒng	strategic missile defense system	7	0

Table 1: Examples of bilingual terms extracted from the training data. "D" means the total number of documents in which the corresponding source term occurs and "M" denotes the number of documents in which the corresponding source term is translated into different target terms. The source side is Chinese Pinyin. To save space, we do not list all the 23 different translations of the source term "Fángyù Xìtǒng".

5 Experiments

In this section, we conducted experiments to answer the following three questions.

1. Are our term translation disambiguation, consistency and bracketing models able to improve translation quality in BLEU?
2. Does the combination of the three models provide further improvements?
3. To what extent do the proposed models affect the translations of test sets?

5.1 Setup

Our training data consist of 4.28M sentence pairs extracted from LDC[1] data with document boundaries explicitly provided. The bilingual training data contain 67,752 documents, 124.8M Chinese words and 140.3M English words. We chose NIST MT05 as the MERT (Och, 2003) tuning set, NIST MT06 as the development test set, and NIST MT08 as the final test set. The numbers of documents/sentences in NIST MT05, MT06 and MT08 are 100/1082, 79/1664 and 109/1357 respectively.

The word alignments were obtained by running GIZA++ (Och and Ney, 2003) on the corpora in both directions and using the "grow-diag-final-and" balance strategy (Koehn et al., 2003). We adopted SRI Language Modeling Toolkit (Stolcke and others, 2002) to train a 4-gram language model with modified Kneser-Ney smoothing on the Xinhua portion of the English Gigaword corpus. For the topic model, we used the open source LDA tool GibbsLDA++[2] with the default setting for training and inference. We performed 100 iterations of the L-BFGS algorithm implemented in the MaxEnt toolkit[3] with both Gaussian prior and event cutoff set to 1 to train the term bracketing prediction model (Section 4.3).

We performed part-of-speech tagging for monolingual term extraction (C-value/NC-vaule method in Section 3) of the source and target languages with the Stanford NLP toolkit[4]. The bilingual term bank was extracted based on the following parameter settings of term extraction methods. Empirically, we set the maximum length of a term to 6 words[5]. For both the C-value/NC-value and LLR-based extraction methods, we set the context window size to 5 words, which is a widely-used setting in previous work. And we set C-value/NC-value score threshold to 0 and LLR score threshold to 10 according to the training corpora.

We used the case-insensitive 4-gram BLEU[6] as our evaluation metric. In order to alleviate the impact of the instability of MERT (Och, 2003), we ran it three times for all our experiments and presented the average BLEU scores on the three runs following the suggestion by Clark et al. (2011).

We used an in-house hierarchical phrase-based decoder to verify our proposed models. Although the decoder translates a document in a sentence-by-sentence fashion, it incorporates document-informed information for sentence translation via the proposed term translation models trained on documents.

[1]The corpora include LDC2003E07, LDC2003E14, LDC2004T07, LDC2004E12, LDC2005E83, LDC2005T06, LDC2005T10, LDC2006E24, LDC2006E34, LDC2006E85, LDC2006E92, LDC2007E87, LDC2007E101, LDC2008E40, LDC2008E56, LDC2009E16 and LDC2009E95.

[4]http://nlp.stanford.edu/software/tagger.shtml

[5]We determine the maximum length of a term by testing {5, 6, 7, 8} in our preliminary experiments. We find that length 6 produces a slightly better performance than other values.

[6]ftp://jaguar.ncsl.nist.gov/mt/resources/mteval-v11b.pl

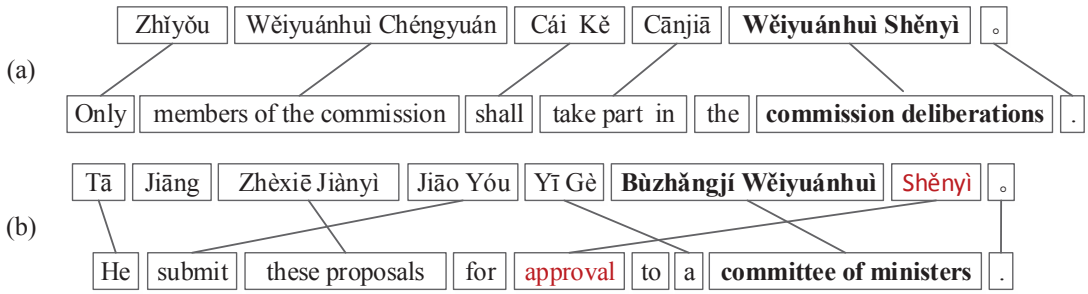

Figure 1: An example of unbracketable source term in the training data. In (a), "Wěiyuánhuì Shěnyì" is bracketable while in (b) it is unbracketable. The solid lines connect bilingual phrases. The source side is Chinese Pinyin.

5.2 Bilingual Term Bank

Before reporting the results of the proposed models, we provide some statistics of the bilingual term bank extracted from the training data.

According to our statistics, about 1.29M bilingual terms are extracted from the training data. 65.07% of the sentence pairs contain bilingual terms in the training data. And on average, a source term has about 1.70 different translations. These statistics indicate that terms are frequently used in real-world data and that a source term can be translated into different target terms.

We also present some examples of bilingual terms extracted from the training data in Table 1. Accordingly, we show the total number of documents in which the corresponding source term occurs and the number of documents in which the corresponding source term is translated into different target terms. The source term "Fángyù Xìtǒng" has 23 different translations in total. They are distributed in 470 documents in the training data. In 414 documents, "Fángyù Xìtǒng" has only one single translation. However, in the other 56 documents it has different translations. This indicates that "Fángyù Xìtǒng" is not consistently translated in these 56 documents. Different from this, the source term "Zhànluè Dǎodàn Fángyù Xìtǒng" only has one translation. And it is translated consistently in all 7 documents where it occurs. In fact, according to our statistics, there are about 5.19% source terms whose translations are not consistent even in the same document.

These examples and statistics suggest 1) that source terms have domain-specific translations and 2) that source terms are not necessarily translated in a consistent manner even in the same document. These are exactly the reasons why we propose the term translation disambiguation and consistency model based on domain information represented by topic distributions.

Actually, 36.13% of the source terms are not necessarily translated into target strings as a whole unit. We show an example of such terms in Figure 1. In Figure 1-(a), "Wěiyuánhuì Shěnyì" is a term, and is translated into "commission deliberations" as a whole unit. Therefore "Wěiyuánhuì Shěnyì" is bracketable in this sentence. However, in Figure 1-(b), "Wěiyuánhuì" and "Shěnyì" are translated separately. Therefore "Wěiyuánhuì Shěnyì" is an unbracketable term in this sentence. This is the reason why we propose a bracketing model to predict whether a source term is bracketable or not.

5.3 Effect of the Proposed Models

In this section, we validate the effectiveness of the proposed term translation disambiguation model, consistency model and bracketing model respectively. In addition to the traditional hiero (Chiang, 2007) system, we also compare against the "CountFeat" method in Ren et al. (2009) who use a binary feature to indicate whether a bilingual phrase contains a term pair. Although Ren et al. (2009)'s experiments are conducted in a phrase-based system, the idea can be easily applied to a hierarchical phrase-based system.

We carried out experiments to investigate the effect of the term translation disambiguation model (Dis-Model) and report the results in Table 2. In order to find the topic number setting with which our model has the best performance, we ran experiments using the MT06 as the development test set. From Table 2, we observe that the Dis-Model obtains steady improvements over the baseline and "CountFeat" method with the topic number K

Models		MT06	MT08	Avg
Baseline		32.43	24.14	28.29
CountFeat		32.77	24.29	28.53
Dis-Model	$K = 50$	32.94*	24.53	28.74
	$K = 100$	33.10*	24.57	28.84
	$K = 150$	**33.16***	**24.67***	**28.92**
	$K = 200$	33.08*	24.55	28.81
Cons-Model	$K = 50$	33.09*	24.59	28.84
	$K = 100$	33.13*	24.74*	28.94
	$K = 150$	**33.32*+**	**24.84*+**	**29.08**
	$K = 200$	33.02*	24.73*	28.88
Brack-Model		**33.09***	**24.66***	**28.88**
Combined-Model		**33.59*+**	**24.99*+**	**29.29**

Table 2: BLEU-4 scores (%) of the term translation disambiguation model (Dis-Model), the term translation consistency model (Cons-Model), the term bracketing model (Brack-Model), and the combination of the three models, on the development test set MT06 and the final test set MT08. $K \in \{50, 100, 150, 200\}$ which is the number of topics for the Dis-Model and the Cons-Model. "Combined-Model" is the combination of the three single modes with topic number 150 for the Dis-Model and the Cons-Model. "Baseline" is the traditional hierarchical phrase-based system. "CountFeat" is the method that adds a counting feature to reward translation hypotheses containing bilingual term pairs. The "*" and "+" denote that the results are significantly (Clark et al., 2011) better than those of the baseline system and the CountFeat method respectively ($p<0.01$).

ranging from 50 to 150. However, when we set K to 200, the performance drops. The highest BLEU scores 33.16 and 24.67 are obtained at the topic setting $K = 150$. In fact, our Dis-Model gains higher performance in BLEU than both the traditional hiero baseline and the "CountFeat" method with all topic settings. The "CountFeat" method rewards translation hypotheses containing bilingual term pairs. However it does not explore any domain information. Our Dis-Model incorporates domain information to conduct translation disambiguation and achieves higher performance. When the topic number is set to 150, we gain the highest BLEU score, which is higher than that of the baseline by 0.73 and 0.53 BLEU points on MT06 and MT08, respectively. The final gain over the baseline is on average 0.63 BLEU points.

We conducted the second group of experiments to study whether the term translation consistency model (Cons-Model) is able to improve the performance in BLEU, as well as to investigate the impact of different topic numbers on the Cons-Model. Results are shown in Table 2, from which we observe the similar phenomena to what we have found in the Dis-Model. Our Cons-Model gains higher BLEU scores than the baseline system and the "CountFeat" method with all topic settings. Setting topic number to 150 achieves the highest BLEU score, which is higher than baseline by 0.89 BLEU points and 0.70 BLEU points on MT06 and MT08 respectively, and on average 0.79 BLEU points.

We also conducted experiments to verify the effectiveness of the term bracketing model (Brack-Model), which conducts bracketing prediction for source terms. Results in Table 2 show that our Brack-Model gains higher BLEU scores than those of the baseline system and the "CountFeat" method. The final gain of Brack-Model over the baseline is 0.66 BLEU points and 0.52 points on MT06 and MT08 respectively, and on average 0.59 BLEU points.

5.4 Combination of the Three Models

As shown in the previous subsection, the term translation disambiguation model, consistency model and bracketing model substantially outperform the baseline. Now, we investigate whether using these three models simultaneously can lead to further improvements. The last row in Table 2 shows that the combination of the three models (Combined-Model) achieves higher BLEU score than all single models, when we set the topic number to 150 for the term translation disambiguation model and consistency model. The final gain

Models	MT06	MT08
Best-Dis-Model	30.89	30.14
Best-Cons-Model	38.04	36.70
Brack-Model	60.46	55.78
Combined-Model	54.39	50.85

Table 3: Percentage (%) of 1-best translations which are generated by the Combined-Model and the three single models with best settings on the development test set MT06 and the final test set MT08. The topic number is 150 for Best-Dis-Model and Best-Cons-Model.

of the Combined-Model over the baseline is 1.16 BLEU points and 0.85 points on MT06 and MT08 respectively, and on average 1.00 BLEU points.

5.5 Analysis

In this section, we investigate to what extent the proposed models affect the translations of test sets. In Table 3, we show the percentage of 1-best translations affected by the Combined-Model and the three single models with best settings on test sets MT06 and MT08. For single models, if the corresponding feature (disambiguation, consistency or bracketing) is activated in the 1-best derivation, the corresponding model has impact on the 1-best translation. For the Combined-Model, if any of the corresponding features is activated in the 1-best derivation, the Combined-Model affects the 1-best translation.

From Table 3, we can see that 1-best translations of source sentences affected by any of the proposed models account for a high proportion (30%∼60%) on both MT06 and MT08. This indicates that all proposed models play an important role in the translation of both test sets. Among the three proposed models, the Brack-Model is the one that affects the largest number of 1-best translations in both test sets. And the percentage is 60.46% and 55.78% on MT06 and MT08 respectively. The Brack-Model only considers source terms during decoding, while the Dis-Model and Cons-Model need to match both source and target terms. The Brack-Model is more likely to be activated. Hence the percentage of 1-best translations affected by this model is higher than those of the other two models. Since we only investigate the 1-best translations generated by the Combined-Model and single models, the translations generated by some single models (e.g., Brack-Model) may not be generated by the Combined-Model. Therefore it is hard to say that the numbers of 1-best translations affected by the Combined-Model must be greater than those of single models.

6 Conclusion and Future Work

We have studied the three issues of term translation and proposed three different term translation models for document-informed SMT. The term translation disambiguation model enables the decoder to favor the most suitable domain-specific translations with domain information for source terms. The term translation consistency model encourages the decoder to translate source terms with a high domain translation consistency strength into target terms rather than other new strings. Finally, the term bracketing model rewards hypotheses that translate bracketable terms into continuous target strings as a whole unit. We integrate the three models into a hierarchical phrase-based SMT system[7] and evaluate their effectiveness on the NIST Chinese-English translation task with large-scale training data. Experiment results show that all three models achieve significant improvements over the baseline. Additionally, combining the three models achieves a further improvement. For future work, we would like to evaluate our models on term translation across a range of different domains.

Beyond Parallel Data: Joint Word Alignment and Decipherment Improves Machine Translation

Abstract

Inspired by previous work, where decipherment is used to improve machine translation, we propose a new idea to combine word alignment and decipherment into a single learning process. We use EM to estimate the model parameters, not only to maximize the probability of parallel corpus, but also the monolingual corpus. We apply our approach to improve Malagasy-English machine translation, where only a small amount of parallel data is available. In our experiments, we observe gains of 0.9 to 2.1 B over a strong baseline.

1 Introduction

State-of-the-art machine translation (MT) systems apply statistical techniques to learn translation rules automatically from parallel data. However, this reliance on parallel data seriously limits the scope of MT application in the real world, as for many languages and domains, there is not enough parallel data to train a decent quality MT system.

However, compared with parallel data, there are much larger amounts of non parallel data. The ability to learn a translation lexicon or even build a machine translation system using monolingual data helps address the problems of insufficient parallel data. Ravi and Knight (2011) are among the first to learn a full MT system using only non parallel data through decipherment. However, the performance of such systems is much lower compared with those trained with parallel data. In another work, Klementiev et al. (2012) show that, given a phrase table, it is possible to estimate parameters for a phrase-based MT system from non parallel data.

Given that we often have some parallel data, it is more practical to improve a translation system trained on parallel data by using additional non parallel data. Rapp (1995) shows that with a seed lexicon, it is possible to induce new word level translations from non parallel data. Motivated by the idea that a translation lexicon induced from non parallel data can be used to translate out of vocabulary words (OOV), a variety of prior research has tried to build a translation lexicon from non parallel or comparable data (Fung and Yee, 1998; Koehn and Knight, 2002; Haghighi et al., 2008; Garera et al., 2009; Bergsma and Van Durme, 2011; Daumé and Jagarlamudi, 2011; Irvine and Callison-Burch, 2013b; Irvine and Callison-Burch, 2013a; Irvine et al., 2013).

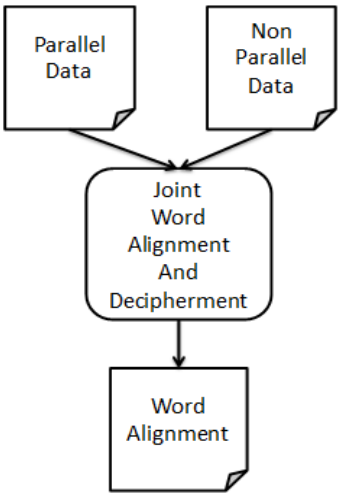

Figure 1: Combine word alignment and decipherment into a single learning process.

Lately, there has been increasing interest in learning translation lexicons from non parallel data with decipherment techniques (Ravi and Knight, 2011; Dou and Knight, 2012; Nuhn et al., 2012; Dou and Knight, 2013). Decipherment views one language as a cipher for another and learns a translation lexicon that produces fluent text in the target (plaintext) language. Previous work has shown that decipherment not only helps find translations for OOVs (Dou and Knight, 2012), but also improves translations of observed words (Dou and Knight, 2013).

We find that previous work using monolingual or comparable data to improve quality of machine translation separates two learning tasks: first, translation rules are learned from parallel data, and then the information learned from parallel data is used to bootstrap learning with non parallel data. Inspired by approaches where joint inference reduces the problems of error propagation and improves system performance, we combine the two separate learning processes into a single one, as shown in Figure 1. The contributions of this work are:

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 557–565,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

- We propose a new objective function for word alignment that combines the process of word alignment and decipherment into a single learning task.

- In experiments, we find that the joint process outperforms the previous pipeline approach, and observe B gains of 0.9 and 2.1 on two different test sets.

- We release 15.3 million tokens of monolingual Malagasy data from the web, as well as a small Malagasy dependency tree bank containing 20k tokens.

2 Joint Word Alignment and Decipherment

2.1 A New Objective Function

In previous work that uses monolingual data to improve machine translation, a seed translation lexicon learned from parallel data is used to find new translations through either word vector based approaches or decipherment. In return, selection of a seed lexicon needs to be careful as using a poor quality seed lexicon could hurt the downstream process. Evidence from a number of previous work shows that a joint inference process leads to better performance in both tasks (Jiang et al., 2008; Zhang and Clark, 2008).

In the presence of parallel and monolingual data, we would like the alignment and decipherment models to benefit from each other. Since the decipherment and word alignment models contain word-to-word translation probabilities $t(f \mid e)$, having them share these parameters during learning will allow us to pool information from both data types. This leads us to develop a new objective function that takes both learning processes into account. Given our parallel data, $(\mathbf{E}^1, \mathbf{F}^1), \ldots, (\mathbf{E}^m, \mathbf{F}^m), \ldots, (\mathbf{E}^M, \mathbf{F}^M)$, and monolingual data $\mathbf{F}^1_{\mathbf{mono}}, \ldots, \mathbf{F}^n_{\mathbf{mono}}, \ldots, \mathbf{F}^N_{\mathbf{mono}}$, we seek to maximize the likelihood of both. Our new objective function is defined as:

$$F_{joint} = \sum_{m=1}^{M} \log P(\mathbf{F}^m \mid \mathbf{E}^m) + \alpha \sum_{n=1}^{N} \log P(\mathbf{F}^n_{\mathbf{mono}}) \quad (1)$$

The goal of training is to learn the parameters that maximize this objective, that is

$$\theta^* = \arg\max_{\theta} F_{joint} \quad (2)$$

In the next two sections, we describe the word alignment and decipherment models, and present how they are combined to perform joint optimization.

2.2 Word Alignment

Given a source sentence $\mathbf{F} = \mathbf{f_1}, \ldots, \mathbf{f_j}, \ldots, \mathbf{f_J}$ and a target sentence $\mathbf{E} = \mathbf{e_1}, \ldots, \mathbf{e_i}, \ldots, \mathbf{e_I}$, word alignment models describe the generative process employed to produce the French sentence from the English sentence through alignments $\mathbf{a} = \mathbf{a_1}, \ldots, \mathbf{a_j}, \ldots, \mathbf{a_J}$.

The IBM models 1-2 (Brown et al., 1993) and the HMM word alignment model (Vogel et al., 1996) use two sets of parameters, *distortion* probabilities and *translation* probabilities, to define the joint probability of a target sentence and alignment given a source sentence.

$$P(\mathbf{F}, \mathbf{a} \mid \mathbf{E}) = \prod_{j=1}^{J} d(a_j \mid a_{j-1}, j) t(f_j \mid e_{a_j}). \quad (3)$$

These alignment models share the same translation probabilities $t(f_j \mid e_{a_j})$, but differ in their treatment of the distortion probabilities $d(a_j \mid a_{j-1}, j)$. Brown et al. (1993) introduce more advanced models for word alignment, such as Model 3 and Model 4, which use more parameters to describe the generative process. We do not go into details of those models here and the reader is referred to the paper describing them.

Under the Model 1-2 and HMM alignment models, the probability of target sentence given source sentence is:

$$P(\mathbf{F} \mid \mathbf{E}) = \sum_{\mathbf{a}} \prod_{j=1}^{J} d(a_j \mid a_{j-1}, j) t(f_j \mid e_{a_j}).$$

Let θ denote all the parameters of the word alignment model. Given a corpus of sentence pairs $(\mathbf{E}^1, \mathbf{F}^1), \ldots, (\mathbf{E}^m, \mathbf{F}^m), \ldots, (\mathbf{E}^M, \mathbf{F}^M)$, the standard approach for training is to learn the maximum likelihood estimate of the parameters, that is,

$$\begin{aligned} \theta^* &= \arg\max_{\theta} \sum_{m=1}^{M} \log P(\mathbf{F}^m \mid \mathbf{E}^m) \\ &= \arg\max_{\theta} \log \left(\sum_{\mathbf{a}} P(\mathbf{F}^m, \mathbf{a} \mid \mathbf{E}^m) \right). \end{aligned}$$

We typically use the EM algorithm (Dempster et al., 1977), to carry out this optimization.

2.3 Decipherment

Given a corpus of N foreign text sequences (ciphertext), $\mathbf{F}^1_{\mathbf{mono}}, \ldots, \mathbf{F}^n_{\mathbf{mono}}, \ldots, \mathbf{F}^N_{\mathbf{mono}}$, decipherment finds word-to-word translations that best describe the ciphertext.

Knight et al. (2006) are the first to study several natural language decipherment problems with unsupervised learning. Since then, there has been increasing interest in improving decipherment techniques and its application to machine translation (Ravi and Knight, 2011;

Dou and Knight, 2012; Nuhn et al., 2012; Dou and Knight, 2013; Nuhn et al., 2013).

In order to speed up decipherment, Dou and Knight (2012) suggest that a frequency list of bigrams might contain enough information for decipherment. According to them, a monolingual ciphertext bigram $\mathbf{F_{mono}}$ is generated through the following generative story:

- Generate a sequence of two plaintext tokens e_1e_2 with probability $P(e_1e_2)$ given by a language model built from large numbers of plaintext bigrams.
- Substitute e_1 with f_1 and e_2 with f_2 with probability $t(f_1|e_1) \cdot t(f_2|e_2)$.

The probability of any cipher bigram F is:

$$P(\mathbf{F_{mono}}) = \sum_{e_1e_2} P(e_1e_2) \cdot t(f_1|e_1) \cdot t(f_2|e_2) \quad (4)$$

And the probability of the corpus is:

$$P(corpus) = \prod_{n=1}^{N} P(\mathbf{F}^n_{\mathbf{mono}}) \quad (5)$$

Given a plaintext bigram language model, the goal is to manipulate $t(f|e)$ to maximize $P(corpus)$. Theoretically, one can directly apply EM to solve the problem (Knight et al., 2006). However, EM has time complexity $O(N \cdot V_e^2)$ and space complexity $O(V_f \cdot V_e)$, where V_f, V_e are the sizes of ciphertext and plaintext vocabularies respectively, and N is the number of cipher bigrams.

There have been previous attempts to make decipherment faster. Ravi and Knight (2011) apply Bayesian learning to reduce the space complexity. However, Bayesian decipherment is still very slow with Gibbs sampling (Geman and Geman, 1987). Dou and Knight (2012) make sampling faster by introducing slice sampling (Neal, 2000) to Bayesian decipherment. Besides Bayesian decipherment, Nuhn et al. (2013) show that beam search can be used to solve a very large 1:1 word substitution cipher. In subsection 2.4.1, we describe our approach that uses slice sampling to compute expected counts for decipherment in the EM algorithm.

2.4 Joint Optimization

We now describe our EM approach to learn the parameters that maximize F_{joint} (equation 2), where the distortion probabilities, $d(a_j \mid a_{j-1}, j)$ in the word alignment model are only learned from parallel data, and the translation probabilities, $t(f \mid e)$ are learned using both parallel and non parallel data. The E step and M step are illustrated in Figure 2.

Our algorithm starts with EM learning only on parallel data for a few iterations. When the joint inference starts, we first compute expected counts from parallel data and non parallel data using parameter values from the last M step separately. Then, we add the expected counts from both parallel data and non parallel data together with different weights for the two. Finally we renormalize the translation table and distortion table to update parameters in the new M step.

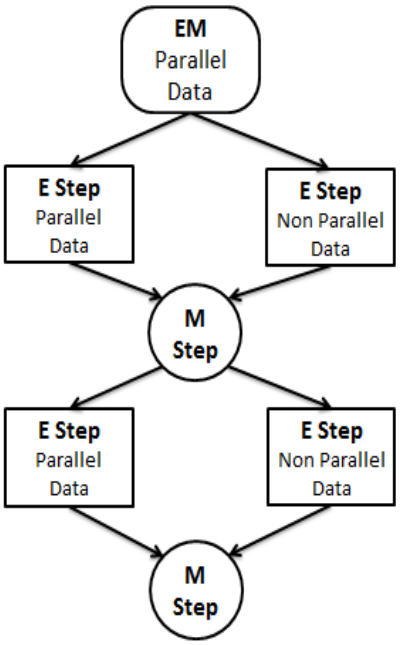

Figure 2: Joint Word Alignment and Decipherment with EM

The E step for parallel part can be computed efficiently using the forward-backward algorithm (Vogel et al., 1996). However, as we pointed out in Section 2.3, the E step for the non parallel part has a time complexity of $O(V^2)$ with the forward-backward algorithm, where V is the size of English vocabulary, and is usually very large. Previous work has tried to make decipherment scalable (Ravi and Knight, 2011; Dou and Knight, 2012; Nuhn et al., 2013; Ravi, 2013). However, all of them are designed for decipherment with either Bayesian inference or beam search. In contrast, we need an algorithm to make EM decipherment scalable. To overcome this problem, we modify the slice sampling (Neal, 2000) approach used by Dou and Knight (2012) to compute expected counts from non parallel data needed for the EM algorithm.

2.4.1 Draw Samples with Slice Sampling

To start the sampling process, we initialize the first sample by performing approximate Viterbi decoding using results from the last EM iteration. For each foreign dependency bigram f_1, f_2, we find the top 50 candidates for f_1 and f_2 ranked by $t(e|f)$, and find the English sequence e_1, e_2 that maximizes $t(e_1|f_1) \cdot t(e_2|f_2) \cdot P(e_1, e_2)$.

Suppose the derivation probability for current sample *e_current* is $P(e\_current)$, we use slice sampling to draw a new sample in two steps:

- Select a threshold T uniformly between 0 and $P(e\_current)$.
- Draw a new sample *e_new* uniformly from a pool

of candidates: $\{e\_new|P(e\_new) > T\}$.

The first step is straightforward to implement. However, it is not trivial to implement the second step. We adapt the idea from Dou and Knight (2012) for EM learning.

Suppose our current sample *e_current* contains English tokens e_{i-1}, e_i, and e_{i+1} at position $i-1$, i, and $i+1$ respectively, and f_i be the foreign token at position i. Using point-wise sampling, we draw a new sample by changing token e_i to a new token e'. Since the rest of the sample remains the same, only the probability of the trigram $P(e_{i-1}e'e_{i+1})$ (The probability is given by a bigram language model.), and the channel model probability $t(f_i|e')$ change. Therefore, the probability of a sample is simplified as shown Equation 6.

$$P(e_{i-1}e'e_{i+1}) \cdot t(f_i|e') \tag{6}$$

Remember that in slice sampling, a new sample is drawn in two steps. For the first step, we choose a threshold T uniformly between 0 and $P(e_{i-1}e_ie_{i+1}) \cdot t(f_i|e_i)$. We divide the second step into two cases based on the observation that two types of samples are more likely to have a probability higher than T (Dou and Knight, 2012): (1) those whose trigram probability is high, and (2) those whose channel model probability is high. To find candidates that have high trigram probability, Dou and Knight (2012) build a top k sorted lists ranked by $P(e_{i-1}e'e_{i+1})$, which can be pre-computed off-line. Then, they test if the last item e_k in the list satisfies the following inequality:

$$P(e_{i-1}e_ke_{i+1}) \cdot c < T \tag{7}$$

where c is a small constant and is set to *prior* in their work. In contrast, we choose c empirically as we do not have a prior in our model. When the inequality in Equation 7 is satisfied, a sample is drawn in the following way: Let set $A = \{e'|e_{i-1}e'e_{i+1} \cdot c > T\}$ and set $B = \{e'|t(f_i|e') > c\}$. Then we only need to sample e' uniformly from $A \cup B$ until $P(e_{i-1}e'e_{i+1}) \cdot t(f_i|e')$ is greater than T. It is easy to prove that all other candidates that are not in the sorted list and with $t(f_i|e') \leq c$ have a upper bound probability: $P(e_{i-1}e_ke_{i+1}) \cdot c$. Therefore, they do not need to be considered.

Second, when the last item e_k in the list does not meet the condition in Equation 7, we keep drawing samples e' randomly until its probability is greater than the threshold T.

As we mentioned before, the choice of the small constant c is empirical. A large c reduces the number of items in set B, but makes the condition $P(e_{i-1}e_ke_{i+1}) \cdot c < T$ less likely to satisfy, which slows down the sampling. On the contrary, a small c increases the number of items in set B significantly as EM does not encourage a sparse distribution, which also slows down the sampling. In our experiments, we set c to 0.001 based on the speed of decipherment. Furthermore, to reduce the size of set B, we rank all the candidate translations of f_i by $t(e'|f_i)$, then we add maximum the first 1000 candidates whose $t(f_i|e') >= c$ into set B. For the rest of the candidates, we set $t(f_i|e')$ to a value smaller than c (0.00001 in experiments).

	Spanish	English
Parallel	10.3k	9.9k
Non Parallel	80 million	400 million

Table 1: Size of parallel and non parallel data for word alignment experiments (Measured in number of tokens)

2.4.2 Compute Expected Counts from Samples

With the ability to draw samples efficiently for decipherment using EM, we now describe how to compute expected counts from those samples. Let f_1, f_2 be a specific ciphertext bigram, N be the number of samples we want to use to compute expected counts, and e_1, e_2 be one of the N samples. The expected counts for pairs (f_1, e_1) and (f_2, e_2) are computed as:

$$\alpha \cdot \frac{count(f_1, f_2)}{N}$$

where $count(f_1, f_2)$ is count of the bigram, and α is the weight for non parallel data as shown in Equation 1. Expected counts collected for f_1, f_2 are accumulated from each of its N samples. Finally, we collect expected counts using the same approach from each foreign bigram.

3 Word Alignment Experiments

In this section, we show that joint word alignment and decipherment improves the quality of word alignment. We choose to evaluate word alignment performance for Spanish and English as manual gold alignments are available. In experiments, our approach improves alignment F score by as much as 8 points.

3.1 Experiment Setup

As shown in Table 1, we work with a small amount of parallel, manually aligned Spanish-English data (Lambert et al., 2005), and a much larger amount of monolingual data.

The parallel data is extracted from Europarl, which consists of articles from European parliament plenary sessions. The monolingual data comes from English and Spanish versions of Gigaword corpra containing news articles from different news agencies.

We view Spanish as a cipher of English, and follow the approach proposed by Dou and Knight (2013) to extract dependency bigrams from parsed Spanish and English monolingual data for decipherment. We only keep bigrams where both tokens appear in the parallel data. Then, we perform Spanish to English (English generating Spanish) word alignment and Spanish to English decipherment simultaneously with the method discussed in section 2.

3.1.1 Results

We align all 500 sentences in the parallel corpus, and tune the decipherment weight (α) for Model 1 and HMM using the last 100 sentences. The best weights are 0.1 for Model 1, and 0.005 for HMM. We start with Model 1 with only parallel data for 5 iterations, and switch to the joint process for another 5 iterations with Model 1 and 5 more iterations of HMM. In the end, we use the first 100 sentence pairs of the corpus for evaluation.

Figure 3 compares the learning curve of alignment F-score between EM without decipherment (baseline) and our joint word alignment and decipherment. From the learning curve, we find that at the 6th iteration, 2 iterations after we start the joint process, alignment F-score is improved from 34 to 43, and this improvement is held through the rest of the Model 1 iterations. The alignment model switches to HMM from the 11th iteration, and at the 12th iteration, we see a sudden jump in F-score for both the baseline and the joint approach. We see consistent improvement of F-score till the end of HMM iterations.

4 Improving Low Density Languages Machine Translation with Joint Word Alignment and Decipherment

In the previous section, we show that the joint word alignment and decipherment process improves quality of word alignment significantly for Spanish and English. In this section, we test our approach in a more challenging setting: improving the quality of machine translation in a real low density language setting.

In this task, our goal is to build a system to translate Malagasy news into English. We have a small amount of parallel data, and larger amounts of monolingual data collected from online websites. We build a dependency parser for Malagasy to parse the monolingual data to perform dependency based decipherment (Dou and Knight, 2013). In the end, we perform joint word alignment and decipherment, and show that the joint learning process improves B scores by up to 2.1 points over a phrase-based MT baseline.

4.1 The Malagasy Language

Malagasy is the official language of Madagascar. It has around 18 million native speakers. Although Madagascar is an African country, Malagasy belongs to the Malayo-Polynesian branch of the Austronesian language family. Malagasy and English have very different word orders. First of all, in contrast to English, which has a subject-verb-object (SVO) word order, Malagasy has a verb-object-subject (VOS) word order. Besides that, Malagasy is a typical head initial language: Determiners precede nouns, while other modifiers and relative clauses follow nouns (e.g. ny "the" boky "book" mena "red"). The significant differences in word order pose great challenges for both machine translation and decipherment.

Source	Malagasy	English
Parallel		
Global Voices	2.0 million	1.8 million
Web News	2.2k	2.1k
Non Parallel		
Gigaword	N/A	2.4 billion
allAfrica	N/A	396 million
Local News	15.3 million	N/A

Table 2: Size of Malagasy and English data used in our experiments (Measured in number of tokens)

4.2 Data

Table 2 shows the data available to us in our experiments. The majority of parallel text comes from Global Voices[1] (GV). The website contains international news translated into different foreign languages. Besides that, we also have a very small amount of parallel text containing local web news, with English translations provided by native speakers at the University of Texas, Austin. The Malagasy side of this small parallel corpus also has syntactical annotation, which is used to train a very basic Malagasy part of speech tagger and dependency parser.

We also have much larger amounts of non parallel data for both languages. For Malagasy, we spent two months manually collecting 15.3 million tokens of news text from local news websites in Madagascar.[2] We have released this data for future research use. For English, we have 2.4 billion tokens from the Gigaword corpus. Since the Malagasy monolingual data is collected from local websites, it is reasonable to argue that those data contain significant amount of information related to Africa. Therefore, we also collect 396 million tokens of African news in English from allAfrica.com.

4.3 Building A Dependency Parser for Malagasy

Since Malagasy and English have very different word orders, we decide to apply dependency based decipherment for the two languages as suggested by Dou and Knight (2013). To extract dependency relations, we need to parse monolingual data in Malagasy and English. For English, there are already many good parsers available. In our experiments, we use Turbo parser (Martins et al., 2013) trained on the English Penn Treebank (Marcus et al., 1993) to parse all our English monolingual data. However, there is no existing good parser for Malagasy.

The quality of a dependency parser depends on the amount of training data available. State-of-the-art English parsers are built from Penn Treebank, which contains over 1 million tokens of annotated syntactical

[1] globalvoicesonline.org

[2] aoraha.com, gazetiko.com, inovaovao.com, expressmada.com, lakroa.com

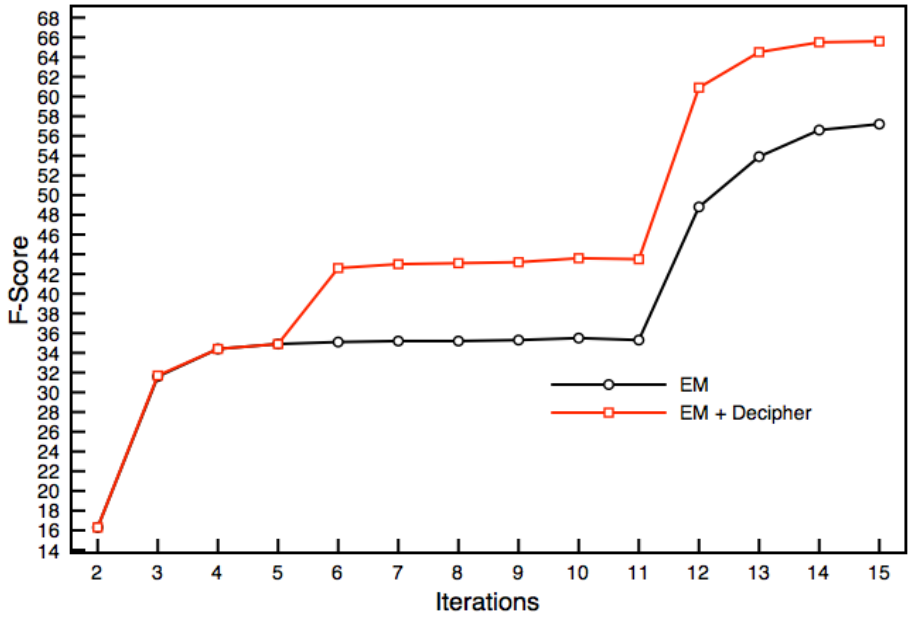

Figure 3: Learning curve showing our joint word alignment and decipherment approach improves word alignment quality over the traditional EM without decipherment (Model 1: Iteration 1 to 10, HMM: Iteration 11 to 15)

trees. In contrast, the available data for training a Malagasy parser is rather limited, with only 168 sentences, and 2.8k tokens, as shown in Table 2. At the very beginning, we use the last 120 sentences as training data to train a part of speech (POS) tagger using a toolkit provided by Garrette et al. (2013) and a dependency parser with the Turbo parser. We test the performance of the parser on the first 48 sentences and obtain 72.4% accuracy.

One obvious way to improve tagging and parsing accuracy is to get more annotated data. We find more data with only part of speech tags containing 465 sentences and 10k tokens released by (Garrette et al., 2013), and add this data as extra training data for POS tagger. Also, we download an online dictionary that contains POS tags for over 60k Malagasy word types from malagasyword.org. The dictionary is very helpful for tagging words never seen in the training data.

It is natural to think that creation of annotated data for training a POS tagger and a parser requires large amounts of efforts from annotators who understand the language well. However, we find that through the help of parallel data and dictionaries, we are able to create more annotated data by ourselves to improve tagging and parsing accuracy. This idea is inspired by previous work that tries to learn a semi-supervised parser by projecting dependency relations from one language (with good dependency parsers) to another (Yarowsky and Ngai, 2001; Ganchev et al., 2009). However, we find those automatic approaches do not work well for Malagasy.

To further expand our Malagasy training data, we first use a POS tagger and parser with poor performance to parse 788 sentences (20k tokens) on the Malagasy side of the parallel corpus from Global Voices. Then, we correct both the dependency links and POS tags based on information from dictionaries[3] and the English translation of the parsed sentence. We spent 3 months to manually project English dependencies to Malagasy and eventually improve test set parsing accuracy from 72.4% to 80.0%. We also make this data available for future research use.

4.4 Machine Translation Experiments

In this section, we present the data used for our MT experiments, and compare three different systems to justify our joint word alignment and decipherment approach.

4.4.1 Baseline Machine Translation System

We build a state-of-the-art phrase-based MT system, PBMT, using Moses (Koehn et al., 2007). PBMT has 3 models: a translation model, a distortion model, and a language model. We train the other models using half of the Global Voices parallel data (the rest is reserved for development and testing), and build a 5-gram language model using 834 million tokens from AFP section of English Gigaword, 396 million tokens from allAfrica, and the English part of the parallel corpus for training. For alignment, we run 10 iterations of Model 1, and 5 iterations of HMM. We did not run Model 3 and Model 4 as we see no improvements in B scores from running those models. We do word

[3] an online dictionary from malagasyword.org, as well as a lexicon learned from the parallel data

alignment in two directions and use grow-diag-final-and heuristic to obtain final alignment. During decoding, we use 8 standard features in Moses to score a candidate translation: direct and inverse translation probabilities, direct and inverse lexical weighting, a language model score, a distortion score, phrase penalty, and word penalty. The weights for the features are learned on the tuning data using minimum error rate training (MERT) (Och, 2003).

To compare with previous decipherment approach to improve machine translation, we build a second baseline system. We follow the work by Dou and Knight (2013) to decipher Malagasy into English, and build a translation lexicon $T_{decipher}$ from decipherment. To improve machine translation, we simply use $T_{decipher}$ as an additional parallel corpus. First, we filter $T_{decipher}$ by keeping only translation pairs (f, e), where f is observed in the Spanish part and e is observed in the English part of the parallel corpus. Then we append all the Spanish and English words in the filtered $T_{decipher}$ to the end of Spanish part and English part of the parallel corpus respectively. The training and tuning process is the same as the baseline machine translation system PBMT. We call this system **Decipher-Pipeline**.

4.4.2 Joint Word Alignment and Decipherment for Machine Translation

When deciphering Malagasy to English, we extract Malagasy dependency bigrams using all available Malagasy monolingual data plus the Malagasy part of the Global Voices parallel data, and extract English dependency bigrams using 834 million tokens from English Gigaword, and 396 million tokens from allAfrica news to build an English dependency language model. In the other direction, we extract English dependency bigrams from English part of the entire parallel corpus plus 9.7 million tokens from allAfrica news [4], and use 17.3 million tokens Malagasy monolingual data (15.3 million from the web and 2.0 million from Global Voices) to build a Malagasy dependency language model. We require that all dependency bigrams only contain words observed in the parallel data used to train the baseline MT system.

During learning, we run Model 1 without decipherment for 5 iterations. Then we perform joint word alignment and decipherment for another 5 iterations with Model 1 and 5 iterations with HMM. We tune decipherment weights (α) for Model 1 and HMM using grid search against B score on a development set. In the end, we only extract rules from one direction $P(English|Malagasy)$, where the decipherment weights for Model 1 and HMM are 0.5 and 0.005 respectively. We chose this because we did not find any benefits to tune the weights on each direction, and then use grow-diag-final-end heuristic to form final alignments. We call this system **Decipher-Joint**.

[4] We do not find further B gains by using more English monolingual data.

Parallel		
	Malagasy	English
Train (GV)	0.9 million	0.8 million
Tune (GV)	22.2k	20.2k
Test (GV)	23k	21k
Test (Web)	2.2k	2.1k
Non Parallel		
	Malagasy	English
Gigaword	N/A	834 million
Web	15.3 million	396 million

Table 3: Size of training, tuning, and testing data in number of tokens (GV: Global Voices)

4.5 Results

We tune each system three times with MERT and choose the best weights based on B scores on tuning set.

Table 4 shows that while using a translation lexicon learnt from decipherment does not improve the quality of machine translation significantly, the joint approach improves B score by 0.9 and 2.1 on Global Voices test set and web news test set respectively. The results show that the parsing quality correlates with gains in B scores. Scores in the brackets in the last row of the table are achieved using a dependency parser with 72.4% attachment accuracy, while scores outside the brackets are obtained using a dependency parser with 80.0% attachment accuracy.

We analyze the results and find the gain mainly comes from two parts. First, adding expected counts from non parallel data makes the distribution of translation probabilities sparser in word alignment models. The probabilities of translation pairs favored by both parallel data and decipherment becomes higher. This gain is consistent with previous observation where a sparse prior is applied to EM to help improve word alignment and machine translation (Vaswani et al., 2012). Second, expected counts from decipherment also help discover new translation pairs in the parallel data for low frequency words, where those words are either aligned to NULL or wrong translations in the baseline.

5 Conclusion and Future Work

We propose a new objective function for word alignment to combine the process of word alignment and decipherment into a single task. In, experiments, we find that the joint process performs better than previous pipeline approach, and observe B gains of 0.9 and 2.1 point on Global Voices and local web news test sets, respectively. Finally, our research leads to the release of 15.3 million tokens of monolingual Malagasy data from the web as well as a small Malagasy dependency tree bank containing 20k tokens.

Given the positive results we obtain by using the joint approach to improve word alignment, we are in-

Decipherment	System	Tune (GV)	Test (GV)	Test (Web)
None	PBMT (Baseline)	18.5	17.1	7.7
Separate	Decipher-Pipeline	18.5	17.4	7.7
Joint	Decipher-Joint	18.9 (18.7)	18.0 (17.7)	9.8 (8.5)

Table 4: Decipher-Pipeline does not show significant improvement over the baseline system. In contrast, Decipher-Joint using joint word alignment and decipherment approach achieves a B gain of 0.9 and 2.1 on the Global Voices test set and the web news test set, respectively. The results in brackets are obtained using a parser trained with only 120 sentences. (GV: Global Voices)

spired to apply this approach to help find translations for out of vocabulary words, and to explore other possible ways to improve machine translation with decipherment.

Latent Domain Phrase-based Models for Adaptation

Abstract

Phrase-based models directly trained on *mix-of-domain corpora* can be sub-optimal. In this paper we equip phrase-based models with a *latent domain* variable and present a novel method for adapting them to an in-domain task represented by a seed corpus. We derive an EM algorithm which alternates between inducing domain-focused phrase pair estimates, and weights for mix-domain sentence pairs reflecting their relevance for the in-domain task. By embedding our latent domain phrase model in a sentence-level model and training the two in tandem, we are able to adapt *all core* translation components together – phrase, lexical and reordering. We show experiments on weighing sentence pairs for relevance as well as adapting phrase-based models, showing significant performance improvement in both tasks.

1 Mix vs. Latent Domain Models

Domain adaptation is usually perceived as utilizing a small seed in-domain corpus to adapt an existing system trained on an *out-of-domain* corpus. Here we are interested in adapting an SMT system trained on a large *mix-domain* corpus C_{mix} to an *in-domain task* represented by a seed parallel corpus C_{in}. The mix-domain scenario is interesting because often a large corpus consists of sentence pairs representing diverse domains, e.g., news, politics, finance, sports, etc.

At the core of a standard state-of-the-art phrase-based system (Och and Ney, 2004) is a phrase table $\{\langle \tilde{e}, \tilde{f} \rangle\}$ extracted from the word-aligned training data together with estimates for $P_t(\tilde{e} \mid \tilde{f})$ and $P_t(\tilde{f} \mid \tilde{e})$. Because the translations of words often vary across domains, it is likely that in a mix-domain corpus C_{mix} the translation ambiguity will increase with the *domain diversity*. Furthermore, the statistics in C_{mix} will reflect translation preferences *averaged* over the diverse domains. In this sense, phrase-based models trained on C_{mix} can be considered *domain-confused*. This often leads to suboptimal performance (Gascó et al., 2012; Irvine et al., 2013).

Recent adaptation techniques can be seen as mixture models, where two or more phrase tables, estimated from in- and mix-domain corpora, are combined together by interpolation, fill-up, or multiple-decoding paths (Koehn and Schroeder, 2007; Bisazza et al., 2011; Sennrich, 2012; Razmara et al., 2012; Sennrich et al., 2013). Here we are interested in the specific question *how to induce* a phrase-based model *from* C_{mix} for *in-domain translation*? We view this as *in-domain focused training* on C_{mix}, a complementary adaptation step which might precede any further combination with other models, e.g., in-, mix- or general-domain.

The main challenge is how to induce from C_{mix} a phrase-based model for the in-domain task, given only C_{in} as evidence? We present an approach whereby the contrast between in-domain prior distributions and "out-domain" distributions is exploited for softly inviting (or recruiting) C_{mix} phrase pairs to either camp. To this end we in-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 566–576,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

troduce a *latent domain variable* D to signify in- (D_1) and out-domain (D_0) respectively.[1]

With the introduction of the latent variables, we extend the translation tables in phrase-based models from generic $P_t(\tilde{e} \mid \tilde{f})$ to domain-focused by conditioning them on D, i.e., $P_t(\tilde{e} \mid \tilde{f}, D)$ and decomposing them as follows:

$$P_t(\tilde{e} \mid \tilde{f}, D) = \frac{P_t(\tilde{e} \mid \tilde{f})P(D \mid \tilde{e}, \tilde{f})}{\sum_{\tilde{e}} P_t(\tilde{e} \mid \tilde{f})P(D \mid \tilde{e}, \tilde{f})}. \quad (1)$$

Where $P(D \mid \tilde{e}, \tilde{f})$ is viewed as the *latent phrase-relevance models*, i.e., the probability that a phrase pair is in- (D_1) or out-domain (D_0). In the end, our goal is to replace the domain-confused tables, $P_t(\tilde{e} \mid \tilde{f})$ and $P_t(\tilde{f} \mid \tilde{e})$, with the in-domain focused ones, $P_t(\tilde{e} \mid \tilde{f}, D_1)$ and $P_t(\tilde{f} \mid \tilde{e}, D_1)$.[2] Note how $P_t(\tilde{e} \mid \tilde{f}, D_1)$ and $P_t(\tilde{f} \mid \tilde{e}, D_1)$ contains $P_t(\tilde{e} \mid \tilde{f})$ and $P_t(\tilde{f} \mid \tilde{e})$ as special case.

Eq. 1 shows that the key to training the latent phrase-based translation models is to train the latent phrase-relevance models, $P(D \mid \tilde{e}, \tilde{f})$. Our approach is to embed $P(D \mid \tilde{e}, \tilde{f})$ in asymmetric sentence-level models $P(D \mid \mathbf{e}, \mathbf{f})$ and train them on C_{mix}. We devise an EM algorithm where at every iteration, in- or out-domain estimates provide full sentence pairs $\langle \mathbf{e}, \mathbf{f} \rangle$ with expectations $\{P(D \mid \mathbf{e}, \mathbf{f}) \mid D \in \{0, 1\}\}$. Once these expectation are in C_{mix}, we induce re-estimates for the latent phrase-relevance models, $P(D \mid \tilde{e}, \tilde{f})$. Metaphorically, during each EM iteration the current in- or out-domain phrase pairs compete on *inviting* C_{mix} sentence pairs to be in- or out-domain, which bring in new (weights for) in- and out-domain phrases. Using the same algorithm we also show how to adapt all core translation components in tandem, including also lexical weights and lexicalized reordering models.

Next we detail our model, the EM-based invitation training algorithm and provide technical solutions to a range of difficulties. We report experiments showing good instance weighting performance as well as significantly improved phrase-based translation performance.

[1] Crucially, the lack of explicit out-domain data in C_{mix} is a major technical difficulty. We follow (Cuong and Sima'an, 2014) and in the sequel present a relatively efficient solution based on a kind of "burn-in" procedure.

[2] It is common to use these domain-focused models as additional features besides the domain-confused features. However, here we are more interested in *replacing* the domain-confused features rather than complementing them. This distinguishes this work from other domain adaptation literature for MT.

2 Model and training by invitation

Eq. 1 shows that the key to training the latent phrase-based translation models is to train the latent phrase-relevance models, $P(D \mid \tilde{e}, \tilde{f})$. As mentioned, for training $P(D \mid \tilde{e}, \tilde{f})$ on parallel sentences in C_{mix} we embed them in two asymmetric sentence-level models $\{P(D \mid \mathbf{e}, \mathbf{f}) \mid D \in \{0, 1\}\}$.

2.1 Domain relevance sentence models

Intuitively, sentence models for domain relevance $P(D \mid \mathbf{e}, \mathbf{f})$ are somewhat related to *data selection* approaches (Moore and Lewis, 2010; Axelrod et al., 2011). The dominant approach to data selection uses the contrast between perplexities of in- and mix-domain language models.[3] In the translation context, however, often a source phrase has different senses/translations in different domains, which cannot be distinguished with monolingual language models (Cuong and Sima'an, 2014). Therefore, our proposed latent sentence-relevance model includes two major latent components - *monolingual domain-focused relevance models* and *domain-focused translation models* derives as follows:

$$P(D \mid \mathbf{e},\ \mathbf{f}) = \frac{P(\mathbf{e}, \mathbf{f}, D)}{\sum_{D \in \{D_1, D_0\}} P(\mathbf{e}, \mathbf{f}, D)}, \quad (2)$$

where $P(\mathbf{e}, \mathbf{f}, D)$ can be decomposed as:

$$P(\mathbf{f}, \mathbf{e}, D) = \frac{1}{2}\Big(P(D)P_{lm}(\mathbf{e} \mid D)P_t(\mathbf{f} \mid \mathbf{e},\ D) + P(D)P_{lm}(\mathbf{f} \mid D)P_t(\mathbf{e} \mid \mathbf{f},\ D)\Big). \quad (3)$$

Here

- $P_t(\mathbf{e}|\mathbf{f}, D)$ and similarly $P_t(\mathbf{f}|\mathbf{e}, D)$: the latent domain-focused translation models aim at capturing the faithfulness of translation with respect to different domains. We simplify this as

[3] Note that earlier work on data selection exploits the contrast between in- and mix-domain. In (Cuong and Sima'an, 2014), we present the idea of using the language and translation models derived separately from in- and out-domain data, and show how it helps for data selection.

"bag-of-possible-phrases" translation models:[4]

$$P_t(\mathbf{e}|\mathbf{f}, D) := \prod_{\langle\tilde{e},\tilde{f}\rangle \in \mathcal{A}(\mathbf{e},\mathbf{f})} P_t(\tilde{e}|\tilde{f}, D)^{c(\tilde{e},\tilde{f})}, \quad (4)$$

where $\mathcal{A}(\mathbf{e}, \mathbf{f})$ is the multiset of phrases in $\langle \mathbf{e}, \mathbf{f} \rangle$ and $c(\cdot)$ denotes their count. Sub-model $P_t(\tilde{e}|\tilde{f}, D)$ is given by Eq. 1.

- $P_{lm}(\mathbf{e}|D)$, $P_{lm}(\mathbf{f}|D)$: the latent monolingual domain-focused relevance models aim at capturing the relevance of $\mathbf{e}$ and $\mathbf{f}$ for identifying domain D but here we consider them language models (LMs).[5] As mentioned, the out-domain LMs differ from previous works, e.g., (Axelrod et al., 2011), which employ mix-domain LMs. Here, we stress the difficulty in finding data to train *out-domain LMs* and present a solution based on *identifying pseudo out-domain data*.

- $P(D)$: the domain priors aim at modeling the percentage of relevant data that the learning framework induces. It can be estimated via phrase-level parameters but here we prefer sentence-level parameters:[6]

$$P(D) := \frac{\sum_{\langle \mathbf{e},\mathbf{f}\rangle \in C_{mix}} P(D \mid \mathbf{e}, \mathbf{f})}{\sum_D \sum_{\langle \mathbf{e},\mathbf{f}\rangle \in C_{mix}} P(D \mid \mathbf{e}, \mathbf{f})} \quad (5)$$

2.2 Training by invitation

Generally, our model can be viewed to have latent parameters $\Theta = \{\Theta_{D_0}, \Theta_{D_1}\}$. The training procedure seeks Θ that maximize the log-likelihood of the observed sentence pairs $\langle \mathbf{e}, \mathbf{f} \rangle \in C_{mix}$:

$$\mathcal{L} = \sum_{\langle \mathbf{e},\mathbf{f}\rangle \in C_{mix}} \log \sum_D P_{\Theta_D}(D, \mathbf{e}, \mathbf{f}). \quad (6)$$

It is obvious that there does not exist a closed-form solution for Equation 6 because of the existence of the log-term $\log \sum$. The EM algorithm (Dempster et al., 1977) comes as an alternative solution to fit the model. It can be seen to maximize $\mathcal{L}$ via block-coordinate ascent on a lower bound $\mathcal{F}(q, \Theta)$ using an auxiliary distribution $q(D \mid \mathbf{e}, \mathbf{f})$

$$\mathcal{F}(q, \Theta) = \sum_{\langle \mathbf{e},\mathbf{f}\rangle} \sum_D q(D \mid \mathbf{e}, \mathbf{f}) \log \frac{P_{\Theta_D}(D, \mathbf{e}, \mathbf{f})}{q(D \mid \mathbf{e}, \mathbf{f})} \quad (7)$$

where the inequality results, i.e., $\mathcal{L} \geq \mathcal{F}(q, \Theta)$, derived from $\log$ being concave and Jensen's inequality. We rewrite the Free Energy $\mathcal{F}(q, \Theta)$ (Neal and Hinton, 1999) as follows:

$$\begin{aligned} \mathcal{F} = & \sum_{\langle \mathbf{e},\mathbf{f}\rangle} \sum_D q(D \mid \mathbf{e}, \mathbf{f}) \log \frac{P_{\Theta_D}(D \mid \mathbf{e}, \mathbf{f})}{q(D \mid \mathbf{e}, \mathbf{f})} \\ & + \sum_{\langle \mathbf{e},\mathbf{f}\rangle} \sum_D q(D \mid \mathbf{e}, \mathbf{f}) \log P_\Theta(\mathbf{e}, \mathbf{f}) \\ & = \sum_{\langle \mathbf{e},\mathbf{f}\rangle} \log P_\Theta(\mathbf{e}, \mathbf{f}) \\ & - KL[q(D \mid \mathbf{e}, \mathbf{f}) \mid\mid P_{\Theta_D}(D \mid \mathbf{e}, \mathbf{f})], \end{aligned} \quad (8)$$

where $KL[\cdot \mid\mid \cdot]$ is the KL-divergence.

With the introduction of the KL-divergence, the alternating E and M steps for our EM algorithm are easily derived as

$$\begin{aligned} & \textbf{E-}step : q^{t+1} \\ & \text{argmax}_{q(D \mid \mathbf{e},\mathbf{f})} \mathcal{F}(q, \Theta^t) \; = \\ & \text{argmin}_{q(D \mid \mathbf{e},\mathbf{f})} KL[q(D|\mathbf{e}, \mathbf{f}) \mid\mid P_{\Theta_D^t}(D|\mathbf{e}, \mathbf{f})] \\ & = P_{\Theta_D^t}(D \mid \mathbf{e}, \mathbf{f}) \end{aligned} \quad (9)$$

$$\begin{aligned} & \textbf{M-}step : \Theta^{t+1} \\ & \text{argmax}_\Theta \mathcal{F}(q^{t+1}, \Theta) \; = \\ & \text{argmax}_\Theta \sum_{\langle \mathbf{e},\mathbf{f}\rangle} \sum_D q(D \mid \mathbf{e}, \mathbf{f}) \log P_{\Theta_D}(D, \mathbf{e}, \mathbf{f}) \end{aligned} \quad (10)$$

The iterative procedure is illustrated in Figure 1.[7] At the E-step, a guess for $P(D \mid \tilde{e}, \tilde{f})$ can be used to update $P_t(\tilde{f} \mid \tilde{e}, D)$ and $P_t(\tilde{e} \mid \tilde{f}, D)$ (i.e., using Eq. 1) and consequently $P_t(\mathbf{f} \mid \mathbf{e}, D)$ and $P_t(\mathbf{e} \mid \mathbf{f}, D)$ (i.e., using Eq. 4). These resulting table estimates, together with the domain-focused LMs and the domain priors are served as *expected counts* to update $P(D \mid \mathbf{e}, \mathbf{f})$.[8] At the M-step,

[4] We design our latent domain translation models with efficiency as our main concern. Future extensions could include the lexical and reordering sub-models (as suggested by an anonymous reviewer.)

[5] Relevance for identification or retrieval could be different from frequency or fluency. We leave this extension for future work.

[6] It should be noted that in most phrase-based SMT systems bilingual phrase probabilities are estimated heuristically from word alignmened data which often leads to overfitting. Estimating $P(D)$ from sentence-level parameters rather than from phrase-level parameters helps us avoid the overfitting which often accompanies phrase extraction.

[7] For simplicity, we ignore the LMs and prior models in the illustration in Fig. 1.

[8] Since we only use the in-domain corpus as priors to initilize the EM parameters, in technical perspective we do not want $P(D \mid \mathbf{e}, \mathbf{f})$ parameters to go too far off from the initialization. We therefore prefer the averaged style in practice, i.e., at the iteration n we update the $P(D \mid \mathbf{e}, \mathbf{f})$ parameters, $P^{(n)}(D|\mathbf{e}, \mathbf{f})$ as $\frac{1}{n}(P^{(n)}(D \mid \mathbf{e}, \mathbf{f}) + \sum_{i=1}^{n-1} P^{(i)}(D \mid \mathbf{e}, \mathbf{f}))$.

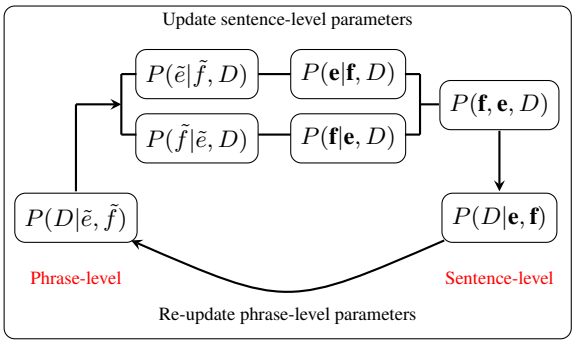

Figure 1: Our probabilistic invitation framework.

the new estimates for $P(D \mid \mathbf{e}, \mathbf{f})$ can be used to (softly) fill in the values of hidden variable D and estimate parameters $P(D \mid \tilde{e}, \tilde{f})$ and $P(D)$. The EM is guaranteed to converge to a local maximum of the likelihood under mild conditions (Neal and Hinton, 1999).

Before EM training starts we must provide a "reasonable" initial guess for $P(D \mid \tilde{e}, \tilde{f})$. We must also train the out-domain LMs, which needs the construction of *pseudo out-domain* data.[9] One simple way to do that is inspired by burn-in in sampling, under the guidance of an in-domain data set, C_{in} as prior. At the beginning, we train $P_t(\tilde{e} \mid \tilde{f}, D_1)$ and $P_t(\tilde{f} \mid \tilde{e}, D_1)$ for all phrases learned from C_{in}. We also train $P_t(\tilde{e} \mid \tilde{f})$ and $P_t(\tilde{f} \mid \tilde{e})$ for all phrases learned from C_{mix}. During burn-in we assume that the out-domain phrase-based models are the domain-confused phrase-based models, i.e., $P_t(\tilde{e} \mid \tilde{f}, D_0) \approx P_t(\tilde{e} \mid \tilde{f})$ and $P_t(\tilde{f} \mid \tilde{e}, D_0) \approx P_t(\tilde{f} \mid \tilde{e})$. We isolate all the LMs and the prior models from our model, and apply a single EM iteration to update $P(D \mid \mathbf{e}, \mathbf{f})$ based on those domain-focused models $P_t(\tilde{e} \mid \tilde{f}, D)$ and $P_t(\tilde{f} \mid \tilde{e}, D)$.

In the end, we use $P(D \mid \mathbf{e}, \mathbf{f})$ to fill in the values of hidden variable D in C_{mix}, so it provides us with an initialization for $P(D \mid \tilde{e}, \tilde{f})$. Subsequently, we also rank sentence pairs in $\mathcal{C}_{mix}$ with $P(D_1 \mid \mathbf{e}, \mathbf{f})$ and select a subset of smallest scoring pairs as a *pseudo out-domain subset* to train $P_{lm}(\mathbf{e} \mid D_0)$ and $P_{lm}(\mathbf{f} \mid D_0)$. Once the latent domain-focused LMs have been trained, the LM probabilities stay *fixed* during EM. Crucially, it is important to scale the probabilities of the four LMs to make them comparable: we normalize the probability that a LM assigns to a sentence by the total probability this LM assigns to all sentences in $\mathcal{C}_{mix}$.

[9]The in-domain LMs $P_{lm}(\mathbf{e} \mid D_1)$ and $P_{lm}(\mathbf{f} \mid D_1)$ can be simply trained on the source and target sides of $\mathcal{C}_{in}$ respectively.

3 Intrinsic evaluation

We evaluate the ability of our model to retrieve "hidden" in-domain data in a large mix-domain corpus, i.e., we hide some in-domain data in a large mix-domain corpus. We weigh sentence pairs under our model with $P(D_1 \mid \tilde{e}, \tilde{f})$ and $P(D_1 \mid \mathbf{e}, \mathbf{f})$ respectively. We report *pseudo*-precision/recall at the *sentence-level* using a range of cut-off criteria for selecting the top scoring instances in the mix-domain corpus. A good relevance model expects to score higher for the hidden in-domain data.

Baselines Two standard perplexity-based selection models in the literature have been implemented as the baselines: cross-entropy difference (Moore and Lewis, 2010) and bilingual cross-entropy difference (Axelrod et al., 2011), investigating their ability to retrieve the hiding data as well. Training them over the data to learn the sentences with their relevance, we then rank the sentences to select top of pairs to evaluate the *pseudo*-precision/recall at the *sentence-level*.

Results We use a mix-domain corpus $\mathcal{C}_g$ of 770K sentence pairs of different genres.[10] There is also a Legal corpus of 183K pairs that serves as the in-domain data. We create $\mathcal{C}_{mix}$ by selecting an arbitrary 83K pairs of in-domain pairs and adding them to $\mathcal{C}_g$ (the hidden in-domain data); we use the remaining 100k in-domain pairs as $\mathcal{C}_{in}$.

To train the baselines, we construct interpolated 4-gram Kneser-Ney LMs using BerkeleyLM (Pauls and Klein, 2011). Training our model on the data takes six EM-iterations to converge.[11]

[10]Count of *sentence pairs*: European Parliament (Koehn, 2005): 183,793; Pharmaceuticals: 190,443, Software: 196,168, Hardware: 196,501.

[11]After the fifth EM iteration we do not observe any significant increase in the likelihood of the data. Note that we use the same setting as for the baselines to train the latent domain-focused LMs for use in our model – interpolated 4-gram Kneser-Ney LMs using BerkeleyLM. This training setting is used for all experiments in this work.

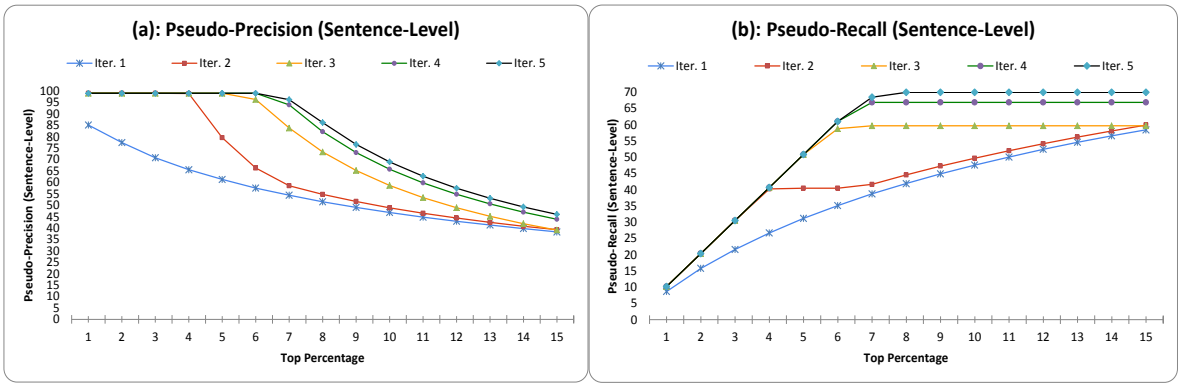

Figure 2: Intrinsic evaluation.

Fig. 2 helps us examine how the pseudo sentence invitation are done during each EM iteration. For later iterations we observe a better pseudo-precision and pseudo-recall at sentence-level (Fig. 2(a), Fig. 2(b)). Fig. 2 also reveals a good learning capacity of our learning framework. Nevertheless, we observe that the baselines do not work well for this task. This is not new, as pointed out in our previous work (Cuong and Sima'an, 2014).

Which component type contributes more to the performance, the latent domain language models or the latent domain translation models? Further experiments have been carried on to neutralize each component type in turn and build a selection system with the rest of our model parameters. It turns out that the latent domain translation models are crucial for performance for the learning framework, while the latent domain LMs make a far smaller yet substantial contribution. We refer readers to our previous work (Cuong and Sima'an, 2014), which provides detail analysis of the data selection problem.

4 Translation experiments: Setting

Data We use a mix-domain corpus consisting of $4M$ sentence pairs, collected from multiple resources including EuroParl (Koehn, 2005), Common Crawl Corpus, UN Corpus, News Commentary. As in-domain corpus we use "Consumer and Industrial Electronics" manually collected by Translation Automation Society (TAUS.com). The corpus statistics are summarized in Table 1.

System We train a standard state-of-the-art phrase-based system, using it as the baseline.[12] There are three main kinds of features for the translation model in the baseline - phrase-based translation features, lexical weights (Koehn et al., 2003) and lexicalized reordering features (Koehn et al., 2005).[13] Other features include the penalties for word, phrase and distance-based reordering.

			English	Spanish
	$\mathbf{C_{mix}}$	Sents	**4M**	
		Words	$113.7M$	127.1M
Domain: Electronics	$\mathbf{C_{in}}$	Sents	**109K**	
		Words	$1,485,558$	$1,685,716$
	Dev	Sents	984	
		Words	13130	$14,955$
	Test	Sents	982	
		Words	$13,493$	$15,392$

Table 1: The data preparation.

The mix-domain corpus is word-aligned using GIZA++ (Och and Ney, 2003) and symmetrized with *grow(-diag)-final-and* (Koehn et al., 2003). We limit phrase length to a maximum of seven words. The LMs are interpolated 4-grams with Kneser-Ney, trained on $2.2M$ English sentences from Europarl augmented with $248.8K$ sentences from News Commentary Corpus (WMT 2013). We tune the system using k-best batch MIRA (Cherry and Foster, 2012). Finally, we use Moses

[12] We use Stanford Phrasal - a standard state-of-the-art phrase-based translation system developed by Cer et al. (2010).

[13] The lexical weights and the lexical reordering features will be described in more detail in Section 6.

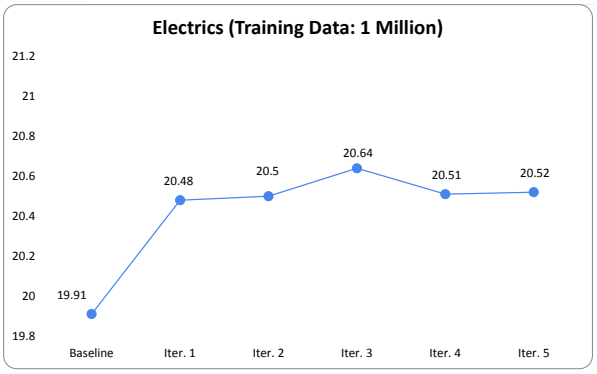

Figure 3: BLEU averaged over multiple runs.

(Koehn et al., 2007) as decoder.[14]

We report BLEU (Papineni et al., 2002), METEOR 1.4 (Denkowski and Lavie, 2011) and TER (Snover et al., 2006), with statistical significance at 95% confidence interval under paired bootstrap re-sampling (Press et al., 1992). For every system reported, we run the optimizer at least three times, before running MultEval (Clark et al., 2011) for resampling and significance testing.

Outlook In Section 5 we examine the effect of training only the latent domain-focused phrase table using our model. In Section 6 we proceed further to estimate also latent domain-focused lexical weights and lexicalized reordering models, examining how they incrementally improve the translation as well.

5 Adapting phrase table only

Here we investigate the effect of adapting the phrase table only; we will delay adapting the lexical weights and lexicalized reordering features to Section 6. We build a phrase-based system with the usual features as the baseline, including two bi-directional phrase-based models, plus the penalties for word, phrase and distortion. We also build a latent domain-focused phrase-based system with the two bi-directional latent phrase-based models, and the standard penalties described above.

We explore training data sizes $1M$, $2M$ and $4M$ sentence pairs. Three baselines are trained yielding $95.77M$, $176.29M$ and $323.88M$ phrases respectively. We run 5 EM iterations to train our learning framework. We use the parameter estimates for $P(D \mid \tilde{e}, \tilde{f})$ derived at each EM iteration to train our latent domain-focused phrase-based systems. Fig. 3 presents the results (in BLEU) at each iteration in detail for the case of $1M$ sentence pairs. Similar improvements are observed for METEOR and TER. Here, we consistently observe improvements at p-value $= 0.0001$ for all cases.

It should be noted that when doubling the training data to $2M$ and $4M$, we observe the similar results.

Finally, for all cases we report their best result in Table 2. Here, note how the improvement could be gained when doubling the training data.

Data	System	Avg	Δ	p-value
$1M$	Baseline	19.91	–	–
	Our System	20.64	**+0.73**	**0.0001**
$2M$	Baseline	20.54	–	–
	Our System	21.41	**+0.87**	**0.0001**
$4M$	Baseline	21.44	–	–
	Our System	22.62	**+1.18**	**0.0001**

Table 2: BLEU averaged over multiple runs.

It is also interesting to consider the average entropy of phrase table entries in the domain-confused systems, i.e.,

$$\frac{-\sum_{\langle\tilde{e},\tilde{f}\rangle} p_t(\tilde{e}|\tilde{f}) \log p_t(\tilde{e}|\tilde{f})}{\text{number of phrases}\langle\tilde{e},\tilde{f}\rangle}$$

against that in the domain-focused systems

$$\frac{-\sum_{\langle\tilde{e},\tilde{f}\rangle} p_t(\tilde{e}|\tilde{f}, D_1) \log p_t(\tilde{e}|\tilde{f}, D_1)}{\text{number of phrases}\langle\tilde{e},\tilde{f}\rangle}.$$

Following (Hasler et al., 2014) in Table 3 we also show that the entropy decreases significantly in

[14] While we implement the latent domain phrase-based models using Phrasal for some advantages, we prefer to use Moses for decoding.

the adapted tables in all cases, which indicates that the distributions over translations of phrases have become sharper.

Baseline	Iter. 1	Iter. 2	Iter. 3	Iter. 4	Iter. 5
0.210	0.187	0.186	0.185	0.185	0.184

Table 3: Average entropy of distributions.

In practice, the third iteration systems usually produce best translations. This is somewhat expected because as EM invites more pseudo in-domain pairs in later iterations, it sharpens the estimates of $P(D_1 \mid \tilde{e}, \tilde{f})$, making pseudo out-domain pairs tend to 0.0. Table 4 shows the percentage of entries with $P(D_1 \mid \tilde{e}, \tilde{f}) < 0.01$ at every iteration, e.g., 34.52% at the fifth iteration. This induced schism in C_{mix} diminishes the difference between the relevance scores for certain sentence pairs, limiting the ability of the latent phrase-based models to further discriminate in the gray zone.

Entries	$P(D_1 \mid \tilde{f}, \tilde{e}) < 0.01$
Iter. 1	22.82%
Iter. 2	27.06%
Iter. 3	30.07%
Iter. 4	32.47%
Iter. 5	34.52%

Table 4: Phrase analyses.

Finally, to give a sense of the improvement in translation, we (randomly) select cases where the systems produce different translations and present some of them in Table 5. These examples are indeed illuminating, e.g., "*can reproduce signs of audio*"/"*can play signals audio*", "*password teacher*"/"*password master*", revealing thoroughly the benefit derived from adapting the phrase models from being domain-confused to being domain-focused. Table 6 presents phrase table entries, i.e., $p_t(e \mid f)$ and $p_t(e \mid f, D_1)$, for the "*can reproduce signs of audio*"/"*can play signals audio*" example.

6 Fully adapted translation model

The preceding experiments reveal that adapting the phrase tables significantly improves translation performance. Now we also adapt the lexical and reordering components. The result is a fully adapted, domain-focused, phrase-based system.

	señales		**reproducir**	
Entries	**signals**	**signs**	**play**	**reproduce**
Baseline	0.29	0.36	0.15	0.20
Iter. 1	0.36	0.23	0.29	0.16
Iter. 2	0.37	0.19	0.32	0.17
Iter. 3	0.37	0.17	0.34	0.16
Iter. 4	0.37	0.16	0.36	0.16
Iter. 5	0.37	0.15	0.37	0.16

Table 6: Phrase entry examples.

Briefly, the lexical weights provide smooth estimates for the phrase pair based on word translation scores $P(e \mid f)$ between pairs of words $\langle e, f \rangle$, i.e., $P(e \mid f) = \frac{c(e,f)}{\sum_e c(e,f)}$ (Koehn et al., 2003). Our latent domain-focused lexical weights, on the other hand, are estimated according to $P(e \mid f,\ D_1)$, i.e., $P(e \mid f,\ D_1) = \frac{P(e \mid f)P(D_1 \mid e,\ f)}{\sum_f P(e \mid f)P(D_1 \mid e,\ f)}$.

The lexicalized reordering models with orientation variable O, $P(O \mid \tilde{e},\ \tilde{f})$, model how likely a phrase $\langle \tilde{e}, \tilde{f} \rangle$ directly follows a previous phrase ($monotone$), swaps positions with it ($swap$), or is not adjacent to it ($discontinous$) (Koehn et al., 2005). We make these domain-focused:

$$P(O \mid \tilde{e},\ \tilde{f}, D_1) = \frac{P(O \mid \tilde{e},\ \tilde{f})P(D_1 \mid O, \tilde{e},\ \tilde{f})}{\sum_O P(O \mid \tilde{e},\ \tilde{f})P(D_1 \mid O, \tilde{e},\ \tilde{f})} \quad (11)$$

Estimating $P(D_1 \mid O,\ \tilde{e},\ \tilde{f})$ and $P(D_1 \mid e,\ f)$ is similar to estimating $P(D_1 \mid \tilde{e},\ \tilde{f})$ and hinges on the estimates of $P(D_1 \mid \mathbf{e},\ \mathbf{f})$ during EM.

The baseline for the following experiments is a standard state-of-the-art phrase-based system, including two bi-directional phrase-based translation features, two bi-directional lexical weights, six lexicalized reordering features, as well as the penalties for word, phrase and distortion. We develop three kinds of domain-adapted systems that are different at their adaptation level to fit the task. The first (**Sys. 1**) adapts only the phrase-based models, using the same lexical weights, lexicalized reordering models and other penalties as the baseline. The second (**Sys. 2**) adapts also the lexical weights, fixing all other features as the baseline. The third (**Sys. 3**) adapts both the phrase-based models, lexical weights and lexicalized re-

Table 7: Metric scores for the systems, which are averages over multiple runs.

Table 7 presents results for training data size of $4M$ parallel sentences. It shows that the fully domain-focused system (**Sys. 3**) significantly improves over the baseline. The table also shows that the latent domain-focused phrase-based models and lexical weights are crucial for the improved performance, whereas adapting the reordering models makes a far smaller contribution.

Finally we also apply our approach to other tasks where the relation between their in-domain data and the mix-domain data varies substantially. Table 8 presents their in-domain, tuning and test data in detail, as well as the translation results over them. It shows that the fully domain-focused systems consistently and significantly improve the translation accuracy for all the tasks.

7 Combining multiple models

Finally, we proceed further to test our latent domain-focused phrase-based translation model on standard domain adaptation. We conduct experiments on the task "Professional & Business Services" as an example.[16] For standard adaptation we follow (Koehn and Schroeder, 2007) where we pass multiple phrase tables directly to the Moses decoder and tune them together. For baseline we combine the standard phrase-based system trained on C_{mix} with the one trained on the in-domain data C_{in}. We also combine our latent domain-focused phrase-based system with the one trained on C_{in}. Table 9 presents the results showing that combining our domain-focused system adapted from C_{mix} with the in-domain model outperforms the baseline.

[15]We run three EM iterations to train our invitation framework, and then use the parameter estimates for $P(D_1 \mid \tilde{e}, \tilde{f})$, $P(D_1 \mid e, f)$ and $P(D_1 \mid O, \tilde{e}, \tilde{f})$ to train these domain-focused features. We adopt this training setting for all other different tasks in the sequel.

[16]We choose this task for additional experiments because it has very small in-domain data ($23K$). This is supposed to make adaptation difficult because of the robust large-scale systems trained on C_{mix}.

8 Related work

A distantly related, but clearly complementary, line of research focuses on the role of document topics (Eidelman et al., 2012; Zhang et al., 2014; Hasler et al., 2014). An off-the-shelf Latent Dirichlet Allocation tool is usually used to infer document-topic distributions. On one hand, this setting may not require in-domain data as prior. On the other hand, it requires meta-information (e.g., document information).

Part of this work (the latent sentence-relevance models) relates to data selection (Moore and Lewis, 2010; Axelrod et al., 2011), where sentence-relevance weights are used for hard-filtering rather than weighting. The idea of using sentence-relevance estimates for phrase-relevance estimates relates to Matsoukas et al. (2009) who estimate the former using meta-information over documents as main features. In contrast, our work overcomes the mutual dependence of sentence and phrase estimates on one another by training both models in tandem.

Adaptation using small in-domain data has a different but complementary goal to another line of research aiming at combining a domain-adapted system with the another trained on the in-domain data (Koehn and Schroeder, 2007; Bisazza et al., 2011; Sennrich, 2012; Razmara et al., 2012; Sennrich et al., 2013). Our work is somewhat related to, but markedly different from, phrase pair weighting (Foster et al., 2010). Finally, our latent domain-focused phrase-based models and invitation training paradigm can be seen to shift attention from adaptation to making explicit the role of domain-focused models in SMT.

9 Conclusion

We present a novel approach for in-domain focused training of a phrase-based system on a mix-of-domain corpus by using prior distributions from a small in-domain corpus. We derive an EM training algorithm for learning latent domain relevance models for the phrase- and sentence-levels in tandem. We also show how to overcome the difficulty of lack of explicit out-domain data by bootstrapping pseudo out-domain data.

In future work, we plan to explore generative Bayesian models as well as discriminative learning approaches with different ways for estimat-

ing the latent domain relevance models. We hypothesize that bilingual, but also monolingual, relevance models can be key to improved performance.

Abstract

In Corpus-Based Machine Translation, the search space of the translation candidates for a given input sentence is often defined by a set of (cycle-free) context-free grammar rules. This happens naturally in Syntax-Based Machine Translation and Hierarchical Phrase-Based Machine Translation (where the representation will be the set of the target-side half of the synchronous rules used to parse the input sentence). But it is also possible to describe Phrase-Based Machine Translation in this framework. We propose a natural extension to this representation by using lattice-rules that allow to easily encode an exponential number of variations of each rules. We also demonstrate how the representation of the search space has an impact on decoding efficiency, and how it is possible to optimize this representation.

1 Introduction

A popular approach to modern Machine Translation is to decompose the translation problem into a modeling step and a search step. The modeling step will consist in defining implicitly a set of possible translations $\mathcal{T}$ for each input sentence. Each translation in $\mathcal{T}$ being associated with a real-valued *model score*. The search step will then consist in finding the translation in $\mathcal{T}$ with the highest model score. The search is non-trivial because it is usually impossible to enumerate all members of $\mathcal{T}$ (its cardinality being typically exponentially dependent on the size of the sentence to be translated).

Since at least (Chiang, 2007), a common way of representing $\mathcal{T}$ has been through a cycle-free context-free grammar. In such a grammar, $\mathcal{T}$ is represented as a set of context-free rules such as can be seen on figure 1. These rules themselves can be generated by the modeling step through the use of phrase tables, synchronous parsing, tree-to-string rules, etc. If the model score of each translation is taken to be the sum of *rule scores* independently given to each rule, the search for the optimal translation is easy with some classic dynamic programming techniques.

However, if the model score is going to take into account informations such as the language model score of each sentence, it cannot be expressed in such a way. Since the language model score has proven empirically to be a very good source of information, (Chiang, 2007) proposed an approximate search algorithm called *cube pruning*.

We propose here to represent $\mathcal{T}$ using context-free lattice-rules such as shown in figure 2. This allows us to compactly encode a large number of rules. One benefit is that it adds flexibility to the modeling step, making it easier: many choices such as whether or not a function word should be included, the relative position of words and non-terminal in the translation, as well as morphological variations can be delegated to the search step by encoding them in the lattice rules. While it is true that the same could be achieved by an explicit enumeration, lattice rules make this easier and more efficient.

In particular, we show that a decoding algorithm working with such lattice rules can be more efficient than one working directly on the enumeration of the rules encoded in the lattice.

A distinct but related idea of this paper is to consider how transforming the structure of the rules defining $\mathcal{T}$ can lead to improvements

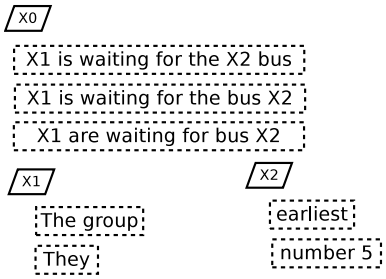

Figure 1: A simple cycle-free context grammar describing a set of possible translations.

in the speed/memory performances of the decoding. In particular, we propose a method to merge and reduce the size of the lattice rules and show that it translates into better performances at decoding time.

In this paper, we will first define more precisely our concept of lattice-rules, then try to give some motivation for them in the context of a tree-to-tree MT system (section 3). In section 4, we then propose an algorithm for preprocessing a representation given in a lattice-rule form that allows for more efficient search. In section 5, we describe a decoding algorithm specially designed for handling lattice-rules. In section 6, we perform some experiments demonstrating the merit of our approach.

2 Notations and Terminology

Here, we define semi-formally the terms we will use in this paper. We assume knowledge of the classic terminology of graph theory and context-free grammar.

2.1 Expansion rules

A *flat expansion rule* is the association of a non-terminal and a "flat" right hand side that we note *RHS*. A *flat RHS* is a sequence of words and non-terminal. See figure 1 for an example of a set of flat expansion rules.

A set of expansion rules is often produced in Hierarchical or Syntax-Based MT, by parsing with synchronous grammars or otherwise. In such a case, the set of rules define a representation of the (weighted) set of possible translations $\mathcal{T}$ of an input sentence.

2.2 Lattice

In the general sense, a lattice can be described as a labeled directed acyclic graph. More precisely, the type of lattice that we consider in this work is such that:

- Edges are labeled by either a word, a non-terminal or an epsilon (ie. an empty string).
- Vertices are only labeled by a unique id by which they can be designated.

Additionally, edges can also be labeled by a real-valued *edge score* and some real-valued *edge features*. Alternatively, a lattice could also be seen as an acyclic Finite State Automaton, with vertices and edges corresponding to states and transitions in the FSA terminology.

For simplicity, we also set the constraint that each lattice has a unique "start" vertex labeled v_S from which each vertex can be reached and a unique "end" vertex v_E that can be reached from each vertex. Each path from v_S to v_E define thus a flat RHS, with score and features obtained by summing the score and features of each edge of the path.

A *lattice expansion rule* is similar to a flat expansion rule, but with the RHS being a lattice. Thus a set of lattice expansion rules can also define a set of possible translations $\mathcal{T}$ of an input sentence.

For a given lattice $\mathcal{L}$, we will often note $v \in \mathcal{L}$ a vertex of $\mathcal{L}$ and $e : v_1 \to v_2 \in \mathcal{L}$ an edge of $\mathcal{L}$ going from vertex v_1 to vertex v_2.

Figures 2 and 3 show examples of such lattices.

2.3 Translation set and Representations

We note $\mathcal{T}$ a set of weighted sentences. $\mathcal{T}$ is intended as representing the set of scored translation candidates generated by a MT system for a given input sentence. As is customary in Corpus-Based MT literature, we will call *decoding* the process of searching for the translation with highest score in $\mathcal{T}$.

A representation of $\mathcal{T}$, noted $\mathcal{R}_T$ is a set of rules in a given formalism that implicitly define $\mathcal{T}$. As we mentioned earlier, in MT, $\mathcal{R}_T$ is often a set of cycle-free context-free grammar rules.

In this paper, we consider representations $\mathcal{R}_T$ consisting in a set of lattice expansion rules. With normal context-free grammar, it is usually necessary that a non-terminal is the

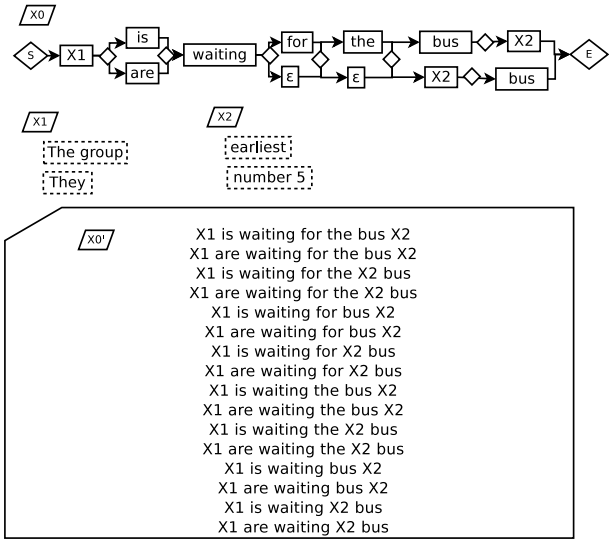

Figure 2: A simple example of lattice rule for non-terminal X0. The lower part list the set of "flat" rules that would be equivalent to the ones expressed by the lattice.

left-hand side of several rules. Using lattice expansion rules, however, it is not necessary, as one lattice RHS can encode an arbitrary number of flat rules (see for example the RHS of X0 in figure 3). Therefore, we set the constraint that there is only one lattice expansion rule for each left-hand non-terminal. And we will note unambiguously $RHS(X)$ the lattice that is the right hand side of this rule.

3 Motivation

3.1 Setting

This work was developed mainly in the context of a syntactic-dependency-based tree-to-tree translation system described in (Richardson et al., 2014). Although it is a tree-to-tree system, we simplify the decoding step by "flattening" the target-side tree translation rules into string expansion rules (keeping track of the dependency structure in state features). Thus our setting is actually quite similar to that of many tree-to-string and string-to-string systems. Aiming at simplicity and generality, we will set aside the question of target-side syntactic information and only describe our algorithms in a "tree-to-string" setting. We will also consider a n-gram language model score as our only stateful non-local feature.

However, this tree-to-tree original setting should be kept in mind, in particular when we describe the issue of the relative position of heads and dependents in section 3.2.2, as such issues do not appear as commonly in "X-to-string" settings.

3.2 Rule ambiguities

Expansion rules are typically created by matching part of the input sentence with some aligned example bilingual sentence. The alignment (and the linguistic structure of the phrase in the case of Syntax-Based Machine Translation) is then used to produce the target-side rule. However, it is often the case that it is difficult to fully specify a rule from an example. Such cases often come from two main reasons:

- Imperfect knowledge (eg. it is unclear whether a given unaligned word should belong to the translation)
- Context dependency (eg. the question of whether "to be" should be in plural form or not, depending on its subject in the constructed translation).

In both situation, it seems like it would be better to delay the full specification of the rule until decoding time, when the decoder can have access to the surrounding context of the rule and make a more informed choice. In particular, we can expect features such as language model or governor-dependent features (in the case of tree-to-tree Machine translation) to help remove the ambiguities.

We detail some cases for which we encode variations as lattice-rule.

3.2.1 Non-aligned words

When rules are extracted from aligned examples, we often find some target words which are not aligned to any source-side word and for which it is difficult to decide whether or not they should be included in the rule. Such words are often function words that do not have an equivalent in the source language. In Japanese-English translations, for example, articles such as "a" and "the" do not typically have equivalent in the Japanese side, and their necessity in the final sentence will often be a matter of context. We can make these edges

optionals by doubling them with an epsilon-edge. Different weights and features can be given to the epsilon edges to balance the tendency of the decoder to skip edges. In figure 2, this is illustrated by the epsilon edges allowing to skip "for" and "the"

3.2.2 Non-terminal positions

In the context of our tree-to-tree translation system, we often find that we know which target word should be the governor of a given non-terminal, but that we are unsure of the order of the words and non-terminals sharing a common governor. It can be convenient to represent such ambiguities in a lattice format as shown in figure 2. In this figure, one can see that the RHS of $X0$ encode two possible ordering for the word "bus" and the non-terminal $X2$.

3.2.3 Word variations

Linguistics phenomenons such as morphological variations can naturally create many minor problems in the setting of Corpus-Based Translation. Especially if the variations in the target language have no equivalence in the source language. An example of this in Japanese-English translation is the fact that verbs in Japanese are "plural-independent", while the verb "to be" in English is not. Therefore, a RHS that is a candidate for translating a large part of a Japanese input sentence can easily use one of the variant of "to be" that is not consistent with the full sentence. To solve this, for each edge corresponding to the words "is" or "are", we add an alternative edge with the same start and end vertices as the other word. The decoder will then be able to choose the edge that gives the best language model score. The same can be done, for example, for the article "a/an". Figure 2 provides an example of this, with two edges "is" and "are" in the RHS of X0.

Alternative edges can be labeled with different weights and features to tune the tendency of the decoder to choose a morphological variation.

While such variations could be fixed in a post-processing step, we feel it is a better option to let the decoder be aware of the possible options, lest it would discard rules due to language model considerations when these rules could actually have been useful with a simple change.

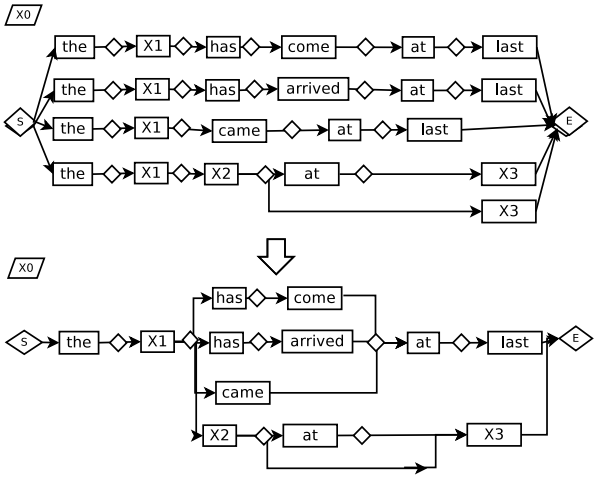

Figure 3: The lattice RHS(X0) optimized with the algorithm described in section 4

4 Representation optimisation

4.1 Goal

Given a description as a set of rule and scores $\mathcal{R}_T^1$ of $\mathcal{T}$, it is often possible to find another description $\mathcal{R}_T^2$ of $\mathcal{T}$ having the same formalism but a different set of rules. Although the $\mathcal{T}$ that is described remains the same, the same search algorithm applied to $\mathcal{R}_T^1$ or $\mathcal{R}_T^2$ might make approximations in a different way, be faster or use less memory.

It is an interesting question to try to transform an initial representation $\mathcal{R}_T^1$ into a representation $\mathcal{R}_T^2$ that will make the search step faster. This is especially interesting if one is going to search the same $\mathcal{T}$ several times, as is often done when one is fine-tuning the parameters of a model, as this representation optimisation needs only be done once.

The optimisation we propose is a natural fit to our framework of lattice rules. As lattice are a special case of Finite-State Automata (FSA), it is easy to adapt existing algorithms for FSA minimization. We describe a procedure in algorithm 1, which is essentially a simplification and adaptation to our case of the more general algorithm of (Hopcroft, 1971) for FSA. The central parts of the algorithm are the two sub-procedures *backward vertex merging* and *forward vertex merging*. An example of the result of an optimisation is given on figure 3.

Data: Representation $\mathcal{R}_T$
Result: Optimized Representation
1 **for** *non-terminal* $X \in \mathcal{R}_T$ **do**
2 | Apply backward vertex merging to $RHS(X)$;
3 | Apply forward vertex merging to $RHS(X)$;
4 **end**
Algorithm 1: Representation optimisation

4.2 Forward and backward merging

We describe the *forward vertex merging* in algorithm 2. This merging will merge vertices and suppress redundant edges, proceeding from left to right. The end result is a lattice with a reduced number of vertices and edges, but encoding the same paths as the initial one.

The basic idea here is to check the vertices from left to right and merge the ones that have identical incoming edges. After having been processed by the algorithm, a vertex is put in the set $\mathcal{P}$ (line 9). At each iteration, the candidate set $\mathcal{C}$ contains the set of vertices that can potentially be merged together. It is updated at each iteration to contain the set of not-yet-processed vertices for which all incoming edges come from processed vertices (done by marking edges at line 6 and then updating $\mathcal{C}$ at line 10). At each iteration, the merging process consists in:

1. Eliminating *duplicate* edges from the processed vertices to the candidate vertices (line 5). These duplicate edges could have been introduced by the merging of previously processed vertices.

2. Merging vertices whose set of incoming edges is *identical*. Here, merging two vertices v_1 and v_2 means that we create a third vertex v_3 such that incoming(v_3) = incoming(v_1) = incoming(v_2), and outgoing(v_3) = outgoing($v_3$1) $\bigcup$ outgoing(v_2), then remove v_1 and v_2.

The backward vertex merging is defined similarly to the forward merging, but with going right to left and inverting the role of the incoming and outgoing edges.

Data: Lattice RHS $\mathcal{L}$
Result: Optimized Lattice RHS
1 $\mathcal{P} \leftarrow \emptyset$ //processed vertices;
2 $\mathcal{C} \leftarrow \{v_S\}$ //candidate set ;
3 **while** $|\mathcal{C}| > 0$ **do**
4 | **for** $v \in \mathcal{C}$ **do**
5 | | Eliminate duplicate edges in incoming(v);
6 | | Mark edges in outgoing(v);
7 | **end**
8 | Merge all vertices $v_1, v_2 \in \mathcal{C}$ such that incoming(v_1) = incoming(v_2);
9 | $\mathcal{P} \leftarrow \mathcal{P} \bigcup \mathcal{C}$;
10 | $\mathcal{C} \leftarrow \{v \in \mathcal{L} \setminus \mathcal{P}$ s.t. all edges in incoming(v) are marked$\}$;
11 **end**
Algorithm 2: Forward Vertex Merging

4.3 Optimizing the whole representation

Algorithm 1 describe the global optimisation procedure. For each lattice RHS, we just perform first a backward merge and then a forward merge.

We have set the constraint in section 2.3 that each non-terminal should have only one lattice RHS. Note here that if there are several RHS for a given non-terminal, we can first merge them by merging their start vertex and end vertex, then apply this optimisation algorithm to obtain a representation with one optimised RHS per non-terminal.

This optimisation could be seen as doing some form of *hypothesis recombination*, but offline.

In term of *rule optimisations*, we only consider here transformations that do not modify the number of non-terminals. But it is worthwhile to note that there are some sequence appearing in the middle of some rules that cannot be merged through a lattice representation, but could be factored as sub-rules appearing in different non-terminals. Indeed, a lattice rule could actually be encoded as a set of "flat" rules by introducing a sufficient number of non-terminals, but this could possibly be less efficient from the search algorithm point of view. We plan to investigate the effects of this type of rule optimisations in conjunction with the described lattice-type opti-

misations in the future.

4.4 Handling of Edge Features

In the context of parameter tuning, we usually want the decoder to output not only the translations, but also a list of features characterizing the way the translation was constructed. Such features are, for example, the number of rules used, the language model of the translation, etc. In out context, some features will be dependent on the specific edges used in a rule. For example, the epsilon edge used to optionally skip non-aligned words (see section 3.2.1) is labeled with a feature "nb-words-skipped" set to 1, so that we can obtain the number of words skipped in a given translation and tune a score penalty for skipping such words. Similar features also exist for picking a word variation (section 3.2.3).

In the description of the merging process of section 4.2, one should thus be aware that two edges are to be considered identical only if both their associated word and their set of feature values are identical. This can sometimes prevent useful merging of states to take place. A solution to this could be to follow (de Gispert et al., 2010) and to discard all these features information during the decoding. The features values are then re-estimated afterward by aligning the translation and the input with a constrained version of the decoder.

We prefer to actually keep track of the features values, even if it can reduce the efficiency of vertex merging. In that setting, we can also adapt the so-called Weight Pushing algorithm (Mohri, 2004) to a multivalues case in order to improve the "mergeability" of vertices. The results of section 6.1 shows that it is still possible to strongly reduce the size of the lattices even when keeping track of the features values.

5 Decoding algorithm

In order to make an optimal use of these lattice-rule representations, we developed a decoding algorithm for translation candidate sets represented as a set of lattice-rules. For the most part, this algorithm re-use many of the techniques previously developed for decoding translation search spaces, but adapt them to our setting.

5.1 Overview

The outline of the decoding algorithm is described by algorithm 3. For simplicity, the description only compute the optimal model score over the translations in the candidate set. It is however trivial to adapt the description to keep track of which sentence correspond to this optimal score and output it instead of the score. Likewise, using the technique described in (Huang and Chiang, 2005), one can easily output k-best lists of translations. For simplicity again, we consider that a n-gram language model score is the only stateful non-local feature used for computing the model score, although in a tree-to-tree setting, other features (local in a tree representation but not in a string representation) could be used. The model score of a translation t has therefore the shape:

$$score(t) = \lambda \cdot lm(t) + \sum_{e} score(e)$$

where λ is the weight of the language model, $lm(t)$ is the language model log-probability of t and the sum is over all edges e crossed to obtain t.

5.2 Scored language model states

Conceptually, in a lattice $\mathcal{L}$, at each vertex v, we can consider the partial translations obtained by starting at v_S and concatenating the words labeling each edge not labeled by a non-terminal until v. If an edge is labeled by a non-terminal X, we first traverse the corresponding lattice $RHS(X)$ following the same process. Such a partial translation can be reduced compactly to a *scored language model state* (l, r, s), where l represent the first n words[1] of the partial translation, r its last n words and s its partial score. It is clear that if two partial translations have the same l and r parts but different score, we can discard the one with the lowest score, as it cannot be a part of the optimal translation.

Further, using the state reduction techniques described in (Li and Khudanpur, 2008) and (Heafield et al., 2011), we can often reduce the size of l and r to less than n, allowing further opportunities for discarding sub-optimal

[1] n being the order of the language mode

partial translations. For better behavior during the cube-pruning step of the algorithm (see later), the partial score s of a partial translation includes rest-costs estimates (Heafield et al., 2012).

We define the concatenation operation on scored language model states to be: $(l_1, r_1, s_1) \oplus (l_2, r_2, s_2) = (l_3, r_3, s_3)$, where $s_3 = s_1 + s_2 + \lambda lm(r_1, l_2)$, with $lm(r_1, l_2)$ being the language model probability of l_2 given r_1 with rest-costs adjustments. r_3 and l_3 are the resulting minimized states. Similarly, if an edge e is labeled by a word, we define the concatenation of a scored state with an edge to be $(l_1, r_1, s_1) \oplus e = (l_2, r_2, s_2)$ where $s_2 = s_1 + score(e) + \lambda lm(word(e)|r_1)$.

Conveniently for us, the KenLM[2] open-source library (Heafield, 2011) provides functionalities for easily computing such concatenation operations.

5.3 Algorithm

Having defined these operations, we can now more easily describe algorithm 3. Each vertex v has a list best[v] of the scored states of the best partial translations found to be ending at v. On line 1, we initialize best[v_S] with $(.,.,0)$, where "." represent an empty language model state. We then traverse the vertices of the lattice in topological order.

For each edge $e : v_1 \rightarrow v_2$, we compute new scored states for best[v_2] as follow:

- if e is labeled by a word or an epsilon, we create a state $st_2 = st_1 \oplus e$ for each st_1 in best[v_1] (line 10).
- if e is labeled by a non-terminal X, we recursively call the decoding algorithm on the lattice $RHS(X)$. The value returned by the line 15 will be a set of states corresponding to optimal partial translations traversing $RHS(X)$. We can concatenate these states with the ones in best[v_1] to obtain states corresponding to partial translations ending at v_2 (line 6).

Results of the calls decode(X) are memoized, as the same non-terminal is likely to appear in several edges of a RHS and in several RHS.

Lines 5 and 6 are the "cube-pruning-like" part of the algorithm. The function $prune_K$ returns the K best combinations of states in best[v] and decode($RHS(X)$), where best means "whose sum of partial score is highest". It can be implemented efficiently through the algorithms proposed in (Huang and Chiang, 2005) or (Chiang, 2007).

The $L \leftarrow_{max} st$ operation on lines 6 and 10 has the following meaning: L is a list of scored language model state and st is a scored language model state. $L \leftarrow_{max} st$ means that, if L already contains a state st_2 with same left and right state as st, L is updated to contain only the scored state with the maximum score. If L do not contain a state similar to st, st in simply inserted into L. This is the "hypothesis recombination" part of the algorithm. The function $trunc_{K'}$ truncate the list best[v] to its K' highest-scored elements.

The final result is obtained by calling decode(X_0), where X_0 is the "top-level" non-terminal. The result of decode(X_0) will contain only one scored state of the form (BOS, EOS, s), with s being the optimal score.

The search procedure of algorithm 3 could be described as "breadth-first", since we systematically visit each edge of the lattice. An alternative would be to use a "best-first" search with an A*-like procedure. We have tried this, but either because of optimisation issues or heuristics of insufficient qualities, we did not obtain better results than with the algorithm we describe here.

6 Evaluation

We now describe a set of experiments aimed at evaluating our approach.

We use the Japanese-English data from the NTCIR-10 Patent MT task[3] (Goto et al., 2013). The training data contains 3 millions parallel sentences for Japanese-English.

6.1 Effect of Lattice Representation and Optimisation

We first evaluate the impact of the lattice representation on the performances of our decoding algorithm. This will allow us to measure

15 **return** best$[v_E]$;

Algorithm 3: Lattice-rule decoding. See body for detailed explanations.

the benefits of our compact lattice representation of rules, as well as the benefits of the representation optimisation algorithm of section 4.

We use our Syntactic-dependency system to generate a lattice-rule representation of the possible translations of the 1800 sentences of the development set of the NTCIR-10 Patent MT task. We then produce two additional representations:

1. An optimized lattice-rule representation using the method described in section 4.

2. An expanded representation, that unfold the original lattice-rule representation into "flat rules" enumerating each path in the original lattice-rule representation (like the list $X0'$ enumerate the lattice $X0$ in figure 2).

Table 1 shows 3 columns. One for each of these 3 representations. We can see that, as expected, the performances in term of average search time or peak memory used are directly related to the number of vertices and edges in the representation. We can also see that our representation optimisation step is quite efficient, since it is able to divide by two the number of vertices in the representation, on average. This leads to a 2-fold speed improvement in the decoding step, as well as a large reduction of memory usage.

6.2 Decoding performances

In order to further evaluate the merit of our approach, we now compare the results obtained by using our decoder with lattice-rules with using a state-of-the-art decoder on the set of flat expanded rules equivalent to these lattice rules.

We use the decoder described in (Heafield et al., 2013), which is available under an open-source license[4] (henceforth called K-decoder). In this experience, we expanded the lattice rules generated by our MT system for 1800 sentences into files having the required format for the K-decoder. This basically mean we computed an equivalent of the expanded representation of section 6.1. This process generated files ranging in size from 20MB to 17GB depending on the sentence. We then ran the K-decoder on these files and compared the results with our own. We used a beam-width of 10000 for the K-decoder. Experiments were run in single thread mode. Partly to obtain more consistent results, and partly because the K-decoder was risking using too much memory for our system.

The results on table 3 show that, as the K-decoder do not have access to a more compact representation of the rules, it end up needing a much larger amount of memory for decoding the same sentences.

In term of model score obtained, the performances are quite similar, with the lattice-rule decoder providing slightly better model score.

It is interesting to note that, on "fair-ground" comparison, that is if our decoder do not have the benefit of a more compact lattice-rule representation, it actually perform quite worse as we can see by comparing with the third column of table 1 (at least in term of decoding time and memory usage, while it would still have a very slight edge in term of model score with the selected settings). On the other hand, the K-decoder is a rather strong baseline, shown to perform several times faster than a previous state-of-the-art implementation in (Heafield et al., 2013). It is well opti-

mized and makes use of advanced techniques with the language model (as the one described in (Heafield et al., 2013)) for which we do not have implemented an equivalent yet. Therefore, we are hopeful we can further improve our decoder in the future.

Also, note that, for practical reason, while we only measured the decoding time for our decoder [5], the K-decoder time include the time taken for loading the rule files.

6.3 Translation quality

Finally, we evaluate the advantages of extracting lattice rules such as proposed in section 3. That is, we consider rules for which null-aligned words are bypassable by epsilon-edges, for which Non-terminal are allowed to take several alternative positions around the word that is thought to be their governor, and for which we consider alternative morphologies of a few words ("is/are", "a/an"). We compare this approach with heuristically selecting only one possibility for each variation present in the lattice rule extracted from a single example.

Results shown on figure 2 show that we do obtain a significant improvement in translation quality. Note that the Moses score (Koehn et al., 2007), taken from the official results of NTCIR-10 is only here "for scale", as our MT system uses a quite different pipeline.

[5] in particular, we factored out the representation optimisation time, which is reasonable if we are in the setting of a parameter tuning step in which the same sentences are translated repeatedly

7 Related work

Searching for the most optimal translation in an implicitly defined set has been the focus of a lot of research in Machine Translation and it would be difficult to cover all of it. Among the most influential approaches, (Koehn et al., 2003) was using a form of stack based decoding for Phrase-Based Machine Translation. (Chiang, 2007) introduced the cube-pruning approach, which has been further improved in the previously mentioned (Heafield et al., 2013). (Rush and Collins, 2011) recently proposed an algorithm promising to find the optimal solution, but that is rather slow in practice.

Weighted Finite State Machines have seen a variety of use in NLP (Mohri, 1997). More specifically, some other previous work on Machine Translation have used lattices (or more generally Weighted Finite State Machines). In the context of Corpus-Based Machine Translation, (Knight and Al-Onaizan, 1998) was already proposing to use Weighted Transducers to decode the "IBM" models of translation (Brown et al., 1993). (Casacuberta and Vidal, 2004) and (Kumar et al., 2006) also propose to directly model the translation process with Finite State Transducers. (Graehl and Knight, 2004) propose to use Tree Transducers for modeling Syntactic Machine Translation. These approaches are however based on different paradigm, typically trying to directly learn a transducer rather than extracting SCFG-like rules.

Closer to our context, (de Gispert et al., 2010) propose to use Finite-State Transducers in the context of Hierarchical Phrase Based Translation. Their method is to iteratively construct and minimize the full "top-level lattice" representing the whole set of translations bottom-up. It is an approach more focused on the Finite State Machine aspect than our,

System	K-decoder	Lattice-rule decoder
Peak memory used	52G	**16G**
Average search time	3.47s	**3.31s**
Average model score	-107.55	**-107.39**
Nb wins	401	**579**

Table 3: Evaluation of the performances of our lattice-rule decoder compared with a state-of-the-art decoder using an expanded flat representation of the lattice rules. "Nb wins" is the number of times one of the decoder found a strictly better model score than the other one, out of 1800 search.

which is more of an hybrid approach that stays closer to the paradigm of cube-pruning. The merit of their approach is that they can apply minimization globally, allowing for more possibilities for vertex merging. On the other hand, for large grammars, the "top-level lattice" will be huge, creating the need to prune vertices during the construction. Furthermore, the composition of the "top-level lattice" with a language model will imply redundant computations (as lower-level lattices will potentially be expanded several times in the top-level lattice). As we do not construct the global lattice explicitly, we do not need to prune vertices (we only prune language model states). And each edge of each lattice rule is crossed only once during our decoding.

Very recently, (Heafield et al., 2014) also considered using the redundancy of translation hypotheses to optimize phrase-based stack decoding. To do so, they group the partial hypotheses in a trie structure.

We are not aware of other work proposing "lattice rules" as a native format for expressing translational equivalences. Work like (de Gispert et al., 2010) rely on SCFG rules created along the (Chiang, 2007) approach, while work like (Casacuberta and Vidal, 2004) adopt a pure Finite State Transducer paradigm (thus without explicit SCFG-like rules).

8 Conclusion

This work proposes to use a lattice-rule representation of the translation search space with two main goals:

- Easily represent the translation ambiguities that arise either due to lack of context or imperfect knowledge.
- Have a method for optimizing the representation of a search space to make this search more efficient.

We demonstrate that many types of ambiguities arising when extracting translation rules can easily be expressed in this framework, and that making these ambiguities explicit and solvable at compile time through lattice-rules leads to improvement in translation quality.

We also demonstrate that making a direct use of the lattice-rules representation allows a decoder to perform better than if working on the expanded set of corresponding "flat rules". And we propose an algorithm for computing more efficient representations of a translation candidate set.

We believe that the the link between the representation of a candidate set and the decoding efficiency is an interesting issue and we intend to explore further the possibilities of optimizing representations both in the contexts we considered in this paper and in others such as Phrase-Based Machine Translation.

The code of the decoder we implemented for this paper is to be released under a GPL license[6].

Abstract

When documents and queries are presented in different languages, the common approach is to translate the query into the document language. While there are a variety of query translation approaches, recent research suggests that combining multiple methods into a single "structured query" is the most effective. In this paper, we introduce a novel approach for producing a unique combination recipe for each query, as it has also been shown that the optimal combination weights differ substantially across queries and other task specifics. Our query-specific combination method generates statistically significant improvements over other combination strategies presented in the literature, such as uniform and task-specific weighting. An in-depth empirical analysis presents insights about the effect of data size, domain differences, labeling and tuning on the end performance of our approach.

1 Introduction

Cross-lingual information retrieval (CLIR) is a special case of information retrieval (IR) in which documents and queries are presented in different languages. In order to overcome the language barrier, the most commonly adopted method is to translate queries into the document language. Many methods have been introduced for translating queries for CLIR, ranging from word-by-word dictionary lookups (Xu and Weischedel, 2005; Darwish and Oard, 2003) to sophisticated use of machine translation (MT) systems (Magdy and Jones, 2011; Ma et al., 2012). Previous research has shown that combining evidence from different translation approaches is superior to any single query translation method (Braschler, 2004; Herbert et al., 2011). While there are numerous combination-of-evidence techniques for both mono-lingual and cross-lingual IR, recent work suggests that there is no one-size-fits-all solution. In fact, the optimal *combination weights* (i.e., weights assigned to each piece of evidence in a linear combination) differ greatly across queries, tasks, languages, and other variants (Ture et al., 2012; Berger and Savoy, 2007).

In this paper, we introduce a novel method for *learning optimal combination weights* when building a linear combination of existing query translation approaches. From standard query-document relevance judgments we train a set of classifiers, which produce a unique combination recipe for each query, based on a large set of features extracted from the query and collection. Experimental results show that the effectiveness of our method is significantly higher than state-of-the-art query translation methods and other combination strategies.

2 Related Work

The earliest approaches to query translation for CLIR used machine-readable bilingual dictionaries (Hull and Grefenstette, 1996; Ballesteros and Croft, 1996), achieving around up to 60% of monolingual IR effectiveness. Xu and Weischedel (2005) showed that effectiveness can be increased to around 80% by weighting each translation proportional to its rank in the dictionary. The practice of weighting translation candidates was later formulated as a "structured query", in which each query term is represented by a probability distribution over its translations in the document language (Pirkola, 1998; Kwok, 1999; Darwish and Oard, 2003). Our approach is based on the structured query formulation.

Some of the earliest studies in IR discovered that with different underlying models, the retrieved document set would vary substantially, al-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 589–599,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

though the effectiveness was similar (McGill et al., 1979). Later studies showed that combining different representations of the query and/or document often produced superior output (Rajashekar and Croft, 1995; Turtle and Croft, 1990; Fox, 1983). This intuitive idea was supported theoretically by Pearl (1988), concluding that multiple pieces of evidence estimates relevance more accurately, but that the benefit strongly depends on the *quality* and *independence* of each piece. Experiments by Belkin et al. (1995) indicated the need to properly weight each representation with respect to its effectiveness. These so-called "combination-of-evidence" techniques became more powerful with the introduction of `Indri`, a probabilistic retrieval framework specifically designed for combining multiple query and document representations (Metzler and Croft, 2005). Croft (2000) provides a detailed summary of earlier query combination approaches in IR, while Peters et al. (2012) cites more recent related work.

The benefits of combination-of-evidence transfer to the cross-lingual case especially well, since the inherent ambiguity of translation readily provides a diverse set of representations. Most CLIR approaches implement a post-retrieval *merging* of ranked lists, each generated from different query (Hiemstra et al., 2001; Savoy, 2001; Gey et al., 2001; Chen and Gey, 2004) or document (Lopez and Romary, 2009) representations, also called "data fusion". In contrast, we focus on a pre-retrieval combination at the modeling stage, so that a single complex query is used in retrieval, instead of multiple simpler ones. Two advantages of the former are easier implementation (since the approach requires no changes to the modeling side) and the possibly greater diversity that can be achieved by having separate retrieval runs. However, each ranked list needs to be limited in size, which might cause some potentially useful documents not to be considered in the combination at all. Since the focus of this paper is on the modeling end of retrieval, pre-retrieval combination was a more suitable choice, though we think that the two approaches have complementary benefits.

The idea of combining query translations before retrieval has been explored previously. Braschler (2004) combines three translation approaches: output of an MT system, a novel translation approach based on a similarity thesaurus built automatically from a comparable corpus, and a dictionary-based translation. The main reason that this combination does not provide much benefit is due to the lower coverage of the thesaurus-based and dictionary-based translation methods. A similar approach by Herbert et al. (2011) uses Wikipedia to provide translations of certain phrases and entities, and combining that with the `Google Translate` MT system yields statistically significant improvements in English-to-German retrieval. More recently, Ture et al. (2012) presented a more sophisticated translation approach using the internal representation of an MT system, and reported statistically significant improvements when a pre-retrieval combination was performed.

All of the previously cited approaches either use uniform weights for combination, or select weights based on collection-level information. However, as stated previously, numerous studies suggest that certain methods work better on certain queries, collections, languages. In fact, when weights are optimized separately on each collection, they differ substantially across different collections (Ture et al., 2012). For monolingual retrieval, there has been a series of learning-to-rank (LTR) papers that determine weights for query concepts (Bendersky et al., 2011), such that retrieval effectiveness is maximized. A recent study extends this idea to the cross-lingual case, by learning how to weight each *translated word* for English-Persian CLIR (Azarbonyad et al., 2013). In contrast, we extract translated word weights from diverse and sophisticated translation methods, then learn how to weight each *translated structured query*, We call this "learning-to-translate" (LTT), which can be formulated as a simpler learning problem. In CLIR, both LTR and LTT are under-explored problems, with a common goal of applying machine learning techniques to improve query translation, yet with complementary benefits.

To our knowledge, there has been one prior LTT approach: a classifier was trained to predict effectiveness of each query translation, using features based on statistics of the query terms (Berger and Savoy, 2007). Instead of weighting, the translations with highest classifier scores were concatenated, yielding statistically significant improvements over using the single-best translation method. However, the translation methods explored in this paper are all based on one-best MT

systems, making it difficult to draw strong conclusions.

3 Query Translation

The primary contribution of this paper is to show how a diverse set of query translation (QT) methods can be combined effectively into a single weighted structured query, with improved retrieval effectiveness. While our approach can applied to any set of translation methods, we focus on three methods that have complementary strengths and that have shown promise in CLIR: word-based probabilistic translation, one-best MT, and n-best probabilistic MT. We briefly present our implementation of each method; more details can be found in earlier work (Darwish and Oard, 2003; Ture et al., 2012).

Each QT method generates a representation of the query in the document language. In the case of word-based and n-best MT approaches, the representation is a structured query itself, where each query word is represented by a probability distribution over translation alternatives. For one-best MT, the query is represented by a bag of translated words.

3.1 One-Best MT

A query translation approach that has become more popular recently is to simply run the query through an MT system, and use the best output as the query:

$$t_1 t_2 \dots t_l = \mathbf{MT}(s_1 s_2 \dots s_k) \quad (1)$$

where $s = s_1 s_2 \dots s_k$ is the query and $t = t_1 t_2 \dots t_l$ is the translated query.

Since modern statistical MT systems generate high-quality translations for many language pairs, this one-best strategy works reasonably well for retrieval and provides a competitive baseline. A practical advantage of this approach is the ease of implementation – one can simply use any MT interface (e.g., `Google Translate`) as a black box in their CLIR system.

3.2 Probabilistic n-best MT

The top translation might sometimes be incorrect, or might lack some of the alternative representations that are very useful in retrieval. Therefore, considering the n highest scored translations (also referred to as the n-best list in MT literature) has become increasingly popular in CLIR approaches.

In order to benefit from the diversity amongst the n-best translations, one can simply concatenate them together, forming a large list of query terms. However, statistical MT systems also assign probabilities to each translation, which can be incorporated into the query representation for better effectiveness, as suggested by Ture et al. (2012).

In this approach, each of the top n translation candidates from the MT system are processed one by one. For each translation candidate, the MT system provides a translation probability, and alignments between words in the query and its translation. As we process each of the n translations, for each query word s_i, we accumulate probabilities on each translated word t_{ij} aligned to s_i. Finally, we normalize the translation probabilities to get $\mathbf{Pr}_{\text{nbest}}(t_{ij}|s_i)$.

3.3 Word-based

One of the most widely used approaches in CLIR is based on translating each query word s_i independently, with probabilities assigned to each translation candidate t_{ij}. Translations are derived automatically from a bilingual corpus using statistical word alignment techniques, which are used as part of the training of statistical MT systems (Brown et al., 1993). These probabilities can be exploited for retrieval based on the technique of Darwish and Oard (2003) for "projecting" text into the document language. After cleaning up the automatically learned translation probabilities (details omitted for space considerations), we end up with the translation probabilities $\mathbf{Pr}_{\text{word}}(t_{ij}|s_i)$.

4 Combination of Evidence

Once we have multiple ways to represent the query q in the document language ($\text{QT}_i(q), i = 1 \dots m$), it is possible to combine these "pieces of evidence" into a single representation as follows:

$$\text{QT}(q) = \sum_{i=1}^{m} w_i(q)\text{QT}_i(q)$$

and each combination-of-evidence approach differs by how the combination weights w_i are computed:

Uniform In this baseline method, we ignore any information we have about the collection or query and assign equal weights to each method (i.e., $w_i(q) = 1/m$). In our case, this means a weight

of 33.3% to each of the one-best, probabilistic n-best, and word-based QT methods.

Task-specific We can optimize the combination weights by overall effectiveness on a specific retrieval task. Given a query set and collection, we perform a grid search on combination weights (with a step interval of 0.1) and select the weights that maximize retrieval effectiveness. The training is performed in a leave-one-out manner: weights for test query q are optimized on all queries except for q.

Query-specific We propose a novel method to compute combination weights specifically for each query, resulting in a more customized optimization that can take into account how effectiveness of each translation method varies across queries.

In the remainder of this section, we describe the details of our novel query-specific combination method.

4.1 Overview of Query-Specific Combination

We present a novel approach for determining query-specific combination weights by training a classifier for each QT method. Prior to training the classifier, we first run retrieval using each QT method, and evaluate the effectiveness of the retrieved documents. The effectiveness of the i^{th} method on query q (i.e., $f_i(q)$) is then converted into a binary label (further described in Section 4.2). Treating each query as a separate instance, a classifier is trained for each method, generating classifiers $C_1, \ldots, C_m$. During retrieval (i.e., at test time), for each query q, each trained classifier C_i is applied to the query, resulting in a predicted label $l_i(q)$ and the classifier's confidence in a positive label, $C_i(q)$.[1] These values are then used to determine combination weights $w_1(q), \ldots, w_m(q)$ that are custom-fit for the query.

4.2 Labeling

First of all, we discard queries in which the difference between the best and worst performing methods is small (specifically, the worst performing method scores at least $k_1\%$ of the best performing one). For such queries, generating fair training labels is more difficult and therefore more likely to introduce noise into the process.[2] Moreover, these are exactly the queries where choosing optimal combination weights is less important (since all methods perform relatively similarly), so it is reasonable to exclude them from training. In fact, a high number of such queries would indicate lower potential for combination-of-evidence approaches.

For each QT method i, we create training instances per query, per retrieval task. Since our goal is to select the best among existing methods, the training label should reflect the effectiveness of method i relative to other methods. A strategy that we call *best-by-measure* assigns a label of 1 if the effectiveness of the i^{th} method (i.e., $f_i(q)$) is at least $k_2\%$ of the maximum effectiveness for that query, and 0 otherwise. While this directly correlates with retrieval effectiveness, labels might be distributed in an unbalanced manner, which might affect the training process negatively. A balanced labeling requires sorting all training instances by how much better the i^{th} method is than other methods ($\max_{i' \neq i}(f_{i'}(q)/f_i(q))$), and then assigning a label of 1 to the lower half and 0 to the higher half. This strategy is called *best-by-rank*.

4.3 Features

We introduce a diverse set of features, in order to train a robust classifier for predicting when each QT method performs better and worse than others. We split the feature set into four meaningful categories, so that we can measure the impact of each subset separately:

Surface features These features do not require a deep analysis of the query: (a) Number of words in query and the translated query, (b) Type of query that we automatically classify based on predefined templates (e.g., fact question, cause-effect, etc.), and (c) Number of stop words in the query and the translated query.

Parse-based features These features are extracted from a deeper syntactic analysis of the query text: (a) Number of related names found in a named entity database, and (b) Existence of syntactic constituents in query and its translation (e.g., "is there a VVB in the query parse tree").

[1] The confidence in a negative label is $1 - C_i(q)$.

[2] We also experimented with including these queries with a third label (e.g., "same") and train a ternary classifier. Having more labels requires more training data, which is not easy to obtain for this task. Also, obtaining a balanced label distribution becomes even more difficult with three labels.

Translation-based features These features consist of statistics computed from the query and its translation: (a) Number of query words that were unaligned in at least half of the n-best query translations, (b) Number of query words that were aligned to multiple target words in at least half of the n-best query translations, (c) Number of query words that were self-aligned (i.e., target word is exactly same string) in at least half of the n-best query translations, (d) Average / Standard deviation / Maximum / Minimum of entropy of $\mathbf{Pr}_{\text{nbest}}$ of each query word, and (e) Average / Standard deviation / Maximum / Minimum of entropy of $\mathbf{Pr}_{\text{word}}$ of each query word.

Index-based features These features are based on frequency statistics from a representative collection:[3] (a) Average / Standard deviation / Maximum / Minimum of document frequency (df) of query words and their translations, (b) Average / Standard deviation / Maximum / Minimum of term frequency averaged across query words and their translations, and (c) Sum / Maximum / Minimum of total probability assigned to words that do not appear in the collection (df $= 0$).

Additionally, the target language is a default feature in all of our experiments. For each classification task, we train a separate classifier on each subset of these four feature categories, so that there are 16 different sets (including the empty set). After we select which categories to pull features from, we optionally perform feature selection to reduce the number of features by a predefined percentage.

In our experimentation, we observed that collection-based features were most useful for classifying the one-best method, whereas parse-based features were most discriminative for probabilistic 10-best. For the word-based QT method, the translation-based features were most effective in our experiments. We further analyze the effect of various features in Section 5.

4.4 Training and Tuning Classifiers

The `scikit-learn` package was used for the training pipeline (Pedregosa et al., 2012). Using an established toolkit allowed us to experiment with many options for classification, such as the learner type (support vector machine, maximum entropy, decision tree), feature set (16 subsets of the four categories described earlier) and two feature selection methods (recursive elimination or selection based on univariate statistical tests). In the end, we get 96 different parameter combinations while training a classifier for a particular QT method, resulting in the need for tuning — picking the parameters that produce highest accuracy on a representative *tuning set*.

Given that we have a set of queries for testing purposes, there are few strategies for selecting a training and tuning set. One approach is to apply a leave-one-out strategy, so that a classifier is trained and tuned on all but one of the test queries, and then applied on the remaining query to predict its label. We call this the *fully-open* setting.

In a more realistic scenario, there will not be relevance judgments for the test queries, yet there might be a small amount of labeled data similar to the test task (e.g., different queries on same collection) that can be utilized for tuning purposes, and a larger set of training queries from different collections. We call this the *half-blind* setting.

If testing in a new domain, queries of similar type are not available for training and tuning purposes. This is a more challenging scenario than the previous two, yet it is important for real-world applications. In order to demonstrate the effectiveness of the training pipeline in this case, we hold out test queries entirely, then train and tune on queries from a completely different task (i.e., different queries *and* collection). We call this the *fully-blind* setting.

4.5 Retrieval

Once we have classifiers trained for all QT methods, we can apply them to a given query on-the-fly, and compute query-specific combination weights. One approach is *hard weighting*, putting all weight onto a single method — when there are more than one methods classified with label 1, we can either pick one randomly or use the classifier confidence value as a tie-breaker. An alternative is *soft weighting*, where the weight of the i^{th} method can be computed either using classifier confidence C_i (i.e., how confident the model is that the i^{th} method will perform well), precision on tuning set precision_i (i.e., how precise the model is at its pre-

[3] We used the BOLT collection in our experiments.

dictions for the i^{th} method), or both:

$$\begin{aligned} w_i^{s1}(q) =& C_i(q) \\ w_i^{s2}(q) =& \text{precision}_i(1) \times l_i(q) \\ &+(1-\text{precision}_i(0)) \times (1 - l_i(q)) \\ w_i^{s3}(q) =& \text{precision}_i(1) \times C_i(q) \\ &+(1-\text{precision}_i(0)) \times (1 - C_i(q)) \end{aligned}$$

The intuition behind all of these weighting schemes is to produce a weight for each QT method, by taking into account the confidence of the classifier, and/or the precision of the classifier on tuning instances.

The computed weights are normalized before constructing the final query for retrieval:

$$w_i^{\text{final}}(q) = w_i(q) / \textstyle\sum_{j=1}^{m} w_j(q)$$

When compared empirically, we noticed that soft weighting is more effective than hard weighting, as the latter is more sensitive to classifier errors. Among the three soft weighting functions, differences were mostly negligible in our experiments. Hence, we decided to use the simplest weighting function w^{s1}.

4.6 Analytical Model

It is time-consuming to implement various combination-of-evidence approaches and run retrieval experiments. Therefore, it is useful to have an analytical model of the process that can provide a rough estimate of how fruitful it would be to spend this effort, given certain details about the task. The model we present in this section estimates the effectiveness of combining QT methods $1 \ldots m$ on a query set Q, given (1) the effectiveness of each method on Q and (2) error rate of binary classifiers $C_1 \ldots C_m$ on Q. Using this formulation, one can assess the benefit of combination without running retrieval, based only on error rates — this saves precious time during development. Moreover, even without trained classifiers, this model can be used to estimate potential benefits by plugging in *hypothetical* error values. In other words, one can ask the question "If I had classifiers with x% error on this query set, what would be the benefit of using these classifiers to combine QT methods?" before developing any combination approach at all.

The analytical model considers a special case of weighted combination: for each query q, we pick a single QT method $i = 1 \ldots m$, for which the classifier predicts a label of 1. If there are more than one such method, one of them is picked randomly. This simplified version allows us to compute expected effectiveness for q as follows:

$$E[f(q)] = \sum_{\text{method } i} \mathbf{Pr}(\text{pick } i|q) f_i(q)$$

While $f_i(q)$ is an observed value (the effectiveness of the i^{th} method on query q), $\mathbf{Pr}(\text{pick } i|q)$ needs to be estimated (the probability of selecting the i^{th} method). Since this depends on the predicted labels, we consider all possible scenarios $l = l_1 l_2 \ldots l_m$, where each value is the prediction of a classifier. For instance, "l=010" means that classifiers C_1 and C_3 predicted a label of 0, while C_2 predicted a positive label. Marginalizing over the 2^m possible scenarios gives us the following estimate:

$$\begin{aligned} &\mathbf{Pr}(\text{pick } i|q) \\ &= \left(\sum_{l_1=0}^{1} \ldots \sum_{l_m=0}^{1} \mathbf{Pr}(l|q) \right) \times \mathbf{Pr}(\text{pick } i|l, q) \\ &= \left(\sum_{l_1=0}^{1} \ldots \sum_{l_m=0}^{1} \prod_{i=1}^{m} \mathbf{Pr}(l_i|q) \right) \times \mathbf{Pr}(i|l, q) \end{aligned}$$

In the final step, we assumed that classifiers make predictions independent of each other, which is a desired property for successful combination. $\mathbf{Pr}(l_i|q)$ can be estimated using classifier error statistics:

$$\mathbf{Pr}(l_i|q) \sim \frac{\text{count}(\text{predicted} = l_i, \text{true} = l_q)}{\text{count}(\text{true} = l_q)}$$

where l_q is the true label of q. If $l_i = l_q$, this expression becomes the true positive or true negative rate, depending on the value. Similarly, if $l_i \neq l_q$, it is either the false positive or false negative rate.

Finally, the probability that the i^{th} method is selected in a particular scenario depends solely on the predicted labels, since it is a random selection: $\mathbf{Pr}(\text{pick } i|l) = l_i / \sum_{j=1}^{m} l_j$

This concludes the derivation of the analytical model of query evidence combination, which we use in Section 5.1 to evaluate the effectiveness of labeling approaches.

5 Evaluation

We evaluated our approach on four different CLIR tasks: TREC 2002 English-Arabic CLIR, NTCIR-8 English-Chinese Advanced Cross-Lingual Infor-

mation Access (ACLIA), and two forum post retrieval tasks as part of the DARPA Broad Operational Language Technologies (BOLT) program: English-Arabic (BOLT_{ar}) and English-Chinese (BOLT_{ch}). The query language is English in all cases, and we preprocess the queries using BBN's information extraction toolkit SERIF (Ramshaw et al., 2011). State-of-the-art English-Arabic (En-Ar) and English-Chinese (En-Ch) MT systems were trained on parallel corpora released in NIST OpenMT 2012, in addition to parallel forum data collected as part of the BOLT program (10m En-Ar words; 30m En-Ch words). From these data, word alignments were learned with GIZA++ (Och and Ney, 2003), using five iterations of each of IBM Models 1–4 and HMM.

3-gram Chinese and 5-gram Arabic Kneser-Ney language models were trained from the Gigaword corpus (1b words each) and non-English side of the training corpus. Chinese and English parallel text were preprocessed through the Treebank Tokenizer,[4] while no special treatment was performed on Arabic.

For retrieval, we used `Indri`, a state-of-the-art probabilistic relevance model that supports weighted query representations through operators `#combine` and `#weight` (Metzler and Croft, 2005). A character-based index was built for Chinese collections, whereas Arabic text was stemmed using `Lucene` before indexing.[5] English text was preprocessed by `Indri`'s implementation of the Porter stemmer (Porter, 1997). Statistics for each collection and query set are summarized in Table 1.

Before performing any combination, we first ran the three baseline QT methods individually and evaluated the retrieved documents. Mean average precision (MAP) was used to measure retrieval effectiveness, which is a widely used and stable metric, estimating the area under the precision-recall curve. We set $n = 10$ for the n-best probabilistic translation method. Baseline scores are reported in Table 2. The average precision (AP) of each query in these tasks was used to label the query and construct training data accordingly.

In subsequent sections, we evaluate the effect of several variants in the training pipeline.

[5] `http://lucene.apache.org`

5.1 Effect of Labeling

In Section 4.2, we introduced two ways to label instances. In our evaluation, we set the free parameters $k_1 = k_2 = 90$, which filters out 33% of queries from the training set of the BOLT_{ar} task; this percentage is 29% in BOLT_{ch}, 44% in TREC, and 27% in NTCIR.

Labeling determines which query translation method is considered effective or not, which consequently determines what the "learning problem" is (since the objective of the classifier is to separate differently labeled instances). As a result, there are two dimensions to consider when comparing labeling strategies. One is the accuracy of the classifiers on held-out data, and the other is how well the trained classifier reflects this accuracy when used in retrieval. To clarify the distinction, consider a case where every instance is labeled 1. This generates a trivial learning problem with no test errors, yet this does not entail that using these classifiers in retrieval will be more effective than other labeling strategies. If, even with high classifier accuracy, the retrieval effectiveness is low, that indicates a bad choice for labeling.

We can *theoretically analyze* how suitable each labeling method is by applying the analytical model to each CLIR task, setting parameters based on a perfect classifier: true positive/negative rate of 1 and false positive/negative rate of 0 (see Section 4.6). Table 2 shows these results in the "Perfect" column, since these scores represent what *could be* achieved if classifiers were trained to predict labels *perfectly* (no training or retrieval is actually performed). There are two values in each row of the "Perfect" column, one for each labeling strategy. In each row, we found these two values to be statistically significantly higher than any of the baseline scores. This shows that both labeling approaches have the *potential* to improve effectiveness significantly.

We also made an empirical comparison of the two labeling approaches by actually training classifiers with each labeling, and then using the classifiers to combine query translations in retrieval. The "Trained" column in Table 2 shows the MAP we get on each CLIR task (and average classifier accuracies), using either labeling.[6]

Based on these results, we conclude that best-

[6] For a fair comparison, we fixed the train-tune setting to fully-open, trained classifiers on the test collection and reported leave-one-out accuracies.

Lang	Collection		Topics	MT Training data	
	Source	Size (docs)		Source (domain)	Size (words)
Arabic	TREC-02	383,872	50	OpenMT-12 (news/web) BOLT (forum)	10m
Arabic	BOLT	12,258,904	45		
Chinese	NTCIR-8	388,589	100	OpenMT-12 (news/web) BOLT (forum)	30m
Chinese	BOLT	6,693,951	45		

Table 1: Summary of the CLIR tasks in our evaluations.

Task	Baseline			Perfect		Trained	
	one-best	ten-best	word	measure	rank	measure	rank
BOLT_{ar}	0.296	0.311	0.318	*0.341*	*0.341*	0.342 (74)	0.330 (72)
BOLT_{ch}	0.370	0.406	0.407	*0.458*	*0.462*	0.438 (68)	0.426 (60)
TREC	0.292	0.298	0.301	*0.327*	*0.330*	0.305 (59)	0.316 (59)
NTCIR	0.146	0.152	0.141	*0.180*	*0.177*	0.163 (56)	0.162 (61)

Table 2: Retrieval effectiveness of baseline QT methods is presented on the left side, and a comparison of labeling strategies is provided on the right side. All numbers represent MAP values, except for classifier accuracy shown in percentage values (in parantheses). Analytically computed values are shown in italics.

by-measure labeling is more useful in practice, supported by typically higher accuracy and effectiveness. Best-by-rank yields better results only on TREC, but a closer look reveals that the increase in MAP is due to only two outlier queries. For BOLT_{ar}, on the other hand, retrieval with best-by-measure labeling is more effective (statistically significant) than best-by-rank; hence, the former is used in remaining parts of our evaluation.

5.2 Effect of Train-Tune Setting

In Section 4.4, we introduced three major train-tune settings: fully-open, half-blind, and fully-blind. In order to implement these settings, we treat each of the three query sets (BOLT, TREC, NTCIR) as a separate training dataset and experiment with a variety of combinations.

For simplicity, let us demonstrate the variety of experiments assuming the test collection is BOLT. For the fully-open case, the default training data is all of the BOLT queries (this training set is referred to as *b*). Additionally, one can include queries from TREC (referred to as *t*) and NTCIR (referred to as *n*) into the training data. This gives us four different training datasets for the fully-open case: b, $b + n$, $b + t$, $b + t + n$. Similarly, each of the half-blind and fully-blind settings can be applied to three different training sets: For BOLT, these are t, n, $t + n$.[7] This results in ten different experiments run for each task — in each experiment, we train a classifier for each QT method, select the best meta-parameters on the tuning set, and then compute combination weights for retrieval using the classifiers.

Each cell on the left side of Table 3 (under column "Query-specific Combination") shows the results of the most effective experiment for a particular task and train-tune setting. Accuracy values for classifiers varied widely across these experiments. Still, even when accuracies dropped close to or below 50% (i.e. random baseline), combined retrieval was always more effective than any single QT approach, which emphasizes the robustness of our approach. For instance, in the fully-blind setting for the NTCIR task, the individual classifiers had accuracies of only 56%, 49%, and 44% but MAP was 0.163, which is higher than the MAP of any individual method for that collection (0.146, 0.152, or 0.141).

Another key observation in Table 3 is that the domain effect (i.e., training and/or tuning on queries similar to test queries) is only noticeable on the two BOLT tasks. For NTCIR and TREC, we do not observe a boost in MAP when queries from the same task are included in training (i.e., fully-open setting). This can be explained by the BOLT-centric nature of our system components: the text analysis tool and MT systems are tuned mainly for forum data, and the collection-based features are extracted from BOLT. Due to this bias, BOLT queries were most useful in our experiments, supported by the fact that BOLT is always

[7] In the case of half-blind, b is split into two: 20% is used for tuning and the remainder is used for testing.

Task	Query-specific Combination						Uniform	Task-specific	Max
	fully-open		half-blind		fully-blind				
$BOLT_{ar}$	**0.342***†	b	0.330	t+n	0.329	t+n	0.324^{12}	0.329^{1}	0.346
$BOLT_{ch}$	**0.438***†	b	0.428	n	0.426	t+n	0.422^{1}	0.431^{1}	0.466
TREC	0.321	b+t	**0.324***†	b+n	0.321	b+n	0.314^{1}	0.318^{1}	0.332
NTCIR	**0.164***	b+n	0.163	b+t	0.163	b	0.162^{13}	0.162^{13}	0.182

Table 3: A comparison of query combination approaches. For query-specific combination, MAP and training data are shown for the most effective experiment of each train-tune setting. For each task, the highest MAP achieved with our approach is shown in bold. Superscripts 1, 2, and 3 indicate statistically significant improvements over baseline methods one-best, probabilistic 10-best, and word-based, whereas * indicates improvements over all three. Superscript † indicates results significantly better than uniform and task-specific combination methods.

included in the train set when testing on TREC or NTCIR (see lowest two rows in Table 3). Also, when there is no domain effect (i.e., half-blind and fully-blind), more data yields higher effectiveness in 6 out of 8 cases (see two right columns on the left side of Table 3).

5.3 Retrieval Effectiveness

In this section, we compare our novel query-specific combination-of-evidence approach to the baseline CLIR approaches, as well as comparable combination methods (uniform and task-specific combination) in terms of retrieval effectiveness. Based on a randomized significance test (Smucker et al., 2007), the best query-specific combination method (shown in boldface in Table 3) outperforms all baseline QT methods in all tasks with 95% confidence (indicated by superscript * in Table 3). This is not the case for uniform or task-specific query combination, which are statistically indistinguishable from at least one of the QT methods, depending on the task (indicated by superscripts 1, 2, and 3 for one-best, probabilistic 10-best, and word-based QT methods, respectively). When we directly compare our query-specific combination approach to other combination methods, the differences are statistically significant for all tasks but NTCIR (indicated by superscript †).

For reference, we also computed effectiveness for a hypothetical system (denoted by "Max" in Table 3) that could select the best QT method for each query and use only that for retrieval. This is not a strict upper bound, since correctly weighting each method can produce better results, but it is still a reasonable target for effectiveness. In our experiments, Arabic retrieval runs were very close to this target with our combination approach, while the gap for Chinese is still substantial, which is worth further exploration.

6 Conclusions and Future Work

In this paper, we introduced a novel combination-of-evidence approach for CLIR, which *learns a custom combination recipe* for each query. We formulate this as a set of binary classification problems, and show that trained classifiers can be used to produce query-specific combination weights effectively. Our deep exploration of many variants (e.g., labeling, training-tuning, weight computation, analytical formulation) and extensive empirical analysis on four different tasks provide insights for future research on the under-studied problem of combining translations for CLIR.

Our approach advances the state of the art of CLIR, yielding higher effectiveness than three advanced query translation approaches, all based on state-of-the-art MT systems. Furthermore, on three of the four tasks, our combination strategy is statistically significantly better than two comparable combination techniques. Experimental results also suggest that even a uniform combination of query translations is consistently better than any individual method. While it is known that combining translations helps CLIR, we confirm this on a set of modern CLIR tasks, including two target languages and a variety of text domains.

Having a simple linear learning problem allows us to train robust models with relatively simpler features. Nevertheless, we are interested in experimenting with more sophisticated learning approaches. In terms of non-linear classifiers, our experience with decision trees in this paper indicated a higher tendency to overfit. In terms of

combining queries in a non-linear fashion, our future plans include integrating our approach into a LTR framework, and directly optimize MAP. This will also allow us to explore more complex features extracted from query *and* document text, as well as external sources.

Another possible future endeavor is to extend these ideas to (i) other query translation approaches and (ii) document translation. While the exact same problem can be formulated for learning to translate documents effectively, a more complicated infrastructure and longer running times are two challenges that need to be considered.

Finally, we hope this to be a significant step towards more context-dependent and robust CLIR models, by taking advantage of modern translation technologies, as well as machine learning techniques.

Abstract

A major challenge in document clustering research arises from the growing amount of text data written in different languages. Previous approaches depend on language-specific solutions (e.g., bilingual dictionaries, sequential machine translation) to evaluate document similarities, and the required transformations may alter the original document semantics. To cope with this issue we propose a new document clustering approach for multilingual corpora that (i) exploits a large-scale multilingual knowledge base, (ii) takes advantage of the multi-topic nature of the text documents, and (iii) employs a tensor-based model to deal with high dimensionality and sparseness. Results have shown the significance of our approach and its better performance w.r.t. classic document clustering approaches, in both a balanced and an unbalanced corpus evaluation.

1 Introduction

Document clustering research was initially focused on the development of general purpose strategies to group unstructured text data. Recent studies have started developing new methodologies and algorithms that take into account both linguistic and topical characteristics, where the former include the size of the text and the type of language, and the latter focus on the communicative function and targets of the documents.

A major challenge in document clustering research arises from the growing amount of text data that are written in different languages, also due to the increased popularity of a number of tools for collaboratively editing through contributors across the world. *Multilingual document clustering* (MDC) aims to detect clusters in a collection of texts written in different languages. This can aid a variety of applications in cross-lingual information retrieval, including statistical machine translation and corpora alignment.

Existing approaches to MDC can be divided in two broad categories, depending on whether a parallel corpus rather than a comparable corpus is used (Kumar et al., 2011c). A *parallel corpus* is typically comprised of documents with their related translations (Kim et al., 2010). These translations are usually obtained through machine translation techniques based on a selected anchor language. Conversely, a *comparable corpus* is a collection of multilingual documents written over the same set of classes (Ni et al., 2011; Yogatama and Tanaka-Ishii, 2009) without any restriction about translation or perfect correspondence between documents. To mine this kind of corpus, external knowledge is employed to map concepts or terms from a language to another (Kumar et al., 2011c; Kumar et al., 2011a), which enables the extraction of cross-lingual document correlations. In this case, a major issue lies in the definition of a cross-lingual similarity measure that can fit the extracted cross-lingual correlations. Also, from a semi-supervised perspective, other works attempt to define must-link constraints to detect cross-lingual clusters (Yogatama and Tanaka-Ishii, 2009). This implies that, for each different dataset, the set of constraints needs to be redefined; in general, the final results can be negatively affected by the quantity and the quality of involved constraints (Davidson et al., 2006).

To the best of our knowledge, existing clustering approaches for comparable corpora are customized for a small set (two or three) of languages (Montalvo et al., 2007). Most of them are not generalizable to many languages as they employ bilingual dictionaries and the translation is performed sequentially considering only pairs of languages. Therefore, the order in which this process is done can seriously impact the results. Another common drawback concerns the way most of the recent approaches perform their analysis: the various languages are analyzed independently of each other (possibly by exploiting external knowledge like Wikipedia to enrich documents (Kumar et al., 2011c; Kumar et al., 2011a)), and then the language-specific results are merged. This two-step analysis however may fail in profitably exploiting cross-language information from the multilingual corpus.

Contributions. We address the problem of MDC by proposing a framework that features three key elements, namely: (1) to model documents over a unified conceptual space, with the support of a large-scale multilingual knowledge base; (2) to decompose the multilingual documents into topically-cohesive segments; and (3) to describe the multilingual corpus under a multi-dimensional data structure.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 600–609,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

The first key element prevents loss of information due to the translation of documents from different languages to a target one. It enables a conceptual representation of the documents in a language-independent way preserving the content semantics. BabelNet (Navigli and Ponzetto, 2012a) is used as multilingual knowledge base. To the extent of our knowledge, this is the first work in MDC that exploits BabelNet.

The second key element, document segmentation, enables us to simplify the document representation according to their multi-topic nature. Previous research has demonstrated that a segment-based approach can significantly improve document clustering performance (Tagarelli and Karypis, 2013). Moreover, the conceptual representation of the document segments enables the grouping of linguistically different (portions of) documents into topically coherent clusters.

The latter aspect is leveraged by the third key element of our proposal, which relies on a tensor-based model (Kolda and Bader, 2009) to effectively handle the high dimensionality and sparseness in text. Tensors are considered as a multi-linear generalization of matrix factorizations, since all dimensions or modes are retained thanks to multi-linear structures which can produce meaningful components. The applicability of tensor analysis has recently attracted growing attention in information retrieval and data mining, including document clustering (e.g., (Liu et al., 2011; Romeo et al., 2013)) and cross-lingual information retrieval (e.g., (Chew et al., 2007)).

The rest of the paper is organized as follows. Section 2 provides an overview of BabelNet and basic notions on tensors. We describe our proposal in Section 3. Data and experimental settings are described in Section 4, while results are presented in Section 5. We summarize our main findings in Section 6, finally Section 7 concludes the paper.

2 Background

2.1 BabelNet

BabelNet (Navigli and Ponzetto, 2012a) is a multilingual semantic network obtained by linking Wikipedia with WordNet, that is, the largest multilingual Web encyclopedia and the most popular computational lexicon. The linking of the two knowledge bases was performed through an automatic mapping of WordNet synsets and Wikipages, harvesting multilingual lexicalization of the available concepts through human-generated translations provided by the Wikipedia interlanguage links or through machine translation techniques. The result is an encyclopedic dictionary containing concepts and named entities lexicalized in 50 different languages.

Multilingual knowledge in BabelNet is represented as a labeled directed graph in which nodes are concepts or named entities and edges connect pairs of nodes through a semantic relation. Each edge is labeled with a relation type (is-a, part-of, etc.), while each node corresponds to a *BabelNet synset*, i.e., a set of lexicalizations of a concept in different languages.

BabelNet can be accessed and easily integrated into applications by means of a Java API provided by the toolkit described in (Navigli and Ponzetto, 2012b). The toolkit also provides functionalities for *graph-based WSD in a multilingual context*. Given an input set of words, a semantic graph is built by looking for related synset paths and by merging all them in a unique graph. Once the semantic graph is built, the graph nodes can be scored with a variety of algorithms. Finally, this graph with scored nodes is used to rank the input word senses by a graph-based approach.

2.2 Tensor model representation

A tensor is a multi-dimensional array $\boldsymbol{\mathcal{T}} \in \Re^{I_1 \times I_2 \times \cdots \times I_M}$. The number of dimensions M, also known as *ways* or *modes*, is called *order* of the tensor, so that a tensor with order M is also said a M-way or M-order tensor. A *higher-order* tensor (i.e., a tensor with order three or higher) is denoted by boldface calligraphic letters, e.g., $\boldsymbol{\mathcal{T}}$; a matrix (2-way tensor) is denoted by boldface capital letters, e.g., $\mathbf{U}$; a vector (1-way tensor) is denoted by boldface lowercase letters, e.g., $\mathbf{v}$. The generic entry (i_1, i_2, i_3) of a third-order tensor $\boldsymbol{\mathcal{T}}$ is denoted by $t_{i_1 i_2 i_3}$, with $i_1 \in [1..I_1], i_2 \in [1..I_2], i_3 \in [1..I_3]$.

A one-dimensional fragment of tensor, defined by varying one index and keeping the others fixed, is a 1-way tensor called *fiber*. A third-order tensor has column, row and tube fibers. Analogously, a two-dimensional fragment of tensor, defined by varying two indices and keeping the rest fixed, is a 2-way tensor called *slice*. A third-order tensor has horizontal, lateral and frontal slices.

The *mode-m matricization* of a tensor $\boldsymbol{\mathcal{T}}$, denoted by $\mathbf{T}_{(\mathrm{m})}$, is obtained by arranging the mode-m fibers as columns of a matrix. A third-order tensor $\boldsymbol{\mathcal{T}} \in \Re^{I_1 \times I_2 \times I_3}$ is *all-orthogonal* if $\sum_{i_1 i_2} t_{i_1 i_2 \alpha} t_{i_1 i_2 \beta} = \sum_{i_1 i_3} t_{i_1 \alpha i_3} t_{i_1 \beta i_3} = \sum_{i_2 i_3} t_{\alpha i_2 i_3} t_{\beta i_2 i_3} = 0$ whenever $\alpha \neq \beta$. The *mode-m product* of a tensor $\boldsymbol{\mathcal{T}} \in \Re^{I_1 \times I_2 \times \cdots \times I_M}$ with a matrix $\mathbf{U} \in \Re^{J \times I_m}$, denoted by $\boldsymbol{\mathcal{T}} \times_m \mathbf{U}$, is a tensor of dimension $I_1 \times \ldots I_{m-1} \times J \times I_{m+1} \times \cdots \times I_M$ and can be expressed in terms of matrix product as $\boldsymbol{\mathcal{Y}} = \boldsymbol{\mathcal{T}} \times_m \mathbf{U}$, whose mode-$m$ matricization is $\mathbf{Y}_{(\mathrm{m})} = \mathbf{U}\mathbf{T}_{(\mathrm{m})}$.

3 Our Proposal

3.1 Multilingual Document Clustering framework

We are given a collection of multilingual documents $\mathcal{D} = \bigcup_{l=1}^{L} \mathcal{D}_l$, where each $\mathcal{D}_l = \{d_{l_i}\}_{i=1}^{N_l}$ represents a subset of documents written in the same language, with $N = \sum_{l=1}^{L} N_l = |\mathcal{D}|$. Our framework can be applied to any multilingual document collection regardless of the languages, and can deal with balanced as well as

Algorithm 1 *SeMDocT* (**Se**gment-based **M**ultiLingual **Doc**ument Clustering via **T**ensor Modeling)

Input: A collection of multilingual documents $\mathcal{D}$, the number k of segment clusters, the number of tensorial components r.
Output: A document clustering solution $\mathcal{C}$ over $\mathcal{D}$.

1: Apply a text segmentation algorithm over each of the documents in $\mathcal{D}$ to produce a collection of document segments $\mathcal{S}$. */* Section 3.1.1 */*
2: Represent $\mathcal{S}$ in either a bag-of-words (BoW) or a bag-of-synsets (BoS) space. */* Section 3.1.2 */*
3: Apply any document clustering algorithm on $\mathcal{S}$ to obtain a segment clustering $\mathcal{C}^{\mathcal{S}} = \{C_i^s\}_{i=1}^k$. */* Section 3.1.2 */*
4: Represent $\mathcal{C}^{\mathcal{S}}$ in either a bag-of-words (BoW) or a bag-of-synsets (BoS) space. */* Section 3.1.3 */*
5: Model $\mathcal{S}$ as a third-order tensor $\boldsymbol{\mathcal{T}} \in \Re^{I_1 \times I_2 \times I_3}$, with $I_1 = |\mathcal{D}|$, $I_2 = |\mathcal{F}|$, and $I_3 = k$. */* Section 3.1.4 */*
6: Decompose the tensor using a Truncated HOSVD. */* Section 3.1.4 */*
7: Apply a document clustering algorithm on the mode-1 factor matrix to obtain the final clusters of documents $\mathcal{C} = \{C_i\}_{i=1}^K$. */* Section 3.1.5 */*

unbalanced corpora. Therefore, no restriction is given on both the number L of languages and the distribution of documents over the languages (i.e., $N_i \lesseqgtr N_j$, with $i, j = 1..L, i \neq j$).

Real-world documents often span multiple topics. We assume that each document in $\mathcal{D}$ is relatively long to be comprised of smaller textual units, or *segments*, each of which can be considered cohesive w.r.t. a topic over the document. This represents a key aspect in our framework as it enables the use of a *tensor model* to conveniently address the multi-faceted nature of the documents.

Our overall framework, named *SeMDocT* (**Se**gment-based **M**ultiLingual **Doc**ument Clustering via **T**ensor Modeling), is shown in Algorithm 1. In the following, we shall describe in details each of the steps involved in *SeMDocT*.

3.1.1 Computing within-document segments

Text segmentation is concerned with the fragmentation of an input text into multi-paragraph, contiguous and disjoint blocks that represent subtopics. Regardless of the presence of logical structure clues in the document, linguistic criteria (Beeferman et al., 1999) and statistical similarity measures (Hearst, 1997; Choi et al., 2001; Cristianini et al., 2001) have been mainly used to detect subtopic boundaries between segments. A common assumption is that terms that discuss a subtopic tend to co-occur locally, and a switch to a new subtopic is detected by the ending of co-occurrence of a given set of terms and the beginning of the co-occurrence of another set of terms.

Our *SeMDocT* does not depend on a specific algorithmic choice to perform text segmentation; in this work, we refer to the classic *TextTiling* (Hearst, 1997), which is the exemplary similarity-block-based method for text segmentation.

3.1.2 Inducing document segment clusters

The result of the previous step is a collection of document segments, henceforth denoted as $\mathcal{S}$. Each segment in $\mathcal{S}$ is represented as a vector of feature occurrences, where a feature can be either *lexical* or *semantic*. This corresponds to two alternative representation models: the standard *bag-of-words* (henceforth *BoW*), whereby features correspond to lemmatized, non-stopword terms, and the obtained feature space results from the union of the vocabularies of the different languages; and *bag-of-synsets* (henceforth *BoS*), whereby features correspond to BabelNet synsets. We shall devote Section 3.2 to a detailed description of our proposed BoS representation.

The segment collection $\mathcal{S}$ is given in input to a document clustering algorithm to produce a clustering of the segments $\mathcal{C}^{\mathcal{S}} = \{C_i^s\}_{i=1}^k$. The obtained clusters of segments can be disjoint or overlapping. Again, our *SeMDocT* is parametric to the clustering algorithm as well; here, we resort to a state-of-the-art clustering algorithm, namely *Bisecting K-Means* (Steinbach et al., 2000), which is widely known to produce high-quality (hard) clustering solutions in high-dimensional, large datasets (Zhao and Karypis, 2004). Note however that it requires as input the number of clusters. To cope with this issue, we adopt the method described in (Salvador and Chan, 2004), which explores how the within-cluster cohesion changes by varying the number of clusters. The number of clusters for which the slope of the plot changes drastically is chosen as a suitable value for the clustering algorithm.

3.1.3 Segment-cluster based representation

Upon the segment clustering, each document is represented by its segments assigned to possibly multiple segment clusters. Therefore, we derive a document-feature matrix for each of the k segment clusters. The features correspond either to the BoW or BoS model, according to the choice made for the segment representation.

Let us denote with $\mathcal{F}$ the feature space for all segments in $\mathcal{S}$. Given a segment cluster C^s, the corresponding document-feature matrix is constructed as follows. The representation of each document $d \in \mathcal{D}$ w.r.t. C^s is a vector of length $|\mathcal{F}|$ that results from the sum of the feature vectors of the d's segments belonging to C^s. Moreover, in order to weight the appearance of a document in a cluster based on its segment-based portion covered in the cluster, the document vector of d w.r.t. C^s is finally obtained by multiplying the sum of the segment-vectors by a scalar representing the portion of d's features that appear in the segments belonging to C^s. The document-feature matrix of C^s resulting from the previous step is finally normalized by column.

3.1.4 Tensor model and decomposition

The document-feature matrices corresponding to the k segment-clusters are used to form a third-order tensor.

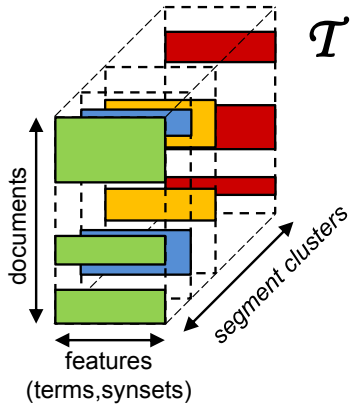

Figure 1: The third-order tensor model for the representation of a multilingual document collection based on segment clusters.

Our third-order tensor model is built by arranging as frontal slices the k segment-cluster matrices. The resulting tensor will be of the form $\boldsymbol{\mathcal{T}} \in \Re^{I_1 \times I_2 \times I_3}$, with $I_1 = |\mathcal{D}|$, $I_2 = |\mathcal{F}|$, and $I_3 = k$. The proposed tensor model is sketched in Fig. 1.

The resulting tensor is decomposed through a Truncated Higher Order SVD (T-HOSVD) (Lathauwer et al., 2000) in order to obtain a low-dimensional representation of the segment-cluster-based representation of the document collection. The T-HOSVD can be considered as an extension of the Truncated Singular Value Decomposition (T-SVD) to the case of three or more dimensions. For a third-order tensor $\boldsymbol{\mathcal{T}} \in \Re^{I_1 \times I_2 \times I_3}$ the T-HOSVD is expressed as

$$\boldsymbol{\mathcal{T}} \approx \boldsymbol{\mathcal{X}} \times_1 \mathbf{U}^{(1)} \times_2 \mathbf{U}^{(2)} \times_3 \mathbf{U}^{(3)}$$

where $\mathbf{U}^{(m)} = [\mathbf{u}_1^{(m)} \mathbf{u}_2^{(m)} \dots \mathbf{u}_{r_m}^{(m)}] \in \Re^{I_m \times r_m}$ $(m = 1, 2, 3)$ are orthogonal matrices, $r_m \ll I_m$, and the core tensor $\boldsymbol{\mathcal{X}} \in \Re^{r_1 \times r_2 \times r_3}$ is an all-orthogonal and ordered tensor. T-HOSVD can be computed in two steps:

1. For $m \in \{1, 2, 3\}$, compute the unfolded matrices $\mathbf{T}_{(\mathrm{m})}$ from $\boldsymbol{\mathcal{T}}$ and related standard SVD: $\mathbf{T}_{(\mathrm{m})} = \mathbf{U}^{(\mathrm{m})} \mathbf{S}^{(\mathrm{m})} \mathbf{V}^{(\mathrm{m})}$. The orthogonal matrix $\mathbf{U}^{(\mathrm{m})}$ contains the leading left singular vectors of $\mathbf{T}_{(\mathrm{m})}$.

2. Compute the core tensor $\boldsymbol{\mathcal{X}}$ using the inversion formula: $\boldsymbol{\mathcal{X}} = \boldsymbol{\mathcal{T}} \times_1 {\mathbf{U}^{(1)}}^T \times_2 {\mathbf{U}^{(2)}}^T \times_3 {\mathbf{U}^{(3)}}^T$.

Note that, since T-HOSVD is computed by means of 3 standard matrix T-SVDs, its computational cost can be reduced by using fast and efficient SVD algorithms. Moreover, the ability of T-HOSVD in effectively capturing the variation in each of the modes independently from the other ones, is particularly important to alleviate the problem of concentration of distances, thus making T-HOSVD well-suited to clustering purposes. In this work, in order to obtain a final clustering solution of the documents, we will consider the mode-1 factor matrix $\mathbf{U}^{(1)}$ of the T-HOSVD.

3.1.5 Document clustering

The mode-1 factor matrix is provided in input to a clustering method to obtain a final organization of the documents into K clusters, i.e., $\mathcal{C} = \{C_i\}_{i=1}^{K}$. Note that there is no principled relation between the number K of final document clusters and k. However, K is expected to reflect the number of topics of interest for the document collection. Also, possibly but not necessarily, the same clustering algorithm used for the segment clustering step (i.e., Bisecting K-Means) can be employed for this step.

3.2 Bag-of-synset representation

In the BoS model, our objective is to represent the document segments in a conceptual feature space instead of the traditional term space. Since we deal with multilingual documents, this task clearly relies on the multilingual lexical knowledge base functionalities of BabelNet. Conceptual features will hence correspond to BabelNet synsets.

The segment collection $\mathcal{S}$ is subject to a two-step processing phase. In the first step, each segment is broken down into a set of lemmatized and POS-tagged sentences, in which each word is replaced with related lemma and associated POS-tag. Let us denote with $\langle w, POS(w) \rangle$ a lemma and associated POS-tag occurring in any sentence sen of the segment. In the second step, a WSD method is applied to each pair $\langle w, POS(w) \rangle$ to detect the most appropriate BabelNet synset σ_w for $\langle w, POS(w) \rangle$ contextually to sen. The WSD algorithm is carried out in such a way that all words from all languages are disambiguated over the same concept inventory, producing a language-independent feature space for the whole multilingual corpus. Each segment is finally modeled as a $|\mathcal{BS}|$-dimensional vector of BabelNet synset frequencies, being $\mathcal{BS}$ the set of retrieved BabelNet synsets.

As previously discussed in Section 2.1, BabelNet provides WSD algorithms for multilingual corpora. More specifically, the authors in (Navigli and Ponzetto, 2012b) suggest to use the Degree algorithm (Navigli and Lapata, 2010), as it showed to yield highly competitive performance in a multilingual context as well. Note that the Degree algorithm, given a semantic graph for the input context, simply selects the sense of the target word with the highest vertex degree. Clearly, other graph-based methods for (unsupervised) WSD, particularly PageRank-style methods (e.g., (Mihalcea et al., 2004; Agirre and Soroa, 2009; Yeh et al., 2009; Tsatsaronis et al., 2010)), can be plugged in to address the multilingual WSD task based on BabelNet. An investigation of the performance of existing WSD algorithms for a multilingual context is however out of the scope of this paper.

4 Evaluation Methodology

In order to evaluate our proposal we need a multilingual comparable document collection with annotated

Table 2: Main characteristics of the corpora.

topics. For this reason, we used *Reuters Corpus Volume 2* (RCV2), a multilingual corpus containing news articles in thirteen language.[1] In the following, we present the corpus characteristics and competing methods used in our analysis.

4.1 Data preparation

We consider a subset of the RCV2 corpus corresponding to three languages: *English*, *French* and *Italian*. It covers six different topics, i.e., different labels of the RCV2 TOPICS field. Topics are chosen according with their coverage in the different languages. The language-specific documents were lemmatized and POS-tagged through the Freeling library (Padró and Stanilovsky, 2012) in order to obtain a suitable representation for the WSD process.

To assess the robustness of our proposal, we design two different scenarios. The first (*Balanced Corpus*) is characterized by a completely balanced dataset. Each language covers all topics and for each pair language/topic the same number of documents is selected. The second scenario corresponds to an *Unbalanced Corpus*. Starting from the balanced corpus, we removed for each topic all the documents belonging to one language. In this way, we obtained a corpus in which each topic is covered by only two of the three languages.

Main characteristics of both evaluation corpora are reported in Table 1 and Table 2. In the latter table, we report the number of documents, number of terms, number of synsets and the dataset density for both representations. To quantify the density of each corpus/representation combination, we counted the non-zero entries of the induced document-synset matrix (alternatively, document-term matrix) and we divided this value by the size of such matrix. This number provides an estimate about the density/sparseness of each dataset. Lower values indicate more sparse data. We can note that BoS model yields more dense datasets for both *Balanced Corpus* and *Unbalanced Corpus*.

Table 4: Average length of document segment in the BoW and BoS spaces, for each topic and language.

As our proposal explicitly models document segments, we also report statistics, considering both topics and languages, related to the average number of segments per document (Table 3), and the average length of segments per document (Table 4). The latter statistic is computed separately for BoW and BoS representations. We made this distinction because a term cannot have a mapping to a synset, or it can be mapped to more than one synset in the BoS space during the WSD process (Section 3.2).

Looking at the average number of segments per document in Table 3, it can be noted that English documents contain, for all topics, a larger number of segments. This means that English documents are generally richer than the ones in the other languages. Italian language corresponds to the smallest documents, each of them containing between 2 and 3.2 segments on average. A sharper difference appears in the *MONETARY/ECONOMIC* topic for which English documents contain 5.2 segments, while the Italian ones are composed, on average, by only 2 segments.

Table 4 shows the average length of segments per document for both space representations. Generally, segments in the BoS representation are smaller than the corresponding segments in the BoW space. More in detail, if we consider the ratio between the segment length in BoS and the one in BoW, this ratio is around 2/3 for the English language, while for both French and Italian it varies between 1/4 and 1/3. This disequilibrium is induced by the multilingual concept coverage of BabelNet, as stated by its authors (Navigli and Ponzetto,

2012a), (Navigli and Ponzetto, 2012b). In particular, the WSD process tightly depends from the concept coverage supplied from the language-specific knowledge base.

4.2 Competing methods and settings

We compare our *SeMDocT* with two standard approaches, namely *Bisecting K-Means* (Steinbach et al., 2000), and *Latent Semantic Analysis (LSA)*-based document clustering (for short, *LSA*). Given a number K of desired clusters, *Bisecting K-Means* produces a K-way clustering solution by performing a sequence of K-1 repeated bisections based on standard K-Means algorithm. This process continues until the number K of clusters is found. *LSA* performs a decomposition of the document collection matrix through Singular Value Decomposition in order to extract a more concise and descriptive representation of the documents. After this step, *Bisecting K-Means* is applied over the new document space to get the final document clustering.

All the three methods, *SeMDocT*, *Bisecting K-Means* and *LSA* are coupled with either BoS or BoW representation models. The comparison between BoS and BoW representations allows us to evaluate the presumed benefits that can be derived by exploiting synsets instead of terms for the multilingual document clustering task.

Both *SeMDocT* and *LSA* require the number of components as input; as concerns specifically *SeMDocT*, we varied r_1 (cf. Section 3.1.4) from 2 to 30, with increments of 2. To determine the number of segment clusters k, we employed an automatic way as discussed in Section 3.1.2. By varying k from 2 to 40, for *Balanced Corpus* and *Unbalanced Corpus*, respectively, the values of k obtained were 22 and 23 under BoS, and 25 and 11 under BoW.

As concerns the step of text segmentation, TextTiling requires the setting of some interdependent parameters, particularly the size of the text unit to be compared and the number of words in a token sequence. We used the setting suggested in (Hearst, 1997) and also confirmed in (Tagarelli and Karypis, 2013), i.e., 10 for the text unit size and 20 for the token-sequence size.

4.3 Assessment criteria

Performance of the different methods are evaluated using two standard clustering validation criteria, namely *F-Measure* and *Rand Index*.

Given a document collection $\mathcal{D}$, let $\mathbf{\Gamma} = \{\Gamma_j\}_{j=1}^{H}$ and $\mathcal{C} = \{C_i\}_{i=1}^{K}$ denote a reference classification and a clustering solution for $\mathcal{D}$, respectively. The local precision and the local recall of a cluster C_i w.r.t. a class Γ_j are defined as $P_{ij} = |C_i \cap \Gamma_j|/|C_i|$ and $R_{ij} = |C_i \cap \Gamma_j|/|\Gamma_j|$, respectively. F-Measure (FM) is computed as follows (Steinbach et al., 2000):

$$F = \sum_{j=1}^{H} \frac{|\Gamma_j|}{|\mathcal{D}|} \max_{i=1\ldots K}\{F_{ij}\}$$

where $F_{ij} = 2P_{ij}R_{ij}/(P_{ij} + R_{ij})$.

Rand Index (RI) (Rand, 1971) measures the percentage of decisions that are correct, penalizing false positive and false negative decisions during clustering. It takes into account the following quantities: *TP*, i.e., the number of pairs of documents that are in the same cluster in $\mathcal{C}$ and in the same class in $\mathbf{\Gamma}$; *TN*, i.e., the number of pairs of documents that are in different clusters in $\mathcal{C}$ and in different classes in $\mathbf{\Gamma}$; *FN*, i.e., the number of pairs of documents that are in different clusters in $\mathcal{C}$ and in the same class in $\mathbf{\Gamma}$; and *FP*, i.e., the number of pairs of documents that are in the same cluster in $\mathcal{C}$ and in different classes in $\mathbf{\Gamma}$. Rand Index is hence defined as:

$$RI = \frac{TP + TN}{TP + TN + FP + FN}$$

Note that for each method, results were averaged over 30 runs and the number of final document clusters K was set equal to the number of topics in the document collection (i.e., 6).

5 Results

We present here our main experimental results. We first provide a comparative evaluation of our *SeMDocT* with the competing methods, on both balanced and unbalanced corpus evaluation cases. Then we provide a per language analysis focusing on *SeMDocT*.

5.1 Evaluation with competing methods

Evaluation on balanced corpus. Figure 2 shows FM and RI results obtained by the various methods coupled with the two document representations on the *Balanced Corpus*. Several remarks stand out. First, the BoS space positively influences the performance of all the employed approaches. This is particularly evident for *Bisecting K-Means* and *LSA* that clearly benefit from this kind of representation. The former almost doubles its performance in terms of FM and significantly improves its result w.r.t. RI. *LSA* shows improvements in both cases. *SeMDocT*-BoS generally outperforms all the competitors for both FM and RI when the number of components is greater than 16. Note that, under the BoW model, *SeMDocT*-BoW still outperforms the other methods.

Evaluation on unbalanced corpus. Figure 3 reports results for the *Unbalanced Corpus*. Also in this evaluation, the best performances for all the methods are reached using the BoS representation. *SeMDocT*-BoS shows similar behavior according to the two measures. It always outperforms the competitors considering a number of components greater than or equal to 12. More precisely, *SeMDocT*-BoW obtains a gain of 0.047 and 0.103 in terms of FM and 0.006 and 0.058 in terms of RI, w.r.t. *LSA*-BoW and *Bisecting K-Means*-BoW, respectively. Similarly, *SeMDocT*-BoS obtains improvements of 0.05 in terms of FM w.r.t. both BoS

competitors, while in terms of RI the differences in performance are 0.012 and 0.019 for *LSA*-BoS and *Bisecting K-Means*-BoS, respectively.

5.2 Per language evaluation of *SeMDocT*-BoS

Starting from the clustering solutions produced by *SeMDocT*-BoS in both balanced and unbalanced cases, for each language we extracted a language-specific projection of the clustering. After that, we computed the clustering validation criteria according to language specific solutions to quantify how well the clustering result fits each specific language. The results of this experiment are reported in Fig. 4 and Fig. 5.

On the *Balanced Corpus*, *SeMDocT*-BoS shows comparable performance for English and French documents, while it behaves slightly worse for Italian texts. This trend is highlighted for both clustering evaluation criteria. Inspecting the results for the *Unbalanced Corpus*, we observe a different trend. Results obtained for the English texts are generally better than the results for the French and Italian documents. For this benchmark, *SeMDocT*-BoS obtains similar results for documents written in French and in Italian.

Dataset	*Language*	*BoW size*	*BoS size*	*avg # synsets per term* (β)
Balanced	English	29 999	12 065	0.4021
	French	17 826	5 310	0.2978
	Italian	16 951	4 471	0.2637
Unbalanced	English	19 432	10 387	0.5345
	French	14 439	4 431	0.3068
	Italian	14 743	4 012	0.2721

Table 5: Statistics by language.

We gained an insight into the above discussed performance behaviors by computing some additional statistics that we report in Table 5: for each language and each dataset, the size of the term and synset dictionaries and the average number of synsets per lemma (β) we retrieved through BabelNet according to the related corpus. More in detail, β is the ratio between the BoS and the BoW dictionaries. This quantity roughly evaluates how many synsets are produced per term during the multilingual WSD process (Section 3.2). As we can observe, this value is always smaller than one, which means that not all the terms have a corresponding mapping to a synset. The β ratio can explain the discrep-

ancy in (language-specific) performances in the two scenarios. In particular, the difference in the β statistic between English and the other languages is more evident for the *Unbalanced Corpus* (i.e., 0.23 between English and French), while it is lower for the *Balanced Corpus* (around 0.1). The relatively large gap in β between the first and the second language (respectively, English and French) for the *Unbalanced Corpus* reduces the relative gap between the second and the third languages (respectively, French and Italian) while this trend is less marked for the *Balanced Corpus* as β range is narrower. In summary, we can state that our framework works well if BabelNet knowledge base provides a good coverage of the terms in the analyzed language. Experimental evidence shows that, if this condition is met, *SeMDocT*-BoS provides better clustering results w.r.t. the competing approaches.

5.3 Runtime of tensor decomposition

As previously discussed, T-HOSVD of a third-order tensor can be computed through three standard SVDs. Furthermore, for clustering purposes, we considered only the mode-1 factor matrix of the decomposition. To compute the SVD, we used the *svds()* function of MATLAB R2012b, which is based on an iterative algorithm.[2] Experiments were carried out on an Intel Core I7-3610QM platform with 16GB DDR RAM.

Figure 6 shows the execution time of the SVD over the mode-1 matricization of our tensor for the *Balanced Corpus*, by varying the number of components, for both BoW and BoS representation models. As it can be observed, in both cases the runtime is linear in the number of components. However, the SVD computation in the BoS setting is one order of magnitude faster than time performance in the BoW setting. This is mainly due to a large difference in size between the feature spaces of BoW and BoS (cf. Table 2), since the selected number of segment clusters (k) was nearly the same (25 for BoW, and 22 for BoS). Therefore, by providing a more compact feature space, BoS clearly allows for a much less expensive SVD computation for our tensor decomposition.

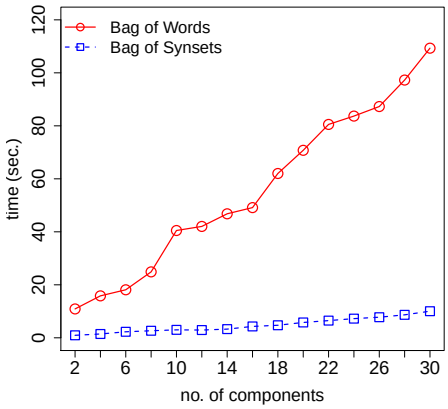

Figure 6: Time performance of SVD over the mode-1 matricization of the *Balanced Corpus* tensor.

6 Discussion

Our work paves the way for the use of a multilingual knowledge base to deal with the multilingual document clustering task. Here we sum up our main findings.

***SeMDocT* vs. *LSA*.** *LSA* achieved its best results for a number of components generally smaller than the one for which *SeMDocT* obtained its maximum. This is due to the initial information that the two methods summarize. *LSA* tries to capture the variation of the initial document-term (alternatively, document-synset) matrix representing the texts in a lower space, whereas *SeMDocT* does the same starting from a richer representation of the documents (i.e., a third-order tensor model). For this reason, *SeMDocT* tends to employ relatively more components in order to summarize the documents content; however, a number of components between 16 and 30 is generally enough to ensure good performance of *SeMDocT*. Moreover, in most cases, the highest performance results by *SeMDocT* are better than the highest performances of *LSA*.

BoS vs. BoW. Our results have highlighted the better quality in multilingual clustering supplied by synsets compared with the one provided by terms. BoS produces a smaller representation space over which documents are projected, but it is enough rich to well capture the documents content. In particular, BoS benefits from the WSD process that is able to discriminate the same term w.r.t. the context in which it appears.

BabelNet. BabelNet is a recent project that supports many different languages. As the intention of the authors is to enrich this resource, in the future our framework will benefit of this fact. Moreover, our framework can deal with documents written in many different languages as they are represented through the same space; the only constraint is related to the available language support in BabelNet. On the other hand, we point out that any other multilingual knowledge base and WSD tools can in principle be integrated in our framework.

7 Conclusion

In this paper we proposed a new approach for multilingual document clustering. Our key idea lies in the combination of a tensor-based model with a bag-of-synsets description, which enables a common space to project multilingual document collections. We evaluated our approach w.r.t. standard document clustering methods, using both term and synset representations. Results have shown the benefits deriving from the use of a multilingual knowledge base in the analysis of comparable corpora, and also shown the significance of our approach in both a balanced and an unbalanced corpus evaluation. Our tensor-based representation of topically-segmented multilingual documents can also be applied to cross-lingual information retrieval or multilingual document categorization.

Abstract

In this paper we examine the lexical substitution task for the medical domain. We adapt the current best system from the open domain, which trains a single classifier for all instances using delexicalized features. We show significant improvements over a strong baseline coming from a distributional thesaurus (DT). Whereas in the open domain system, features derived from WordNet show only slight improvements, we show that its counterpart for the medical domain (UMLS) shows a significant additional benefit when used for feature generation.

1 Introduction

The task of lexical substitution (McCarthy and Navigli, 2009) deals with the substitution of a *target term* within a sentence with words having the same meaning. Thus, the task divides into two subtasks:

- Identification of *substitution candidates*, i.e. terms that are, for some contexts, substitutable for a given target term.
- Ranking the substitution candidates according to their context

Such a substitution system can help for semantic text similarity (Bär et al., 2012), textual entailment (Dagan et al., 2013) or plagiarism detection (Chong and Specia, 2011).

Datasets provided by McCarthy and Navigli (2009) and Biemann (2012) offer manually annotated substitutes for a given set of target words within a context (sentence). Contrary to these two datasets in Kremer et al. (2014) a dataset is offered where all words have are annotated with substitutes. All the datasets are suited for the open domain.

But a system performing lexical substitution is not only of interest for the open domain, but also for the medical domain. Such a system could then be applied to medical word sense disambiguation, entailment or question answering tasks. Here we introduce a new dataset and adapt the lexical substitution system, provided by Szarvas et al. (2013), to the medical domain. Additionally, we do not make use of WordNet (Miller, 1995) to provide similar terms, but rather employ a Distributional Thesaurus (DT), computed on medical texts.

2 Related Work

For the general domain, the lexical substitution task was initiated by a Semeval-2007 Task (McCarthy and Navigli, 2009). This task was won by an unsupervised method (Giuliano et al., 2007), which uses WordNet for the substitution candidate generation and then relies on the Google Web1T n-grams (Brants and Franz, 2006)[1] to rank the substitutes.

The currently best system, to our knowledge, is proposed by Szarvas et al. (2013). This is a supervised approach, where a single classifier is trained using delexicalized features for all substitutes and can thus be applied even to previously unseen substitutes. Although there have been many approaches for solving the task for the general domain, only slight effort has been done in adapting it to different domains.

3 Method

To perform lexical substitution, we follow the delexicalization framework of Szarvas et al. (2013). We automatically build Distributional Thesauri (DTs) for the medical domain and use features from the Unified Medical Language System (UMLS) ontology. The dataset for supervised lexical substitution consists of sentences, containing an annotated target word t. Considering the sentence being the context for the target word, the target word might have different meanings. Thus annotated substitute candidates $s_{g_1} \dots s_{g_n} \in s_g$, need to be provided for each context. The negative examples are substitute candidates that either are incorrect for the target word, do not fit into the context or both. We will refer to these substitutes as *false substitute candidates* $s_{f_1} \dots s_{f_m} \in s_f$ with $s_f \cap s_g = \emptyset$.

For the generation of substitute candidates we do not use WordNet, as done in previous works (Szarvas et al., 2013), but use only substitutes from a DT. To train a single classifier, features that distinguishing the meaning of words in different context need to be considered. Such features could be e.g. n-grams, features from distributional semantics or features which are extracted

[1] http://catalog.ldc.upenn.edu/LDC2006T13

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 610–614,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

relative to the target word, such as the ratio between frequencies of the substitute candidate and the target word. After training, we apply the algorithm to unseen substitute candidates and rank them according to their positive probabilities, given by the classifier. Contrary to Szarvas et al. (2013), we do not use any weighting in the training if a substitute has been supplied by many annotators, as we could not observe any improvements. Additionally, we use logistic regression (Fan et al., 2008) as classifier[2].

4 Resources

For the substitutes and for the generation of delexicalized features, we rely on DTs, the UMLS and Google Web1T.

4.1 Distributional thesauri (DTs)

We computed two different DTs using the framework proposed in Biemann and Riedl (2013)[3].

The first DT is computed based on Medline[4] abstracts. This thesaurus uses the left and the right word as context features. To include multi-word expressions, we allow the number of tokens that form a term to be up to the length of three.

The second DT is based on dependencies as context features from a English Slot Grammar (ESG) parser (McCord et al., 2012) modified to handle medical data. The ESG parser is also capable of finding multi-word expressions. As input data we use 3.3 GB of texts from medical textbooks, encyclopedias and clinical reference material as well as selected journals. This DT is also used for the generation of candidates supplied to annotators when creating the gold standard and therefore is the main resource to provide substitute candidates.

4.2 UMLS

The Unified Medical Language System (UMLS) is an ontology for the medical domain. In contrast to Szarvas et al. (2013), which uses WordNet (Miller, 1995) to generate substitute candidates and also for generating features, we use UMLS solely for feature generation.

4.3 Google Web1T

We use the Google Web1T to generate n-gram features as we expect this open domain resource to have considerable coverage for most specific domains as well. For accessing the resource, we use JWeb1T[5] (Giuliano et al., 2007).

[2]We use a Java port of LIBLINEAR (`http://www.csie.ntu.edu.tw/~cjlin/liblinear/`) available from `http://liblinear.bwaldvogel.de/`

[3]We use Lexicographer's Mutual Information (LMI) (Evert, 2005) as significance measure and consider only the top 1000 ($p = 1000$) features per term.

[4]`http://www.nlm.nih.gov/bsd/licensee/2014_stats/baseline_med_filecount.html`

[5]https://code.google.com/p/jweb1t/

5 Lexical Substitution dataset

Besides the lexical substitution data sets for the open domain (McCarthy and Navigli, 2009; Biemann, 2012; Kremer et al., 2014) there is no dataset available that can be used for the medical domain. Therefore, we constructed an annotation task for the medical domain using a medical corpus and domain experts.

In order to provide the annotators with a clear task, we presented a question, and a passage that contains the correct answer to the question. We restricted this to a subset of passages that were previously annotated as justifying the answer to the question. This is related to a textual entailment task, essentially the passage entails the question with the answer substituted for the focus of the question. We instructed the annotators to first identify the terms that were relevant for the entailment relation. For each relevant term we randomly extracted 10 terms from the ESG-based DT within the top 100 most similar terms. Using this list of distributionally similar terms, the annotators selected those terms that would preserve the entailment relation if substituted. This resulted in a dataset of 699 target terms with substitutes. On average from the 10 terms 0.846 are annotated as correct substitutes. Thus, the remaining terms can be used as false substitute candidates.

The agreement on this task by Fleiss Kappa was 0.551 indicating "moderate agreement" (Landis and Koch, 1977). On the metric of pairwise agreement, as defined in the SemEval lexical substitution task, we achieve 0.627. This number is not directly comparable to the pairwise agreement score of 0.277 for the SemEval lexical substitution task (McCarthy and Navigli, 2009) since in our task the candidates are given. However, it shows promise that subjectivity may be reduced by casting lexical substitution into a task of maintaining entailment.

6 Evaluation

For the evaluation we use a ten-fold cross validation and report P@1 (also called Average Precision (AP) at 1) and Mean Average Precision (MAP) (Buckley and Voorhees, 2004) scores. The P@1 score indicates how often the first substitute of the system matches the gold standard. The MAP score is the mean of all AP from 1 to the number of all substitutes.

- Google Web 1T:
  We use the same Google n-gram features, as used in Giuliano et al. (2007) and Szarvas et al. (2013). These are frequencies of n-grams formed by the substitute candidate s_i and the left and right words, taken from the context sentence, normalized by the frequency of the same context n-gram with the target term t. Additionally, we add the same features, normalized by the frequency sum of all n-grams of the substitute candidates. Another feature is generated using the frequencies where t and s are listed together using the words

and, *or* and *","* as separator and also add the left and right words of that phrase as context. Then we normalize this frequency by the frequency of the context occurring only with t.

- DT features:
  To characterize if t and s_i have similar words in common, and therefore are similar, we compute the percentage of words their thesauri entries share, considering the top n words in each entry with $n = 1, 5, 20, 50, 100, 200$. During the DT calculation we also calculate the significances between each word and its context features (see Section 4.1). Using this information, we compute if the words in the sentences also occur as context features for the substitute candidate. A third feature group relying on DTs is created by the overlapping context features for the top m entries of t and s_i with $m = 1, 5, 20, 50, 100, 1000$, which are ranked regarding their significance score. Whereas, the similarities between the trigram-based and the ESG-based DT are similar, the context features are different. Both feature types can be applied to the two DTs. Additionally, we extract the thesaurus entry for the target word t and generate a feature indicating whether the substitute s_i is within the top k entries with $k = 1, 5, 10, 20, 100$ entries[6].

- Part-of-speech n-grams:
  To identify the context of the word we use the POS-tag (only the first letter) of s_i and t as feature and POS-tag combinations of up to three neighboring words.

- UMLS:
  Considering UMLS we look up all concept unique identifiers (CUIs) for s_i and t. The first two features are the number of CUIs for s_i and t. The next features compute the number of CUIs that s_i and t share, starting from the minimal to the maximum number of CUIs. Additionally, we use a feature indicating that s_i and t do not share any CUI.

6.1 Substitute candidates

The candidates for the substitution are taken from the ESG based DT. For each target term we use the gold substitute candidates as correct instances and add all possible substitutes for the same target term occurring in a different context and do not have been annotated as valid in the present context as false instances.

7 Results

Running the experiment, we get the results as shown in Table 1. As baseline system we use the ranking of the ESG-based DT. As can be seen, the baseline is already quite high, which can be attributed to the fact that this resource was used to generate substitutes und thus contains all positive instances. Using the supervised approach, we can beat the baseline by 0.10 for the MAP score and by 0.176 for the P@1 score, which is a significant improvement ($p < 0.0001$, using a two tailed permutation test). To get insights of the contribution of individual feature types, we perform an ablation test. We observe that the most prominent features are coming from the two DTs as we only achieve results below the baseline, when removing DT features. We still obtain significant improvements over the baseline when removing other feature groups. The second most important feature comes from the UMLS. Features coming from the Google n-grams improve the system only slightly. The lowest improvement is derived from the part-of-speech features. This leads us to summarize that a hybrid approach for feature generation using manually created resources (UMLS) and unsupervised features (DTs) leads to the best result for lexical substitution for the medical domain.

System	MAP	P@1
Baseline	0.6408	0.5365
ALL	0.7048	0.6366
w/o DT	0.5798	0.4835
w/o UMLS	0.6618	0.5651
w/o Ngrams	0.7009	0.6252
w/o POS	0.7027	0.6323

Table 1: Results for the evaluation using substitute candidates from the DT.

8 Analysis

For a better insight into the lexical substitution we analyzed how often we outperform the baseline, get equal results or get decreased scores. According to Table 2 in around 26% of the cases we observe a decreased MAP score, which is on average 0.16 smaller then the scores achieved with the baseline. On the other hand, we see improvements in around 39% of the cases: an average improvements of 0.26, which is much higher then the loss. For the remaining 25% of cases we observe the same score.

performance	# of instances	Avg. Δ MAP
decline	180	-0.16
equal	244	0
improvements	275	0.26

Table 2: Error analysis for the task respectively to the MAP score.

Looking inside the data, the largest error class is caused by antonyms. A sub-class of this error are multi-word expressions having an adjective modifier. This problems might be solved by additional features using the UMLS resource. An example is shown in Figure 1.

[6]Whereas in Szarvas et al. (2013) only $k = 100$ is used, we gained an improvement in performance when also adding smaller values of k.

Sentence: he most common cause of thrombocytopenia during pregnancy is gestational thrombocytopenia, which is a **mild thrombocytopenia** with platelet levels remaining greater than 70,000/mL.

Gold: decreased platelet=1

Baseline: decreased platelet:17.0, severe thrombocytopenia: 16.0, macrothrombocytopenia:16.0, prolonged aptt:16.0, normal platelet count:16.0, hepatosplenomegaly:15.0, hypoxaemia:13.0, short finger:12.0, lymphadenopathy:11.0, mild symptom:11.0

System: severe thrombocytopenia:0.272, normal platelet count:0.204, macrothrombocytopenia:0.190, hepatosplenomegaly:0.174, prolonged aptt:0.168, decreased platelet:0.156, mild symptom:0.113, lymphadenopathy:0.085, hypoxaemia:0.067, short finger:0.053

Figure 1: Example sentence for the target term *mild thrombocytopenia*. The system returns a wrong ranking, as the adjective changes the meaning and turns the first ranked term into an antonym.

For feature generation, we currently lookup multi-word expressions as one term, both in the DT and the UMLS resource and do not split them into their single tokens. This error also suggests considering the single words inside the multi-word expression, especially adjectives, and looking them up in a resource (e.g. UMLS) to detect synonymy and antonymy.

Figure 2 shows the case, where the ranking is performed correctly, but the precise substitute is not annotated as a correct one. The term *nail plate* might be even more precise in the context as the manual annotated term *nail bed*. Due to the missing annotation the

Sentence: 7 Yellow nail syndrome is a rare disorder characterized by the triad of yellow and thickened **nails**, lymphedema and respiratory manifestation commonly pleural effusion and other complications like bronchiectasis and chronic sinusitis. Lymphedema in yellow nail syndrome is characteristically non-pitting and involves the lower extremities in symmetric fashion

Gold: finger nail=1, nail bed=1

Baseline: finger nail:58, nail bed:54.0, nail plate:49.0, scalp:47.0, hand:26.0, arms and legs:25.0, eye:23.0, cranial bone:19.0, palm:16.0, urinary organ:16.0

System: nail plate:0.676, finger nail:0.158, nail bed:0.144, scalp:0.106, hand:0.044, arms and legs:0.043, urinary organ:0.017, eye:0.016, palm:0.016, cranial bone:0.014

Figure 2: Example sentence for the target term *nails*. Here the ranking from the system is correct, but the first substitute from the system was not annotated as such.

baseline gets better scores then the result from the system.

9 Conclusion

In summary, we have examined the lexical substitution task for the medical domain and could show that a system for open domain text data can be applied to the medical domain. We can show that following a hybrid approach using features from UMLS and distributional semantics leads to the best results. In future work, we will work on integrating DTs using other context features, as we could see an impact of using two different DTs. Furthermore, we want to incorporate features using n-grams computed on a corpus from the domain and include co-occurrence features.

Abstract

This paper presents a system which learns to answer questions on a broad range of topics from a knowledge base using few hand-crafted features. Our model learns low-dimensional embeddings of words and knowledge base constituents; these representations are used to score natural language questions against candidate answers. Training our system using pairs of questions and structured representations of their answers, and pairs of question paraphrases, yields competitive results on a recent benchmark of the literature.

1 Introduction

Teaching machines how to automatically answer questions asked in natural language on any topic or in any domain has always been a long standing goal in Artificial Intelligence. With the rise of large scale structured knowledge bases (KBs), this problem, known as open-domain question answering (or open QA), boils down to being able to query efficiently such databases with natural language. These KBs, such as FREEBASE (Bollacker et al., 2008) encompass huge ever growing amounts of information and ease open QA by organizing a great variety of answers in a structured format. However, the scale and the difficulty for machines to interpret natural language still makes this task a challenging problem.

The state-of-the-art techniques in open QA can be classified into two main classes, namely, information retrieval based and semantic parsing based. Information retrieval systems first retrieve a broad set of candidate answers by querying the search API of KBs with a transformation of the question into a valid query and then use fine-grained detection heuristics to identify the exact answer (Kolomiyets and Moens, 2011; Unger et al., 2012; Yao and Van Durme, 2014). On the other hand, semantic parsing methods focus on the correct interpretation of the meaning of a question by a semantic parsing system. A correct interpretation converts a question into the exact database query that returns the correct answer. Interestingly, recent works (Berant et al., 2013; Kwiatkowski et al., 2013; Berant and Liang, 2014; Fader et al., 2014) have shown that such systems can be efficiently trained under indirect and imperfect supervision and hence scale to large-scale regimes, while bypassing most of the annotation costs.

Yet, even if both kinds of system have shown the ability to handle large-scale KBs, they still require experts to hand-craft lexicons, grammars, and KB schema to be effective. This non-negligible human intervention might not be generic enough to conveniently scale up to new databases with other schema, broader vocabularies or languages other than English. In contrast, (Fader et al., 2013) proposed a framework for open QA requiring almost no human annotation. Despite being an interesting approach, this method is outperformed by other competing methods. (Bordes et al., 2014b) introduced an embedding model, which learns low-dimensional vector representations of words and symbols (such as KBs constituents) and can be trained with even less supervision than the system of (Fader et al., 2013) while being able to achieve better prediction performance. However, this approach is only compared with (Fader et al., 2013) which operates in a simplified setting and has not been applied in more realistic conditions nor evaluated against the best performing methods.

In this paper, we improve the model of (Bordes et al., 2014b) by providing the ability to answer more complicated questions. The main contributions of the paper are: (1) a more sophisticated inference procedure that is both efficient and can consider longer paths ((Bordes et al., 2014b) considered only answers directly connected to the

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 615–620,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

question in the graph); and (2) a richer representation of the answers which encodes the question-answer path and surrounding subgraph of the KB. Our approach is competitive with the current state-of-the-art on the recent benchmark WEBQUESTIONS (Berant et al., 2013) without using any lexicon, rules or additional system for part-of-speech tagging, syntactic or dependency parsing during training as most other systems do.

2 Task Definition

Our main motivation is to provide a system for open QA able to be trained as long as it has access to: (1) a training set of questions paired with answers and (2) a KB providing a structure among answers. We suppose that all potential answers are entities in the KB and that questions are sequences of words that include one identified KB entity. When this entity is not given, plain string matching is used to perform entity resolution. Smarter methods could be used but this is not our focus.

We use WEBQUESTIONS (Berant et al., 2013) as our evaluation bemchmark. Since it contains few training samples, it is impossible to learn on it alone, and this section describes the various data sources that were used for training. These are similar to those used in (Berant and Liang, 2014).

WebQuestions This dataset is built using FREEBASE as the KB and contains 5,810 question-answer pairs. It was created by crawling questions through the Google Suggest API, and then obtaining answers using Amazon Mechanical Turk. We used the original split (3,778 examples for training and 2,032 for testing), and isolated 1k questions from the training set for validation. WEBQUESTIONS is built on FREEBASE since all answers are defined as FREEBASE entities. In each question, we identified one FREEBASE entity using string matching between words of the question and entity names in FREEBASE. When the same string matches multiple entities, only the entity appearing in most triples, i.e. the most popular in FREEBASE, was kept. Example questions (answers) in the dataset include *"Where did Edgar Allan Poe died?"* (`baltimore`) or *"What degrees did Barack Obama get?"* (`bachelor_of_arts`, `juris_doctor`).

Freebase FREEBASE (Bollacker et al., 2008) is a huge and freely available database of general facts; data is organized as triplets (`subject`, `type1.type2.predicate`, `object`), where two entities `subject` and `object` (identified by `mids`) are connected by the relation type `type1.type2.predicate`. We used a subset, created by only keeping triples where one of the entities was appearing in either the WEBQUESTIONS training/validation set or in CLUEWEB extractions. We also removed all entities appearing less than 5 times and finally obtained a FREEBASE set containing 14M triples made of 2.2M entities and 7k relation types.[1] Since the format of triples does not correspond to any structure one could find in language, we decided to transform them into automatically generated questions. Hence, all triples were converted into questions "What is the `predicate` of the `type2` `subject`?" (using the `mid` of the subject) with the answer being `object`. An example is *"What is the* `nationality` *of the* `person` `barack_obama`*?"* (`united_states`). More examples and details are given in a longer version of this paper (Bordes et al., 2014a).

ClueWeb Extractions FREEBASE data allows to train our model on 14M questions but these have a fixed lexicon and vocabulary, which is not realistic. Following (Berant et al., 2013), we also created questions using CLUEWEB extractions provided by (Lin et al., 2012). Using string matching, we ended up with 2M extractions structured as (`subject`, "text string", `object`) with both `subject` and `object` linked to FREEBASE. We also converted these triples into questions by using simple patterns and FREEBASE types. An example of generated question is *"Where* `barack_obama` *was allegedly bear in?"* (`hawaii`).

Paraphrases The automatically generated questions that are useful to connect FREEBASE triples and natural language, do not provide a satisfactory modeling of natural language because of their semi-automatic wording and rigid syntax. To overcome this issue, we follow (Fader et al., 2013) and supplement our training data with an indirect supervision signal made of pairs of question paraphrases collected from the WIKIANSWERS website. On WIKIANSWERS, users can tag pairs of questions as rephrasings of each other: (Fader et al., 2013) harvested a set of 2M distinct questions from WIKIANSWERS, which were grouped into 350k paraphrase clusters.

[1] WEBQUESTIONS contains ∼2k entities, hence restricting FREEBASE to 2.2M entities does not ease the task for us.

3 Embedding Questions and Answers

Inspired by (Bordes et al., 2014b), our model works by learning low-dimensional vector embeddings of words appearing in questions and of entities and relation types of FREEBASE, so that representations of questions and of their corresponding answers are close to each other in the joint embedding space. Let q denote a question and a a candidate answer. Learning embeddings is achieved by learning a scoring function $S(q, a)$, so that S generates a high score if a is the correct answer to the question q, and a low score otherwise. Note that both q and a are represented as a combination of the embeddings of their individual words and/or symbols; hence, learning S essentially involves learning these embeddings. In our model, the form of the scoring function is:

$$S(q, a) = f(q)^\top g(a). \quad (1)$$

Let $\mathbf{W}$ be a matrix of $\mathbb{R}^{k \times N}$, where k is the dimension of the embedding space which is fixed a-priori, and N is the dictionary of embeddings to be learned. Let N_W denote the total number of words and N_S the total number of entities and relation types. With $N = N_W + N_S$, the i-th column of $\mathbf{W}$ is the embedding of the i-th element (word, entity or relation type) in the dictionary. The function $f(.)$, which maps the questions into the embedding space $\mathbb{R}^k$ is defined as $f(q) = \mathbf{W}\phi(q)$, where $\phi(q) \in \mathbb{N}^N$, is a sparse vector indicating the number of times each word appears in the question q (usually 0 or 1). Likewise the function $g(.)$ which maps the answer into the same embedding space $\mathbb{R}^k$ as the questions, is given by $g(a) = \mathbf{W}\psi(a)$. Here $\psi(a) \in \mathbb{N}^N$ is a sparse vector representation of the answer a, which we now detail.

3.1 Representing Candidate Answers

We now describe possible feature representations for a single candidate answer. (When there are multiple correct answers, we average these representations, see Section 3.4.) We consider three different types of representation, corresponding to different subgraphs of FREEBASE around it.

(i) *Single Entity*. The answer is represented as a single entity from FREEBASE: $\psi(a)$ is a 1-of-N_S coded vector with 1 corresponding to the entity of the answer, and 0 elsewhere.

(ii) *Path Representation*. The answer is represented as a path from the entity mentioned in the question to the answer entity. In our experiments, we considered 1- or 2-hops paths (i.e. with either 1 or 2 edges to traverse): (`barack_obama`, `people.person.place_of_birth`, `honolulu`) is a 1-hop path and (`barack_obama`, `people.person.place_of_birth`, `location.location.containedby`, `hawaii`) a 2-hops path. This results in a $\psi(a)$ which is a 3-of-N_S or 4-of-N_S coded vector, expressing the start and end entities of the path and the relation types (but not entities) in-between.

(iii) *Subgraph Representation*. We encode both the path representation from (ii), and the entire subgraph of entities connected to the candidate answer entity. That is, for each entity connected to the answer we include both the relation type and the entity itself in the representation $\psi(a)$. In order to represent the answer path differently to the surrounding subgraph (so the model can differentiate them), we double the dictionary size for entities, and use one embedding representation if they are in the path and another if they are in the subgraph. Thus we now learn a parameter matrix $\mathbb{R}^{k \times N}$ where $N = N_W + 2N_S$ (N_S is the total number of entities and relation types). If there are C connected entities with D relation types to the candidate answer, its representation is a $3+C+D$ or $4+C+D$-of-N_S coded vector, depending on the path length.

Our hypothesis is that including more information about the answer in its representation will lead to improved results. While it is possible that all required information could be encoded in the k dimensional embedding of the single entity *(i)*, it is unclear what dimension k should be to make this possible. For example the embedding of a country entity encoding all of its citizens seems unrealistic. Similarly, only having access to the path ignores all the other information we have about the answer entity, unless it is encoded in the embeddings of either the entity of the question, the answer or the relations linking them, which might be quite complicated as well. We thus adopt the subgraph approach. Figure 1 illustrates our model.

3.2 Training and Loss Function

As in (Weston et al., 2010), we train our model using a margin-based ranking loss function. Let $\mathcal{D} = \{(q_i, a_i) : i = 1, \ldots, |\mathcal{D}|\}$ be the training set

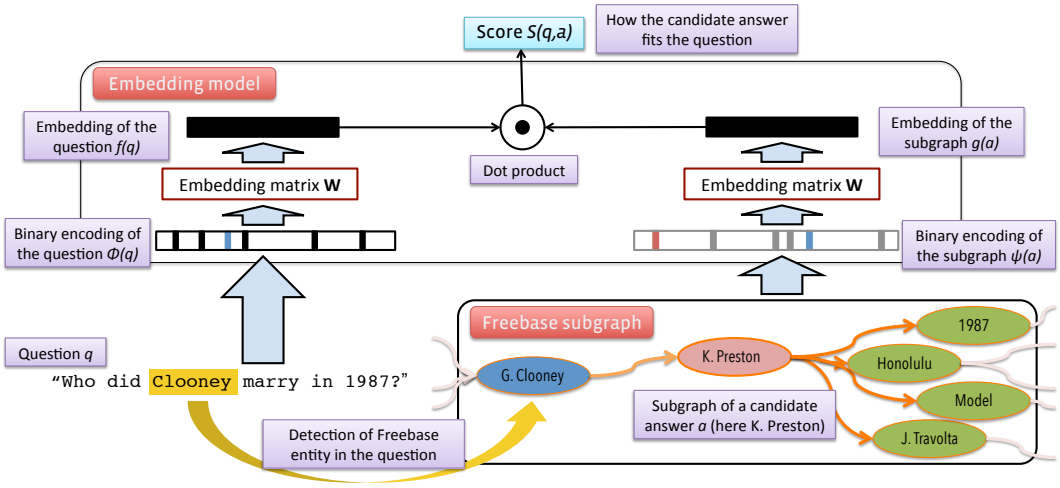

Figure 1: Illustration of the subgraph embedding model scoring a candidate answer: (i) locate entity in the question; (ii) compute path from entity to answer; (iii) represent answer as path plus all connected entities to the answer (the subgraph); (iv) embed both the question and the answer subgraph separately using the learnt embedding vectors, and score the match via their dot product.

of questions q_i paired with their correct answer a_i. The loss function we minimize is

$$\sum_{i=1}^{|\mathcal{D}|} \sum_{\bar{a} \in \bar{\mathcal{A}}(a_i)} \max\{0, m - S(q_i, a_i) + S(q_i, \bar{a})\}, \quad (2)$$

where m is the margin (fixed to 0.1). Minimizing Eq. (2) learns the embedding matrix $\mathbf{W}$ so that the score of a question paired with a correct answer is greater than with any incorrect answer $\bar{a}$ by at least m. $\bar{a}$ is sampled from a set of incorrect candidates $\bar{\mathcal{A}}$. This is achieved by sampling 50% of the time from the set of entities connected to the entity of the question (i.e. other candidate paths), and by replacing the answer entity by a random one otherwise. Optimization is accomplished using stochastic gradient descent, multi-threaded with Hogwild! (Recht et al., 2011), with the constraint that the columns w_i of $\mathbf{W}$ remain within the unit-ball, i.e., $\forall_i, ||w_i||_2 \leq 1$.

3.3 Multitask Training of Embeddings

Since a large number of questions in our training datasets are synthetically generated, they do not adequately cover the range of syntax used in natural language. Hence, we also multi-task the training of our model with the task of paraphrase prediction. We do so by alternating the training of S with that of a scoring function $S_{prp}(q_1, q_2) = f(q_1)^\top f(q_2)$, which uses the same embedding matrix $\mathbf{W}$ and makes the embeddings of a pair of questions (q_1, q_2) similar to each other if they are paraphrases (i.e. if they belong to the same paraphrase cluster), and make them different otherwise. Training S_{prp} is similar to that of S except that negative samples are obtained by sampling a question from another paraphrase cluster.

We also multitask the training of the embeddings with the mapping of the `mids` of FREEBASE entities to the actual words of their names, so that the model learns that the embedding of the `mid` of an entity should be similar to the embedding of the word(s) that compose its name(s).

3.4 Inference

Once $\mathbf{W}$ is trained, at test time, for a given question q the model predicts the answer with:

$$\hat{a} = \text{argmax}_{a' \in \mathcal{A}(q)} S(q, a') \quad (3)$$

where $\mathcal{A}(q)$ is the candidate answer set. This candidate set could be the whole KB but this has both speed and potentially precision issues. Instead, we create a candidate set $\mathcal{A}(q)$ for each question.

We recall that each question contains one identified FREEBASE entity. $\mathcal{A}(q)$ is first populated with all triples from FREEBASE involving this entity. This allows to answer simple factual questions whose answers are directly connected to them (i.e. 1-hop paths). This strategy is denoted C_1.

Since a system able to answer only such questions would be limited, we supplement $\mathcal{A}(q)$ with examples situated in the KB graph at 2-hops from the entity of the question. We do not add all such quadruplets since this would lead to very large candidate sets. Instead, we consider the following general approach: given that we are predicting a path, we can predict its elements in turn using

Method	P@1 (%)	F1 (Berant)	F1 (Yao)
Baselines			
(Berant et al., 2013)	–	31.4	–
(Bordes et al., 2014b)	31.3	29.7	31.8
(Yao and Van Durme, 2014)	–	33.0	42.0
(Berant and Liang, 2014)	–	39.9	43.0
Our approach			
Subgraph & $\mathcal{A}(q) = C_2$	**40.4**	39.2	43.2
Ensemble with (Berant & Liang, 14)	–	**41.8**	**45.7**
Variants			
Without multiple predictions	**40.4**	31.3	34.2
Subgraph & $\mathcal{A}(q) =$ All 2-hops	38.0	37.1	41.4
Subgraph & $\mathcal{A}(q) = C_1$	34.0	32.6	35.1
Path & $\mathcal{A}(q) = C_2$	36.2	35.3	38.5
Single Entity & $\mathcal{A}(q) = C_1$	25.8	16.0	17.8

Table 1: Results on the WEBQUESTIONS test set.

a beam search, and hence avoid scoring all candidates. Specifically, our model first ranks relation types using Eq. (1), i.e. selects which relation types are the most likely to be expressed in q. We keep the top 10 types (10 was selected on the validation set) and only add 2-hops candidates to $\mathcal{A}(q)$ when these relations appear in their path. Scores of 1-hop triples are weighted by 1.5 since they have one less element than 2-hops quadruplets. This strategy, denoted C_2, is used by default.

A prediction a' can commonly actually be a set of candidate answers, not just one answer, for example for questions like *"Who are David Beckham's children?"*. This is achieved by considering a prediction to be all the entities that lie on the same 1-hop or 2-hops path from the entity found in the question. Hence, all answers to the above question are connected to `david_beckham` via the same path (`david_beckham`, `people.person.children`, $\star$). The feature representation of the prediction is then the average over each candidate entity's features (see Section 3.1), i.e. $\psi_{all}(a') = \frac{1}{|a'|} \sum_{a'_j : a'} \psi(a'_j)$ where a'_j are the individual entities in the overall prediction a'. In the results, we compare to a baseline method that can only predict single candidates, which understandly performs poorly.

4 Experiments

We compare our system in terms of F1 score as computed by the official evaluation script[2] (F1 (Berant)) but also with a slightly different F1 definition, termed F1 (Yao) which was used in (Yao and Van Durme, 2014) (the difference being the way that questions with no answers are dealt with), and precision @ 1 (p@1) of the first candidate entity (even when there are a set of correct answers), comparing to recently published systems.[3] The upper part of Table 1 indicates that our approach outperforms (Yao and Van Durme, 2014), (Berant et al., 2013) and (Bordes et al., 2014b), and performs similarly as (Berant and Liang, 2014).

The lower part of Table 1 compares various versions of our model. Our default approach uses the Subgraph representation for answers and C_2 as the candidate answers set. Replacing C_2 by C_1 induces a large drop in performance because many questions do not have answers thatare directly connected to their inluded entity (not in C_1). However, using all 2-hops connections as a candidate set is also detrimental, because the larger number of candidates confuses (and slows a lot) our ranking based inference. Our results also verify our hypothesis of Section 3.1, that a richer representation for answers (using the local subgraph) can store more pertinent information. Finally, we demonstrate that we greatly improve upon the model of (Bordes et al., 2014b), which actually corresponds to a setting with the Path representation and C_1 as candidate set.

We also considered an ensemble of our approach and that of (Berant and Liang, 2014). As we only had access to their test predictions we used the following combination method. Our approach gives a score $S(q, a)$ for the answer it predicts. We chose a threshold such that our approach predicts 50% of the time (when $S(q, a)$ is above its value), and the other 50% of the time we use the prediction of (Berant and Liang, 2014) instead. We aimed for a 50/50 ratio because both methods perform similarly. The ensemble improves the state-of-the-art, and indicates that our models are significantly different in their design.

5 Conclusion

This paper presented an embedding model that learns to perform open QA using training data made of questions paired with their answers and of a KB to provide a structure among answers, and can achieve promising performance on the competitive benchmark WEBQUESTIONS.

[2] Available from www-nlp.stanford.edu/software/sempre/

[3] Results of baselines except (Bordes et al., 2014b) have been extracted from the original papers. For our experiments, all hyperparameters have been selected on the WEBQUESTIONS validation set: k was chosen among $\{64, 128, 256\}$, the learning rate on a log. scale between 10^{-4} and 10^{-1} and we used at most 100 paths in the subgraph representation.

Correcting Keyboard Layout Errors and Homoglyphs in Queries

Derek Barnes debarnes@ebay.com
Mahesh Joshi mahesh.joshi@ebay.com
Hassan Sawaf hsawaf@ebay.com

eBay Inc., 2065 Hamilton Ave, San Jose, CA, 95125, USA

Abstract

Keyboard layout errors and homoglyphs in cross-language queries impact our ability to correctly interpret user information needs and offer relevant results. We present a machine learning approach to correcting these errors, based largely on character-level n-gram features. We demonstrate superior performance over rule-based methods, as well as a significant reduction in the number of queries that yield null search results.

1 Introduction

The success of an eCommerce site depends on how well users are connected with products and services of interest. Users typically communicate their desires through search queries; however, queries are often incomplete and contain errors, which impact the quantity and quality of search results.

New challenges arise for search engines in cross-border eCommerce. In this paper, we focus on two cross-linguistic phenomena that make interpreting queries difficult: **(i) Homoglyphs**: (Miller, 2013): Tokens such as "саse" (underlined letters Cyrillic), in which users mix characters from different character sets that are visually similar or identical. For instance, English and Russian alphabets share homoglyphs such as c, a, e, o, y, k, etc. Although the letters are visually similar or in some cases identical, the underlying character codes are different. **(ii) Keyboard Layout Errors (KLEs)**: (Baytin et al., 2013): When switching one's keyboard between language modes, users at times enter terms in the wrong character set. For instance, "чехол шзфв" may appear to be a Russian query. While "чехол" is the Russian word for "case", "шзфв" is actually the user's attempt to enter the characters "ipad" while leaving their keyboard in Russian language mode. Queries containing KLEs or homoglyphs are unlikely to produce any search results, unless the intended ASCII sequences can be recovered. In a test set sampled from Russian/English queries with null (i.e. empty) search results (see Section 3.1), we found approximately 7.8% contained at least one KLE or homoglyph.

In this paper, we present a machine learning approach to identifying and correcting query tokens containing homoglyphs and KLEs. We show that the proposed method offers superior accuracy over rule-based methods, as well as significant improvement in search recall. Although we focus our results on Russian/English queries, the techniques (particularly for KLEs) can be applied to other language pairs that use different character sets, such as Korean-English and Thai-English.

2 Methodology

In cross-border trade at eBay, multilingual queries are translated into the inventory's source language prior to search. A key application of this, and the focus of this paper, is the translation of Russian queries into English, in order to provide Russian users a more convenient interface to English-based inventory in North America. The presence of KLEs and homoglyphs in multilingual queries, however, leads to poor query translations, which in turn increases the incidence of null search results. We have found that null search results correlate with users exiting our site.

In this work, we seek to correct for KLEs and homoglyphs, thereby improving query translation, reducing the incidence of null search results, and increasing user engagement. Prior to translation and search, we preprocess multilingual queries by identifying and transforming KLEs and homoglyphs as follows (we use the query "чехол шзфв 2 new" as a running example):

(a) Tag Tokens: label each query token

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 621–626,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

with one of the following semantically motivated classes, which identify the user's information need: (i) E: a token intended as an English search term; (ii) R: a Cyrillic token intended as a Russian search term; (iii) K: A KLE, e.g. "шзфв" for the term "ipad". A token intended as an English search term, but at least partially entered in the Russian keyboard layout; (iv) H: A Russian homoglyph for an English term, e.g. "вмw" (underlined letters Cyrillic). Employs visually similar letters from the Cyrillic character set when spelling an intended English term; (v) A: Ambiguous tokens, consisting of numbers and punctuation characters with equivalent codes that can be entered in both Russian and English keyboard layouts. Given the above classes, our example query "чехол шзфв 2 new" should be tagged as "R K A E".

(b) Transform Queries: Apply a deterministic mapping to transform KLE and homoglyph tokens from Cyrillic to ASCII characters. For KLEs the transformation maps between characters that share the same location in Russian and English keyboard layouts (e.g. ф → a, ы → s). For homoglyphs the transformation maps between a smaller set of visually similar characters (e.g. е → e, м → m). Our example query would be transformed into "чехол ipad 2 new".

(c) Translate and Search: Translate the transformed query (into "case ipad 2 new" for our example), and dispatch it to the search engine.

In this paper, we formulate the token-level tagging task as a standard multiclass classification problem (each token is labeled independently), as well as a sequence labeling problem (a first order conditional Markov model). In order to provide end-to-end results, we preprocess queries by deterministically transforming into ASCII the tokens tagged by our model as KLEs or homoglyphs. We conclude by presenting an evaluation of the impact of this transformation on search.

2.1 Features

Our classification and sequence models share a common set of features grouped into the following categories:

2.1.1 Language Model Features

A series of 5-gram, character-level language models (LMs) capture the structure of different types of words. Intuitively, valid Russian terms will have high probability in Russian LMs. In contrast, KLEs or homoglyph tokens, despite appearing on the surface to be Russian terms, will generally have low probability in the LMs trained on valid Russian words. Once mapped into ASCII (see Section 2 above), however, these tokens tend to have higher probability in the English LMs. LMs are trained on the following corpora:

English and Russian Vocabulary: based on a collection of open source, parallel English/Russian corpora (∼50M words in all).

English Brands: built from a curated list of 35K English brand names, which often have distinctive linguistic properties compared with common English words (Lowrey et al., 2013).

Russian Transliterations: built from a collection of Russian transliterations of proper names from Wikipedia (the Russian portion of `guessed-names.ru-en` made available as a part of WMT 2013[1]).

For every input token, each of the above LMs fires a real-valued feature — the negated log-probability of the token in the given language model. Additionally, for tokens containing Cyrillic characters, we consider the token's KLE and homoglyph ASCII mappings, where available. For each mapping, a real-valued feature fires corresponding to the negated log-probability of the mapped token in the English and Brands LMs. Lastly, an equivalent set of LM features fires for the two preceding and following tokens around the current token, if applicable.

2.1.2 Token Features

We include several features commonly used in token-level tagging problems, such as case and shape features, token class (such as letters-only, digits-only), position of the token within the query, and token length. In addition, we include features indicating the presence of characters from the ASCII and/or Cyrillic character sets.

2.1.3 Dictionary Features

We incorporate a set of features that indicate whether a given lowercased query token is a member of one of the lexicons described below.

UNIX: The English dictionary shipped with CentOS, including ∼480K entries, used as a lexicon of common English words.

BRANDS: An expanded version of the curated list of brand names used for LM features. Includes

[1] `www.statmt.org/wmt13/translation-task.html#download`

∼58K brands.

PRODUCT TITLES: A lexicon of over 1.6M entries extracted from a collection of 10M product titles from eBay's North American inventory.

QUERY LOGS: A larger, in-domain collection of approximately 5M entries extracted from ∼100M English search queries on eBay.

Dictionary features fire for Cyrillic tokens when the KLE and/or homoglyph-mapped version of the token appears in the above lexicons. Dictionary features are binary for the Unix and Brands dictionaries, and weighted by relative frequency of the entry for the Product Titles and Query Logs dictionaries.

3 Experiments

3.1 Datasets

The following datasets were used for training and evaluating the baseline (see Section 3.2 below) and our proposed systems:

Training Set: A training set of 6472 human-labeled query examples (17,239 tokens).

In-Domain Query Test Set: A set of 2500 Russian/English queries (8,357 tokens) randomly selected from queries with null search results. By focusing on queries with null results, we emphasize the presence of KLEs and homoglyphs, which occur in 7.8% of queries in our test set.

Queries were labeled by a team of Russian language specialists. The test set was also independently reviewed, which resulted in the correction of labels for 8 out of the 8,357 query tokens.

Although our test set is representative of the types of problematic queries targeted by our model, our training data was not sampled using the same methodology. We expect that the differences in distributions between training and test sets, if anything, make the results reported in Section 3.3 somewhat pessimistic[2].

3.2 Dictionary Baseline

We implemented a rule-based baseline system employing the dictionaries described in Section 2.1.3. In this system, each token was assigned a class $k \in \{\texttt{E}, \texttt{R}, \texttt{K}, \texttt{H}, \texttt{A}\}$ using a set of rules: a token among a list of 101 Russian stopwords[3] is tagged as R. A token containing only ASCII characters is labeled as A if all characters are common to English and Russian keyboards (i.e. numbers and some punctuation), otherwise E. For tokens containing Cyrillic characters, KLE and homoglyph-mapped versions are searched in our dictionaries. If found, K or H are assigned. If both mapped versions are found in the dictionaries, then either K or H is assigned probabilistically[4]. In cases where neither mapped version is found in the dictionary, the token assigned is either R or A, depending on whether it consists of purely Cyrillic characters, or a mix of Cyrillic and ASCII, respectively.

Note that the above tagging rules allow tokens with classes E and A to be identified with perfect accuracy. As a result, we omit these classes from all results reported in this work. We also note that this simplification applies because we have restricted our attention to the Russian → English direction. In the bidirectional case, ASCII tokens could represent either English tokens or KLEs (i.e. a Russian term entered in the English keyboard layout). We leave the joint treatment of the bidirectional case to future work.

Tag	Prec	Recall	F1
K	.528	.924	.672
H	.347	.510	.413
R	.996	.967	.982

Table 1: Baseline results on the test set, using UNIX, BRANDS, and the PRODUCT TITLES dictionaries.

We experimented with different combinations of dictionaries, and found the best combination to be UNIX, BRANDS, and PRODUCT TITLES dictionaries (see Table 1). We observed a sharp decrease in precision when incorporating the QUERY LOGS dictionary, likely due to noise in the user-generated content.

Error analysis suggests that shorter words are the most problematic for the baseline system[5]. Shorter Cyrillic tokens, when transformed from Cyrillic to ASCII using KLE or homoglyph mappings, have a higher probability of spuriously mapping to valid English acronyms, model IDs, or short words. For instance, Russian car brand "ваз" maps across keyboard layouts to "dfp",

[2] As expected, cross-validation experiments on the training data (for parameter tuning) yielded results slightly higher than the results reported in Section 3.3, which use a held-out test set

[3] Taken from the Russian Analyzer packaged with Lucene — see lucene.apache.org.

[4] We experimented with selecting K or H based on a prior computed from training data; however, results were lower than those reported, which use random selection.

[5] Stopwords are particularly problematic, and hence excluded from consideration as KLEs or homoglyphs.

	Tag	Classification			Sequence		
		P	R	F1	P	R	F1
LR	K	.925	.944	.935	.915	.934	.925
	H	.708	.667	.687	.686	.686	.686
	R	.996	.997	.996	.997	.996	.997
RF	K	.926	.949	.937	.935	.949	.942
	H	.732	.588	.652	.750	.588	.659
	R	.997	.997	.997	.996	.998	.997

Table 2: Classification and sequence tagging results on the test set

a commonly used acronym in product titles for "Digital Flat Panel". Russian words "муки" and "рук" similarly map by chance to English words "verb" and "her".

A related problem occurs with product model IDs, and highlights the limits of treating query tokens independently. Consider Cyrillic query "БМВ e46". The first token is a Russian transliteration for the BMW brand. The second token, "e46", has three possible interpretations: i) as a Russian token; ii) a homoglyph for ASCII "e46"; or iii) a KLE for "t46". It is difficult to discriminate between these options without considering token context, and in this case having some prior knowledge that e46 is a BMW model.

3.3 Machine Learning Models

We trained linear classification models using logistic regression (LR)[6], and non-linear models using random forests (RFs), using implementations from the Scikit-learn package (Pedregosa et al., 2011). Sequence models are implemented as first order conditional Markov models by applying a beam search ($k = 3$) on top of the LR and RF classifiers. The LR and RF models were tuned using 5-fold cross-validation results, with models selected based on the mean F1 score across R, K, and H tags.

Table 2 shows the token-level results on our in-domain test set. As with the baseline, we focus the model on disambiguating between classes R, K and H. Each of the reported models performs significantly better than the baseline (on each tag), with statistical significance evaluated using McNemar's test. The differences between LR and RF models, as well as sequence and classification variants, however, are not statistically significant. Each of the machine learning models achieves a query-level accuracy score of roughly 98% (the LR sequence model achieved the lowest with 97.78%, the RF sequence model the highest with 97.90%).

Our feature ablation experiments show that the majority of predictive power comes from the character-level LM features. Dropping LM features results in a significant reduction in performance (F1 scores .878 and .638 for the RF Sequence model on classes K and H). These results are still significantly above the baseline, suggesting that token and dictionary features are by themselves good predictors. However, we do not see a similar performance reduction when dropping these feature groups.

We experimented with lexical features, which are commonly used in token-level tagging problems. Results, however, were slightly lower than the results reported in this section. We suspect the issue is one of overfitting, due to the limited size of our training data, and general sparsity associated with lexical features. Continuous word presentations (Mikolov et al., 2013), noted as future work, may offer improved generalization.

Error analysis for our machine learning models suggests patterns similar to those reported in Section 3.2. Although errors are significantly less frequent than in our dictionary baseline, shorter words still present the most difficulty. We note as future work the use of word-level LM scores to target errors with shorter words.

3.4 Search Results

Recall that we translate multilingual queries into English prior to search. KLEs and homoglyphs in queries result in poor query translations, often leading to null search results.

To evaluate the impact of KLE and homoglyph correction, we consider a set of 100k randomly selected Russian/English queries. We consider the subset of queries that the RF or baseline models predict as containing a KLE or homoglyph. Next, we translate into English both the original query, as well as a transformed version of it, with KLEs and homoglyphs replaced with their ASCII mappings. Lastly, we execute independent searches using original and transformed query translations.

Table 3 provides details on search results for original and transformed queries. The baseline model transforms over 12.6% of the 100k queries. Of those, 24.3% yield search results where the unmodified queries had null search results (i.e. Null → Non-null). In 20.9% of the cases, however, the

[6]Although CRFs are state-of-the-art for many tagging problems, in our experiments they yielded results slightly lower than LR or RF models.

transformations are destructive (i.e. Non-null → Null), and yield null results where the unmodified query produced results.

Compared with the baseline, the RF model transforms only 7.4% of the 100k queries; a fraction that is roughly in line with the 7.8% of queries in our test set that contain KLEs or homoglyphs. In over 42% of the cases (versus 24.3% for the baseline), the transformed query generates search results where the original query yields none. Only 4.81% of the transformations using the RF model are destructive; a fraction significantly lower than the baseline.

Note that we distinguish here only between queries that produce null results, and those that do not. We do not include queries for which original and transformed queries both produce (potentially differing) search results. Evaluating these cases requires deeper insight into the relevance of search results, which is left as future work.

	Baseline	**RF model**
#Transformed	12,661	7,364
Null → Non-Null	3,078 (24.3%)	**3,142 (42.7%)**
Non-Null → Null	2,651 (20.9%)	**354 (4.81%)**

Table 3: Impact of KLE and homoglyph correction on search results for 100k queries

4 Related Work

Baytin et al. (2013) first refer to keyboard layout errors in their work. However, their focus is on predicting the performance of spell-correction, not on fixing KLEs observed in their data. To our knowledge, our work is the first to introduce this problem and to propose a machine learning solution. Since our task is a token-level tagging problem, it is very similar to the part-of-speech (POS) tagging task (Ratnaparkhi, 1996), only with a very small set of candidate tags. We chose a supervised machine learning approach in order to achieve maximum precision. However, this problem can also be approached in an unsupervised setting, similar to the method Whitelaw et al. (2009) use for spelling correction. In that setup, the goal would be to directly choose the correct transformation for an ill-formed KLE or homoglyph, instead of a tagging step followed by a deterministic mapping to ASCII.

5 Conclusions and Future Work

We investigate two kinds of errors in search queries: keyboard layout errors (KLEs) and homoglyphs. Applying machine learning methods, we are able to accurately identify a user's intended query, in spite of the presence of KLEs and homoglyphs. The proposed models are based largely on compact, character-level language models. The proposed techniques, when applied to multilingual queries prior to translation and search, offer significant gains in search results.

In the future, we plan to focus on additional features to improve KLE and homoglyph discrimination for shorter words and acronyms. Although lexical features did not prove useful for this work, presumably due to data sparsity and overfitting issues, we intend to explore the application of continuous word representations (Mikolov et al., 2013). Compared with lexical features, we expect continuous representations to be less susceptible to overfitting, and to generalize better to unknown words. For instance, using continuous word representations, Turian et al. (2010) show significant gains for a named entity recognition task.

We also intend on exploring the use of features from in-domain, word-level LMs. Word-level features are expected to be particularly useful in the case of spurious mappings (e.g. "вaз" vs. "dfp" from Section 3.2), where context from surrounding tokens in a query can often help in resolving ambiguity. Word-level features may also be useful in re-ranking translated queries prior to search, in order to reduce the incidence of erroneous query transformations generated through our methods. Finally, our future work will explore KLE and homoglyph correction bidirectionally, as opposed to the unidirectional approach explored in this work.

Acknowledgments

We would like to thank Jean-David Ruvini, Mike Dillinger, Saša Hasan, Irina Borisova and the anonymous reviewers for their valuable feedback. We also thank our Russian language specialists Tanya Badeka, Tatiana Kontsevich and Olga Pospelova for their support in labeling and reviewing datasets.

Non-linear Mapping for Improved Identification of 1300+ Languages

Ralf D. Brown
Carnegie Mellon University Language Technologies Institute
5000 Forbes Avenue, Pittsburgh PA 15213 USA
ralf@cs.cmu.edu

Abstract

Non-linear mappings of the form $P(ngram)^\gamma$ and $\frac{log(1+\tau P(ngram))}{log(1+\tau)}$ are applied to the n-gram probabilities in five trainable open-source language identifiers. The first mapping reduces classification errors by 4.0% to 83.9% over a test set of more than one million 65-character strings in 1366 languages, and by 2.6% to 76.7% over a subset of 781 languages. The second mapping improves four of the five identifiers by 10.6% to 83.8% on the larger corpus and 14.4% to 76.7% on the smaller corpus. The subset corpus and the modified programs are made freely available for download at http://www.cs.cmu.edu/∼ralf/langid.html.

1 Introduction

Language identification, particularly of short strings, is a task which is becoming quite important as a preliminary step in much automated processing of online data streams such as microblogs (e.g. Twitter). In addition, an increasing number of languages are represented online, so it is desireable that performance remain high as more languages are added to the identifier.

In this paper, we stress-test five open-source n-gram-based language identifiers by presenting them with 65-character strings (about one printed line of text in a book) in up to 1366 languages. We then apply a simple modification to their scoring algorithms which improves the classification accuracy of all five of them, three quite dramatically.

2 Method

The selected modification to the scoring algorithm is to apply a non-linear mapping which spreads out the lower probability values while compacting the higher ones. This low-end spreading of values is the opposite of what one sees in a Zipfian distribution (Zipf, 1935), where the probabilities of the most common items are the most spread out while the less frequent items become ever more crowded as there are increasing numbers of them in ever-smaller ranges. The hypothesis is that regularizing the spacing between values will improve language-identification accuracy by avoiding over-weighting frequent items (from having higher probabilities in the training data and also occurring more frequently in the test string).

Two functions were selected for experiments:

$$x = P(ngram)$$

$$\text{gamma:} \quad y = x^\gamma$$

$$\text{loglike:} \quad y = \frac{log(1 + 10^\tau x)}{log(1 + 10^\tau)}$$

The first simply raises the n-gram probability to a non-unity power; this exponent is named "gamma" as in image processing (Poynton, 1998). The second mapping function is a normalized variant of the logarithm function; the normalization provides fixed points at 0 and 1, as is the case for *gamma*. Each of the functions *gamma* and *loglike* has one tunable parameter, γ and τ, respectively.

3 Related Work

Although n-gram statistics as a basis for language identification has been in use for two decades since Cavnar and Trenkle (1994) and Dunning (1994), little work has been done on trying to optimize the values used for those n-gram statistics. Where some form of frequency mapping is used, it is often implicit (as in Cavnar and Trenkle's use of ranks instead of frequencies) and generally goes unremarked as such.

Vogel and Tresner-Kirsch (2012) use the logarithm of the frequency for some experimental runs, reporting that it improved accuracy in some cases. Gebre *et al* (2013) used logarithmic term-frequency scaling of words in an English-language

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 627–632,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

essay to classify the native language of the writer, reporting an improvement from 82.36% accuracy to 84.55% in conjunction with inverse document frequency (IDF) weighting, and from 79.18% accuracy to 80.82% without IDF.

4 Programs

4.1 `LangDetect`

`LangDetect`, version 2011-09-13 (Shuyo, 2014), uses the Naive Bayes approach. Inputs are split into a bag of character n-grams of length 1 through 3; each randomly-drawn n-gram's probability in each of the trained models is multiplied by the current score for that model. After 1000 n-grams, or when periodic renormalization into a probability distribution detects that one model has accumulated an overwhelming probability mass, the iteration is terminated. After averaging seven randomized iterations, each with a random gaussian offset (mean 5×10^{-6}, standard deviation 0.5×10^{-6}) that is added to each probability prior to multiplication (to avoid multiplication by zero), the highest-scoring model is declared to be the language of the input.

The mapping function is applied to the model's probability before adding the randomized offset. To work around the limitation of one model per language code, disambiguating digits are appended to the language code during training and removed from the output prior to scoring.

4.2 `libtextcat`

`libtextcat`, version 2.2-9 (Hugueney, 2011), is a C reimplementation of the Cavnar and Trenkle (1994) method. It compiles "fingerprints" containing a ranked list of the 400 (by default) most frequent 1- through 5-grams in the training data. An unknown text is classified by forming its fingerprint and comparing that fingerprint against the trained fingerprints. A penalty is assigned based on the number of positions by which each n-gram differs between the input and the trained model; n-grams which appear in only one of the two are assigned the maximum penalty, equal to the size of the fingerprints. The model with the lowest penalty score is selected as the language of the input.

For this work, the `libtextcat` source code was modified to remove the hard-coded fingerprint size of 400 n-grams. While adding the frequency mapping, the code was discovered to also hard-code the maximum distortion penalty at 400; this was corrected to set the maximum penalty equal to the maximum size of any loaded fingerprint.[1]

Score mapping was implemented by dividing each penalty value by the maximum penalty to produce a proportion, applying the mapping function, and then multiplying the result by the maximum penalty and rounding to an integer (to avoid other code changes). Because there are only a limited number of possible penalties, a lookup table is pre-computed, eliminating the impact on speed.

4.3 `mguesser`

`mguesser`, version 0.4 (Barkov, 2008), is part of the mnoGoSearch search engine. While its documentation indicates that it implements the Cavnar and Trenkle approach, its actual similarity computation is very different. Each training and test text is converted into a 4096-element hash table by extracting byte n-grams of length 6 (truncated at control characters and multiple consecutive blanks), hashing each n-gram using CRC-32, and incrementing the count for the corresponding hash entry. The hash table entries are then normalized to a mean of 0.0 and standard deviation of 1.0, and the similarity is computed as the inner (dot) product of the hash tables treated as vectors. The trained model receiving the highest similarity score against the input is declared the language of the input.

Nonlinear mapping was added by inserting a step just prior to the normalization of the hash table. The counts in the table are converted to probabilities by dividing by the sum of counts, the mapping is applied to that probability, and the result is converted back into a count by multiplying by the original sum of counts.

4.4 `whatlang`

`whatlang`, version 1.24 (Brown, 2014a), is the stand-alone identification program from LA-Strings (Brown, 2013). It performs identification by computing the inner product of byte trigrams through k-grams (k=6 by default and in this work) between the input and the trained models; for speed, the computation is performed incrementally, adding the length-weighted probabil-

[1] The behavior observed by (Brown, 2013) of performance rapidly degrading for fingerprints larger than 500 disappears with this correction. It was an artifact of an increasing proportion of n-grams present in the model receiving penalties greater than n-grams absent from the model.

ity of each n-gram as it is encountered in the input. Models are formed by finding the highest-frequency n-grams of the configured lengths, with some filtering as described in (Brown, 2012).

4.5 YALI

YALI (Yet Another Language Identifier) (Majlis, 2012) is an identifier written in Perl. It performs minor text normalization by collapsing multiple blanks into a single blank and removing leading and trailing blanks from lines. Thereafter, it uses a sliding window to generate byte n-grams of a (configurable) fixed length, and sums the probabilities for each n-gram in each trained model. As with whatlang, this effectively computes the inner products between the input and the models.

Mapping was added by applying the mapping function to the model probabilities as they are read in from disk. As with LangDetect, disambiguating digits were used to allow multiple models per language code.

5 Data

The data used for the experiments described in this paper comes predominantly from Bible translations, Wikipedia, and the Europarl corpus of European parliamentary proceedings (Koehn, 2005). The 1459 files of the training corpus generate 1483 models in 1368 languages. A number of training files generate models in both UTF-8 and ISO 8859-1, numerous languages have multiple training files in different writing systems, and several have multiple files for different regional variants (e.g. European and Brazilian Portugese).

The text for a language is split into training, test, and possibly a disjoint development set. The amount of text per language varies, with quartiles of 1.19/1.47/2.22 million bytes. In general, every thirtieth line of text is reserved for the test set; some smaller languages reserve a higher proportion. If more than 3.2 million bytes remain after reserving the test set, every thirtieth line of the remaining text is reserved as a development set. There are development sets for 220 languages. The unreserved test is used for model training.

The test data is word-wrapped to 65 characters or less, and wrapped lines shorter than 25 bytes are excluded. Up to the first 1000 lines of wrapped text are used for testing. One language with fewer than 50 test strings is excluded from the test set, as is the constructed language Klingon due to heavy pollution with English. In total, the test files contain 1,090,571 lines of text in 1366 languages.

Wikipedia text and many of the Bible translations are redistributable under Creative Commons licenses, and have been packaged into the LTI LangID Corpus (Brown, 2014b). This smaller corpus contains 781 languages, 119 of them with development sets, and a total of 649,589 lines in the test files. The languages are a strict subset of those in the larger corpus, but numerous languages have had Wikipedia text substituted for non-redistributable Bible translations.

6 Experiments

Using the data sets described in the previous section, we ran a sweep of different gamma and tau values for each language identifier to determine their optimal values on both development and test strings. Step sizes for γ were generally 0.1, while those for τ were 1.0, with smaller steps near the minima. Since it does not provide explicit control over model sizes, LangDetect was trained on a maximum of 1,000,000 bytes per model, as reported optimal in (Brown, 2013). The other programs were trained on a maximum of 2,500,000 bytes per model; libtextcat and whatlang used default model sizes of 400 and 3500, respectively, while mguesser was set to the previously-reported 1500 n-grams per model. After some experimentation, YALI was set to use 5-grams, with 3500 n-grams per model to match whatlang.

7 Results

Tables 1 and 2 show the absolute performance and relative percentage change in classification errors for the five programs using the two mapping functions, as well as the values of γ and τ at which the fewest errors were made on the development set. Overall, the smaller corpus performed worse due to the greater percentage of Wikipedia texts, which are polluted with words and phrases in other languages. In the test set, this occasionally causes a correct identification as another language to be scored as an error.

Figures 2 and 3 graph the classification error rates (number of incorrectly-labeled strings divided by total number of strings in the test set) in percent for different values of γ. A gamma of 1.0 is the baseline condition. The dramatic improvements in mguesser, whatlang and YALI are quite evident, while the smaller but non-trivial im-

		gamma mapping			*loglike* mapping

YALI	8.726	2.972	-65.9	0.09	2.989	-65.7	9.0

Table 2: Language-identification accuracy on the 781-language corpus. γ and τ were tuned on the 119-language development set. `libtextcat` did not improve with the *loglike* mapping (see text).

provements in `libtextcat` are difficult to discern at this scale. Since `libtextcat` uses much smaller models than the others by default, Figure 1 gives a closer look at its performance for larger model sizes. As the models grow, the absolute baseline performance improves, but the change from gamma-correction decreases and the optimal value of γ also decreases toward 1.0. This hints that the implicit mapping of ranks either becomes closer to optimal, or that *gamma* becomes less effective at correcting it. At a model size of 3000 n-grams, the baseline error rate is 2.465% while the best performance is 2.457% at $\gamma = 1.10$.

That the best γ for `libtextcat` is greater than 1.0 was not entirely unexpected. The power-law distribution of n-gram frequencies implies that the conversion from frequencies to ranks is essentially logarithmic, and $\log n$ eventually becomes less than n^c for any $c > 0$. The implication of $\gamma > 1$ is simply that the conversion to ranks is too strong a correction, which must be partially undone by the *gamma* mapping.

Figures 4 and 5 graph the error rates for different values of τ. On the graph, zero is the baseline condition without mapping for comparison purposes; the mapping function is not the identity for $\tau = 0$. It can clearly be seen that `libtextcat` is hurt by the *loglike* mapping, which never reduces values, even with negative τ. Using the inverse of

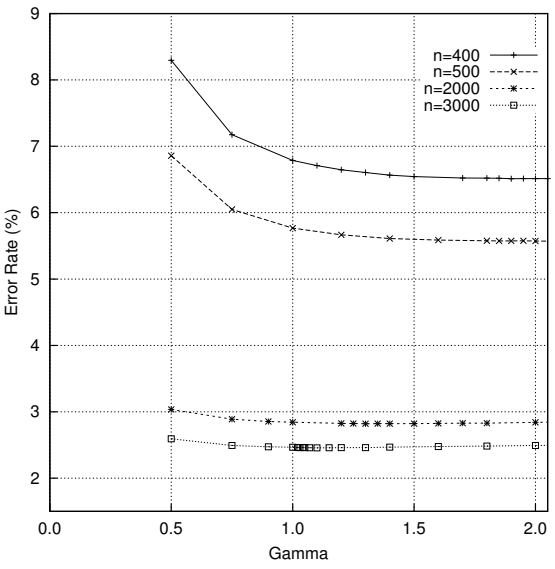

Figure 1: `libtextcat` performance at different fingerprint sizes. $\gamma = 1$ is the baseline.

the *loglike* mapping should improve performance, but has not yet been tried. The other programs show very similar behavior to their results with *gamma*.

8 Conclusions and Future Work

Non-linear mapping is shown to be effective at improving the accuracy of five different language

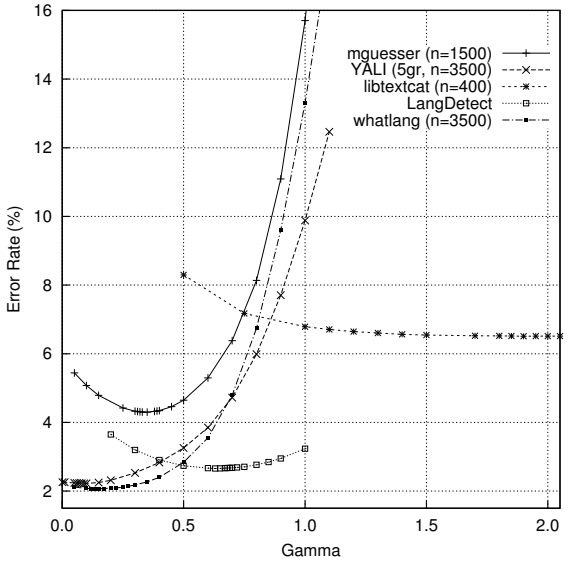

Figure 2: Performance of the identifiers on the 1366-language corpus using the *gamma* mapping.

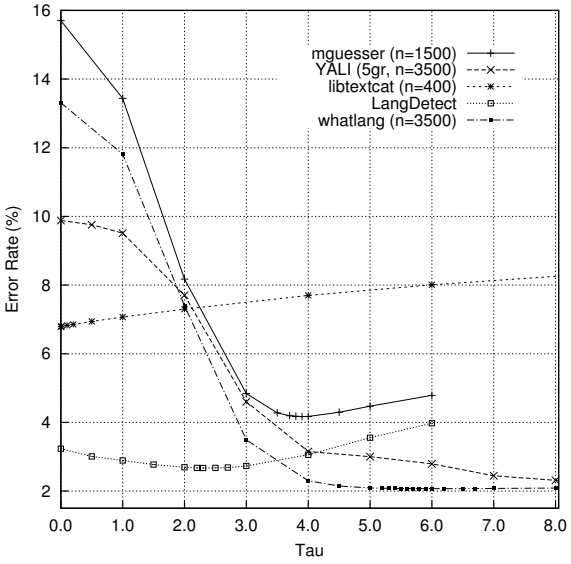

Figure 4: Performance of the identifiers on the 1366-language corpus using the *loglike* mapping.

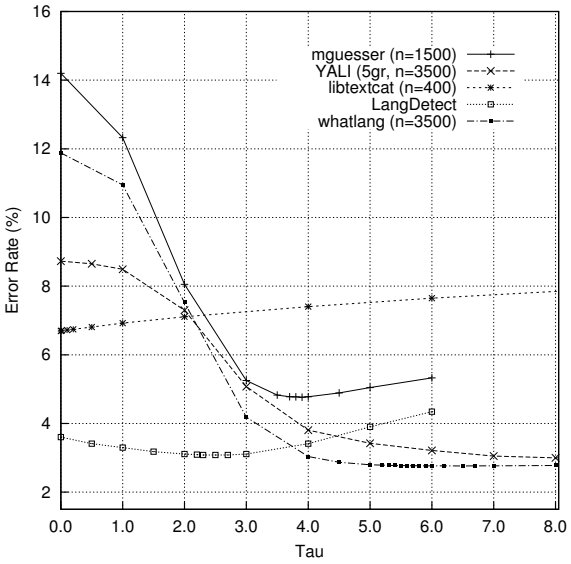

Figure 5: Performance of the identifiers on the 781-language corpus using the *loglike* mapping.

identifier using four highly-divergent algorithms for computing model scores from n-gram statistics. Improvements range from small – 2.6% reduction in classification errors – to dramatic for the three programs with the worst baselines – 65.2 to 76.7% reduction in errors on the smaller corpus and 72.4 to 83.9% on the larger. While both mappings have similar performance for four of the programs, `libtextcat` only benefits from the *gamma* mapping, as it can also reduce n-gram scores, unlike the *loglike* mapping.

Training data, source code, and supplementary information may be downloaded from http://www.cs.cmu.edu/∼ralf/langid.html.

Future work includes modifying additional language identifiers such as `langid.py` (Lui and Baldwin, 2012) and `VarClass` (Zampieri and Gebre, 2014), experimenting with other mapping functions, and investigating the method's efficacy on pluricentric languages like those `VarClass` is designed to identify.

Abstract

Text classification methods for tasks like factoid question answering typically use manually defined string matching rules or bag of words representations. These methods are ineffective when question text contains very few individual words (e.g., named entities) that are indicative of the answer. We introduce a recursive neural network (RNN) model that can reason over such input by modeling textual compositionality. We apply our model, QANTA, to a dataset of questions from a trivia competition called quiz bowl. Unlike previous RNN models, QANTA learns word and phrase-level representations that combine across sentences to reason about entities. The model outperforms multiple baselines and, when combined with information retrieval methods, rivals the best human players.

1 Introduction

Deep neural networks have seen widespread use in natural language processing tasks such as parsing, language modeling, and sentiment analysis (Bengio et al., 2003; Socher et al., 2013a; Socher et al., 2013c). The vector spaces learned by these models cluster words and phrases together based on similarity. For example, a neural network trained for a sentiment analysis task such as restaurant review classification might learn that "tasty" and "delicious" should have similar representations since they are synonymous adjectives.

These models have so far only seen success in a limited range of text-based prediction tasks, where inputs are typically a single sentence and outputs are either continuous or a limited discrete set. Neural networks have not yet shown to be useful for tasks that require mapping paragraph-length inputs to rich output spaces.

Later in its existence, this polity's leader was chosen by a group that included three bishops and six laymen, up from the seven who traditionally made the decision. Free imperial cities in this polity included Basel and Speyer. Dissolved in 1806, its key events included the Investiture Controversy and the Golden Bull of 1356. Led by Charles V, Frederick Barbarossa, and Otto I, for 10 points, name this polity, which ruled most of what is now Germany through the Middle Ages and rarely ruled its titular city.

Figure 1: An example quiz bowl question about the Holy Roman Empire. The first sentence contains no words or named entities that by themselves are indicative of the answer, while subsequent sentences contain more and more obvious clues.

Consider factoid question answering: given a description of an entity, identify the person, place, or thing discussed. We describe a task with high-quality mappings from natural language text to entities in Section 2. This task—quiz bowl—is a challenging natural language problem with large amounts of diverse and compositional data.

To answer quiz bowl questions, we develop a dependency tree recursive neural network in Section 3 and extend it to combine predictions across sentences to produce a question answering neural network with trans-sentential averaging (QANTA). We evaluate our model against strong computer and human baselines in Section 4 and conclude by examining the latent space and model mistakes.

2 Matching Text to Entities: Quiz Bowl

Every weekend, hundreds of high school and college students play a game where they map raw text to well-known entities. This is a trivia competition called *quiz bowl*. Quiz bowl questions consist of four to six sentences and are associated with factoid answers (e.g., history questions ask players to identify specific battles, presidents, or events). Every sentence in a quiz bowl question is guaranteed to contain clues that uniquely identify its answer, even without the context of previous sentences. Players answer at any time—ideally more quickly than the opponent—and are rewarded for correct answers.

Automatic approaches to quiz bowl based on existing NLP techniques are doomed to failure. Quiz bowl questions have a property called *pyramidality*, which means that sentences early in a question contain harder, more obscure clues, while later sentences are "giveaways". This design rewards players with deep knowledge of a particular subject and thwarts bag of words methods. Sometimes the first sentence contains no named entities—answering the question correctly requires an actual understanding of the sentence (Figure 1). Later sentences, however, progressively reveal more well-known and uniquely identifying terms.

Previous work answers quiz bowl questions using a bag of words (naïve Bayes) approach (Boyd-Graber et al., 2012). These models fail on sentences like the first one in Figure 1, a typical hard, initial clue. Recursive neural networks (RNNs), in contrast to simpler models, can capture the compositional aspect of such sentences (Hermann et al., 2013).

RNNs require many redundant training examples to learn meaningful representations, which in the quiz bowl setting means we need multiple questions about the same answer. Fortunately, hundreds of questions are produced during the school year for quiz bowl competitions, yielding many different examples of questions asking about any entity of note (see Section 4.1 for more details). Thus, we have built-in redundancy (the number of "askable" entities is limited), but also built-in diversity, as difficult clues cannot appear in every question without becoming well-known.

3 Dependency-Tree Recursive Neural Networks

To compute distributed representations for the individual sentences within quiz bowl questions, we use a dependency-tree RNN (DT-RNN). These representations are then aggregated and fed into a multinomial logistic regression classifier, where class labels are the answers associated with each question instance.

In previous work, Socher et al. (2014) use DT-RNNs to map text descriptions to images. DT-RNNs are robust to similar sentences with slightly different syntax, which is ideal for our problem since answers are often described by many sentences that are similar in meaning but different in structure. Our model improves upon the existing DT-RNN model by jointly learning answer and question representations in the same vector space rather than learning them separately.

3.1 Model Description

As in other RNN models, we begin by associating each word w in our vocabulary with a vector representation $x_w \in \mathbb{R}^d$. These vectors are stored as the columns of a $d \times V$ dimensional word embedding matrix W_e, where V is the size of the vocabulary. Our model takes dependency parse trees of question sentences (De Marneffe et al., 2006) and their corresponding answers as input.

Each node n in the parse tree for a particular sentence is associated with a word w, a word vector x_w, and a hidden vector $h_n \in \mathbb{R}^d$ of the same dimension as the word vectors. For internal nodes, this vector is a phrase-level representation, while at leaf nodes it is the word vector x_w mapped into the hidden space. Unlike in constituency trees where all words reside at the leaf level, internal nodes of dependency trees are associated with words. Thus, the DT-RNN has to combine the current node's word vector with its children's hidden vectors to form h_n. This process continues recursively up to the root, which represents the entire sentence.

We associate a separate $d \times d$ matrix W_r with each dependency relation r in our dataset and learn these matrices during training.[1] Syntactically untying these matrices improves com-

[1] We had 46 unique dependency relations in our quiz bowl dataset.

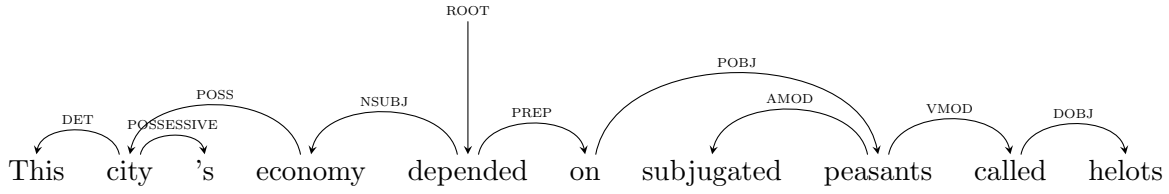

Figure 2: Dependency parse of a sentence from a question about Sparta.

positionality over the standard RNN model by taking into account relation identity along with tree structure. We include an additional $d \times d$ matrix, W_v, to incorporate the word vector x_w at a node into the node vector h_n.

Given a parse tree (Figure 2), we first compute leaf representations. For example, the hidden representation h_{helots} is

$$h_{\text{helots}} = f(W_v \cdot x_{\text{helots}} + b), \quad (1)$$

where f is a non-linear activation function such as tanh and b is a bias term. Once all leaves are finished, we move to interior nodes with already processed children. Continuing from "helots" to its parent, "called", we compute

$$h_{\text{called}} = f(W_{\text{DOBJ}} \cdot h_{\text{helots}} + W_v \cdot x_{\text{called}} + b). \quad (2)$$

We repeat this process up to the root, which is

$$h_{\text{depended}} = f(W_{\text{NSUBJ}} \cdot h_{\text{economy}} + W_{\text{PREP}} \cdot h_{\text{on}} + W_v \cdot x_{\text{depended}} + b). \quad (3)$$

The composition equation for any node n with children $K(n)$ and word vector x_w is $h_n =$

$$f(W_v \cdot x_w + b + \sum_{k \in K(n)} W_{R(n,k)} \cdot h_k), \quad (4)$$

where $R(n, k)$ is the dependency relation between node n and child node k.

3.2 Training

Our goal is to map questions to their corresponding answer entities. Because there are a limited number of possible answers, we can view this as a multi-class classification task. While a softmax layer over every node in the tree could predict answers (Socher et al., 2011; Iyyer et al., 2014), this method overlooks that most answers are themselves words (features) in other questions (e.g., a question on *World War II* might mention the *Battle of the Bulge* and vice versa). Thus, word vectors associated with such answers can be trained in the same vector space as question text,[2] enabling us to model relationships between answers instead of assuming incorrectly that all answers are independent.

To take advantage of this observation, we depart from Socher et al. (2014) by training both the answers and questions jointly in a single model, rather than training each separately and holding embeddings fixed during DT-RNN training. This method cannot be applied to the multimodal text-to-image mapping problem because text captions by definition are made up of words and thus cannot include images; in our case, however, question text can and frequently does include answer text.

Intuitively, we want to encourage the vectors of question sentences to be near their correct answers and far away from incorrect answers. We accomplish this goal by using a contrastive max-margin objective function described below. While we are not interested in obtaining a ranked list of answers,[3] we observe better performance by adding the weighted approximate-rank pairwise (WARP) loss proposed in Weston et al. (2011) to our objective function.

Given a sentence paired with its correct answer c, we randomly select j incorrect answers from the set of all incorrect answers and denote this subset as Z. Since c is part of the vocabulary, it has a vector $x_c \in W_e$. An incorrect answer $z \in Z$ is also associated with a vector $x_z \in W_e$. We define S to be the set of all nodes in the sentence's dependency tree, where an individual node $s \in S$ is associated with the

[2] Of course, questions never contain their own answer as part of the text.

[3] In quiz bowl, all wrong guesses are equally detrimental to a team's score, no matter how "close" a guess is to the correct answer.

hidden vector h_s. The error for the sentence is

$$C(S,\theta) = \sum_{s\in S}\sum_{z\in Z} L(rank(c,s,Z))\max(0, 1 - x_c \cdot h_s + x_z \cdot h_s), \quad (5)$$

where the function $rank(c,s,Z)$ provides the rank of correct answer c with respect to the incorrect answers Z. We transform this rank into a loss function[4] shown by Usunier et al. (2009) to optimize the top of the ranked list, $L(r) = \sum_{i=1}^{r} 1/i$.

Since $rank(c,s,Z)$ is expensive to compute, we approximate it by randomly sampling K incorrect answers until a violation is observed ($x_c \cdot h_s < 1 + x_z \cdot h_s$) and set $rank(c,s,Z) = (|Z|-1)/K$, as in previous work (Weston et al., 2011; Hermann et al., 2014). The model minimizes the sum of the error over all sentences T normalized by the number of nodes N in the training set,

$$J(\theta) = \frac{1}{N}\sum_{t\in T} C(t,\theta). \quad (6)$$

The parameters $\theta = (W_{r\in R}, W_v, W_e, b)$, where R represents all dependency relations in the data, are optimized using AdaGrad(Duchi et al., 2011).[5] In Section 4 we compare performance to an identical model (FIXED-QANTA) that excludes answer vectors from W_e and show that training them as part of θ produces significantly better results.

The gradient of the objective function,

$$\frac{\partial C}{\partial \theta} = \frac{1}{N}\sum_{t\in T}\frac{\partial J(t)}{\partial \theta}, \quad (7)$$

is computed using backpropagation through structure (Goller and Kuchler, 1996).

3.3 From Sentences to Questions

The model we have just described considers each sentence in a quiz bowl question independently. However, previously-heard sentences within the same question contain useful information that we do not want our model to ignore. While past work on RNN models have been restricted to the sentential and sub-sentential levels, we show that sentence-level representations can be easily combined to generate useful representations at the larger paragraph level.

The simplest and best[6] aggregation method is just to average the representations of each sentence seen so far in a particular question. As we show in Section 4, this method is very powerful and performs better than most of our baselines. We call this averaged DT-RNN model QANTA: a question answering neural network with trans-sentential averaging.

4 Experiments

We compare the performance of QANTA against multiple strong baselines on two datasets. QANTA outperforms all baselines trained only on question text and improves an information retrieval model trained on all of Wikipedia. QANTA requires that an input sentence describes an entity without mentioning that entity, a constraint that is not followed by Wikipedia sentences.[7] While IR methods can operate over Wikipedia text with no issues, we show that the representations learned by QANTA over just a dataset of question-answer pairs can significantly improve the performance of IR systems.

4.1 Datasets

We evaluate our algorithms on a corpus of over 100,000 question/answer pairs from two different sources. First, we expand the dataset used in Boyd-Graber et al. (2012) with publically-available questions from quiz bowl tournaments held after that work was published. This gives us 46,842 questions in fourteen different categories. To this dataset we add 65,212 questions from NAQT, an organization that runs quiz bowl tournaments and generously shared with us all of their questions from 1998–2013.

[4] Our experiments show that adding this loss term to the objective function not only increases performance but also speeds up convergence

[5] We set the initial learning rate $\eta = 0.05$ and reset the squared gradient sum to zero every five epochs.

[6] We experimented with weighting earlier sentences less than later ones in the average as well as learning an additional RNN on top of the sentence-level representations. In the former case, we observed no improvements over a uniform average, while in the latter case the model overfit even with strong regularization.

[7] We tried transforming Wikipedia sentences into quiz bowl sentences by replacing answer mentions with appropriate descriptors (e.g., "Joseph Heller" with "this author"), but the resulting sentences suffered from a variety of grammatical issues and did not help the final result.

Because some categories contain substantially fewer questions than others (e.g., astronomy has only 331 questions), we consider only literature and history questions, as these two categories account for more than 40% of the corpus. This leaves us with 21,041 history questions and 22,956 literature questions.

4.1.1 Data Preparation

To make this problem feasible, we only consider a limited set of the most popular quiz bowl answers. Before we filter out uncommon answers, we first need to map all raw answer strings to a canonical set to get around formatting and redundancy issues. Most quiz bowl answers are written to provide as much information about the entity as possible. For example, the following is the raw answer text of a question on the Chinese leader Sun Yat-sen: *Sun Yat-sen; or Sun Yixian; or Sun Wen; or Sun Deming; or Nakayama Sho; or Nagao Takano*. Quiz bowl writers vary in how many alternate acceptable answers they provide, which makes it tricky to strip superfluous information from the answers using rule-based approaches.

Instead, we use Whoosh,[8] an information retrieval library, to generate features in an active learning classifier that matches existing answer strings to Wikipedia titles. If we are unable to find a match with a high enough confidence score, we throw the question out of our dataset. After this standardization process and manual vetting of the resulting output, we can use the Wikipedia page titles as training labels for the DT-RNN and baseline models.[9]

65.6% of answers only occur once or twice in the corpus. We filter out all answers that do not occur at least six times, which leaves us with 451 history answers and 595 literature answers that occur on average twelve times in the corpus. These pruning steps result in 4,460 usable history questions and 5,685 literature questions. While ideally we would have used all answers, our model benefits from many training examples per answer to learn meaningful representations; this issue can possibly be addressed with techniques from zero shot learning (Palatucci et al., 2009; Pasupat and Liang, 2014), which we leave to future work.

We apply basic named entity recognition (NER) by replacing all occurrences of answers in the question text with single entities (e.g., *Ernest Hemingway* becomes *Ernest_Hemingway*). While we experimented with more advanced NER systems to detect non-answer entities, they could not handle multi-word named entities like the book *Love in the Time of Cholera* (title case) or battle names (e.g., *Battle of Midway*). A simple search/replace on all answers in our corpus works better for multi-word entities.

The preprocessed data are split into folds by tournament. We choose the past two national tournaments[10] as our test set as well as questions previously answered by players in Boyd-Graber et al. (2012) and assign all other questions to train and dev sets. History results are reported on a training set of 3,761 questions with 14,217 sentences and a test set of 699 questions with 2,768 sentences. Literature results are reported on a training set of 4,777 questions with 17,972 sentences and a test set of 908 questions with 3,577 sentences.

Finally, we initialize the word embedding matrix W_e with word2vec (Mikolov et al., 2013) trained on the preprocessed question text in our training set.[11] We use the hierarchical skip-gram model setting with a window size of five words.

4.2 Baselines

We pit QANTA against two types of baselines: bag of words models, which enable comparison to a standard NLP baseline, and information retrieval models, which allow us to compare against traditional question answering techniques.

BOW The BOW baseline is a logistic regression classifier trained on binary unigram indicators.[12] This simple discriminative model is an improvement over the generative quiz bowl answering model of Boyd-Graber et al. (2012).

[8] `https://pypi.python.org/pypi/Whoosh/`

[9] Code and non-NAQT data available at `http://cs.umd.edu/~miyyer/qblearn`.

[10] The tournaments were selected because NAQT does not reuse any questions or clues within these tournaments.

[11] Out-of-vocabulary words from the test set are initialized randomly.

[12] Raw word counts, frequencies, and TF-IDF weighted features did not increase performance, nor did adding bigrams to the feature set (possibly because multi-word named entities are already collapsed into single words).

BOW-DT The BOW-DT baseline is identical to BOW except we augment the feature set with dependency relation indicators. We include this baseline to isolate the effects of the dependency tree structure from our compositional model.

IR-QB The IR-QB baseline maps questions to answers using the state-of-the-art Whoosh IR engine. The knowledge base for IR-QB consists of "pages" associated with each answer, where each page is the union of training question text for that answer. Given a partial question, the text is first preprocessed using a query language similar to that of Apache Lucene. This processed query is then matched to pages uses BM-25 term weighting, and the top-ranked page is considered to be the model's guess. We also incorporate fuzzy queries to catch misspellings and plurals and use Whoosh's built-in query expansion functionality to add related keywords to our queries. **IR-WIKI** The IR-WIKI model is identical to the IR-QB model except that each "page" in its knowledge base also includes all text from the associated answer's Wikipedia article. Since all other baselines and DT-RNN models operate only on the question text, this is not a valid comparison, but we offer it to show that we can improve even this strong model using QANTA.

4.3 DT-RNN Configurations

For all DT-RNN models the vector dimension d and the number of wrong answers per node j is set to 100. All model parameters other than W_e are randomly initialized. The non-linearity f is the normalized tanh function,[13]

$$f(v) = \frac{\tanh(v)}{\|\tanh(v)\|}. \quad (8)$$

QANTA is our DT-RNN model with feature averaging across previously-seen sentences in a question. To obtain the final answer prediction given a partial question, we first generate a feature representation for each sentence within that partial question. This representation is computed by concatenating together the word embeddings and hidden representations averaged over all nodes in the tree as well as the root node's hidden vector. Finally, we send the average of all of the individual sentence features[14] as input to a logistic regression classifier for answer prediction.

FIXED-QANTA uses the same DT-RNN configuration as QANTA except the answer vectors are kept constant as in the text-to-image model.

4.4 Human Comparison

Previous work provides human answers (Boyd-Graber et al., 2012) for quiz bowl questions. We use human records for 1,201 history guesses and 1,715 literature guesses from twenty-two of the quiz bowl players who answered the most questions.[15]

The standard scoring system for quiz bowl is **10** points for a correct guess and **-5** points for an incorrect guess. We use this metric to compute a total score for each human. To obtain the corresponding score for our model, we force it to imitate each human's guessing policy. For example, Figure 3 shows a human answering in the middle of the second sentence. Since our model only considers sentence-level increments, we compare the model's prediction after the first sentence to the human prediction, which means our model is privy to less information than humans.

The resulting distributions are shown in Figure 4—our model does better than the average player on history questions, tying or defeating sixteen of the twenty-two players, but it does worse on literature questions, where it only ties or defeats eight players. The figure indicates that literature questions are harder than history questions for our model, which is corroborated by the experimental results discussed in the next section.

5 Discussion

In this section, we examine why QANTA improves over our baselines by giving examples of questions that are incorrectly classified by all baselines but correctly classified by QANTA. We also take a close look at some sentences that all models fail to answer correctly. Finally, we visualize the answer space learned by QANTA.

[13]The standard tanh function produced heavy saturation at higher levels of the trees, and corrective weighting as in Socher et al. (2014) hurt our model because named entities that occur as leaves are often more important than non-terminal phrases.

[14]Initial experiments with L_2 regularization hurt performance on a validation set.

[15]Participants were skilled quiz bowl players and are not representative of the general population.

	History			Literature		
Model	Pos 1	Pos 2	Full	Pos 1	Pos 2	Full
BOW	27.5	51.3	53.1	19.3	43.4	46.7
BOW-DT	35.4	57.7	60.2	24.4	51.8	55.7
IR-QB	37.5	65.9	71.4	27.4	54.0	61.9
FIXED-QANTA	38.3	64.4	66.2	28.9	57.7	62.3
QANTA	**47.1**	**72.1**	**73.7**	**36.4**	**68.2**	**69.1**
IR-WIKI	53.7	76.6	77.5	41.8	74.0	73.3
QANTA+IR-WIKI	**59.8**	**81.8**	**82.3**	**44.7**	**78.7**	**76.6**

Table 1: Accuracy for history and literature at the first two sentence positions of each question and the full question. The top half of the table compares models trained on questions only, while the IR models in the bottom half have access to Wikipedia. QANTA outperforms all baselines that are restricted to just the question data, and it substantially improves an IR model with access to Wikipedia despite being trained on much less data.

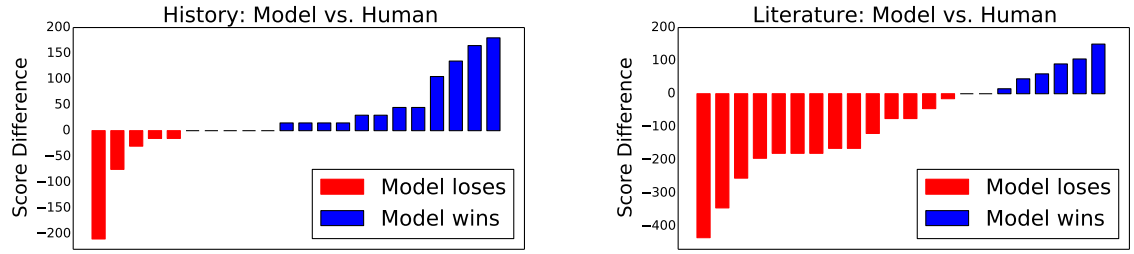

Figure 4: Comparisons of QANTA+IR-WIKI to human quiz bowl players. Each bar represents an individual human, and the bar height corresponds to the difference between the model score and the human score. Bars are ordered by human skill. Red bars indicate that the human is winning, while blue bars indicate that the model is winning. QANTA+IR-WIKI outperforms most humans on history questions but fails to defeat the "average" human on literature questions.

A minor character in this play can be summoned by a bell that does not always work; that character also doesn't have eyelids. Near the end, a woman who drowned her illegitimate child attempts to stab another woman in the Second Empire-style ◇ room in which the entire play takes place. For 10 points, Estelle and Ines are characters in which existentialist play in which Garcin claims "Hell is other people", written by Jean-Paul Sartre?

Figure 3: A question on the play "No Exit" with human buzz position marked as ◇. Since the buzz occurs in the middle of the second sentence, our model is only allowed to see the first sentence.

5.1 Experimental Results

Table 1 shows that when bag of words and information retrieval methods are restricted to question data, they perform significantly worse than QANTA on early sentence positions. The performance of BOW-DT indicates that while the dependency tree structure helps by itself, the compositional distributed representations learned by QANTA are more useful. The significant improvement when we train answers as part of our vocabulary (see Section 3.2) indicates that our model uses answer occurrences within question text to learn a more informative vector space.

The disparity between IR-QB and IR-WIKI indicates that the information retrieval models need lots of external data to work well at all sentence positions. IR-WIKI performs better than other models because Wikipedia contains many more sentences that partially match specific words or phrases found in early clues than the question training set. In particular, it is impossible for all other models to answer clues in the test set that have no semantically similar

or equivalent analogues in the training question data. With that said, IR methods can also operate over data that does not follow the special constraints of quiz bowl questions (e.g., every sentence uniquely identifies the answer, answers don't appear in their corresponding questions), which QANTA cannot handle. By combining QANTA and IR-WIKI, we are able to leverage access to huge knowledge bases along with deep compositional representations, giving us the best of both worlds.

5.2 Where the Attribute Space Helps Answer Questions

We look closely at the first sentence from a literature question about the author Thomas Mann: "He left unfinished a novel whose title character forges his father's signature to get out of school and avoids the draft by feigning desire to join".

All baselines, including IR-WIKI, are unable to predict the correct answer given only this sentence. However, QANTA makes the correct prediction. The sentence contains no named entities, which makes it almost impossible for bag of words or string matching algorithms to predict correctly. Figure 6 shows that the plot description associated with the "novel" node is strongly indicative of the answer. The five highest-scored answers are all male authors,[16] which shows that our model is able to learn the answer type without any hand-crafted rules.

Our next example, the first sentence in Table 2, is from the first position of a question on John Quincy Adams, which is correctly answered by only QANTA. The bag of words model guesses Henry Clay, who was also a Secretary of State in the nineteenth century and helped John Quincy Adams get elected to the presidency in a "corrupt bargain". However, the model can reason that while Henry Clay was active at the same time and involved in the same political problems of the era, he did not represent the Amistad slaves, nor did he negotiate the Treaty of Ghent.

5.3 Where all Models Struggle

Quiz bowl questions are intentionally written to make players work to get the answer, especially at early sentence positions. Our model fails to answer correctly more than half the time after hearing only the first sentence. We examine some examples to see if there are any patterns to what makes a question "hard" for machine learning models.

Consider this question about the Italian explorer John Cabot: "As a young man, this native of Genoa disguised himself as a Muslim to make a pilgrimage to Mecca".

While it is obvious to human readers that the man described in this sentence is not actually a Muslim, QANTA has to accurately model the verb *disguised* to make that inference. We show the score plot of this sentence in Figure 7. The model, after presumably seeing many instances of *muslim* and *mecca* associated with Mughal emperors, is unable to prevent this information from propagating up to the root node. On the bright side, our model is able to learn that the question is expecting a human answer rather than non-human entities like the Umayyad Caliphate.

More examples of impressive answers by QANTA as well as incorrect guesses by all systems are shown in Table 2.

5.4 Examining the Attribute Space

Figure 5 shows a t-SNE visualization (Van der Maaten and Hinton, 2008) of the 451 answers in our history dataset. The vector space is divided into six general clusters, and we focus in particular on the US presidents. Zooming in on this section reveals temporal clustering: presidents who were in office during the same timeframe occur closer together. This observation shows that QANTA is capable of learning attributes of entities during training.

6 Related Work

There are two threads of related work relevant to this paper. First, we discuss previous applications of compositional vector models to related NLP tasks. Then, we examine existing work on factoid question-answering and review the similarities and differences between these tasks and the game of quiz bowl.

6.1 Recursive Neural Networks for NLP

The principle of *semantic composition* states that the meaning of a phrase can be derived

[16] three of whom who also have well-known unfinished novels

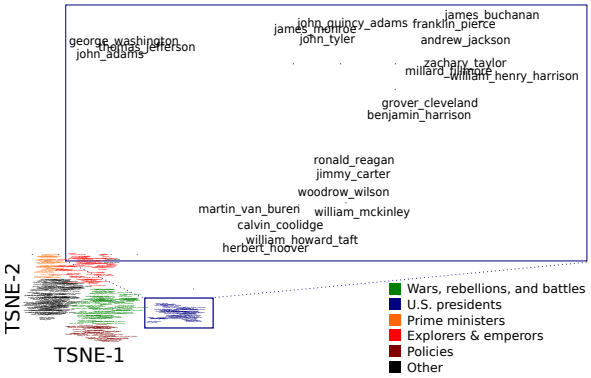

Figure 5: t-SNE 2-D projections of 451 answer vectors divided into six major clusters. The blue cluster is predominantly populated by U.S. presidents. The zoomed plot reveals temporal clustering among the presidents based on the years they spent in office.

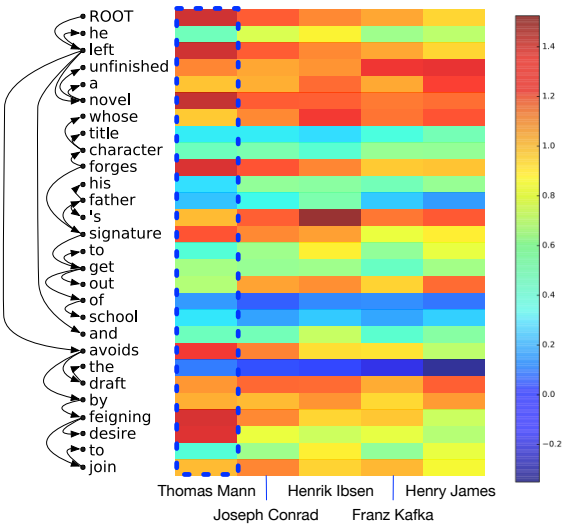

Figure 6: A question on the German novelist Thomas Mann that contains no named entities, along with the five top answers as scored by QANTA. Each cell in the heatmap corresponds to the score (inner product) between a node in the parse tree and the given answer, and the dependency parse of the sentence is shown on the left. All of our baselines, including IR-WIKI, are wrong, while QANTA uses the plot description to make a correct guess.

from the meaning of the words that it contains as well as the syntax that glues those words together. Many computational models of compositionality focus on learning vector spaces (Zanzotto et al., 2010; Erk, 2012; Grefenstette et al., 2013; Yessenalina and Cardie, 2011). Recent approaches towards modeling compositional vector spaces with neural networks have been successful, although simpler functions have been proposed for short phrases (Mitchell and Lapata, 2008).

Recursive neural networks have achieved state-of-the-art performance in sentiment analysis and parsing (Socher et al., 2013c; Hermann and Blunsom, 2013; Socher et al., 2013a). RNNs have not been previously used for learning attribute spaces as we do here, although recursive tensor networks were unsuccessfully applied to a knowledge base completion task (Socher et al., 2013b). More relevant to this work are the dialogue analysis model proposed by Kalchbrenner & Blunsom (2013) and the paragraph vector model described in Le and Mikolov (2014), both of which are able to generate distributed representations of paragraphs. Here we present a simpler approach where a single model is able to learn complex sentence representations and average them across paragraphs.

6.2 Factoid Question-Answering

Factoid question answering is often functionally equivalent to information retrieval. Given a knowledge base and a query, the goal is to return the answer. Many approaches to this problem rely on hand-crafted pattern matching and answer-type classification to narrow down the search space (Shen, 2007; Bilotti et al., 2010; Wang, 2006). More recent factoid QA systems incorporate the web and social media into their retrieval systems (Bian et al., 2008). In contrast to these approaches, we place the burden of learning answer types and patterns on the model.

7 Future Work

While we have shown that DT-RNNs are effective models for quiz bowl question answering, other factoid QA tasks are more challenging. Questions like *what does the* AARP *stand for?* from TREC QA data require additional infrastructure. A more apt comparison would be to IBM's proprietary Watson system (Lally et al., 2012) for Jeopardy, which is limited to single sentences, or to models trained on Yago (Hoffart et al., 2013).

We would also like to fairly compare QANTA

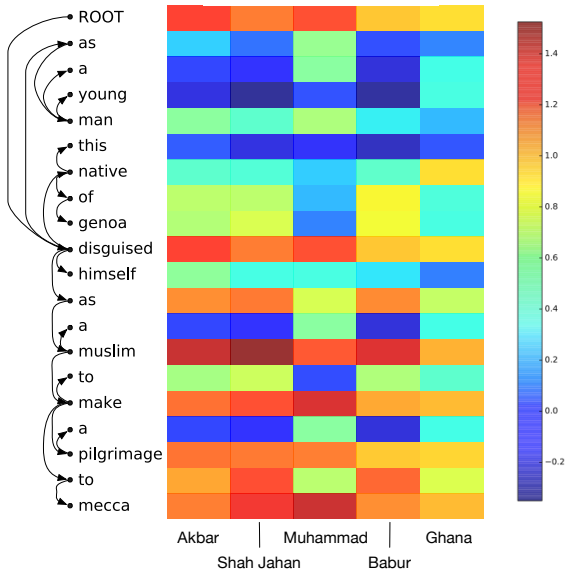

Figure 7: An extremely misleading question about John Cabot, at least to computer models. The words *muslim* and *mecca* lead to three Mughal emperors in the top five guesses from QANTA; other models are similarly led awry.

Q	he also successfully represented the amistad slaves and negotiated the treaty of ghent and the annexation of florida from spain during his stint as secretary of state under james monroe
A	**john quincy adams**, henry clay, andrew jackson
Q	this work refers to people who fell on their knees in hopeless cathedrals and who jumped off the brooklyn bridge
A	**howl**, the tempest, paradise lost
Q	despite the fact that twenty six martyrs were crucified here in the late sixteenth century it remained the center of christianity in its country
A	**nagasaki**, guadalcanal, ethiopia
Q	this novel parodies freudianism in a chapter about the protagonist 's dream of holding a live fish in his hands
A	billy budd, the ambassadors, all my sons
Q	a contemporary of elizabeth i he came to power two years before her and died two years later
A	grover cleveland, benjamin harrison, henry cabot lodge

Table 2: Five example sentences occuring at the first sentence position along with their top three answers as scored by QANTA; correct answers are marked with blue and wrong answers are marked with red. QANTA gets the first three correct, unlike all other baselines. The last two questions are too difficult for all of our models, requiring external knowledge (e.g., *Freudianism*) and temporal reasoning.

with IR-WIKI. A promising avenue for future work would be to incorporate Wikipedia data into QANTA by transforming sentences to look like quiz bowl questions (Wang et al., 2007) and to select relevant sentences, as not every sentence in a Wikipedia article directly describes its subject. Syntax-specific annotation (Sayeed et al., 2012) may help in this regard.

Finally, we could adapt the attribute space learned by the DT-RNN to use information from knowledge bases and to aid in knowledge base completion. Having learned many facts about entities that occur in question text, a DT-RNN could add new facts to a knowledge base or check existing relationships.

8 Conclusion

We present QANTA, a dependency-tree recursive neural network for factoid question answering that outperforms bag of words and information retrieval baselines. Our model improves upon a contrastive max-margin objective function from previous work to dynamically update answer vectors during training with a single model. Finally, we show that sentence-level representations can be easily and effectively combined to generate paragraph-level representations with more predictive power than those of the individual sentences.

Abstract

Transforming a natural language (NL) question into a corresponding logical form (LF) is central to the knowledge-based question answering (KB-QA) task. Unlike most previous methods that achieve this goal based on mappings between lexicalized phrases and logical predicates, this paper goes one step further and proposes a novel embedding-based approach that maps NL-questions into LFs for KB-QA by leveraging semantic associations between lexical representations and KB-properties in the latent space. Experimental results demonstrate that our proposed method outperforms three KB-QA baseline methods on two publicly released QA data sets.

1 Introduction

Knowledge-based question answering (KB-QA) involves answering questions posed in natural language (NL) using existing knowledge bases (KBs). As most KBs are structured databases, how to transform the input question into its corresponding structured query for KB (KB-query) as a logical form (LF), also known as semantic parsing, is the central task for KB-QA systems. Previous works (Mooney, 2007; Liang et al., 2011; Cai and Yates, 2013; Fader et al., 2013; Berant et al., 2013; Bao et al., 2014) usually leveraged mappings between NL phrases and logical predicates as lexical triggers to perform transformation tasks in semantic parsing, but they had to deal with two limitations: (i) as the meaning of a logical predicate often has different natural language expression (NLE) forms, the lexical triggers extracted for a predicate may at times are limited in size; (ii) entities detected by the named entity recognition (NER) component will be used to compose the logical forms together with the logical predicates, so their types should be consistent with the predicates as well. However, most NER components used in existing KB-QA systems are independent from the NLE-to-predicate mapping procedure.

We present a novel embedding-based KB-QA method that takes all the aforementioned limitations into account, and maps NLE-to-entity and NLE-to-predicate simultaneously using simple vector operations for structured query construction. First, low-dimensional embeddings of n-grams, entity types, and predicates are jointly learned from an existing knowledge base and from entries $<entity_{subj}$, *NL relation phrase,* $entity_{obj}>$ that are mined from NL texts labeled as KB-properties with weak supervision. Each such entry corresponds to an NL expression of a triple $<entity_{subj}$, *predicate,* $entity_{obj}>$ in the KB. These embeddings are used to measure the semantic associations between lexical phrases and two properties of the KB, entity type and logical predicate. Next, given an NL-question, all possible structured queries as candidate LFs are generated and then they are ranked by the similarity between the embeddings of observed features (n-grams) in the NL-question and the embeddings of logical features in the structured queries. Last, answers are retrieved from the KB using the selected LFs.

The contributions of this work are two-fold: (1) as a smoothing technique, the low-dimensional embeddings can alleviate the coverage issues of lexical triggers; (2) our joint approach integrates entity span selection and predicate mapping tasks for KB-QA. For this we built independent entity embeddings as the additional component, solving the entity disambiguation problem.

2 Related Work

Supervised semantic parsers (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Mooney, 2007) heavily rely on the *<sentence, semantic an-*

notation> pairs for lexical trigger extraction and model training. Due to the data annotation requirement, such methods are usually restricted to specific domains, and struggle with the coverage issue caused by the limited size of lexical triggers.

Studies on weakly supervised semantic parsers have tried to reduce the amount of human supervision by using question-answer pairs (Liang et al., 2011) or distant supervision (Krishnamurthy and Mitchell, 2012) instead of full semantic annotations. Still, for KB-QA, the question of how to leverage KB-properties and analyze the question structures remains.

Bordes et al. (2012) and Weston et al. (2013) designed embedding models that connect free texts with KBs using the relational learning method (Weston et al., 2010). Their inputs are often statement sentences which include subject and object entities for a given predicate, whereas NL-questions lack either a subject or object entity that is the potential answer. Hence, we can only use the information of a subject or object entity, which leads to a different training instance generation procedure and a different training criterion.

Recently, researchers have developed open domain systems based on large scale KBs such as FREEBASE[1] (Cai and Yates, 2013; Fader et al., 2013; Berant et al., 2013; Kwiatkowski et al., 2013; Bao et al., 2014; Berant and Liang, 2014; Yao and Van Durme, 2014). Their semantic parsers for Open QA are unified formal and scalable: they enable the NL-question to be mapped into the appropriate logical form. Our method obtains similar logical forms, but using only low-dimensional embeddings of n-grams, entity types, and predicates learned from texts and KB.

3 Setup

3.1 Relational Components for KB-QA

Our method learns semantic mappings between NLEs and the KB[2] based on the paired relationships of the following three components: $\mathcal{C}$ denotes a set of bag-of-words (or n-grams) as context features (c) for NLEs that are the lexical representations of a logical predicate (p) in KB; $\mathcal{T}$ denotes a set of entity types (t) in KB and each type can be used as the abstract expression of a subject entity (s) that occurs in the input question; $\mathcal{P}$ denotes a set of logical predicates (p) in KB, each of which is the canonical form of different NLEs sharing an identical meaning (bag-of-words; c).

Based on the components defined above, the paired relationships are described as follows: $\mathcal{T}$-$\mathcal{P}$ can investigate the relationship between subject entity and logical predicate, as object entity is always missing in KB-QA; $\mathcal{C}$-$\mathcal{T}$ can scrutinize subject entity's attributes for the entity span selection such as its positional information and relevant entity types to the given context, which may solve the entity disambiguation problem in KB-QA; $\mathcal{C}$-$\mathcal{P}$ can leverage the semantic overlap between question contexts (n-gram features) and logical predicates, which is important for mapping NL-questions to their corresponding predicates.

3.2 NLE-KB Pair Extraction

This section describes how we extract the semantic associated pairs of NLE-entries and KB-triples to learn the relational embeddings (Section 4.1).

<Relation Mention, Predicate> Pair ($\mathcal{MP}$) Each relation mention denotes a lexical phrase of an existing KB-predicate. Following information extraction methods, such as PATTY (Nakashole et al., 2012), we extracted the *<relation mention, logical predicate>* pairs from English WIKIPEDIA[3], which is closely connected to our KB, as follows: Given a KB-triple *<entity$_{subj}$, logical predicate, entity$_{obj}$>*, we extracted NLE-entries *<entity$_{subj}$, relation mention, entity$_{obj}$>* where *relation mention* is the shortest path between *entity$_{subj}$* and *entity$_{obj}$* in the dependency tree of sentences. The assumption is that any *relation mention* (m) in the NLE-entry containing such entity pairs that occurred in the KB-triple is likely to express the *predicate* (p) of that triple.

With obtaining high-quality $\mathcal{MP}$ pairs, we kept only relation mentions that were highly associated with a predicate measured by the scoring function:

$$S(m,p) = \mathsf{PMI}(e_m; e_p) + \mathsf{PMI}(u_m; u_p) \quad (1)$$

where e_x is the set of total pairs of both-side entities of entry x (m or p) and u_x is the set of unique (distinct) pairs of both-side entities of entry x. In this case, the both-side entities indicate *entity$_{subj}$* and *entity$_{obj}$*. For a frequency-based probability, $\mathsf{PMI}(x;y) = \log \frac{P(x,y)}{P(x)P(y)}$

[1] http://www.freebase.com

[2] For this paper, we used a large scale knowledge base that contains 2.3B entities, 5.5K predicates, and 18B assertions. A 16-machine cluster was used to host and serve the whole data.

[3] http://en.wikipedia.org/

(Church and Hanks, 1990) can be re-written as $\mathsf{PMI}(x;y) = \log \frac{|x \bigcap y| \cdot C}{|x| \cdot |y|}$, where C denotes the total number of items shown in the corpus. The function is partially derived from the *support* score (Gerber and Ngonga Ngomo, 2011), but we focus on the correlation of shared entity pairs between relation mentions and predicates using the PMI computation.

<Question Pattern, Predicate> Pair ($\mathcal{QP}$) Since WIKIPEDIA articles have no information to leverage interrogative features which highly depend on the object entity (answer), it is difficult to distinguish some questions that are composed of only different *5W1H* words, e.g., {*When*|*Where*} *was Barack Obama born?* Hence, we used the method of collecting question patterns with human labeled predicates that are restricted by the set of predicates used in $\mathcal{MP}$ (Bao et al., 2014).

4 Embedding-based KB-QA

Our task is as follows. First, our model learns the semantic associations of $\mathcal{C}$-$\mathcal{T}$, $\mathcal{C}$-$\mathcal{P}$, and $\mathcal{T}$-$\mathcal{P}$ (Section 3.1) based on NLE-KB pairs (Section 3.2), and then predicts the semantic-related KB-query which can directly find the answer to a given NL-question.

For our feature space, given an NLE-KB pair, the NLE (*relation mention* in $\mathcal{MP}$ or *question pattern* in $\mathcal{QP}$) is decomposed into n-gram features: $\mathbb{C} = \{c \mid c \textit{ is a segment of NLE}\}$, and the KB-properties are represented by entity type t of *entity$_{subj}$* and predicate p. Then we can obtain a training triplet $w = [\mathbb{C}, t, p]$. Each feature ($c \in \mathcal{C}, t \in \mathcal{T}, p \in \mathcal{P}$) is encoded in the distributed representation which is n-dimensional embedding vectors ($\mathbb{E}^n$): $\forall x,\ x \overset{encode}{\Rightarrow} \mathbb{E}(x) \in \mathbb{E}^n$.

All n-gram features ($\mathbb{C}$) for an NLE are merged into one embedding vector to help speed up the learning process: $\mathbb{E}(\mathbb{C}) = \sum_{c \in \mathbb{C}} \mathbb{E}(c)/|\mathbb{C}|$. This feature representation is inspired by previous work in embedding-based relation extraction (Weston et al., 2013), but differs in the following ways: (1) entity information is represented on a separate embedding, but its positional information remains as symbol ⟨entity⟩; (2) when the vectors are combined, we use the average of each index to normalize features.

For our joint relational approach, we focus on the set of paired relationships $\mathbb{R} = \{\mathbb{C}\text{-}t, \mathbb{C}\text{-}p, t\text{-}p\}$ that can be semantically leveraged. Formally, these features are embedded into the same latent space ($\mathbb{E}^n$) and their semantic similarities can be computed by a dot product operation:

$$Sim(a,b) = Sim(r_{ab}) = \mathbb{E}(a)^{\intercal}\mathbb{E}(b) \quad (2)$$

where r_{ab} denotes a paired relationship a-b (or (a, b)) in the above set $\mathbb{R}$. We believe that our joint relational learning can smooth the surface (lexical) features for semantic parsing using the aligned entity and predicate.

4.1 Joint Relational Embedding Learning

Our ranking-based relational learning is based on a ranking loss (Weston et al., 2010) that supports the idea that the similarity scores of observed pairs in the training set (*positive instances*) should be larger than those of any other pairs (*negative instances*):

$$\forall i, \forall y' \neq y_i,\ Sim(x_i, y_i) > 1 + Sim(x_i, y') \quad (3)$$

More precisely, for each triplet $w_i = [\mathbb{C}_i, t_i, p_i]$ obtained from an NLE-KB pair, the relationships $\mathbb{R}_i = \{\mathbb{C}_i\text{-}t_i,\ \mathbb{C}_i\text{-}p_i,\ t_i\text{-}p_i\}$ are trained under the soft ranking criterion, which conducts Stochastic Gradient Descent (SGD). We thus aim to minimize the following:

$$\forall i, \forall y' \neq y_i, \max(0, 1 - Sim(x_i, y_i) + Sim(x_i, y')) \quad (4)$$

Our learning strategy is as follows. First, we initialize embedding space $\mathbb{E}^n$ by randomly giving mean 0 and standard deviation $1/n$ to each vector. Then for each training triplet w_i, we select the negative pairs against positive pairs ($\mathbb{C}_i$-t_i, $\mathbb{C}_i$-p_i, and t_i-p_i) in the triplet. Last, we make a stochastic gradient step to minimize Equation 4 and update $\mathbb{E}^n$ at each step.

4.2 KB-QA using Embedding Models

Our goal for KB-QA is to translate a given NL-question to a KB-query with the form <*subject entity, predicate, ?*>, where *?* denotes the answer entity we are looking for. The decoding process consists of two stages. The first stage involves generating all possible KB-queries ($\mathcal{K}^q$) for an NL-question q. We first extract n-gram features ($\mathbb{C}^q$) from the NL-question q. Then for a KB-query k^q, we find all available entity types (t^q) of the identified subject entities (s^q) using the dictionary-based entity detection on the NL-question q (all of spans can be candidate entities), and assign all items of predicate set ($\mathcal{P}$) as the candidate predicates (p^q). Like the training triplets,

q	*where is the city of david?*
$\hat{k}(q)$	[The City of David, contained_by, ?]
$\mathbb{C}^q$	n-grams of "where is ⟨entity⟩ ?"
t^q	location
p^q	contained_by

Table 1: The corresponding KB-query $\hat{k}(q)$ for a NL-question q and its decoding triplet w^q.

we also represent the above features as the triplet form $w_i^q = [\mathbb{C}_i^q, t_i^q, p_i^q]$ which is directly linked to a KB-query $k_i^q = [s_i^q, p_i^q, ?]$. The second stage involves ranking candidate KB-queries based on the similarity scores between the following paired relationships from the triplet w_i^q: $\mathbb{R}_i^q = \{\mathbb{C}_i^q\text{-}t_i^q, \mathbb{C}_i^q\text{-}p_i^q, t_i^q\text{-}p_i^q\}$. Unlike in the training step, the similarities of $\mathbb{C}_i^q$-t_i^q and $\mathbb{C}_i^q$-p_i^q are computed by summation of all pairwise elements (each context embedding $\mathbb{E}(c)$, not $\mathbb{E}(\mathbb{C})$, with each paired $\mathbb{E}(t)$ or $\mathbb{E}(p)$) for a more precise measurement. Since similarites of $\mathbb{R}^q$ are calculated on different scales, we normalize each value using Z-score ($Z(x) = \frac{x-\mu}{\sigma}$) (Kreyszig, 1979). The final score is measured by:

$$Sim_{q2k}(q, k^q) = \sum_{r \in \mathbb{R}^q} Z(Sim(r)) \qquad (5)$$

Then, given any NL-question q, we can predict the corresponding KB-query $\hat{k}(q)$:

$$\hat{k}(q) = \arg\max_{k \in \mathcal{K}^q} Sim_{q2k}(q, k) \qquad (6)$$

Last, we can retrieve an answer from the KB using a structured query $\hat{k}(q)$. Table 1 shows an example of our decoding process.

Multi-related Question Some questions include two-subject entities, both of which are crucial to understanding the question. For the question *who plays gandalf in the lord of the rings?* Gandalf (character) and The Lord Of The Rings (film) are explicit entities that should be joined to a pair of the two entities (implicit entity). More precisely, the two entities can be combined into one concatenated entity (character-in-film) using our manual rule, which compares the possible pairs of entity types in the question with the list of pre-defined entity type pairs that can be merged into a concatenated entity. Our solution enables a multi-related question to be transformed to a single-related question which can be directly translated to a KB-query. Then, the two entity mentions are replaced with the symbol ⟨entity⟩ (who play ⟨entity⟩ in ⟨entity⟩ ?). We regard the result of this transformation as one of the candidate KB-queries in the decoding step.

	# Entries	Accuracy
$\mathcal{MP}$ pairs	291,585	89%
$\mathcal{QP}$ pairs	4,764	98%

Table 2: Statistics of NLE-KB pairs

5 Experiments

Experimental Setting We first performed preprocessing, including lowercase transformation, lemmatization and tokenization, on NLE-KB pairs and evaluation data. We used 71,310 n-grams (uni-, bi-, tri-), 990 entity types, and 660 predicates as relational components shown in Section 3.1. The sum of these three numbers (72,960) equals the size of the embeddings we are going to learn. In Table 2, we evaluated the quality of NLE-KB pairs ($\mathcal{MP}$ and $\mathcal{QP}$) described in Section 3.2. We can see that the quality of $\mathcal{QP}$ pairs is good, mainly due to human efforts. Also, we obtained $\mathcal{MP}$ pairs that have an acceptable quality using *threshold 3.0* for Equation 1, which leverages the redundancy information in the large-scale data (WIKIPEDIA). For our embedding learning, we set the embedding dimension n to 100, the learning rate (λ) for SGD to 0.0001, and the iteration number to 30. To make the decoding procedure computable, we kept only the popular KB-entity in the dictionary to map different entity mentions into a KB-entity.

We used two publicly released data sets for QA evaluations: **Free917** (Cai and Yates, 2013) includes the annotated lambda calculus forms for each question, and covers 81 domains and 635 Freebase relations; **WebQ.** (Berant et al., 2013) provides 5,810 question-answer pairs that are built by collecting common questions from Web-query logs and by manually labeling answers. We used the previous three approaches (Cai and Yates, 2013; Berant et al., 2013; Bao et al., 2014) as our baselines.

Experimental Results Table 3 reports the overall performances of our proposed KB-QA method on the two evaluation data sets and compares them with those of the three baselines. Note that we did not re-implement the baseline systems, but just borrowed the evaluation results reported in their

Methods	Free917	WebQ.
Cai and Yates (2013)	59.00%	N/A
Berant et al. (2013)	62.00%	31.40%
Bao et al. (2014)	N/A	37.50%
Our method	71.38%	41.34%

Table 3: Accuracy on the evaluation data

Methods	Free917	WebQ.
Our method	71.38%	41.34%
w/o $\mathcal{T}$-$\mathcal{P}$	70.65%	40.55%
w/o $\mathcal{C}$-$\mathcal{T}$	67.03%	38.44%
w/o $\mathcal{C}$-$\mathcal{P}$	31.16%	19.24%

Table 4: Ablation of the relationship types

papers. Although the KB used by our system is much larger than FREEBASE, we still think that the experimental results are directly comparable because we disallow all the entities that are not included in FREEBASE.

Table 3 shows that our method outperforms the baselines on both **Free917** and **WebQ.** data sets. We think that using the low-dimensional embeddings of n-grams rather than the lexical triggers greatly improves the coverage issue. Unlike the previous methods which perform entity disambiguation and predicate prediction separately, our method jointly performs these two tasks. More precisely, we consider the relationships $\mathcal{C}$-$\mathcal{T}$ and $\mathcal{C}$-$\mathcal{P}$ simultaneously to rank candidate KB-queries. In Table 1, the most independent NER in KB-QA systems may detect David as the subject entity, but our joint approach can predict the appropriate subject entity The City of David by leveraging not only the relationships with other components but also other relationships at once. The syntax-based (grammar formalism) approaches such as Combinatory Categorial Grammar (CCG) may experience errors if a question has grammatical errors. However, our bag-of-words model-based approach can handle any question as long as the question contains keywords that can help in understanding it.

Table 4 shows the contributions of the relationships ($\mathbb{R}$) between relational components $\mathcal{C}$, $\mathcal{T}$, and $\mathcal{P}$. For each row, we remove the similarity from each of the relationship types described in Section 3.1. We can see that the $\mathcal{C}$-$\mathcal{P}$ relationship plays a crucial role in translating NL-questions to KB-queries, while the other two relationships are slightly helpful.

Result Analysis Since the majority of questions in **WebQ.** tend to be more natural and diverse, our method cannot find the correct answers to many questions. The errors can be caused by any of the following reasons. First, some NLEs cannot be easily linked to existing KB-predicates, making it difficult to find the answer entity. Second, some entities can be mentioned in several different ways, e.g., nickname (*shaq*→Shaquille O'neal) and family name (*hitler*→Adolf Hitler). Third, in terms of KB coverage issues, we cannot detect the entities that are unpopular. Last, feature representation for a question can fail when the question consists of rare n-grams.

The two training sets shown in Section 3.2 are complementary: $\mathcal{QP}$ pairs provide more opportunities for us to learn the semantic associations between interrogative words and predicates. Such resources are especially important for understanding NL-questions, as most of them start with such 5W1H words; on the other hand, $\mathcal{MP}$ pairs enrich the semantic associations between context information (n-gram features) and predicates.

6 Conclusion

In this paper, we propose a novel method that transforms NL-questions into their corresponding logical forms using joint relational embeddings. We also built a simple and robust KB-QA system based on only the learned embeddings. Such embeddings learn the semantic associations between natural language statements and KB-properties from NLE-KB pairs that are automatically extracted from English WIKIPEDIA using KB-triples with weak supervision. Then, we generate all possible structured queries derived from latent logical features of the given NL-question, and rank them based on the similarity scores between those relational attributes. The experimental results show that our method outperforms the latest three KB-QA baseline systems. For our future work, we will build concept-level context embeddings by leveraging latent meanings of NLEs rather than their surface n-grams with the aligned logical features on KB.

Abstract

Wikipedia's link structure is a valuable resource for natural language processing tasks, but only a fraction of the concepts mentioned in each article are annotated with hyperlinks. In this paper, we study how to augment Wikipedia with additional high-precision links. We present *3W*, a system that identifies concept mentions in Wikipedia text, and links each mention to its referent page. *3W* leverages rich semantic information present in Wikipedia to achieve high precision. Our experiments demonstrate that *3W* can add an average of seven new links to each Wikipedia article, at a precision of 0.98.

1 Introduction

Wikipedia forms a valuable resource for many Natural Language Processing and Information Extraction tasks, such as Entity Linking (Cucerzan, 2007; Han and Zhao, 2009), Ontology Construction (Wu and Weld, 2008; Syed et al., 2008) and Knowledge Base Population (Hoffart et al., 2013; Lehmann et al., 2013). Wikipedia's links provide disambiguated semantic information. For example, when a system processes the text *"Chicago was received with critical acclaim"* from an article, the system does not need to infer the referent entity of *"Chicago"* if the word is already hyperlinked to the Wikipedia page of the Oscar-winning film. Unfortunately, in Wikipedia only a fraction of the phrases that can be linked are in fact annotated with a hyperlink. This is due to Wikipedia's conventions of only linking to each concept once, and only when the links have a certain level of utility for human readers.[1] We see this as an opportunity to improve Wikipedia as a resource for NLP systems. Our experiments estimate that as of September 2013, there were an average of 30 references to Wikipedia concepts left unlinked within each of English Wikipedia's four million pages.

In this paper, our goal is to augment Wikipedia with additional high-precision links, in order to provide a new resource for systems that use Wikipedia's link structure as a foundation. Identifying references to concepts (called *mentions*) in text and linking them to Wikipedia is a task known as *Wikification*. Wikification for general text has been addressed in a wide variety of recent work (Mihalcea and Csomai, 2007; Milne and Witten, 2008b; McNamee and Dang, 2009; Ratinov et al., 2011). The major challenge of this task is to resolve the ambiguity of phrases, and recent work makes use of various kinds of information found in the document to tackle the challenge. In contrast to this body of work, here we focus on the special case of Wikifying *Wikipedia articles*, instead of general documents. This gives us an advantage over general-text systems due to Wikipedia's rich content and existing link structure.

We introduce *3W*, a system that identifies mentions within Wikipedia and links each to its referent concept. We show how a Wikipedia-specific Semantic Relatedness measure that leverages the link structure of Wikipedia (Milne and Witten, 2008b) allows *3W* to be radically more precise at high levels of yield when compared to baseline Wikifiers that target general text. Our experiment shows that *3W* can add on average seven new links per article at precision of 0.98, adding approximately 28 million new links to 4 million articles across English Wikipedia.[2]

2 Problem Definition

In this section, we define our link extraction task. A link l is a pair of a surface form s_l and a concept t_l. A *surface form* is a span of tokens in an article, and the *concept* is a Wikipedia article referred to by the surface form. For existing hyperlinks, the surface form corresponds to the anchor text and the concept is the link target. For example, a hyperlink *[[Chicago City | Chicago]]* has surface form *"Chicago City"* and referent concept *Chicago*.[3] Given documents $\mathcal{D} = \{d_1, ..., d_{|\mathcal{D}|}\}$ and a set of links $\mathcal{L} = \{l_1, .., l_{|\mathcal{L}|}\} \in \mathcal{D}$, our goal is to generate a set of high-precision links $\mathcal{L}^*$ for $\mathcal{D}$, distinct from $\mathcal{L}$. In this paper, the document set $\mathcal{D}$ consists of articles from English Wikipedia, and $\mathcal{L}$ is the set of existing links on Wikipedia.

The task can be divided into 3 steps. The first step is to *extract* a set of potential mentions $\mathcal{M} = \{m_1, .., m_{|\mathcal{M}|}\}$ where m is, similar to l, a pair of surface form s_m and a set of candidate concepts $\mathcal{C}(m) = \{t_1, ..., t_{|\mathcal{C}(m)|}\}$. For m having $|\mathcal{C}(m)| > 1$, we need to *disambiguate* it by selecting only one target concept $t_m \in \mathcal{C}(m)$. Since the correct concept may not exist in $\mathcal{C}(m)$ and the previous step could output an incorrect concept, the final step is to decide whether to *link* and include m in $\mathcal{L}^*$. We describe the details of these steps in the following section.

3 System Overview

In this section, we describe in detail how *3W* adds high-precision links to Wikipedia.

3.1 Mention Extraction

In this step, we are given a document d, and the goal is to output a set of mentions $\mathcal{M}$. Our system finds a set of potential surface forms, s_m, by finding substrings in d that match the surface form of some links in $\mathcal{L}$. For example, from the phrase *"map of the United States on the wall"*, we can match 4 potential surface forms: *"map"*, *"United States"*, *"map of the United States"*, and *"wall"*. Notice that some of them are overlapping. The system selects a non-overlapping subset of the surface forms that maximizes the following score function:

$$Score(\mathcal{M}) = \sum_{m \in \mathcal{M}} \frac{T(s_m) PL(s_m)}{|\mathcal{C}(m)|} \quad (1)$$

[3] http://en.wikipedia.org/wiki/Chicago

where $PL(s_m)$ is the probability that the text s_m is linked (that is, the fraction of the occurrences of the string s_m in the corpus that are hyperlinked), $T(s_m)$ is the number of tokens in s_m, and $|\mathcal{C}(m)|$ is the number of candidate concepts. Intuitively, we prefer a longer surface form that is frequently linked and has a specific meaning. Furthermore, we eliminate common surface forms (i.e. *"wall"*) by requiring that $PL(s_m)$ exceed a threshold. In the previous example, we are left with only *"map of the United States"*.

Because Wikipedia's concepts are largely noun phrases, *3W* only looks for surface forms from top-level noun phrases generated by the Stanford Parser (Socher et al., 2013). In addition, each name entity (NE) (Finkel et al., 2005) is treated as an atomic token, meaning that multi-word NEs such as *"California Institute of the Arts"* will not be broken into multiple surface forms.

Finally, the system pairs the result surface forms with a set of candidate concepts, $\mathcal{C}(m)$, and outputs a set of mentions. $\mathcal{C}(m)$ consists of those concepts previously linked to the surface form in $\mathcal{L}$. For instance, the surface form *"map of the United States"* has been linked to three distinct concepts in English Wikipedia.

3.2 Disambiguation

Given a set of mentions $\mathcal{M}$ from the previous step, The next step is to select a concept $t \in \mathcal{C}(m)$ for each $m \in \mathcal{M}$. We take the common approach of ranking the candidate concepts. *3W* uses a machine learning model to perform pair-wise ranking of $t \in \mathcal{C}(m)$ and select the top-ranked candidate concept. We refer to *3W*'s disambiguation component as the *ranker*. The ranker requires a feature vector for each candidate concept of a mention. The rest of this section describes the features utilized by the ranker. The first two feature groups are commonly used in Wikification systems. The third feature group is specifically designed for mentions in Wikipedia articles.

3.2.1 Prior Probability Features

The conditional probability of a concept t given mention surface s_m, $P(t|s_m)$, is a common feature used for disambiguation. It forms a very strong Wikification baseline ($\sim$ 86% in micro-accuracy). This probability can be estimated using Wikipedia links ($\mathcal{L}$). In addition, we use the *external* partition of the

Google "Cross-Lingual Dictionary" described in (Spitkovsky and Chang, 2012) to get the estimates for the probability from links outside Wikipedia.

3.2.2 Lexical Features

To make use of text around a mention m, we create bag-of-word vectors of the mention's source document $d(m)$, and of a set of words surrounding the mention, referred to as the *context* $c(m)$. To compare with a concept, we also create bag-of-word vectors of candidate concept's document $d(t)$ and candidate concept's context $c(t)$. We then compute cosine similarities between the mention's vectors for $d(m)$ and $c(m)$, with the concept candidate vectors for $d(t)$ and $c(t)$ as in the Illinois Wikifier (Ratinov et al., 2011). In addition to similarities computed over the top-200 words (utilized in the Illinois Wikifier), we also compute similarity features over vectors of all words.

3.2.3 Wikipedia-specific Features

Because the links in an article are often related to one another, the existing links in a document form valuable clues for disambiguating mentions in the document. For each concept candidate $t \in \mathcal{C}(m)$, we compute a Semantic Relatedness (SR) measure between t and each concept from existing links in the source document. Our SR measure is based on the proportion of shared inlinks, as introduced by Milne and Witten (2008b). However, because Milne and Witten were focused on general text, they computed SR only between t and the *unambiguous* mentions (i.e. those m with $|\mathcal{C}(m)| = 1$) identified in the document. In our work, $d(m)$ is a Wikipedia article which is rich in existing links to Wikipedia concepts, and we can compute SR with all of them, resulting in a valuable feature for disambiguation as illustrated in our experiments. We use the SR implementation of Hecht et al. (2012). It is a modified version of Milne and Witten's measure that emphasizes links in Wikipedia article's overview. In addition, we add boolean features indicating whether s_m or t has already been linked in a document.

3.2.4 Reranking

The millions of existing Wikipedia links in $\mathcal{L}$ form a valuable source of training examples for our ranker. However, simply training on the links in $\mathcal{L}$ may result in poor performance, because those links exhibit systematic differences from the mentions in $\mathcal{M}$ that the ranker will be applied to. The reason is that our mention extractor attempts to populate $\mathcal{M}$ with *all* mentions, whereas $\mathcal{L}$ which contains only the specific subset of mentions that meet the hyperlinking conventions of Wikipedia, As a result, the features for $\mathcal{M}$ are distributed differently from those in $\mathcal{L}$, and a model trained on $\mathcal{L}$ may not might not perform well on $\mathcal{M}$. Our strategy is to leverage $\mathcal{L}$ to train an initial ranker, and then hand-label a small set of mentions from $\mathcal{M}$ to train a second-stage *re-ranker* that takes the ranking output of the initial ranker as a feature.

3.3 Linker

Our linker is a binary classifier that decides whether to include (link) each mention in $\mathcal{M}$ to the final output $\mathcal{L}^*$. Previous work has typically used a linker to determine so-called NIL mentions, where the referred-to concept is not in the target knowledge base (e.g., in the TAC KBP competition, half of the given mentions are NIL (Ji and Grishman, 2011)). The purpose of our linker is slightly different, because we also use a linker to control the precision of our output. We use a *probabilistic linker* that predicts a confidence estimate that the mention with its top-ranked candidate is correct. Our linker uses the same features as the ranker and an additional set of confidence signals: the number of times the top candidate concept appears in $\mathcal{L}$, and the score difference between the top-ranked candidate and the second-ranked candidate.

4 Experiments and Result

In this section, we provide an evaluation of our system and its subcomponents.

4.1 Experiment Setup

We trained our initial ranker models from 100,000 randomly selected existing links ($\mathcal{L}$). These links were excluded when building feature values (i.e. the prior probability, or Semantic Relatedness).

We formed an evaluation set of new links by applying our mention extractor to 2,000 randomly selected articles, and then manually labeling 1,900 of the mentions with either the correct concept or "no correct concept." We trained and tested our system on the evaluation set, using 10-fold cross validation. For each fold, we partitioned data

Model	Acc	Prec	Recall	F1
Prior	0.876	0.891	0.850	0.870
OnlyWikiLink −Wiki	0.896	0.905	0.871	0.888
OnlyWikiLink	0.944	0.950	0.920	0.935

Table 1: 10-fold cross validation performance of the initial rankers by Accuracy (excluded $\emptyset$-candidate mentions), BOT Precision, BOT Recall, BOT F1 on the 100,000 existing links.

Model	Acc	Yield	%Yield
Baseline	0.828	5	0.33%
OnlyWikiLink	0.705	150	9.80%
3W−Wiki	0.868	253	16.54%
3W	0.877	365	23.86%

Table 2: 10-fold cross validation performance of the system over 1,900 labeled mentions. Acc is disambiguation accuracy of *solvable* mentions. Yield is the number of output new mentions at precision ≥ 0.98, and %Yield is the percentage of Yield over the *solvable* mentions (recall).

into 3 parts. We used 760 mentions for training the final ranker. The linker was trained with 950 mentions and we tested our system using the other 190 mentions. Previous work has used various ML approaches for ranking, such as SVMs (Dredze et al., 2010). We found logistic regression produces similar accuracy to SVMs, but is faster for our feature set. For the linker, we use an SVM with probabilistic output (Wu et al., 2004; Chang and Lin, 2011) to estimate a confidence score for each output link.

4.2 Result

We first evaluate *3W*'s mention extraction. From the selected $2,000$ articles, the system extracted $59,454$ mentions ($\sim$30/article), in addition to the original $54,309$ links ($\sim$27/article). From the $1,900$ hand-labeled mentions, $1,530$ (80.5%) were *solvable* in that *3W* candidate set contained the correct target.

As described in section 3.2.4, *3W* employs a 2-stage ranker. We first evaluate just the initial ranker, using 10-fold cross validation on 100,000 existing links. We show micro accuracy and bag-of-title (BOT) performance used by Milne and Witten (2008b) in Table 1. The ranker with all features (*OnlyWikiLink*) outperforms the ranker without Wikipedia-specific features (*OnlyWikiLink−Wiki*) by approximately five points in F1. This demonstrates that Wikipedia's rich semantic content is helpful for disambiguation.

Next, we evaluate our full system performance (disambiguation and linking) over the hand-labeled evaluation set. We experimented with different configurations of the rankers and linkers. Our *Baseline* system disambiguates a mention m by selecting the most common concept for the surface $s(m)$. *OnlyWikiLink* uses the ranker model trained on only Wikipedia links, ignoring the labeled mentions. *3W* is our system using all features described in section 3.2,

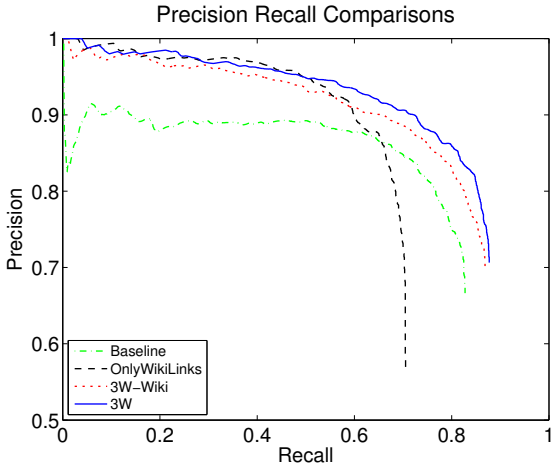

Figure 1: Plot between Precision and Recall of systems on 1,900 mentions from 10-fold cross validation.

and *3W−Wiki* is *3W* without Wikipedia-specific features. The last two configurations are trained using the labeled mentions.

Table 2 shows the disambiguation accuracy of each system over the solvable mentions. Our final system, *3W*, has the best disambiguation accuracy.

To evaluate the linking performance, we select the confidence threshold such that the system outputs mentions with precision of ≥ 0.98. The third column in Table 2 shows the *yield*, i.e. the number of mentions output at precision 0.98. *3W* outputs the largest number of new links (365). Nearly half (157) are new concepts that have not been linked in the source article. We find that the Rerank feature helps increase recall: without it, the yield of *3W* drops by 27%. Using %Yield, we estimate that *3W* will output $14,000$ new links for the selected $2,000$ articles ($\sim$7/article), and approximately 28 million new links across the 4 million articles of English Wikipedia.

Adjusting the confidence threshold allows the system to trade off precision and recall. Figure 1 shows a precision and recall curve. *3W* and *OnlyWikiLink* are comparable for

many high-precision points, but below 0.95 *OnlyWikiLink*'s precision drops quickly. Plots that finish at higher rightmost points in the graph indicate systems that achieve higher accuracy on the complete evaluation set.

5 Conclusions and Future Work

We presented *3W*, a system that adds high-precision links to Wikipedia. Whereas many Wikification systems focus on general text, *3W* is specialized toward Wikipedia articles. We showed that leveraging the link structure of Wikipedia provides advantages in disambiguation. In experiments, *3W* was shown to Wikipedia with $\sim$7 new links per article (an estimated 28m across 4 million Wikipedia articles) at high precision.

Abstract

In this paper we present our task-based evaluation of query biased summarization for cross-language information retrieval (CLIR) using relevance prediction. We describe our 13 summarization methods each from one of four summarization strategies. We show how well our methods perform using Farsi text from the CLEF 2008 shared-task, which we translated to English automtatically. We report precision/recall/F1, accuracy and time-on-task. We found that different summarization methods perform optimally for different evaluation metrics, but overall query biased word clouds are the best summarization strategy. In our analysis, we demonstrate that using the ROUGE metric on our sentence-based summaries cannot make the same kinds of distinctions as our evaluation framework does. Finally, we present our recommendations for creating much-needed evaluation standards and datasets.

1 Introduction

Despite many recent advances in query biased summarization for cross-language information retrieval (CLIR), there are no existing evaluation standards or datasets to make comparisons among different methods, and across different languages (Tombros and Sanderson, 1998; Pingali et al., 2007; McCallum et al., 2012; Bhaskar and Bandyopadhyay, 2012). Consider that creating this kind of summary requires familiarity with techniques from machine translation (MT), summarization, and information retrieval (IR). In this paper, we arrive at the intersection of each of these research areas. Query biased summarization (also known as *query-focused*, *query-relevant*, and *query-dependent*) involves automatically capturing relevant ideas and content from a document with respect to a given query, and presenting it as a condensed version of the original document. This kind of summarization is mostly used in search engines because when search results are tailored to a user's information need, the user can find texts that they are looking for more quickly and more accurately (Tombros and Sanderson, 1998; Mori et al., 2004). Query biased summarization is a valuable research area in natural language processing (NLP), especially for CLIR. Users of CLIR systems meet their information needs by submitting their queries in L_1 to search through documents that have been composed in L_2, even though they may not be familiar with L_2 (Hovy et al., 1999; Pingali et al., 2007).

There are no standards for objectively evaluating summaries for CLIR – a research gap that we begin to address in this paper. The problem we explore is two-fold: what kinds of summaries are well-suited for CLIR applications, and how should the summaries be evaluated. Our evaluation is *extrinsic*, that is to say we are interested in how summarization affects performance on a different task (Mani et al., 2002; McKeown et al., 2005; Dorr et al., 2005; Murray et al., 2009; McCallum et al., 2012). We use relevance prediction as our extrinsic task: a human must decide if a summary for a given document is relevant to a particular information need, or not. Relevance prediction is known to be useful as it correlates with some automatic *intrinsic* methods as well (President and Dorr, 2006; Hobson et al., 2007). To the best of our knowledge, we are the first to apply this evaluation framework to cross language query biased summarization.

Each one of the summarization methods that we

present in this paper belongs to one of the following strategies: (1) unbiased full machine translated text, (2) unbiased word clouds, (3) query biased word clouds, and (4) query biased sentence summaries. The methods and strategies that we present are fast, cheap, and language-independent. All of these strategies are *extractive*, meaning that we used existing parts of a document to create the condensed version, or summary.

We approach our task as an engineering problem: the goal is to decide if summaries are good enough to help CLIR system users find what they are looking for. We have simplified the task by assuming that a set of documents has already been retrieved from a search engine, as CLIR techniques are outside the scope of this paper. We predict that showing the full MT English text as a summarization strategy would not be particularly helpful in our relevance prediction task because the words in the text could be mixed-up, or sentences could be nonsensical, resulting in poor readability. For the same reasons, we expect that showing the full MT English text would take longer to arrive at a relevance decision. Finally, we predict that query biased summaries will result in faster, more accurate decisions from the participants (Tombros and Sanderson, 1998).

We treat the actual CLIR search engine as if it were a black box so that we can focus on evaluating if the summaries themselves are useful. As a starting point, we begin with some principles that we expect to hold true when we evaluate. These principles provide us with the kind of framework that we need for a productive and judicious discussion about how well a summarization method works. We encourage the NLP community to consider the following concepts when developing evaluation standards for this problem:

- End-user intelligiblity
- Query-salience
- Retrieval-relevance

Summaries should be presented to the end-user in a way that is both concise and intelligible, even if the machine translated text is difficult to understand. Our notions of *query-salience* and *retrieval-relevance* capture the expectation that good summaries will be efficient enough to help end-users fulfill their information needs. For query-salience, we want users to positively identify relevant documents. Similarly, for retrieval-relevance we want users to be able to find as many relevant documents as possible.

This paper is structured as follows: Section 2 presents related work; Section 3 describes our data and pre-processing; Section 4 details our summarization methods and strategies; Section 5 describes our experiments; Section 6 shows our results and analysis; and in Section 7, we conclude and discuss some future directions for the NLP community.

2 Related Work

Automatic summarization is generally a well-investigated research area. Summarization is a way of describing the relationships of words in documents to the information content of that document (Luhn, 1958; Edmunson, 1969; Salton and Yang, 1973; Robertson and Walker, 1994; Church and Gale, 1999; Robertson, 2004). Recent work has looked at creating summaries of single and multiple documents (Radev et al., 2004; Erkan and Radev, 2004; Wan et al., 2007; Yin et al., 2012; Chatterjee et al., 2012), as well as summary evaluation (Jing et al., 1998; Tombros and Sanderson 1998; Mani et al., 1998; Mani et al., 1999; Mani, 2001; Lin and Hovy, 2003; Lin, 2004; Nenkova et al., 2007; Hobson et al., 2007; Owczarzak et al., 2012), query and topic biased summarization (Berger and Mittal, 2000; Otterbacher et al., 2005; Daume and Marcu, 2006; Chali and Joty, 2008; Otterbacher et al., 2009; Bando et al., 2010; Bhaskar and Bandyopadhyay, 2012; Harwath and Hazen, 2012; Yin et al., 2012), and summarization across languages (Pingali et al., 2007; Orăsan and Chiorean, 2008; Wan et al., 2010; Azarbonyad et al., 2013).

2.1 Query Biased Summarization

Previous work most closely related to our own comes from Pingali et al., (2007). In their work, they present their method for cross-language query biased summarization for Telugu and English. Their work was motivated by the need for people to have access to foreign-language documents from a search engine even though the users were not familiar with the foreign language, in their case English. They used language modeling and translation probability to translate a user's query into L_2, and then summarized each document in L_2 with respect to the query. In their final step, they translated the summary from L_2 back

to L_1 for the user. They evaluated their method on the DUC 2005 query-focused summarization shared-task with ROUGE scores. We compare our methods to this work also on the DUC 2005 task. Our work demonstrates the first attempt to draw at a comparison between user-based studies and intrinsic evaluation with ROUGE. However, one of the limitations with evaluating this way is that the shared-task documents and queries are monolingual.

Bhaskar and Bandyopadhyay (2012) tried a subjective evaluation of extractive cross-language query biased summarization for 7 different languages. They extracted sentences, then scored and ranked the sentences to generate query dependent snippets of documents for their cross lingual information access (CLIA) system. However, the snippet quality was determined subjectively based on scores on a scale of 0 to 1 (with 1 being best). Each score indicated annotator satisfaction for a given snippet. Our evaluation methodology is objective: we ask users to decide if a given document is relevant to an information need, or not.

2.2 Machine Translation Effects

Machine translation quality can affect summarization quality. Wan et al. (2010) researched the effects of MT quality prediction on cross-language document summarization. They generated 5-sentence summaries in Chinese using English source documents. To select sentences, they used predicted translation quality, sentence position, and sentence informativeness. In their evaluation, they employed 4 Chinese-speakers to subjectively rate summaries on a 5-point scale (5 being best) along the dimensions of content, readability, and overall impression. They showed that their approach of using MT quality scores did improve summarization quality on average. While their findings are important, their work did not address query biasing or objective evaluation of the summaries. We attempt to overcome limitations of machine translation quality by using word clouds as one of our summarization strategies.

Knowing when to translate is another challenge for cross-language query biased summarization. Several options exist for when and what to translate during the summarization process: (1) the source documents can be translated, (2) the user's query can be translated, (3) the final summary can be translated, or (4) some combination of these. An example of translating only the summaries themselves can be found in Wan et al., (2010). On the other hand, Pingali et al. (2007) translated the queries and the summaries. In our work, we used gold-translated queries from the CLEF 2008 dataset, and machine translated source documents. We briefly address this in our work, but note that a full discussion of when and what to translate, and those effects on summarization quality, is outside of the scope of this paper.

2.3 Summarization Evaluation

There has been a lot of work towards developing metrics for understanding what makes a summary good. Evaluation metrics are either *intrinsic* or *extrinsic*. Intrinsic metrics, such as ROUGE, measure the quality of a summary with respect to gold human-generated summaries (Lin, 2004; Lin and Hovy, 2003). Generating gold standard summaries is expensive and time-consuming, a problem that persists with cross-language query biased summarization because those summaries must be query biased as well as in a different language from the source documents.

On the other hand, extrinsic metrics measure the quality of summaries at the system level, by looking at overall system performance on downstream tasks (Jing et al, 1998; Tombros and Sanderson, 1998). One of the most important findings for query biased summarization comes from Tombros and Sanderson (1998). In their monolingual task-based evaluation, they measured user speed and accuracy at identifying relevant documents. They found that query biased summarization improved the user speed and accuracy when the user was asked to make relevance judgements for IR tasks. We also expect that our evaluation will demonstrate that user speed and accuracy is better when summaries are query biased.

3 Data and Pre-Processing

We used data from the Farsi CLEF 2008 ad hoc task (Agirre et al., 2009). Each of the queries included in this dataset consisted of a title, narrative, and description. Figure 1 shows an example of the elements of a CLEF 2008 query. All of the automatic query-biasing in this work was based on the query titles. For our human relevance prediction task on Mechanical Turk, we used the narrative version. The CLEF 2008 dataset included a ground-truth answer key indicating which docu-

ments were relevant to each query. For each query, we randomly selected 5 documents that were relevant as well as 5 documents that were not relevant. The subset of CLEF 2008 data that we used therefore consisted of 500 original Farsi documents and 50 parallel English-Farsi queries. Next we will describe our text pre-processing steps for both languages as well as how we created our parallel English documents.

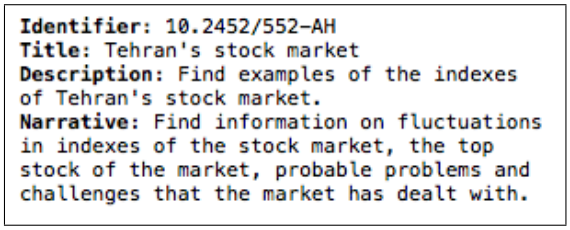

Figure 1: Full MT English summary and CLEF 2008 English query (title, description, narrative).

3.1 English Documents

All of our English documents were created automatically by translating the original Farsi documents into English (Drexler et al., 2012). The translated documents were sentence-aligned with one sentence per line. For all of our summarization experiments (except unbised full MT text), we processed the text as follows: removed extra spaces, removed punctuation, folded to lowercase, and removed digits. We also removed common English stopwords[2] from the texts.

3.2 Farsi Documents

We used the original CLEF 2008 Farsi documents for two of our summarization methods. We stemmed words in each document using automatic morphological analysis with Morfessor CatMAP. We note that within-sentence punctuation was removed during this process (Creutz and Lagus, 2007). We also removed Farsi stopwords and digits.

4 Summarization Strategies

All of our summarization methods were extractive except for unbiased full machine translated text. In this section, we describe each of our 13 summarization methods which we have organized into one of the following strategies: (1) unbiased full machine translated text, (2) unbiased word cloud summaries, (3) query biased word cloud summaries, and (4) query biased sentence summaries. Regardless of which summarization method used, we highlighted words in yellow that also appeard in the query. Let t be a term in document d where $d \in D_L$ and D_L is a collection of documents in a particular language. Note that for our summarization methods, term weightings were calculated separately for each language. While $|D| = 1000$, we calculated term weightings based on $|D_E| = 500$ and $|D_F| = 500$. Finally, let q be a query where $q \in Q$ and Q is our set of 50 parallel English-Farsi CLEF queries. Assume that log refers to log_{10}.

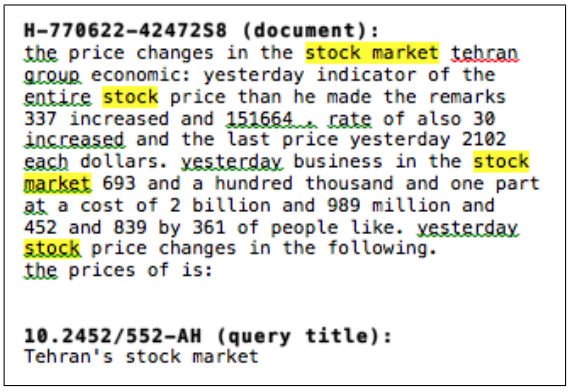

Figure 2: Full MT English summary and CLEF 2008 English query.

4.1 Unbiased Full Machine Translated English

Our first baseline approach was to use all of the raw machine translation output (no subsets of the sentences were used). Each summary therefore consisted of the full text of an entire document automatically translated from Farsi to English (Drexler et al., 2012). Figure 2 shows an example full text document translated from Farsi to English and a gold-standard English CLEF query. Note that we use this particular document-query pair as an example throughout this paper (document: H-770622-42472S8, query: 10.2452/552-AH). According to the CLEF answer key, the sample document is relevant to the sample query.

4.2 Unbiased Word Clouds

For our second baseline approach, we ranked terms in a document and displayed them as *word clouds*. Word clouds are one a way to arrange a collection of words where each word can vary

[2]English and Farsi stopword lists from: http://members.unine.ch/jacques.savoy/clef/index.html

in size. We used word clouds as a summarization strategy to overcome any potential disfluencies from the machine translation output and also to see if they are feasible at all for summarization. All of our methods for word clouds used words from machine translated English text. Each term-ranking method below generates different ranked lists of terms, which we used to create different word clouds. We created one word cloud per document using the top 12 ranked words. We used the raw term scores to scale text font size, so that words with a highter score appeared larger and more prominent in a word cloud. Words were shuffled such that the exact ordering of words was at random.

I: Term Frequency (TF) Term frequency is very commonly used for finding important terms in a document. Given a term t in a document d, the number of times that term occurs is:

$$tf_{t,d} = |t \in d|$$

II: Inverse Document Frequency (IDF) The idf term weighting is typically used in IR and other text categorization tasks to make distinctions between documents. The version of idf that we used throughout our work came from Erkan and Radev (2004) and Otterbacher et al. (2009), in keeping consistent with theirs. Let N be the number of documents in the collection, such that $N = |D|$ and n_t is the number of documents that contain term t, such that $n_t = |\{d \in D : t \in d\}|$, then:

$$idf_t = log \frac{N+1}{0.5 \times n_t}$$

While *idf* is usually thought of as a type of heuristic, there have been some discussions about its theoretical basis (Robertson, 2004; Robertson and Walker, 1994; Church and Gale, 1999; Salton and Yang, 1973). An example of this summary is shown in Figure 3.

III: Term Frequency Inverse Document Frequency (TFIDF) We use $tfidf_{t,d}$ term weighting to find terms which are both rare and important for a document, with respect to terms across all other documents in the collection:

$$tfidf_{t,d} = tf_{t,d} \times idf_t$$

4.3 Query Biased Word Clouds

We generated query biased word clouds following the same principles as our unbiased word clouds,

Figure 3: Word cloud summary for inverse document frequency (IDF), for query "Tehran's stock market".

namely the text font scaling and highlighting remained the same.

IV. Query Biased Term Frequency (TFQ) In Figure 4 we show a sample word cloud summary based on query biased term frequency. We define query biased term frequency tfQ at the document level, as:

$$tfQ_{t,d,q} = \begin{cases} 2tf_{t,d}, & \text{if } t \in q \\ tf_{t,d}, & \text{otherwise} \end{cases}$$

Figure 4: Word cloud summary for query biased term frequency (TFQ), for query "Tehran's stock market".

V. Query Biased Inverse Document Frequency (IDFQ) Since idf helps with identifying terms that discriminate documents in a collection, we would expect that query biased idf would help to identify documents that are relevant to a query:

$$idfQ_{t,q} = \begin{cases} 2idf_t, & \text{if } t \in q \\ idf_t, & \text{otherwise} \end{cases}$$

VI. Query Biased TFIDF (TFIDFQ) We define query biased $tf \times idf$ similarly to our TFQ and IDFQ, at the document level:

$$tfidfQ_{t,d,q} = \begin{cases} 2tf_{t,d} \times idf_t, & \text{if } t \in q \\ tf_{t,d} \times idf_t, & \text{otherwise} \end{cases}$$

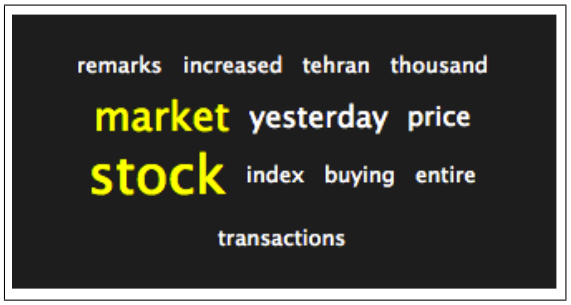

Figure 5: Word cloud summary for scaled query biased term frequency (SFQ) for query "Tehran's stock market".

VII. Query Biased Scaled Frequency (SFQ) This term weighting scheme, which we call scaled query biased term frequency or sfQ, is a variant of the traditional $tf \times idf$ weighting. First, we project the usual term frequency into log-space, for a term t in document d with:

$$tfS_{t,d} = log(tf_{t,d})$$

We let $tfS_{t,d} \approx 0$ when $tf_{t,d} = 1$. We believe that singleton terms in a document provide no indication that a document is query-relevant, and treament of singleton terms in this way would have the potential to reduce false-positives in our relevance prediction task. Note that scaled term frequency differs from Robertson's (2004) *inverse total term frequency* in the sense that our method involves no consideration of term position within a document. Scaled query biased term frequency, shown in Figure 5, is defined as:

$$sfQ_{t,d,q} = \begin{cases} 2tfS_{t,d} \times idf_t, & \text{if } t \in q \\ tfS_{t,d} \times idf_t, & \text{otherwise} \end{cases}$$

VIII. Word Relevance (W) We adapted an existing relevance weighting from Allan et al., (2003), that was originally formulated for ranking sentences with respect to a query. However, we modified their originaly ranking method so that we could rank individual terms in a document instead of sentences. Our method for word relevance, W is defined as:

$$W_{t,d,q} = log(tf_{t,d} + 1) \times log(tf_{t,q} + 1) \times idf_t$$

In W, term frequency values are *smoothed* by adding 1. The smoothing could especially affect rare terms and singletons, when $tf_{t,d}$ is very low. All terms in a query or a document will be weighted and each term could potentially contribute to summary.

4.4 Query Biased Sentence Summaries

Sentences are a canonical unit to use in extractive summaries. In this section we describe four different sentence scoring methods that we used. These methods show how to calculate sentence scores for a given document with respect to a given query. Sentences for a document were always ranked using the raw score value output generated from a scoring method. Each document summary contained the top 3 ranked sentences where the sentences were simply listed out. Each of these methods used sentence-aligned English machine translated documents, and two of them also used the original Farsi text.

IX. Sentence Relevance (REL) Our sentence relevance scoring method comes from Allan et al. (2003). The sentence weight is a summation over words that appear in the query. We provide their sentence scoring formula here. This calculates the relevance score for a sentence s from document d, to a query q:

$$rel_{(s|q)} = \sum_{t \in s} log(tf_{t,s} + 1) \times log(tf_{t,q} + 1) \times idf_t$$

Terms will occur in either the sentence or the query, or both. We applied this method to machine tranlsated English text. The output of this method is a relevance score for each sentence in a given document. We used those scores to rank sentences in each document from our English machine translated text.

X. Query Biased Lexrank (LQ) We implemented query biased LexRank, a well-known graph-based summarization method (Otterbacher et al., 2009). It is a modified version of the original LexRank algorithm (Erkan and Radev, 2004; Page et al., 1998). The similarity metric, $sim_{x,y}$, also known as *idf-modified cosine similarity*, measures the distance between two sentences x and y in a document d, defined as:

$$sim_{x,y} = \frac{\sum_{t \in x,y} tf_{t,x} \times tf_{t,y} \times (idf_t)^2}{\sqrt{\sum_{t \in x} tfidf_{t,x}^2} \sqrt{\sum_{t \in y} tfidf_{t,y}^2}}$$

We used $sim_{x,y}$ to score the similarity of sentence-to-sentence, resulting in a similarity

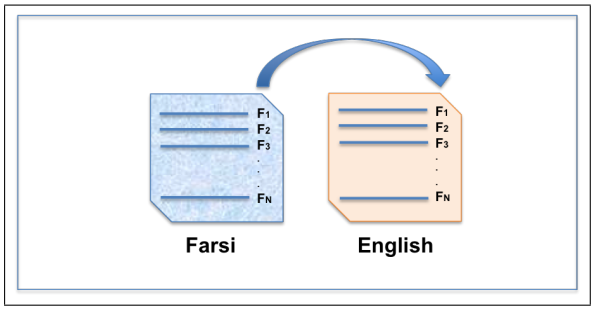

Figure 6: LQP - projecting Farsi sentence scores onto parallel English sentences.

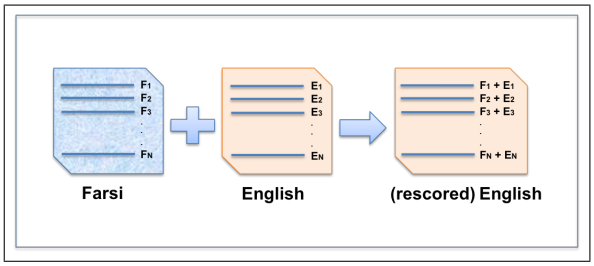

Figure 7: LQC - Farsi sentence scores are combined with parallel English sentence scores to obtain sentence re-ranking.

graph where each vertex was a sentence and each edge was the cosine similarity between sentences. We normalized the cosine matrix with a similarity threshold ($t = 0.05$), so that sentences above this threshold were given similarity 1, and 0 otherwise. We used $rel_{(s|q)}$ to score sentence-to-query. The LexRank score for each sentence was then calculated as:

$$LQ_{s|q} = \frac{d \times rel_{s|q}}{\sum_{z \in C} rel_{z|q}} + (1-d) \times \sum_{v \in adj[s]} \frac{sim_{s,v}}{\sum_{r \in adj[v]} sim_{v,r}} LQ_{v|q}$$

where C is the set of all sentences in a given document. Here the parameter d is just a damper to designate a probability of randomly jumping to one of the sentences in the graph ($d = 0.7$). We found the stationary distribution by applying the power method ($\epsilon = 5$), which is guaranteed to converge to a stationary distribution (Otterbacher et al., 2009). The output of LQ is a score for each sentence from a given document with respect to a query. We used that score to rank sentences in each document from our English machine translated text.

XI. Projected Cross-Language Query Biased Lexrank (LQP) We introduce LQP to describe a way of scoring and ranking sentences such that the L_1 (English) summaries are biased from the L_2 (Farsi) query and source document. Our gold-standard Farsi queries were included with our CLEF 2008 data, making them more reliable than what we could get from automatic translation. First, sentences from each Farsi document were scored with Farsi queries using LQ, described above. Then each LQ score was projected onto sentence-aligned English. We demonstrate LQP in Figure 6. By doing this, we simulated translating the user's English query into Farsi with the best possible query translation, before proceeding with summarization. This approach to cross-language summarization could be of interest for CLIR systems that do query translation on-the-fly. It is also of interest for summarization systems that need to utilize previously translated source documents the capability is lacking to translate summaries from L_2 to L_1.

XII. Combinatory Query Biased Lexrank (LQC) Another variation of LexRank that we introduce in this work is LQC, which combines LexRank scores from both languages to re-rank sentences. A visual summary of this method is shown in Figure 7. We accomplished our re-ranking by first running LQ on Farsi and English separately, then adding the two scores together. This combination of Farsi and English scores provided us with a different way to score and rank sentences, compared with LQ and LQP. The idea behind combinatory query biased LexRank is to take advantage of sentences which are high-ranking in Farsi but not in English. The LQC method exploits all available resources in our dataset: L_1 and L_2 queries as well as L_1 and L_2 documents.

5 Experiments

We tested each of our summarization methods and overall strategies in a task-based evaluation framework using relevance prediction. We used Mechanical Turk for our experiments since it has been shown to be useful for evaluating NLP systems (Callison-Burch 2009; Gillick and Liu, 2010). We obtained human judgments for whether or not a document was considered relevant to a query, or information need. We measured the relevance

judgements by precision/recall/F1, accuracy, and also time-on-task based on the average response time per Human Intelligence Task (HIT).

5.1 Mechanical Turk

In our Mechanical Turk experiment, we used terminology from CLEF 2008 to describe a query as an "information need". All of the Mechanical Turk workers were presented with the following for their individual HIT: instructions, an information need and one summary for a document. Workers were asked to indicate if the given summary for a document was relevant to the given information need (Hobson et al., 2007). Workers were not shown the original Farsi source documents. We paid workers $0.01 per HIT. We obtained 5 HITs for each information need and summary pair. We used a built-in approval rate qualification provided by Mechanical Turk to restrict which workers could work on our tasks. Each worker had an approval rate of at least 95

> Instructions: Each image below consists of a statement summarizing the information you are trying to find from a set of documents followed by a summary of one of the documents returned when you query the documents. Based on the summary, choose whether you think the document returned is relevant to the information need. NOTE: It may be difficult to distinguish whether the document is relevant as the text may be difficult to understand. Just use your best judgment.

6 Results and Analysis

We present our experiment results and additional analysis. First, we report the results of our relevance prediction task, showing performance for individual summarization methods as well as performance for the overall strategies. Then we show analysis of our results from the monolingual question-biased shared-task for DUC 2005, as well as a comparison to previous work.

6.1 Results for Individual Methods

Our results are shown in Table 1. We report performance for 13 individual methods as well as overall peformance on the 4 different summarization strategies. To calculate the performance for each strategy, we used the arithmetic mean of the corresponding individual methods. We measured precision, recall and F1 to give us a sense of our summaries might influence document retrieval in an actual CLIR system. We also measured accuracy and time-on-task. For these latter two metrics, we distinguish between summaries that were relevant (R) and non-relevant (NR).

All of the summarization-based methods favored recall over precision: documents were marked 'relevant' more often than 'non-relevant'. For many of the methods shown in Table 1, workers spent more time correctly deciding 'relevant' than correctly deciding 'non-relevant'. This suggests some workers participated in our Mechanical Turk task purposefully. For many of the summarization methods, workers were able to positively identify relevant documents.

From Table 1 we see that Full MT performed better on precision than all of the other methods and strategies, but we note that performance on precision was generally very low. This might be due to Mechanical Turk workers overgeneralizing by marking summaries as relevant when they were not. Some individual methods preserve our principle of *retrieval-relevance*, as indicated by the higher recall scores for SQF, LQEF, and TFQ. That is to say, these particular query biased summarization methods can be used to assist users with identifying more relevant documents. The accuracy on relevant documents addresses our principle of *query-salience*, and it is especially high for our query-biased methods: LQEF, SQF, LQ, and TFQ. The results also seem to fit our intuition that the summary in Figure 3 seems less relevant to the summaries shown in Figures 4 & 5 even though these are the same documents biased on the same query "Tehran stock market".

Overall, query biased word clouds outperform the other summarization strategies for 5 out of 7 metrics. This could be due to the fact that word clouds provide a very concise and overview of a document, which is one of the main goals for automatic summarization. Along these lines, word clouds are probably not subject to the effects of MT quality and we believe it is possible that MT quality could have had a negative impact on our query biased extracted sentence summaries, as well as our full MT English texts.

Table 1: Individual method results: precision/recall/F1, time-on-task, and accuracy. Note that results for time-on-task and accuracy scores are distinguished for relevant (R) and non-relevant (NR) documents.

6.2 Analysis with DUC 2005

We analysed our summarization methods by comparing two of our sentence-based methods (LQ and REL) with peers from the monolingual question-biased summarization shared-task for DUC 2005. Even though DUC 2005 is a monolingual task, we decided to use it as part of our analysis for two reasons: (1) to see how well we could do with query/question biasing while ignoring the variables introduced by MT and cross-language text, and (2) to make a comparison to previous work. Pingali et al., (2007) also used this the same DUC task to assess their cross-language query biased summarization system. Systems from the DUC 2005 question-biased summarization task were evaluated automatically against human gold-standard summaries using ROUGE (Lin and Hovy, 2003) . Our results from the DUC 2005 shared-task are shown in Table 2, reported as ROUGE-2 and ROUGE-SU4 f-scores, as these two variations of ROUGE are the most helpful (Dang, 2005; Pingali et al., 2007).

Table 2 shows scores for several top peer systems, as well as results for the Tel-Eng-Sum method from Pingali et al., (2007). While we have reported f-scores in our analysis, we also note that our implementations of LQ and REL outperform all of the DUC 2005 peer systems for precision, as shown in Table 3. We also know that ROUGE cannot be used for comparing sentence summaries to ranked lists of words and there are no existing intrinsic methods to make that kind of comparison. Therefore we were able to successfully compare just 2 of our sentence-based methods to previous work using ROUGE.

7 Discussion and Future Work

Cross-language query biased summarization is an important part of CLIR, because it helps the user decide which foreign-language documents they might want to read. But, how do we know if

Table 3: Top 3 system precision scores for ROUGE-2 and ROUGE-SU4.

Peer ID	ROUGE-2	ROUGE-SU4
LQ	**0.08272**	**0.15197**
REL	**0.0809**	**0.15049**
15	0.07249	0.13129

a query biased summary is "good enough" to be used in a real-world CLIR system? We want to be able to say that we can do query biased summarization just as well for both monolingual and cross-language IR systems. From previous work, there has been some variability with regard to when and what to translate - variables which have no impact on monolingual summarization. We attempted to address this issue with two of our methods: LQP and LQC. To fully exploit the MT variable, we would need many more relevance prediction experiments using humans who know L_1 and others who know L_2. Unfortunately in our case, we were not able to find Farsi speakers on Mechanical Turk. Access to these speakers would have allowed us to try further experiments as well as other kinds of analysis.

Our results on the relevance prediction task tell us that query biased summarization strategies help users identify relevant documents faster and with better accuracy than unbiased summaries. Our findings support the findings of Tombros and Sanderson (1998). Another important finding is that now we can weigh tradeoffs so that different summarization methods could be used to optimize over different metrics. For example, if we want to optimize for retrieval-relevance we might select a summarization method that tends to have higher recall, such as scaled query biased term frequency (SFQ). Similarly, we could optimize over accuracy on relevant documents, and use Combinatory LexRank (LQC) with Farsi and English together.

We have shown that the relevance prediction tasks can be crowdsourced on Mechanical Turk with reasonable results. The data we used from the Farsi CLEF 2008 ad-hoc task included an answer key, but there were no parallel English documents. However, in order for the NLP community to make strides in evaluating cross-language query biased summarization for CLIR, we will need stardards and data. Optimal data would be parallel datasets consisting of documents in L_1 and L_2 with queries in L_1 and L_2 along with an answer key specifying which documents are relevant to the queries. Further we would also need sets of human gold-standard query biased summaries in L_1 and L_2. These standards and data would allow us to compare method-to-method across different languages, while simultaneously allowing us to tease apart other variables such as: when and what to translate, translation quality, methods for biasing, and type of summarization strategy (sentences, words, etc). And of course it would be better if this standard dataset was multilingual instead of billingual, for obvious reasons.

We have approached cross-language query biased summarization as a stand-alone problem, treating the CLIR system and document retrieval as a black box. However, summaries need to preserve query-salience: summaries should not make it more difficult to positively identify relavant documents. And they should also preserve retrieval-relevance: summaries should help users identify as many relevant documents as possible.

Acknowledgments

We would like to express thanks to David Harwath at MIT Computer Science and Artificial Intelligence Laboratory (CSAIL), who helped us develop and implement ideas in this paper. We also want to thank Terry Gleason from MIT Lincoln Laboratory for providing machine translations.

Abstract

We propose a model for Chinese poem generation based on recurrent neural networks which we argue is ideally suited to capturing poetic content and form. Our generator *jointly* performs content selection ("what to say") and surface realization ("how to say") by learning representations of individual characters, and their combinations into one or more lines as well as how these mutually reinforce and constrain each other. Poem lines are generated incrementally by taking into account the entire history of what has been generated so far rather than the limited horizon imposed by the previous line or lexical *n*-grams. Experimental results show that our model outperforms competitive Chinese poetry generation systems using both automatic and manual evaluation methods.

相 思
Missing You
红 豆 生 南 国， (* Z P P Z)
Red berries born in the warm southland.
春 来 发 几 **枝**？ (P P Z Z P)
How many branches flush in the spring?
愿 君 多 采 撷， (* P P Z Z)
Take home an armful, for my sake,
此 物 最 相 **思**。 (* Z Z P P)
As a symbol of our love.

Table 1: An example of a 5-char *quatrain* exhibiting one of the most popular tonal patterns. The tone of each character is shown at the end of each line (within parentheses); P and Z are shorthands for *Ping* and *Ze* tones, respectively; * indicates that the tone is not fixed and can be either. Rhyming characters are shown in boldface.

1 Introduction

Classical poems are a significant part of China's cultural heritage. Their popularity manifests itself in many aspects of everyday life, e.g., as a means of expressing personal emotion, political views, or communicating messages at festive occasions as well as funerals. Amongst the many different types of classical Chinese poetry, *quatrain* and *regulated verse* are perhaps the best-known ones. Both types of poem must meet a set of structural, phonological, and semantic requirements, rendering their composition a formidable task left to the very best scholars.

An example of a quatrain is shown in Table 1. Quatrains have four lines, each five or seven characters long. Characters in turn follow specific phonological patterns, within each line and across lines. For instance, the final characters in the second, fourth and (optionally) first line must rhyme, whereas there are no rhyming constraints for the third line. Moreover, poems must follow a prescribed tonal pattern. In traditional Chinese, every character has one tone, *Ping* (level tone) or *Ze* (downward tone). The poem in Table 1 exemplifies one of the most popular tonal patterns (Wang, 2002). Besides adhering to the above formal criteria, poems must exhibit concise and accurate use of language, engage the reader/hearer, stimulate their imagination, and bring out their feelings.

In this paper we are concerned with generating traditional Chinese poems automatically. Although computers are no substitute for poetic creativity, they can analyze very large online text repositories of poems, extract statistical patterns, maintain them in memory and use them to generate many possible variants. Furthermore, while amateur poets may struggle to remember and apply formal tonal and structural constraints, it is relatively straightforward for the machine to check

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 670–680,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

whether a candidate poem conforms to these requirements. Poetry generation has received a fair amount of attention over the past years (see the discussion in Section 2), with dozens of computational systems written to produce poems of varying sophistication. Beyond the long-term goal of building an autonomous intelligent system capable of creating meaningful poems, there are potential short-term applications for computer generated poetry in the ever growing industry of electronic entertainment and interactive fiction as well as in education. An assistive environment for poem composition could allow teachers and students to create poems subject to their requirements, and enhance their writing experience.

We propose a model for Chinese poem generation based on recurrent neural networks. Our generator *jointly* performs content selection ("what to say") and surface realization ("how to say"). Given a large collection of poems, we learn representations of individual characters, and their combinations into one or more lines as well as how these mutually reinforce and constrain each other. Our model generates lines in a poem probabilistically: it estimates the probability of the current line given the probability of all previously generated lines. We use a recurrent neural network to learn the representations of the lines generated so far which in turn serve as input to a recurrent language model (Mikolov et al., 2010; Mikolov et al., 2011b; Mikolov et al., 2011a) which generates the current line. In contrast to previous approaches (Greene et al., 2010; Jiang and Zhou, 2008), our generator makes no Markov assumptions about the dependencies of the words within a line and across lines.

We evaluate our approach on the task of quatrain generation (see Table 1 for a human-written example). Experimental results show that our model outperforms competitive Chinese poetry generation systems using both automatic and manual evaluation methods.

2 Related Work

Automated poetry generation has been a popular research topic over the past decades (see Colton et al. (2012) and the references therein). Most approaches employ templates to construct poems according to a set of constraints (e.g., rhyme, meter, stress, word frequency) in combination with corpus-based and lexicographic resources. For example, the Haiku poem generator presented in Wu et al. (2009) and Tosa et al. (2008) produces poems by expanding user queries with rules extracted from a corpus and additional lexical resources. Netzer et al. (2009) generate Haiku with Word Association Norms, Agirrezabal et al. (2013) compose Basque poems using patterns based on parts of speech and WordNet (Fellbaum, 1998), and Oliveira (2012) presents a generation algorithm for Portuguese which leverages semantic and grammar templates.

A second line of research uses genetic algorithms for poem generation (Manurung, 2003; Manurung et al., 2012; Zhou et al., 2010). Manurung et al. (2012) argue that at a basic level all (machine-generated) poems must satisfy the constraints of grammaticality (i.e., a poem must syntactically well-formed), meaningfulness (i.e., a poem must convey a message that is meaningful under some interpretation) and poeticness (i.e., a poem must exhibit features that distinguishes it from non-poetic text, e.g., metre). Their model generates several candidate poems and then uses stochastic search to find those which are grammatical, meaningful, and poetic.

A third line of research draws inspiration from statistical machine translation (SMT) and related text-generation applications such as summarization. Greene et al. (2010) infer meters (stressed/unstressed syllable sequences) from a corpus of poetic texts which they subsequently use for generation together with a cascade of weighted finite-state transducers interpolated with IBM Model 1. Jiang and Zhou (2008) generate Chinese couplets (two line poems) using a phrase-based SMT approach which translates the first line to the second line. He et al. (2012) extend this algorithm to generate four-line quatrains by sequentially translating the current line from the previous one. Yan et al. (2013) generate Chinese quatrains based on a query-focused summarization framework. Their system takes a few keywords as input and retrieves the most relevant poems from a corpus collection. The retrieved poems are segmented into their constituent terms which are then grouped into clusters. Poems are generated by iteratively selecting terms from clusters subject to phonological, structural, and coherence constraints.

Our approach departs from previous work in two important respects. Firstly, we model the tasks of surface realization and content selection jointly

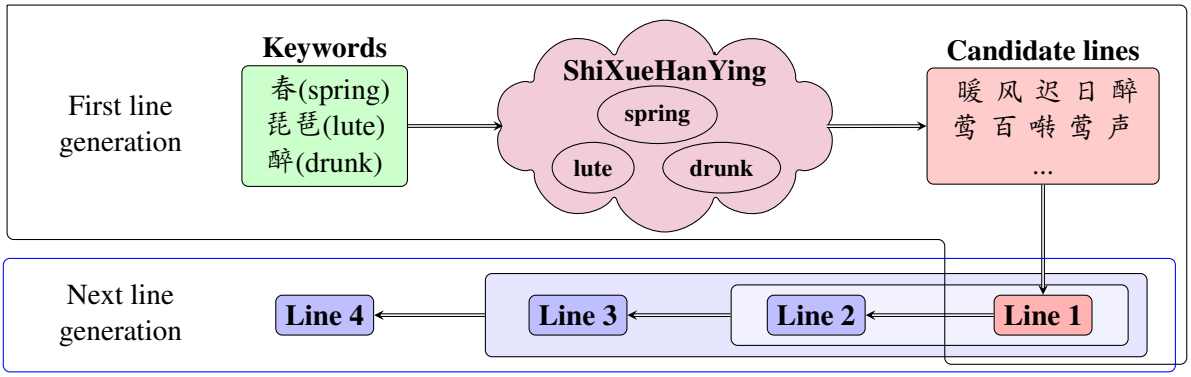

Figure 1: Poem generation with keywords *spring*, *lute*, and *drunk*. The keywords are expanded into phrases using a poetic taxonomy. Phrases are then used to generate the first line. Following lines are generated by taking into account the representations of all previously generated lines.

using recurrent neural networks. Structural, semantic, and coherence constraints are captured naturally in our framework, through learning the representations of individual characters and their combinations. Secondly, generation proceeds by taking into account multi-sentential context rather than the immediately preceding sentence. Our work joins others in using continuous representations to express the meaning of words and phrases (Socher et al., 2012; Mikolov et al., 2013) and how these may be combined in a language modeling context (Mikolov and Zweig, 2012). More recently, continuous translation models based on recurrent neural networks have been proposed as a means to map a sentence from the source language to sentences in the target language (Auli et al., 2013; Kalchbrenner and Blunsom, 2013). These models are evaluated on the task of rescoring n-best lists of translations. We use neural networks more directly to perform the actual poem generation task.

3 The Poem Generator

As common in previous work (Yan et al., 2013; He et al., 2012) we assume that our generator operates in an interactive context. Specifically, the user supplies keywords (e.g., *spring*, *lute*, *drunk*) highlighting the main concepts around which the poem will revolve. As illustrated in Figure 1, our generator expands these keywords into a set of related phrases. We assume the keywords are restricted to those attested in the *ShiXueHanYing* poetic phrase taxonomy (He et al., 2012; Yan et al., 2013). The latter contains 1,016 manual clusters of phrases (Liu, 1735); each cluster is labeled with a keyword id describing general poem-worthy topics. The generator creates the first line of the poem based on these keywords. Subsequent lines are generated based on all previously generated lines, subject to phonological (e.g., admissible tonal patterns) and structural constraints (e.g., whether the quatrain is five or seven characters long).

To create the first line, we select all phrases corresponding to the user's keywords and generate all possible combinations satisfying the tonal pattern constraints. We use a language model to rank the generated candidates and select the best-ranked one as the first line in the poem. In implementation, we employ a character-based recurrent neural network language model (Mikolov et al., 2010) interpolated with a Kneser-Ney trigram and find the n-best candidates with a stack decoder (see Section 3.5 for details). We then generate the second line based on the first one, the third line based on the first two lines, and so on. Our generation model computes the probability of line $S_{i+1} = w_1, w_2, \ldots, w_m$, given all previously generated lines $S_{1:i} (i \geq 1)$ as:

$$P(S_{i+1}|S_{1:i}) = \prod_{j=1}^{m-1} P(w_{j+1}|w_{1:j}, S_{1:i}) \qquad (1)$$

Equation (1), decomposes $P(S_{i+1}|S_{1:i})$ as the product of the probability of each character w_j in the current line given all previously generated characters $w_{1:j-1}$ and lines $S_{1:i}$. This means that $P(S_{i+1}|S_{1:i})$ is sensitive to previously generated content and currently generated characters.

The estimation of the term $P(w_{j+1}|w_{1:j}, S_{1:i})$ lies at the heart of our model. We learn representations for $S_{1:i}$, the context generated so far, using a recurrent neural network whose output

serves as input to a second recurrent neural network used to estimate $P(w_{j+1}|w_{1:j}, S_{1:i})$. Figure 2 illustrates the generation process for the $(j+1)$th character w_{j+1} in the $(i+1)$th line S_{i+1}. First, lines $S_{1:i}$ are converted into vectors $v_{1:i}$ with a *convolutional sentence model* (CSM; described in Section 3.1). Next, a *recurrent context model* (RCM; see Section 3.2) takes $v_{1:i}$ as input and outputs u_i^j, the representation needed for generating $w_{j+1} \in S_{i+1}$. Finally, $u_i^1, u_i^2, \ldots, u_i^j$ and the first j characters $w_{1:j}$ in line S_{i+1} serve as input to a *recurrent generation model* (RGM) which estimates $P(w_{j+1} = k|w_{1:j}, S_{1:i})$ with $k \in V$, the probability distribution of the $(j+1)$th character over all words in the vocabulary V. More formally, to estimate $P(w_{j+1}|w_{1:j}, S_{1:i})$ in Equation (1), we apply the following procedure:

$$v_i = \text{CSM}(S_i) \tag{2a}$$

$$u_i^j = \text{RCM}(v_{1:i}, j) \tag{2b}$$

$$P(w_{j+1}|w_{1:j}, S_{1:i}) = \text{RGM}(w_{1:j+1}, u_i^{1:j}) \tag{2c}$$

We obtain the probability of the $(i+1)$th sentence $P(S_{i+1}|S_{1:i})$, by running the RGM in (2c) above $m-1$ times (see also Equation (1)). In the following, we describe how the different components of our model are obtained.

3.1 Convolutional Sentence Model (CSM)

The CSM converts a poem line into a vector. In principle, any model that produces vector-based representations of phrases or sentences could be used (Mitchell and Lapata, 2010; Socher et al., 2012). We opted for the convolutional sentence model proposed in Kalchbrenner and Blunsom (2013) as it is n-gram based and does not make use of any parsing, POS-tagging or segmentation tools which are not available for Chinese poems. Their model computes a continuous representation for a sentence by sequentially merging neighboring vectors (see Figure 3).

Let V denote the character vocabulary in our corpus; $L \in \mathbb{R}^{q \times |V|}$ denotes a character embedding matrix whose columns correspond to character vectors (q represents the hidden unit size). Such vectors can be initialized randomly or obtained via a training procedure (Mikolov et al., 2013). Let w denote a character with index k; $e(w) \in \mathbb{R}^{|V| \times 1}$ is a vector with zero in all positions except $e(w)_k = 1$; $T^l \in \mathbb{R}^{q \times N^l}$ is the sentence representation in the lth layer, where N^l is the number of columns in the lth layer ($N^l = 1$ in the top layer); $C^{l,n} \in \mathbb{R}^{q \times n}$ is an array of weight matrices which compress neighboring n columns in the lth layer to one column in the $(l+1)$th layer. Given a sentence $S = w_1, w_2, \ldots, w_m$, the first layer is represented as:

$$\begin{aligned} T^1 &= [L \cdot e(w_1), L \cdot e(w_2), \ldots, L \cdot e(w_m)] \\ N^1 &= m \end{aligned} \tag{3}$$

The $(l+1)$th layer is then computed as follows:

$$\begin{aligned} T^{l+1}_{:,j} &= \sigma\Big(\sum_{i=1}^{n} T^l_{:,j+i-1} \odot C^{l,n}_{:,i}\Big) \\ N^{l+1} &= N^l - n + 1 \\ 1 &\le j \le N^{l+1} \end{aligned} \tag{4}$$

where T^l is the representation of the previous layer l, $C^{l,n}$ a weight matrix, $\odot$ element-wise vector product, and σ a non-linear function. We compress two neighboring vectors in the first two layers and three neighboring vectors in the remaining layers. Specifically, for quatrains with seven characters, we use $C^{1,2}$, $C^{2,2}$, $C^{3,3}$, $C^{4,3}$ to merge vectors in each layer (see Figure 3); and for quatrains with five characters we use $C^{1,2}$, $C^{2,2}$, $C^{3,3}$.

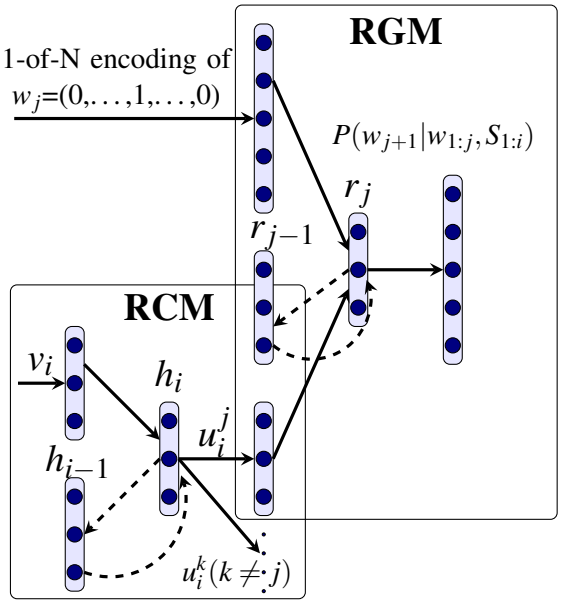

Figure 2: Generation of the $(j+1)$th character w_{j+1} in the $(i+1)$th line S_{i+1}. The recurrent context model (RCM) takes i lines as input (represented by vectors $v_1, \ldots, v_i$) and creates context vectors for the recurrent generation model (RGM). The RGM estimates the probability $P(w_{j+1}|w_{1:j}, S_{1:i})$.

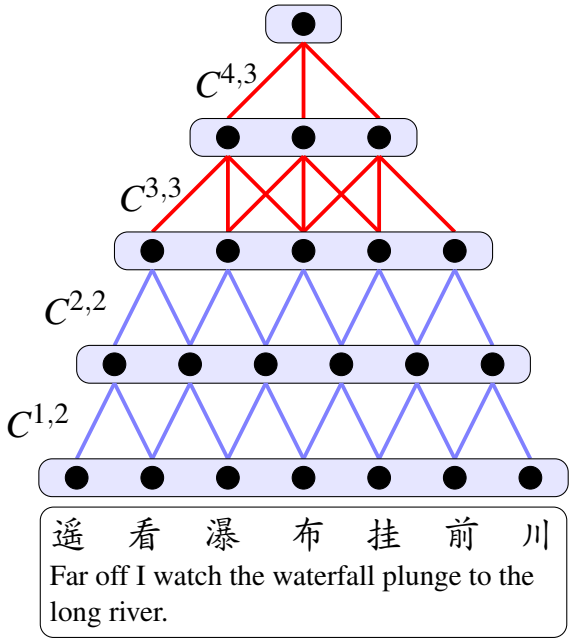

Figure 3: Convolutional sentence model for 7-char quatrain. The first layer has seven vectors, one for each character. Two neighboring vectors are merged to one vector in the second layer with weight matrix $C^{1,2}$. In other layers, either two or three neighboring vectors are merged.

3.2 Recurrent Context Model (RCM)

The RCM takes as input the vectors representing the i lines generated so far and reduces them to a single context vector which is then used to generate the next character (see Figure 2). We compress the i previous lines to one vector (the hidden layer) and then decode the compressed vector to different character positions in the current line. The output layer consists thus of several vectors (one for each position) connected together. This way, different aspects of the context modulate the generation of different characters.

Let $v_1, \ldots, v_i \quad (v_i \in \mathbb{R}^{q\times 1})$ denote the vectors of the previous i lines; $h_i \in \mathbb{R}^{q\times 1}$ is their compressed representation (hidden layer) which is obtained with matrix $M \in \mathbb{R}^{q\times 2q}$; matrix U_j decodes h_i to $u_i^j \in \mathbb{R}^{q\times 1}$ in the $(i+1)$th line. The computation of the RCM proceeds as follows:

$$\begin{aligned} h_0 &= \mathbf{0} \\ h_i &= \sigma(M \cdot \begin{bmatrix} v_i \\ h_{i-1} \end{bmatrix}) \\ u_i^j &= \sigma(U_j \cdot h_i) \qquad 1 \le j \le m-1 \end{aligned} \tag{5}$$

where σ is a non-linear function such as sigmoid and m the line length. Advantageously, lines in classical Chinese poems have a fixed length of five or seven characters. Therefore, the output layer of the recurrent context model only needs two weight matrices (one for each length) and the number of parameters still remains tractable.

3.3 Recurrent Generation Model (RGM)

As shown in Figure 2, the RGM estimates the probability distribution of the next character (over the entire vocabulary) by taking into account the context vector provided by the RCM and the 1-of-N encoding of the previous character. The RGM is essentially a recurrent neural network language model (Mikolov et al., 2010) with an auxiliary input layer, i.e., the context vector from the RCM. Similar strategies for encoding additional information have been adopted in related language modeling and machine translation work (Mikolov and Zweig, 2012; Kalchbrenner and Blunsom, 2013; Auli et al., 2013).

Let $S_{i+1} = w_1, w_2, \ldots, w_m$ denote the line to be generated. The RGM must estimate $P(w_{j+1}|w_{1:j}, S_{1:i})$, however, since the first i lines have been encoded in the context vector u_i^j, we compute $P(w_{j+1}|w_{1:j}, u_i^j)$ instead. Therefore, the probability $P(S_{i+1}|S_{1:i})$ becomes:

$$P(S_{i+1}|S_{1:i}) = \prod_{j=1}^{m-1} P(w_{j+1}|w_{1:j}, u_i^j) \tag{6}$$

Let $|V|$ denote the size of the character vocabulary. The RGM is specified by a number of matrices. Matrix $H \in \mathbb{R}^{q\times q}$ (where q represents the hidden unit size) transforms the context vector to a hidden representation; matrix $X \in \mathbb{R}^{q\times|V|}$ transforms a character to a hidden representation, matrix $R \in \mathbb{R}^{q\times q}$ implements the recurrent transformation and matrix $Y \in \mathbb{R}^{|V|\times q}$ decodes the hidden representation to weights for all words in the vocabulary. Let w denote a character with index k in V; $e(w) \in \mathbb{R}^{|V|\times 1}$ represents a vector with zero in all positions except $e(w)_k = 1$, r_j is the hidden layer of the RGM at step j, and y_{j+1} the output of the RGM, again at step j. The RGM proceeds as follows:

$$r_0 = \mathbf{0} \tag{7a}$$

$$r_j = \sigma(R \cdot r_{j-1} + X \cdot e(w_j) + H \cdot u_i^j) \tag{7b}$$

$$y_{j+1} = Y \cdot r_j \tag{7c}$$

where σ is a nonlinear function (e.g., sigmoid).

The probability of the $(j+1)$th word given the previous j words and the previous i lines is estimated by a *softmax* function:

$$P(w_{j+1} = k | w_{1:j}, u_i^j) = \frac{\exp(y_{j+1,k})}{\sum_{k=1}^{|V|} \exp(y_{j+1,k})} \quad (8)$$

We obtain $P(S_{i+1}|S_{1:i})$ by multiplying all the terms in the right hand-side of Equation (6).

3.4 Training

The objective for training is the cross entropy errors of the predicted character distribution and the actual character distribution in our corpus. An l_2 regularization term is also added to the objective. The model is trained with back propagation through time (Rumelhart et al., 1988) with sentence length being the time step. The objective is minimized by stochastic gradient descent. During training, the cross entropy error in the output layer of the RGM is back-propagated to its hidden and input layers, then to the RCM and finally to the CSM. The same number of hidden units ($q = 200$) is used throughout (i.e., in the RGM, RCM, and CSM). In our experiments all parameters were initialized randomly, with the exception of the word embedding matrix in the CSM which was initialized with *word2vec* embeddings (Mikolov et al., 2013) obtained from our poem corpus (see Section 4 for details on the data we used).

To speed up training, we employed word-classing (Mikolov et al., 2011b). To compute the probability of a character, we estimate the probability of its class and then multiply it by the probability of the character conditioned on the class. In our experiments we used 82 (square root of $|V|$) classes which we obtained by applying hierarchical clustering on character embeddings. This strategy outperformed better known frequency-based classing methods (Zweig and Makarychev, 2013) on our task.

Our poem generator models content selection and lexical choice and their interaction, but does not have a strong notion of local coherence, as manifested in poetically felicitous line-to-line transitions. In contrast, machine translation models (Jiang and Zhou, 2008) have been particularly successful at generating adjacent lines (couplets). To enhance coherence, we thus interpolate our model with two machine translation features (i.e., inverted phrase translation model feature and inverted lexical weight feature). Also note, that in our model surface generation depends on the last observed character and the state of the hidden layer before this observation. This way, there is no explicitly defined context, and history is captured implicitly by the recurrent nature of the model. This can be problematic for our texts which must obey certain stylistic conventions and sound poetic. In default of a better way of incorporating poeticness into our model, we further interpolate it with a language model feature (i.e., a Kneser-Ney trigram model).

Throughout our experiments, we use the RNNLM toolkit to train the character-based recurrent neural network language model (Mikolov et al., 2010). Kneser-Ney n-grams were trained with KenLM (Heafield, 2011).

3.5 Decoding

Our decoder is a stack decoder similar to Koehn et al. (2003). In addition, it implements the tonal pattern and rhyming constraints necessary for generating well-formed Chinese quatrains. Once the first line in a poem is generated, its tonal pattern is determined. During decoding, phrases violating this pattern are ignored. As discussed in Section 1, the final characters of the second and the fourth lines must rhyme. We thus remove during decoding fourth lines whose final characters do not rhyme with the second line. Finally, we use MERT training (Och, 2003) to learn feature weights for the decoder.

4 Experimental Design

Data We created a corpus of classical Chinese poems by collating several online resources: *Tang Poems*, *Song Poems*, *Song Ci*, *Ming Poems*, *Qing Poems*, and *Tai Poems*. The corpus consists of 284,899 poems in total. 78,859 of these are quatrains and were used for training and evaluating our model.[1] Table 2 shows the different partitions of this dataset (POEMLM) into training (QTRAIN)[2], validation (QVALID) and testing (QTEST). Half of the poems in QVALID and QTEST are 5-char quatrains and the other half are 7-char quatrains. All poems except QVALID

[1]The data used in our experiments can be downloaded from `http://homepages.inf.ed.ac.uk/mlap/index.php?page=resources`.

[2]Singleton characters in QTRAIN (6,773 in total) were replaced by <R> to reduce data sparsity.

	Poems	Lines	Characters
QTRAIN	74,809	299,236	2,004,460
QVALID	2,000	8,000	48,000
QTEST	2,050	8,200	49,200
POEMLM	280,849	2,711,034	15,624,283

Table 2: Dataset partitions of our poem corpus.

Models	Perplexity
KN5	172
RNNLM	145
RNNPG	**93**

Table 3: Perplexities for different models.

and QTEST were used for training the character-based language models (see row POEMLM in Table 2). We also trained *word2vec* embeddings on POEMLM. In our experiments, we generated quatrains following the eight most popular tonal patterns according to Wang (2002).

Perplexity Evaluation Evaluation of machine-generated poetry is a notoriously difficult task. Our evaluation studies were designed to assess Manurung et al.'s (2012) criteria of grammaticality, meaningfulness, and poeticness. As a sanity check, we first measured the perplexity of our model with respect to the goldstandard. Intuitively, a better model should assign larger probability (and therefore lower perplexity) to goldstandard poems.

BLEU-based Evaluation We also used BLEU to evaluate our model's ability to generate the second, third and fourth line given previous goldstandard lines. A problematic aspect of this evaluation is the need for human-authored references (for a partially generated poem) which we do not have. We obtain references automatically following the method proposed in He et al. (2012). The main idea is that if two lines share a similar topic, the lines following them can be each other's references. Let A and B denote two adjacent lines in a poem, with B following A. Similarly, let line B' follow line A' in another poem. If lines A and A' share some keywords in the same cluster in the *Shixuehanying* taxonomy, then B and B' can be used as references for both A and A'. We use this algorithm on the *Tang Poems* section of our corpus to build references for poems in the QVALID and QTEST data sets. Poems in QVALID (with auto-generated references) were used for MERT training and Poems in QTEST (with auto-generated references) were used for BLEU evaluation.

Human Evaluation Finally, we also evaluated the generated poems by eliciting human judgments. Specifically, we invited 30 experts[3] on Chinese poetry to assess the output of our generator (and comparison systems). These experts were asked to rate the poems using a 1–5 scale on four dimensions: *fluency* (is the poem grammatical and syntactically well-formed?), *coherence* (is the poem thematically and logically structured?), *meaningfulness* (does the poem convey a meaningful message to the reader?) and *poeticness* (does the text display the features of a poem?). We also asked our participants to evaluate system outputs by ranking the generated poems relative to each other as a way of determining overall poem quality (Callison-Burch et al., 2012).

Participants rated the output of our model and three comparison systems. These included He et al.'s (2012) SMT-based model (SMT), Yan et al.'s (2013) summarization-based system (SUM), and a random baseline which creates poems by randomly selecting phrases from the *Shixuehanying* taxonomy given some keywords as input. We also included human written poems whose content matched the input keywords. All systems were provided with the same keywords (i.e., the same cluster names in the *ShiXueHanYing* taxonomy). In order to compare all models on equal footing, we randomly sampled 30 sets of keywords (with three keywords in each set) and generated 30 quatrains for each system according to two lengths, namely 5-char and 7-char. Overall, we obtained ratings for 300 ($5\times30\times2$) poems.

5 Results

The results of our perplexity evaluation are summarized in Table 3. We compare our RNN-based poem generator (RNNPG) against Mikolov's (2010) recurrent neural network language model (RNNLM) and a 5-gram language model with Kneser-Ney smoothing (KN5). All models were trained on QTRAIN and tuned on QVALID. The perplexities were computed on QTEST. Note that

[3] 27 participants were professional or amateur poets and three were Chinese literature students who had taken at least one class on Chinese poetry composition.

Models	1 → 2		2 → 3		3 → 4		Average	
	5-char	7-char	5-char	7-char	5-char	7-char	5-char	7-char
SMT	0.0559	0.0906	0.0410	0.1837	0.0547	**0.1804**	0.0505	0.1516
RNNPG	**0.0561**	**0.1868**	**0.0515**	**0.2102**	**0.0572**	0.1800	**0.0549**	**0.1923**

Table 4: BLEU-2 scores on 5-char and 7-char quatrains. Given i goldstandard lines, BLEU-2 scores are computed for the next $(i+1)$th lines.

Models	Fluency		Coherence		Meaning		Poeticness		Rank	
	5-char	7-char	5-char	7-char	5-char	7-char	5-char	7-char	5-char	7-char
Random	2.52	2.18	2.22	2.16	2.02	1.93	1.77	1.71	0.31	0.26
SUM	1.97	1.91	2.08	2.33	1.84	1.98	1.66	1.73	0.25	0.22
SMT	2.81	3.01	2.47	2.76	2.33	2.73	2.08	2.36	0.43	0.53
RNNPG	$\mathbf{4.01}^{**}$	$\mathbf{3.44}^{*}$	$\mathbf{3.18}^{**}$	$\mathbf{3.12}^{*}$	$\mathbf{3.20}^{**}$	**3.02**	$\mathbf{2.80}^{**}$	$\mathbf{2.68}^{*}$	$\mathbf{0.73}^{**}$	$\mathbf{0.64}^{*}$
Human	4.31^{+}	4.19^{++}	3.81^{++}	4.00^{++}	3.61^{+}	3.91^{++}	3.29^{++}	3.49^{++}	0.79	0.84^{++}

Table 5: Mean ratings elicited by humans on 5-char and 7-char quatrains. Diacritics ** ($p < 0.01$) and * ($p < 0.05$) indicate our model (RNNPG) is significantly better than all other systems except Human. Diacritics $^{++}$ ($p < 0.01$) and $^{+}$ ($p < 0.05$) indicate Human is significantly better than all other systems.

the RNNPG estimates the probability of a poem line given at least one previous line. Therefore, the probability of a quatrain assigned by the RNNPG is the probability of the last three lines. For a fair comparison, RNNLM and KN5 only leverage the last three lines of each poem during training, validation and testing. The results in Table 3 indicate that the generation ability of the RNNPG is better than KN5 and RNNLM. Note that this perplexity-style evaluation is not possible for models which cannot produce probabilities for gold standard poems. For this reason, other related poem generators (Yan et al., 2013; He et al., 2012) are not included in the table.

The results of our evaluation using BLEU-2 are summarized in Table 4. Here, we compare our system against the SMT-based poem generation model of He et al. (2012).[4] Their system is a linear combination of two translation models (one with five features and another one with six). Our model uses three of their features, namely the inverted phrase translation model feature, the lexical weight feature, and a Kneser-Ney trigram feature. Unfortunately, it is not possible to evaluate Yan et al.'s (2013) summarization-based system with BLEU, as it creates poems as a whole and there is no obvious way to generate next lines with their algorithm. The BLEU scores in Table 4 indicate that, given the same context lines, the RNNPG is better than SMT at generating what to say next. BLEU scores should be, however, viewed with some degree of caution. Aside from being an approximation of human judgment (Callison-Burch et al., 2012), BLEU might be unnecessarily conservative for poem composition which by its very nature is a creative endeavor.

The results of our human evaluation study are shown in Table 5. Each column reports mean ratings for a different dimension (e.g., fluency, coherence). Ratings for 5-char and 7-char quatrains are shown separately. The last column reports rank scores for each system (Callison-Burch et al., 2012). In a ranked list of N items ($N = 5$ here), the score of the ith ranked item is $\frac{(N-i)}{(N-1)}$. The numerator indicates how many times a systems won in pairwise comparisons, while the denominator normalizes the score.

With respect to 5-char quatrains, RNNPG is significantly better than Random, SUM and SMT on fluency, coherence, meaningfulness, poeticness and ranking scores (using a t-test). On all dimensions, human-authored poems are rated as significantly better than machine-generated ones, with the exception of overall ranking. Here, the difference between RNNPG and Human is not significant. We obtain similar results with 7-char quatrains. In general, RNNPG seems to perform better on the shorter poems. The mean ratings

[4] Our re-implementation of their system delivered very similar scores to He et al. (2012). For example, we obtained an average BLEU-1 of 0.167 for 5-char quatrains and 0.428 for 7-char quatrains compared to their reported scores of 0.141 and 0.380, respectively.

白鹭窥鱼立, Egrets stood, peeping fishes. 青山照水开. Water was still, reflecting mountains. 夜来风不动, The wind went down by nightfall, 明月见楼台. as the moon came up by the tower.	满怀风月一枝春, Budding branches are full of romance. 未见梅花亦可人. Plum blossoms are invisible but adorable. 不为东风无此客, With the east wind comes Spring. 世间何处是前身. Where on earth do I come from?

Table 6: Example output produced by our model (RNNPG).

are higher and the improvements over other systems are larger. Also notice, that the score margins between the human- and machine-written poems become larger for 7-char quatrains. This indicates that the composition of 7-char quatrains is more difficult compared to 5-char quatrains. Table 6 shows two example poems (5-char and 7-char) produced by our model which received high scores with respect to poeticness.

Interestingly, poems generated by SUM[5] are given ratings similar to Random. In fact SUM is slightly worse (although not significantly) than Random on all dimensions, with the exception of coherence. In the human study reported in Yan et al. (2013), SUM is slightly better than SMT. There are several reasons for this discrepancy. We used a more balanced experimental design: all systems generated poems from the same keywords which were randomly chosen. We used a larger dataset to train the SMT model compared to Yan et al. (284,899 poems vs 61,960). The Random baseline is not a straw-man; it selects phrases from a taxonomy of meaningful clusters edited by humans and closely related to the input keywords.

6 Conclusions

In this paper we have presented a model for Chinese poem generation based on recurrent neural networks. Our model jointly performs content selection and surface realization by learning representations of individual characters and their combinations within and across poem lines. Previous work on poetry generation has mostly leveraged contextual information of limited length (e.g., one sentence). In contrast, we introduced two recurrent neural networks (the recurrent context model and recurrent generation model) which naturally capture multi-sentential content. Experimental results show that our model yields high quality poems compared to the state of the art. Perhaps unsurprisingly, our human evaluation study revealed that machine-generated poems lag behind human-generated ones. It is worth bearing in mind that poetry composition is a formidable task for humans, let alone machines. And that the poems against which our output was compared have been written by some of the most famous poets in Chinese history!

Avenues for future work are many and varied. We would like to generate poems across different languages and genres (e.g., Engish sonnets or Japanese haiku). We would also like to make the model more sensitive to line-to-line transitions and stylistic conventions by changing its training objective to a combination of cross-entropy error and BLEU score. Finally, we hope that some of the work described here might be of relevance to other generation tasks such as summarization, concept-to-text generation, and machine translation.

[5]We made a good-faith effort to re-implement their poem generation system. We are grateful to Rui Yan for his help and technical advice.

Acknowledgments

We would like to thank Eva Halser for valuable discussions on the machine translation baseline. We are grateful to the 30 Chinese poetry experts for participating in our rating study. Thanks to Gujing Lu, Chu Liu, and Yibo Wang for their help with translating the poems in Table 6 and Table 1.

Abstract

This paper explores alternate algorithms, reward functions and feature sets for performing multi-document summarization using reinforcement learning with a high focus on reproducibility. We show that ROUGE results can be improved using a unigram and bigram similarity metric when training a learner to select sentences for summarization. Learners are trained to summarize document clusters based on various algorithms and reward functions and then evaluated using ROUGE. Our experiments show a statistically significant improvement of 1.33%, 1.58%, and 2.25% for ROUGE-1, ROUGE-2 and ROUGE-L scores, respectively, when compared with the performance of the state of the art in automatic summarization with reinforcement learning on the DUC2004 dataset. Furthermore query focused extensions of our approach show an improvement of 1.37% and 2.31% for ROUGE-2 and ROUGE-SU4 respectively over query focused extensions of the state of the art with reinforcement learning on the DUC2006 dataset.

1 Introduction

The multi-document summarization problem has received much attention recently (Lyngbaek, 2013; Sood, 2013; Qian and Liu, 2013) due to its ability to reduce large quantities of text to a human processable amount as well as its application in other fields such as question answering (Liu et al., 2008; Chali et al., 2009a; Chali et al., 2009b; Chali et al., 2011b). We expect this trend to further increase as the amount of linguistic data on the web from sources such as social media, wikipedia, and online newswire increases. This paper focuses specifically on utilizing reinforcement learning (Sutton and Barto, 1998; Szepesv, 2009) to create a policy for summarizing clusters of multiple documents related to the same topic.

The task of extractive automated multi-document summarization (Mani, 2001) is to select a subset of textual units, in this case sentences, from the source document cluster to form a summary of the cluster in question. This extractive approach allows the learner to construct a summary without concern for the linguistic quality of the sentences generated, as the source documents are assumed to be of a certain linguistic quality. This paper aims to expand on the techniques used in Ryang and Abekawa (2012) which uses a reinforcement learner, specifically $TD(\lambda)$, to create summaries of document clusters. We achieve this through introducing a new algorithm, varying the feature space and utilizing alternate reward functions.

The $TD(\lambda)$ learner used in Ryang and Abekawa (2012) is a very early reinforcement learning implementation. We explore the option of leveraging more recent research in reinforcement learning algorithms to improve results. To this end we explore the use of $SARSA$ which is a derivative of $TD(\lambda)$ that models the action space in addition to the state space modelled by $TD(\lambda)$. Furthermore we explore the use of an algorithm not based on temporal difference methods, but instead on policy iteration techniques. Approximate Policy Iteration (Lagoudakis and Parr, 2003) generates a policy, then evaluates and iterates until convergence.

The reward function in Ryang and Abekawa (2012) is a delayed reward based on $tf*idf$ values. We further explore the reward space by introducing similarity metric calculations used in ROUGE (Lin, 2004) and base our ideas on Saggion et al. (2010). The difference between immediate rewards and delayed rewards is that the learner re-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 681–690,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

ceives immediate feedback at every action in the former and feedback only at the end of the episode in the latter. We explore the performance difference of both reward types. Finally we develop query focused extensions to both reward functions and present their results on more recent Document Understanding Conference (DUC) datasets which ran a query focused task.

We first evaluate our systems using the DUC2004 dataset for comparison with the results in Ryang and Abekawa (2012). We then present the results of query focused reward functions against the DUC2006 dataset to provide reference with a more recent dataset and a more recent task, specifically a query-focused summarization task. Evaluations are performed using ROUGE for ROUGE-1, ROUGE-2 and ROUGE-L values for general summarization, while ROUGE-2 and ROUGE-SU4 is used for query-focused summarization. Furthermore we selected a small subset of query focused summaries to be subjected to human evaluations and present the results.

Our implementation is named REAPER (**R**elatedness-focused **E**xtractive **A**utomatic summary **P**reparation **E**xploiting **R**einfocement learning) thusly for its ability to harvest a document cluster for ideal sentences for performing the automatic summarization task. REAPER is not just a reward function and feature set, it is a full framework for implementing summarization tasks using reinforcement learning and is available online for experimentation.[1] The primary contributions of our experiments are as follows:

- Exploration of $TD(\lambda)$, $SARSA$ and Approximate Policy Iteration.
- Alternate REAPER reward function.
- Alternate REAPER feature set.
- Query focused extensions of automatic summarization using reinforcement learning.

2 Previous Work and Motivation

Previous work using reinforcement learning for natural language processing tasks (Branavan et al., 2009; Wan, 2007; Ryang and Abekawa, 2012; Chali et al., 2011a; Chali et al., 2012) inspired us to use a similar approach in our experiments. Ryang and Abekawa (2012) implemented a reinforcement learning approach to multi-document summarization which they named Automatic Summarization using Reinforcement Learning (ASRL). ASRL uses TD(λ) to learn and then execute a policy for summarizing a cluster of documents. The algorithm performs N summarizations from a blank state to termination, updating a set of state-value predictions as it does so. From these N episodes a policy is created using the estimated state-value pairs, this policy greedily selects the best action until the summary enters its terminal state. This summary produced is the output of ASRL and is evaluated using ROUGE-1, ROUGE-2, and ROUGE-L (Lin, 2004). The results segment of the paper indicates that ASRL outperforms greedy and integer linear programming (ILP) techniques for the same task.

There are two notable details that provide the motivation for our experiments; TD(λ) is relatively old as far as reinforcement learning (RL) algorithms are concerned, and the optimal ILP did not outperform ASRL using the same reward function. The intuition gathered from this is that if the optimal ILP algorithm did not outperform the suboptimal ASRL on the ROUGE evaluation, using the same reward function, then there is clearly room for improvement in the reward function's ability to accurately model values in the state space. Furthermore one may expect to achieve a performance boost exploiting more recent research by utilizing an algorithm that intends to improve upon the concepts on which $TD(\lambda)$ is based. These provide the motivation for the remainder of the research preformed.

Query focused multi-document summarization (Li and Li, 2013; Chali and Hasan, 2012b; Yin et al., 2012; Wang et al., 2013) has recently gained much attention due to increasing amounts of textual data, as well as increasingly specific user demands for extracting information from said data. This is reflected in the query focused tasks run in the Document Understanding Conference (DUC) and Text Analysis Conference (TAC) over the past decade. This has motivated us to design and implement query focused extensions to these reinforcement learning approaches to summarization.

There has been some research into the effects of sentence compression on the output of automatic summarization systems (Chali and Hasan, 2012a), specifically the evaluation results garnered from compressing sentences before evaluation (Qian and Liu, 2013; Lin and Rey, 2003; Ryang and

[1] https://github.com/codyrioux/REAPER

Abekawa, 2012). However Ryang and Abekawa (2012) found this technique to be ineffective in improving ROUGE metrics using a similar reinforcement learning approach to this paper, as a result we will not perform any further exploration into the effects of sentence compression.

3 Problem Definition

We use an identical problem definition to Ryang and Abekawa (2012). Assume the given cluster of documents is represented as a set of textual units $D = \{x_1, x_2, \cdots, x_n\}$ where $|D| = n$ and x_i represents a single textual unit. Textual units for the purposes of this experiment are the individual sentences in the document cluster, that is $D = D_1 \cup D_2 \cup \cdots \cup D_m$ where m is the number of documents in the cluster and each D_i represents a document.

The next necessary component is the score function, which is to be used as the reward for the learner. The function $score(s)$ can be applied to any $s \subset D$. s is a summary of the given document or cluster of documents.

Given these parameters, and a length limitation k we can define an optimal summary s^* as:

$$s^* = argmax\ score(s) \quad where\ s \subset D\ and\ length(s) \leq k \quad (1)$$

It is the objective of our learner to create a policy that produces the optimal summary for its provided document cluster D. Henceforth the length limitations used for general summarization will be 665 bytes, and query focused summarization will use 250 words. These limitations on summary length match those set by the Document Understanding Conferences associated with the dataset utilized in the respective experiments.

4 Algorithms

$TD(\lambda)$ and $SARSA$ (Sutton and Barto, 1998) are temporal difference methods in which the primary difference is that $TD(\lambda)$ models state value predictions, and $SARSA$ models state-action value predictions. Approximate Policy Iteration (API) follows a different paradigm by iteratively improving a policy for a markov decision process until the policy converges.

4.1 TD(λ)

In the ASRL implementation of $TD(\lambda)$ the learning rate α_k and temperature τ_k decay as learning progresses with the following equations with k set to the number of learning episodes that had taken place.

$$\alpha_k = 0.001 \cdot 101/(100 + k^{1.1}) \quad (2)$$

$$\tau_k = 1.0 * 0.987^{k-1} \quad (3)$$

One can infer from the decreasing values of α_k that as the number of elapsed episodes increases the learner adjusts itself at a smaller rate. Similarly as the temperature τ_k decreases the action selection policy becomes greedier and thus performs less exploration, this is evident in (5) below.

Note that unlike traditional $TD(\lambda)$ implementations the eligibility trace e resets on every episode. The reasons for this will become evident in the experiments section of the paper in which $\lambda = 1, \gamma = 1$ and thus there is no decay during an episode and complete decay after an episode. The same holds true for $SARSA$ below.

The action-value estimation $Q(s, a)$ is approximated as:

$$Q(s, a) = r + \gamma V(s') \quad (4)$$

The policy is implemented as such:

$$policy(a|s; \theta; \tau) = \frac{e^{Q(s,a)/\tau}}{\sum_{a \in A} e^{Q(s,a)/\tau}} \quad (5)$$

Actions are selected probabilistically using softmax selection (Sutton and Barto, 1998) from a Boltzmann distribution. As the value of τ approaches 0 the distribution becomes greedier.

4.2 $SARSA$

$SARSA$ is implemented in a very similar manner and shares α_k, τ_k, $\phi(s)$, m, and $policy(s)$ with the $TD(\lambda)$ implementation above. $SARSA$ is also a temporal difference algorithm and thus behaves similarly to $TD(\lambda)$ with the exception that values are estimated not only on the state s but a state-action pair $[s, a]$.

4.3 Approximate Policy Iteration

The third algorithm in our experiment uses Approximate Policy Iteration (Lagoudakis and Parr, 2003) to implement a reinforcement learner. The

novelty introduced by (Lagoudakis and Parr, 2003) is that they eschew standard representations for a policy and instead use a classifier to represent the current policy π. Further details on the algorithm can be obtained from Lagoudakis and Parr (2003).

5 Experiments

Our state space S is represented simply as a three-tuple $[s\ a\ f]$ in which s is the set of textual units (sentences) that have been added to the summary, a is a sequence of actions that have been performed on the summary and f is a boolean with value 0 representing non-terminal states and 1 representing a summary that has been terminated.

The individual units in our action space are defined as [:insert x_i] where x_i is a textual unit as described earlier, let us define D_i as the set [:insert x_i] for all $x_i \in D$ where D is the document set. We also have one additional action [:finish] and thus we can define our action space.

$$A = D_i \cup \{[:\ finish]\} \tag{6}$$

The actions eligible to be executed on any given state s is defined by a function $actions(A, s)$:

$$actions(A, s) = \begin{cases} [:\ finish] & \text{if } length(s) > k \\ A - a_t & otherwise \end{cases} \tag{7}$$

The state-action transitions are defined below:

$$[s_t\ , a_t\ , 0] \xrightarrow{a=insert x_i} [s_t \cup x_i\ , a_t \cup a\ , 0] \tag{8}$$

$$[s_t\ , a_t\ , 0] \xrightarrow{:finish} [s_t\ , a_t\ , 1] \tag{9}$$

$$[s_t\ , a_{t+1}\ , 1] \xrightarrow{any} [s_t\ , a_t\ , 1] \tag{10}$$

Insertion adds both the content of the textual unit x_i to the set s as well as the action itself to set a. Conversely finishing does not alter s or a but it flips the f bit to on. Notice from (10) that once a state is terminal any further actions have no effect.

5.1 Feature Space

We present an alternate feature set called REAPER feature set based on the ideas presented in Ryang and Abekawa (2012). Our proposed feature set follows a similar format to the previous one but depends on the presence of top **bigrams** instead of $tf * idf$ words.

- One bit $b \in 0, 1$ for each of the top n **bigrams** (Manning and Schütze, 1999) present in the summary.
- Coverage ratio calculated as the sum of the bits in the previous feature divided by n.
- Redundancy Ratio calculated as the number of redundant times a bit in the first feature is flipped on, divided by n.
- Length Ratio calculated as $length(s)/k$ where k is the length limit.
- Longest common subsequence length.
- Length violation bit. Set to 1 if $length(s) > k$

Summaries which exceed the length limitation k are subject to the same reduction as the ASRL feature set (Ryang and Abekawa, 2012) to an all zero vector with the final bit set to one.

5.2 Reward Function

Our reward function (termed as REAPER reward) is based on the n-gram concurrence score metric, and the longest-common-subsequence recall metric contained within ROUGE (Lin, 2004).

$$reward(s) = \begin{cases} -1, & \text{if } length(s) > k \\ score(s) & \text{if } s \text{ is terminal} \\ 0 & \text{otherwise} \end{cases} \tag{11}$$

Where $score$ is defined identically to ASRL, with the exception that Sim is a new equation based on ROUGE metrics.

$$score(s) = \sum_{x_i \in S} \lambda_s Rel(x_i) - \sum_{x_i, x_j \in S, i<j} (1 - \lambda_s) Red(x_i, x_j) \tag{12}$$

$$Rel(x_i) = Sim(x_i, D) + Pos(x_i)^{-1} \tag{13}$$

$$Red(x_i, x_j) = Sim(x_i, x_j) \tag{14}$$

Ryang and Abekawa (2012) experimentally determined a value of 0.9 for the λ_s parameter. That value is used herein unless otherwise specified. Sim has been redefined as:

$$\begin{aligned} Sim(s) =& 1 * ngco(1, D, s) + \\ & 4 * ngco(2, D, s) + \\ & 1 * ngco(3, D, s) + \\ & 1 * ngco(4, D, s) + \\ & 1 * rlcs(D, s) \end{aligned} \quad (15)$$

and $ngco$ is the ngram co-occurence score metric as defined by Lin (2004).

$$ngco(n, D, s) = \frac{\sum_{r \in D} \sum_{ngram \in r} Count_{match}(ngram)}{\sum_{S_r \in D} \sum_{ngram \in r} Count(ngram)} \quad (16)$$

Where n is the n-gram count for example 2 for bigrams, D is the set of documents, and s is the summary in question. $Count_{match}$ is the maximum number of times the ngram occurred in either D or s.

The $rlcs(R, S)$ is also a recall oriented measure based on longest common subsequence (Hirschberg, 1977). Recall was selected as DUC2004 tasks favoured a β value for F-Measure (Lin, 2004) high enough that only recall would be considered. lcs is the longest common subsequence, and $length(D)$ is the total number of tokens in the reference set D.

$$rlcs(D, s) = \frac{lcs(D, s)}{length(D)} \quad (17)$$

We are measuring similarity between sentences and our entire reference set, and thusly our D is the set of documents defined in section 3. This is also a delayed reward as the provided reward is zero until the summary is terminal.

5.2.1 Query Focused Rewards

We have proposed an extension to both reward functions to allow for query focused (QF) summarization. We define a function $score'$ which aims to balance the summarization abilities of the reward with a preference for selecting textual units related to the provided query q. Both ASRL and REAPER $score$ functions have been extended in the following manner where Sim is the same similarity functions used in equation (13) and (15).

$$score'(q, s) = \beta Sim(q, s) + (1 - \beta) score(s) \quad (18)$$

The parameter β is a balancing factor between query similarity and overall summary score in which $0 <= \beta <= 1$, we used an arbitrarily chosen value of 0.9 in these experiments. In the case of ASRL the parameter q is the vectorized version of the query function with $tf * idf$ values, and for Sim q is a sequence of tokens which make up the query, stemmed and stop-words removed.

5.2.2 Immediate Rewards

Finally we also employ immediate versions of the reward functions which behave similarly to their delayed counterparts with the exception that the score is always provided to the caller regardless of the terminal status of state s.

$$reward(s) = \begin{cases} -1, & \text{if } length(s) > k \\ score(s) & \text{otherwise} \end{cases} \quad (19)$$

6 Results

We first present results[2] of our experiments, specifying parameters, and withholding discussion until the following section. We establish a benchmark using ASRL and other top-scoring summarization systems compared with REAPER using ROUGE. For generic multi-document summarization we run experiments on all 50 document clusters, each containing 10 documents, of DUC2004 task 2 with parameters for REAPER and ASRL fixed at $\lambda = 1$, $\gamma = 1$, and $k = 665$. Sentences were stemmed using a Porter Stemmer (Porter, 1980) and had the ROUGE stop word set removed. All summaries were processed in this manner and then projected back into their original (unstemmed, with stop-words) state and output to disk.

Config	R-1	R-2	R-L
REAPER	0.40339	0.11397	0.36574
ASRL	0.39013	0.09479	0.33769
MCKP	0.39033	0.09613	0.34225
PEER65	0.38279	0.09217	0.33099
ILP	0.34712	0.07528	0.31241
GREEDY	0.30618	0.06400	0.27507

Table 1: Experimental results with ROUGE-1, ROUGE-2 and ROUGE-L scores on DUC2004.

[2]ROUGE-1.5.5 run with -m -s -p 0

Table 1 presents results for REAPER, ASRL (Ryang and Abekawa, 2012), MCKP (Takamura and Okumura, 2009), PEER65 (Conroy et al., 2004) , and GREEDY (Ryang and Abekawa, 2012) algorithms on the same task. This allows us to make a direct comparison with the results of Ryang and Abekawa (2012).

REAPER results are shown using the $TD(\lambda)$ algorithm, REAPER reward function, and ASRL feature set. This is to establish the validity of the reward function holding all other factors constant. REAPER results for ROUGE-1, ROUGE-2 and ROUGE-L are statistically significant compared to the result set presented in Table 2 of Ryang and Abekawa (2012) using $p < 0.01$.

Run	R-1	R-2	R-L
REAPER 0	0.39536	0.10679	0.35654
REAPER 1	0.40176	0.11048	0.36450
REAPER 2	0.39272	0.11171	0.35766
REAPER 3	0.39505	0.11021	0.35972
REAPER 4	0.40259	0.11396	0.36539
REAPER 5	0.40184	0.11306	0.36391
REAPER 6	0.39311	0.10873	0.35481
REAPER 7	0.39814	0.11001	0.35786
REAPER 8	0.39443	0.10740	0.35586
REAPER 9	0.40233	0.11397	0.36483
Average	0.39773	0.11063	0.36018

Table 2: REAPER run 10 times on the DUC2004.

We present the results of 10 runs of REAPER, with REAPER feature set.. As with ASRL, REAPER does not converge on a stable solution which is attributable to the random elements of $TD(\lambda)$. Results in all three metrics are again statistically significant compared to ASRL results presented in the Ryang and Abekawa (2012) paper. All further REAPER experiments use the bigram oriented feature space.

Reward	R-1	R-2	R-L
$Delayed$	0.39773	0.11397	0.36018
$Immediate$	0.32981	0.07709	0.30003

Table 3: REAPER with delayed and immediate rewards on DUC2004.

Table 3 shows the performance difference of REAPER when using a delayed and immediate reward. The immediate version of REAPER provides feedback on every learning step, unlike the delayed version which only provides score at the end of the episode.

Features	R-1	R-2	R-L
$ASRL$	0.40339	0.11397	0.36574
$REAPER$	0.40259	0.11396	0.36539

Table 4: REAPER with alternate feature spaces on DUC2004.

We can observe the results of using REAPER with various feature sets in Table 4. Experiments were run using REAPER reward, $TD(\lambda)$, and the specified feature set.

Algorithm	R-1	R-2	R-L
$TD(\lambda)$	0.39773	0.11063	0.36018
$SARSA$	0.28287	0.04858	0.26172
API	0.29163	0.06570	0.26542

Table 5: REAPER with alternate algorithms on DUC2004.

Table 5 displays the performance of REAPER with alternate algorithms. $TD(\lambda)$ and $SARSA$ are run using the delayed reward feature, while API requires an immediate reward and was thus run with the immediate reward.

System	R-2	R-SU4
$REAPER$	0.07008	0.11689
$ASRL$	0.05639	0.09379
$S24$	0.09505	0.15464
Baseline	0.04947	0.09788

Table 6: QF-REAPER on DUC2006.

For query-focused multi-document summarization we experimented with the DUC2006 system task, which contained 50 document clusters consisting of 25 documents each. Parameters were fixed to $\lambda = 1$, $\gamma = 1$ and $k = 250$ **words**. In Table 6 we can observe the results[3] of our query focused systems against DUC2006's top scorer (S24) for ROUGE-2, and a baseline. The baseline was generated by taking the most recent document in the cluster and outputting the first 250 words.

Human Evaluations: We had three native English-speaking human annotators evaluate a set of four randomly chosen summaries produced by REAPER on the DUC2004 dataset.

[3]ROUGE-1.5.5 run with -n 2 -x -m -2 4 -u -c 95 -r 1000 -f A -p 0.5 -t 0 -l 250

Metric	A1	A2	A3	AVG
Grammaticality	3.00	4.00	4.00	**3.67**
Redundancy	4.75	4.25	2.75	**3.92**
Referential Clarity	4.00	4.50	3.50	**4.00**
Focus	4.50	3.50	2.25	**3.42**
Structure	3.50	4.00	3.00	**3.50**
Responsiveness	4.25	3.75	3.00	**3.67**

Table 7: Human evaluation scores on DUC2004.

Table 7 shows the evaluation results according to the DUC2006 human evaluation guidelines. The first five metrics are related entirely to the linguistic quality of the summary in question and the final metric, Responsiveness, rates the summary on its relevance to the source documents. Columns represent the average provided by a given annotator over the four summaries, and the AVG column represents the average score for all three annotators over all four summaries. Score values are an integer between 1 and 5 inclusive.

7 Discussion

First we present a sample of a summary generated from a randomly selected cluster. The following summary was generated from cluster $D30017$ of the DUC 2004 dataset using REAPER reward with $TD(\lambda)$ and REAPER feature space.

A congressman who visited remote parts of North Korea last week said Saturday that the food and health situation there was desperate and deteriorating, and that millions of North Koreans might have starved to death in the last few years. North Korea is entering its fourth winter of chronic food shortages with its people malnourished and at risk of dying from normally curable illnesses, senior Red Cross officials said Tuesday. More than five years of severe food shortages and a near-total breakdown in the public health system have led to devastating malnutrition in North Korea and probably left an entire generation of children physically and mentally impaired, a new study by international aid groups has found. Years of food shortages have stunted the growth of millions of North Korean children, with two-thirds of children under age seven suffering malnourishment, U.N. experts said Wednesday. The founder of South Korea's largest conglomerate plans to visit his native North Korea again next week with a gift of 501 cattle, company officials said Thursday. "There is enough rice.

We can observe that the summary is both syntactically sound, and elegantly summarizes the source documents.

Our baseline results table (Table 1) shows REAPER outperforming ASRL in a statistically significant manner on all three ROUGE metrics in question. However we can see from the absolute differences in score that very few additional important words were extracted (ROUGE-1) however REAPER showed a significant improvement in the structuring and ordering of those words (ROUGE-2, and ROUGE-L).

The balancing factors used in the REAPER reward function are responsible for the behaviour of the reward function, and thus largely responsible for the behaviour of the reinforcement learner. In equation 15 we can see balance numbers of 1, 4, 1, 1, 1 for 1-grams, 2-grams, 3-grams, 4-grams, and LCS respectively. In adjusting these values a user can express a preference for a single metric or a specific mixture of these metrics. Given that the magnitude of scores for n-grams decrease as n increases and given that the magnitude of scores for 1-grams is generally 3 to 4 times larger, in our experience, we can see that this specific reward function favours bigram similarity over unigram similarity. These balance values can be adjusted to suit the specific needs of a given situation, however we leave exploration of this concept for future work.

We can observe in Figure 1 that ASRL does not converge on a stable value, and dips towards the 300^{th} episode while in Figure 2 REAPER does not take nearly such a dramatic dip. These figures display average normalized reward for all 50 document clusters on a single run. Furthermore we can observe that ASRL reaches it's peak reward around episode 225 while REAPER does so around episode 175 suggesting that REAPER converges faster.

7.1 Delayed vs. Immediate Rewards

The delayed vs. immediate rewards results in Table 3 clearly show that delaying the reward provides a significant improvement in globally optimizing the summary for ROUGE score. This can be attributed to the $\lambda = 1$ and $\gamma = 1$ parameter values being suboptimal for the immediate reward situation. This has the added benefit of being much more performant computationally as far fewer reward calculations need be done.

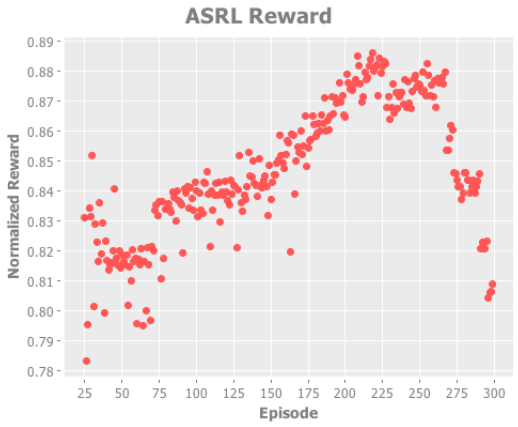

Figure 1: ASRL normalized reward.

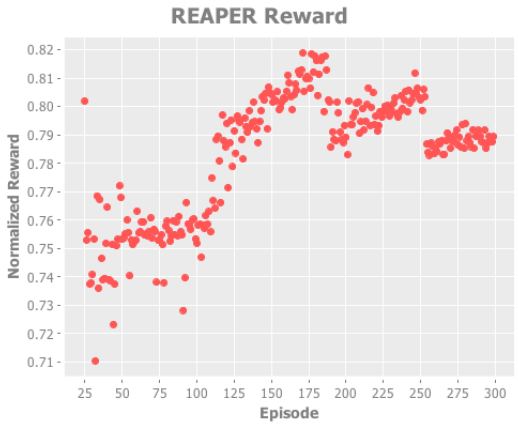

Figure 2: REAPER normalized reward.

7.2 Feature Space

The feature space experiments in Table 4 seem to imply that REAPER performs similarly with both feature sets. We are confident that an improvement could be made through further experimentation. Feature engineering, however, is a very broad field and we plan to pursue this topic in depth in the future.

7.3 Algorithms

$TD(\lambda)$ significantly outperformed both $SARSA$ and API in the algorithm comparison. Ryang and Abekawa (2012) conclude that the feature space is largely responsible for the algorithm performance. This is due to the fact that poor states such as those that are too long, or those that contain few important words will reduce to the same feature set and receive negative rewards collectively. $SARSA$ loses this benefit as a result of its modelling of state-action pairs.

API on the other hand may have suffered a performance loss due to its requirements of an immediate reward, this is because when using a delayed reward if the trajectory of a rollout does not reach a terminal state the algorithm will not be able to make any estimations about the value of the state in question. We propose altering the policy iteration algorithm to use a trajectory length of one episode instead of a fixed number of actions in order to counter the need for an immediate reward function.

7.4 Query Focused Rewards

From the ROUGE results in Table 6 we can infer that while REAPER outperformed ASRL on the query focused task, however it is notable that both systems under performed when compared to the top system from the DUC2006 conference.

We can gather from these results that it is not enough to simply naively calculate similarity with the provided query in order to produce a query-focused result. Given that the results produced by the generic summarization task is rather acceptable according to our human evaluations we suggest that further research be focused on a proper similarity metric between the query and summary to improve the reward function's overall ability to score summaries in a query-focused setting.

8 Conclusion and Future Work

We have explored alternate reward functions, feature sets, and algorithms for the task of automatic summarization using reinforcement learning. We have shown that REAPER outperforms ASRL on both generic summarization and the query focused tasks. This suggests the effectiveness of our reward function and feature space. Our results also confirm that $TD(\lambda)$ performs best for this task compared to $SARSA$ and API.

Due to the acceptable human evaluation scores on the general summarization task it is clear that the algorithm produces acceptable summaries of newswire data. Given that we have a framework for generating general summaries, and the current popularity of the query-focused summarization task, we propose that the bulk of future work in this area be focused on the query-focused task specifically in assessing the relevance of a summary to a provided query. Therefore we intend to pursue future research in utilizing word-sense disambiguation and synonyms, as well as other techniques for furthering REAPER's query similarity

metrics in order to improve its ROUGE and human evaluation scores on query-focused tasks.

Abstract

In this paper, we focus on the problem of using sentence compression techniques to improve multi-document summarization. We propose an innovative sentence compression method by considering every node in the constituent parse tree and deciding its status – remove or retain. Integer liner programming with discriminative training is used to solve the problem. Under this model, we incorporate various constraints to improve the linguistic quality of the compressed sentences. Then we utilize a pipeline summarization framework where sentences are first compressed by our proposed compression model to obtain top-n candidates and then a sentence selection module is used to generate the final summary. Compared with state-of-the-art algorithms, our model has similar ROUGE-2 scores but better linguistic quality on TAC data.

1 Introduction

Automatic summarization can be broadly divided into two categories: extractive and abstractive summarization. Extractive summarization focuses on selecting salient sentences from the document collection and concatenating them to form a summary; while abstractive summarization is generally considered more difficult, involving sophisticated techniques for meaning representation, content planning, surface realization, etc.

There has been a surge of interest in recent years on generating compressed document summaries as a viable step towards abstractive summarization. These compressive summaries often contain more information than sentence-based extractive summaries since they can remove insignificant sentence constituents and make space for more salient information that is otherwise dropped due to the summary length constraint. Two general strategies have been used for compressive summarization. One is a pipeline approach, where sentence-based extractive summarization is followed or proceeded by sentence compression (Lin, 2003; Zajic et al., 2007; Vanderwende et al., 2007; Wang et al., 2013). Another line of work uses joint compression and summarization. Such methods have been shown to achieve promising performance (Daumé, 2006; Chali and Hasan, 2012; Almeida and Martins, 2013; Qian and Liu, 2013), but they are typically computationally expensive.

In this study, we propose an innovative sentence compression model based on expanded constituent parse trees. Our model uses integer linear programming (ILP) to search the entire space of compression, and is discriminatively trained. It is built based on the discriminative sentence compression model from (McDonald, 2006) and (Clarke and Lapata, 2008), but our method uses an expanded constituent parse tree rather than only the leaf nodes in previous work. Therefore we can extract rich features for every node in the constituent parser tree. This is an advantage of tree-based compression technique (Knight and Marcu, 2000; Galley and McKeown, 2007; Wang et al., 2013). Similar to (Li et al., 2013a), we use a pipeline summarization framework where multiple compression candidates are generated for each pre-selected important sentence, and then an ILP-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 691–701,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

based summarization model is used to select the final compressed sentences. We evaluate our proposed method on the TAC 2008 and 2011 data sets using the standard ROUGE metric (Lin, 2004) and human evaluation of the linguistic quality. Our results show that using our proposed sentence compression model in the summarization system can yield significant performance gain in linguistic quality, without losing much performance on the ROUGE metric.

2 Related Work

Summarization research has seen great development over the last fifty years (Nenkova and McKeown, 2011). Compared to the abstractive counterpart, extractive summarization has received considerable attention due to its clear problem formulation: to extract a set of salient and non-redundant sentences from the given document set. Both unsupervised and supervised approaches have been explored for sentence selection. Supervised approaches include the Bayesian classifier (Kupiec et al., 1995), maximum entropy (Osborne, 2002), skip-chain CRF (Galley, 2006), discriminative reranking (Aker et al., 2010), among others. The extractive summary sentence selection problem can also be formulated in an optimization framework. Previous methods include using integer linear programming (ILP) and submodular functions to solve the optimization problem (Gillick et al., 2009; Li et al., 2013b; Lin and Bilmes, 2010).

Compressive summarization receives increasing attention in recent years, since it offers a viable step towards abstractive summarization. The compressed summaries can be generated through a joint model of the sentence selection and compression processes, or through a pipeline approach that integrates a sentence compression model with a summary sentence pre-selection or post-selection step.

Many studies have explored the joint sentence compression and selection setting. Martins and Smith (2009) jointly performed sentence extraction and compression by solving an ILP problem. Berg-Kirkpatrick et al. (2011) proposed an approach to score the candidate summaries according to a combined linear model of extractive sentence selection and compression. They trained the model using a margin-based objective whose loss captures the final summary quality. Woodsend and Lapata (2012) presented another method where the summary's informativeness, succinctness, and grammaticality are learned separately from data but optimized jointly using an ILP setup. Yoshikawa et al. (2012) incorporated semantic role information in the ILP model.

Our work is closely related with the pipeline approach, where sentence-based extractive summarization is followed or proceeded by sentence compression. There have been many studies on sentence compression, independent of the summarization task. McDonald (2006) firstly introduced a discriminative sentence compression model to directly optimize the quality of the compressed sentences produced. Clarke and Lapata (2008) improved the above discriminative model by using ILP in decoding, making it convenient to add constraints to preserve grammatical structure. Nomoto (2007) treated the compression task as a sequence labeling problem and used CRF for it. Thadani and McKeown (2013) presented an approach for discriminative sentence compression that jointly produces sequential and syntactic representations for output text. Filippova and Altun (2013) presented a method to automatically build a sentence compression corpus with hundreds of thousands of instances on which deletion-based compression algorithms can be trained.

In addition to the work on sentence compression as a stand-alone task, prior studies have also investigated compression for the summarization task. Knight and Marcu (2000) utilized the noisy channel and decision tree method to perform sentence compression in the summarization task. Lin (2003) showed that pure syntactic-based compression may not significantly improve the summarization performance. Zajic et al. (2007) compared two sentence compression approaches for multi-document summarization, including a 'parse-and-trim' and a noisy-channel approach. Galanis and Androutsopoulos (2010) used the maximum entropy model to generate the candidate compressions by removing branches from the source sentences. Woodsend and Lapata (2010) presented a joint content selection and compression model for single-document summarization. They operated over a phrase-based representation of the source document which they obtained by merging information from PCFG parse trees and dependency graphs. Liu and Liu (2013) adopted the CRF-based sentence compression approach for summa-

rizing spoken documents. Unlike the word-based operation, some of these models e.g (Knight and Marcu, 2000; Siddharthan et al., 2004; Turner and Charniak, 2005; Galanis and Androutsopoulos, 2010; Wang et al., 2013), are tree-based approaches that operate on the parse trees and thus the compression decision can be made for a constituent, instead of a single word.

3 Sentence Compression Method

Sentence compression is a task of producing a summary for a single sentence. The compressed sentence should be shorter, contain important content from the original sentence, and be grammatical. In some sense, sentence compression can be described as a 'scaled down version of the text summarization problem' (Knight and Marcu, 2002). Here similar to much previous work on sentence compression, we just focus on how to remove/select words in the original sentence without using operation like rewriting sentence.

3.1 Discriminative Compression Model by ILP

McDonald (2006) presented a discriminative compression model, and Clarke and Lapata (2008) improved it by using ILP for decoding. Since our proposed method is based upon this model, in the following we briefly describe it first. Details can be found in (Clarke and Lapata, 2008). In this model, the following score function is used to evaluate each compression candidate:

$$s(\mathbf{x}, \mathbf{y}) = \sum_{j=2}^{|\mathbf{y}|} s(\mathbf{x}, L(y_{j-1}), L(y_j)) \tag{1}$$

where $\mathbf{x} = x_1 x_2, ..., x_n$ represents an original sentence and $\mathbf{y} = y_1 y_2, ..., y_m$ denotes a compressed sentence. Because the sentence compression problem is defined as a word deletion task, y_j must occur in $\mathbf{x}$. Function $L(y_i) \in [1...n]$ maps word y_i in the compression to the word index in the original sentence $\mathbf{x}$. Note that $L(y_i) < L(y_{i+1})$ is required, that is, each word in x can only occur at most once in compression y. In this model, a first order Markov assumption is used for the score function. Decoding this model is to find the combination of bigrams that maximizes the score function in Eq (1). Clarke and Lapata (2008) introduced the following variables and used ILP to solve it:

$$\delta_i = \begin{cases} 1 & if\ x_i\ is\ in\ the\ compression \\ 0 & otherwise \end{cases} \quad \forall i \in [1..n]$$

$$\alpha_i = \begin{cases} 1 & if\ x_i\ starts\ the\ compression \\ 0 & otherwise \end{cases} \quad \forall i \in [1..n]$$

$$\beta_i = \begin{cases} 1 & if\ x_i\ ends\ the\ compression \\ 0 & otherwise \end{cases} \quad \forall i \in [1..n]$$

$$\gamma_{ij} = \begin{cases} 1 & if\ x_i, x_j\ are\ in\ the\ compression \\ 0 & otherwise \end{cases} \quad \forall i \in [1..n-1] \forall j \in [i+1..n]$$

Using these variables, the objective function can be defined as:

$$\begin{aligned} \max z \quad &= \sum_{i=1}^{n} \alpha_i \cdot s(\mathbf{x}, 0, i) \\ &+ \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \gamma_{ij} \cdot s(\mathbf{x}, i, j) \\ &+ \sum_{i=1}^{n} \beta_i \cdot s(\mathbf{x}, i, n+1) \end{aligned} \tag{2}$$

The following four basic constraints are used to make the compressed result reasonable:

$$\sum_{i=1}^{n} \alpha_i = 1 \tag{3}$$

$$\delta_j - \alpha_j - \sum_{i=1}^{j} \gamma_{ij} = 0 \quad \forall j \in [1..n] \tag{4}$$

$$\delta_i - \sum_{j=i+1}^{n} \gamma_{ij} - \beta_i = 0 \quad \forall i \in [1..n] \tag{5}$$

$$\sum_{i=1}^{n} \beta_i = 1 \tag{6}$$

Formula (3) and (6) denote that exactly one word can begin or end a sentence. Formula (4) means if a word is in the compressed sentence, it must either start the compression or follow another word; formula (5) represents if a word is in the

compressed sentence, it must either end the sentence or be followed by another word.

Furthermore, discriminative models are used for the score function:

$$s(\mathbf{x}, \mathbf{y}) = \sum_{j=2}^{|\mathbf{y}|} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, L(y_{j-1}), L(y_j)) \quad (7)$$

High dimensional features are used and their corresponding weights are trained discriminatively.

Above is the basic supervised ILP formulation for sentence compression. Linguistically and semantically motivated constraints can be added in the ILP model to ensure the correct grammar structure in the compressed sentence. For example, Clarke and Lapata (2008) forced the introducing term of prepositional phrases and subordinate clauses to be included in the compression if any word from within that syntactic constituent is also included, and vice versa.

3.2 Compression Model based on Expanded Constituent Parse Tree

In the above ILP model, variables are defined for each word in the sentence, and the task is to predict each word's status. In this paper, we propose to adopt the above ILP framework, but operate directly on the nodes in the constituent parse tree, rather than just the words (leaf nodes in the tree). This way we can remove or retain a chunk of the sentence rather than isolated words, which we expect can improve the readability and grammar correctness of the compressed sentences.

The top part of Fig1 is a standard constituent parse tree. For some levels of the tree, the nodes at that same level can not represent a sentence. We extend the parse tree by duplicating non-POS constituents so that leaf nodes (words and their corresponding POS tags) are aligned at the bottom level as shown in bottom of as Fig1. In the example tree, the solid lines represent relationship of nodes from the original parse tree, the long dot lines denote the extension of the duplication nodes from the upper level to the lower level, and the nodes at the same level are connected (arrowed lines) to represent that is a sequence. Based on this expanded constituent parse tree, we can consider every level as a 'sentence' and the tokens are POS tags and parse tree labels. We apply the above compression model in Section 3.1 on every level to decide every node's status in the final compressed sentence. In order to make the compressed parsed tree reasonable, we model the relationship of nodes between

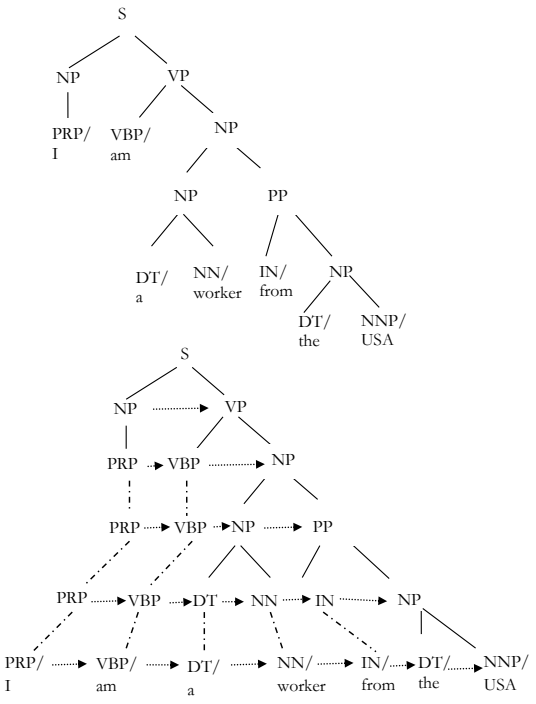

Figure 1: A regular constituent parse tree and its Expanded constituent tree.

adjacent levels as following: if the parent node is labeled as removed, all of its children will be removed; one node will retain if at least one of its children is kept.

Therefore, the objective function in the new ILP formulation is:

$$\begin{aligned} \max z \quad = & \sum_{l=1}^{height} \Big(\sum_{i=1}^{n_l} \alpha_i^l \cdot s(\mathbf{x}, 0, l_i) \\ & + \sum_{i=1}^{n_l - 1} \sum_{j=i+1}^{n_l} \gamma_{ij}^l \cdot s(\mathbf{x}, l_i, l_j) \\ & + \sum_{i=1}^{n_l} \beta_i^l \cdot s(\mathbf{x}, l_i, n_l + 1) \Big) \end{aligned} \quad (8)$$

where height is the depth for a parse tree (starting from level 1 for the tree), and n_l means the length of level l (for example, $n_5 = 6$ in the example in Fig1). Then every level will have a set of parameters $\delta_i^l, \alpha_i^l, \beta_i^l$, and γ_{ij}^l, and the corresponding constraints as shown in Formula (3) to (6). The relationship between nodes from adjacent levels can be expressed as:

$$\delta_i^l \geq \delta_j^{(l+1)} \quad (9)$$

$$\delta_i^l \leq \sum \delta_j^{(l+1)} \quad (10)$$

in which node j at level $(l+1)$ is the child of node

i at level l. In addition, $1 \leq l \leq height - 1$, $1 \leq i \leq n_l$ and $1 \leq j \leq n_{l+1}$.

3.3 Linguistically Motivated Constraints

In our proposed model, we can jointly decide the status of every node in the constituent parse tree at the same time. One advantage is that we can add constraints based on internal nodes or relationship in the parse tree, rather than only using the relationship based on words. In addition to the constraints proposed in (Clarke and Lapata, 2008), we introduce more linguistically motivated constraints to keep the compressed sentence more grammatically correct. The following describes the constraints we used based on the constituent parse tree.

- If a node's label is 'SBAR', its parent's label is 'NP' and its first child's label is 'WHNP' or 'WHPP' or 'IN', then if we can find a noun in the left siblings of 'SBAR', this subordinate clause could be an attributive clause or appositive clause. Therefore the found noun node should be included in the compression if the 'SBAR' is also included, because the node 'SBAR' decorates the noun. For example, the top part of Fig 2 is part of expanded constituent parse tree of sentence 'Those who knew David were all dead.' The nodes in ellipse should share the same status.

- If a node's label is 'SBAR', its parent's label is 'VP' and its first child's label is 'WHNP', then if we can find a verb in the left siblings of 'SBAR', this subordinate clause could be an objective clause. Therefore, the found verb node should be included in the compression if the 'SBAR' node is also included, because the node 'SBAR' is the object of that verb. An example is shown in the bottom part of Fig 2. The nodes in ellipse should share the same status.

- If a node's label is 'SBAR', its parent's label is 'VP' and its first child's label is 'WHADVP', then if the first leaf for this node is a wh-word (e.g., 'where, when, why') or 'how', this clause may be an objective clause (when the word is 'why, how, where') or attributive clause (when the word is 'where') or adverbial clause (when the word is 'when'). Therefore, similar to above, if a verb or noun is found in the left siblings of 'SBAR', the found verb or noun node should be included in the compression if the 'SBAR' node is also included.

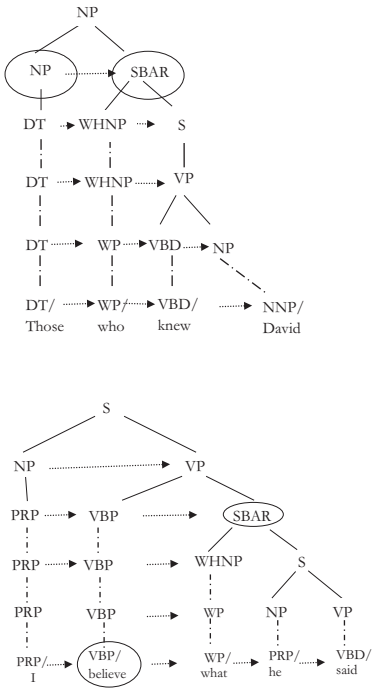

Figure 2: Expanded constituent parse tree for examples.

- If a node's label is 'SBAR' and its parent's label is 'ADJP', then if we can find a 'JJ', 'JJR', or 'JJS' in the left siblings of 'SBAR', the 'SBAR' node should be included in the compression if the found 'JJ', 'JJR' or 'JJS' node is also included because the node 'SBAR' is decorated by the adjective.

- The node with a label of 'PRN' can be removed without other constraints.

We also include some other constraints based on the Stanford dependency parse tree. Table 1 lists the dependency relations we considered.

- For type I relations, the parent and child node with those relationships should have the same value in the compressed result (both are kept or removed).

- For type II relations, if the child node in those relations is retained in the compressed sentence, the parent node should be also retained.

	Dependency Relation	Example
I	prt: phrase verb particle	They shut down the station. prt(shut,down)
	prep: prepositional modifier	He lives in a small village. prep(lives,in)
	pobj: object of a preposition	I sat on the chair. pobj(on,chair)
	nsubj: nominal subject	The boy is cute. nsubj(cute,boy)
	cop: copula	Bill is big. cop(big,is)
II	partmod: participial modifier	Truffles picked during the spring are tasty. partmod(truffles,picked)
	nn: noun compound modifier	Oil price futures. nn(futures,oil)
	acomp: adjectival complement	She looks very beautiful. acomp(looks,beautiful)
III	pcomp: prepositional complement	He felt sad after learning that tragedy. pcomp(after,learning)
	ccomp: clausal complement	I am certain that he did it. ccomp(certain,did)
	tmod: temporal modifier	Last night I swam in the pool. tmod(swam,night)

Table 1: Some dependency relations used for extra constraints. All the examples are from (Marneffe and Manning, 2002)

- For type III relations, if the parent node in these relations is retained, the child node should be kept as well.

3.4 Features

So far we have defined the decoding process and related constraints used in decoding. These all rely on the score function $s(\mathbf{x}, \mathbf{y}) = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, L(y_{j-1}), L(y_j))$ for every level in the constituent parse tree. We included all the features introduced in (Clarke and Lapata, 2008) (those features are designed for leaves). Table 2 lists the additional features we used in our system.

General Features for Every Node
1. individual node label and concatenation of a pair of nodes
2. distance of two nodes at the same level
3. is the node at beginning or end at that level?
4. do the two nodes have the same parent?
5. if two nodes do not have the same parent, then is the left node the rightmost child of its parent? is the right node the leftmost child of its parent?
6. combination of parent label if the node pair are not under the same parent
7. number of node's children: 1/0/>1
8. depth of nodes in the parse tree
Extra Features for Leaf nodes
1. word itself and concatenation of two words
2. POS and concatenation of two words' POS
3. whether the word is a stopword
4. node's named entity tag
5. dependency relationship between two leaves

Table 2: Features used in our system besides those used in (Clarke and Lapata, 2008).

3.5 Learning

To learn the feature weights during training, we perform ILP decoding on every sentence in the training set, to find the best hypothesis for each node in the expanded constituent parse tree. If the hypothesis is incorrect, we update the feature weights using the structured perceptron learning strategy (Collins, 2002). The reference label for every node in the expanded constituent parse tree is obtained automatically from the bottom to the top of the tree. Since every leaf node (word) is human annotated (removed or retain), we annotate the internal nodes as removed if all of its children are removed. Otherwise, the node is annotated as retained.

During perceptron training, a fixed learning rate is used and parameters are averaged to prevent overfitting. In our experiment, we observe stable convergence using the held-out development corpus, with best performance usually obtained around 10-20 epochs.

4 Summarization System

Similar to (Li et al., 2013a), our summarization system is , which consists of three key components: an initial sentence pre-selection module to select some important sentence candidates; the above compression model to generate n-best compressions for each sentence; and then an ILP summarization method to select the best summary sentences from the multiple compressed sentences.

The sentence pre-selection model is a simple supervised support vector regression (SVR) model that predicts a salience score for each sentence and selects the top ranked sentences for further processing (compression and summarization). The target value for each sentence during training is the ROUGE-2 score between the sentence and the human written abstracts. We use three common features: (1) sentence position in the document; (2) sentence length; and (3) interpolated n-gram document frequency as introduced in (Ng et al., 2012).

The final sentence selection process follows the

ILP method introduced in (Gillick et al., 2009). Word bi-grams are used as concepts, and their document frequency is used as weights. Since we use multiple compressions for one sentence, an additional constraint is used: for each sentence, only one of its n-best compressions may be included in the summary.

For the compression module, using the ILP method described above only finds the best compression result for a given sentence. To generate n-best compression candidates, we use an iterative approach – we add one more constraints to prevent it from generating the same answer every time after getting one solution.

5 Experimental Results

5.1 Experimental Setup

Summarization Data For summarization experiments, we use the standard TAC data sets[1], which have been used in the NIST competitions. In particular, we used the TAC 2010 data set as training data for the SVR sentence pre-selection model, TAC 2009 data set as development set for parameter tuning, and the TAC 2008 and 2011 data as the test set for reporting the final summarization results. The training data for the sentence compression module in the summarization system is summary guided compression corpus annotated by (Li et al., 2013a) using TAC2010 data. In the compression module, for each word we also used its document level feature.[2]

Compression Data We also evaluate our compression model using the data set from (Clarke and Lapata, 2008). It includes 82 newswire articles with manually produced compression for each sentence. We use the same partitions as (Martins and Smith, 2009), i.e., 1,188 sentences for training and 441 for testing.

Data Processing We use Stanford CoreNLP toolkit[3] to tokenize the sentences, extract name entity tags, and generate the dependency parse tree. Berkeley Parser (Petrov et al., 2006) is adopted to obtain the constituent parse tree for every sentence and POS tag for every token. We use Pocket CRF[4] to implement the CRF sentence compression model. SVMlight[5] is used for the summary sentence pre-selection model. Gurobi ILP solver[6] does all ILP decoding.

5.2 Summarization Results

We compare our summarization system against four recent studies, which have reported some of the highest published results on this task. Berg-Kirkpatrick et al. (2011) introduced a joint model for sentence extraction and compression. Woodsend and Lapata (2012) learned individual summary aspects from data, e.g., informativeness, succinctness, grammaticalness, stylistic writing conventions, and jointly optimized the outcome in an ILP framework. Ng et al. (2012) exploited category-specific information for multi-document summarization. Almeida and Martins (2013) proposed compressive summarization method by dual decomposition and multi-task learning. Our summarization framework is the same as (Li et al., 2013a), except they used a CRF-based compression model. In addition to the four previous studies, we also report the best achieved results in the TAC competitions.

Table 3 shows the summarization results of our method and others. The top part contains the results for TAC 2008 data and bottom part is for TAC 2011 data. We use the ROUGE evaluation metrics (Lin, 2004), with R-2 measuring the bigram overlap between the system and reference summaries and R-SU4 measuring the skip-bigram with the maximum gap length of 4. In addition, we evaluate the linguistic quality (LQ) of the summaries for our system and (Li et al., 2013a).[7] The linguistic quality consists of two parts. One evaluates the grammar quality within a sentence. For this, annotators marked if a compressed sentence is grammatically correct. Typical grammar errors include lack of verb or subordinate clause. The other evaluates the coherence between sentences, including the order of sentences and irrelevant sentences. We invited 3 English native speakers to do this evaluation. They gave every compressed sentence a grammar score and a coherence score for

[1] http://www.nist.gov/tac/data/index.html

[2] Document level features for a word include information such as the word's document frequency in a topic. These features cannot be extracted from a single sentence, as in the standard sentence compression task, and are related to the document summarization task.

[4] http://sourceforge.net/projects/pocket-crf-1/

[5] http://svmlight.joachims.org/

[6] http://www.gurobi.com

[7] We chose to evaluate the linguistic quality for this system because of two reasons: one is that we have an implementation of that method; the other more important one is that it has the highest reported ROUGE results among the compared methods.

System	R-2	R-SU4	Gram	Cohere
TAC'08 Best System	11.03	13.96	n/a	n/a
(Berg-Kirk et al., 2011)	11.70	14.38	n/a	n/a
(Woodsend et al., 2012)	11.37	14.47	n/a	n/a
(Almeida et al.,2013)	12.30	15.18	n/a	n/a
(Li et al., 2013a)	**12.35**	15.27	3.81	3.41
Our System	12.23	**15.47**	**4.29**	**4.11**
TAC'11 Best System	13.44	16.51	n/a	n/a
(Ng et al., 2012)	13.93	16.83	n/a	n/a
(Li et al., 2013a)	**14.40**	**16.89**	3.67	3.32
Our System	14.04	16.67	**4.18**	**4.07**

Table 3: Summarization results on the TAC 2008 and 2011 data sets.

each topic. The score is scaled and ranges from 1 (bad) to 5 (good). Therefore, in table 3, the grammar score is the average score for each sentence and coherence score is the average for each topic. We measure annotators' agreement in the following way: we consider the scores from each annotator as a distribution and we find that these three distributions are not statistically significantly different each other ($p > 0.05$ based on paired t-test).

We can see from the table that in general, our system achieves better ROUGE results than most previous work except (Li et al., 2013a) on both TAC 2008 and TAC 2011 data. However, our system's linguistic quality is better than (Li et al., 2013a). The CRF-based compression model used in (Li et al., 2013a) can not well model the grammar. Particularly, our results (ROUGE-2) are statistically significantly ($p < 0.05$) higher than TAC08 Best system, but are not statistically significant compared with (Li et al., 2013a) ($p > 0.05$). The pattern is similar in TAC 2011 data. Our result (R-2) is statistically significantly ($p < 0.05$) better than TAC11 Best system, but not statistically ($p > 0.05$) significantly different from (Li et al., 2013a). However, for the grammar and coherence score, our results are statistically significantly ($p < 0.05$) than (Li et al., 2013a). All the above statistics are based on paired t-test.

5.3 Compression Results

The results above show that our summarization system is competitive. In this section we focus on the evaluation of our proposed compression method. We compare our compression system against four other models. HedgeTrimmer in Dorr et al. (2003) applied a variety of linguistically-motivated heuristics to guide the sentences compression; McDonald (2006) used the output of two parsers as features in a discriminative model that decomposes over pairs of consecutive words; Martins and Smith (2009) built the compression model in the dependency parse and utilized the relationship between the head and modifier to preserve the grammar relationship; Wang et al. (2013) developed a novel beam search decoder using the tree-based compression model on the constituent parse tree, which could find the most probable compression efficiently.

System	C Rate (%)	Uni-F1	Rel-F1
HedgeTrimmer	57.64	0.64	0.50
McDonald (2006)	70.95	0.77	0.55
Martins (2009)	71.35	0.77	0.56
Wang (2013)	68.06	0.79	0.59
Our System	71.19	0.77	0.58

Table 4: Sentence compression results. The human compression rate of the test set is 69%.

Table 4 shows the compression results of various systems, along with the compression ratio (C Rate) of the system output. We adopt the compression metrics as used in (Martins and Smith, 2009) that measures the macro F-measure for the retained unigrams (Uni-F1), and the one used in (Clarke and Lapata, 2008) that calculates the F1 score of the grammatical relations labeled by (Briscoe and Carroll, 2002) (Rel-F1). We can see that our proposed compression method performs well, similar to the state-of-the-art systems.

To evaluate the power of using the expanded parse tree in our model, we conducted another experiment where we only consider the bottom level of the constituent parse tree. In some sense, this could be considered as the system in (Clarke and Lapata, 2008). Furthermore, we use two different setups: one uses the lexical features (about the words) and the other does not. Table 5 shows the results using the data in (Clarke and Lapata, 2008). For a comparison, we also include the results using the CRF-based compression model (the one used in (Nomoto, 2007; Li et al., 2013a)). We report results using both the automatically calculated compression metrics and the linguistic quality score. Three English native speaker annotators were asked to judge two aspects of the compressed sentence compared with the gold result: one is the content that looks at whether the important words are kept and the other is the grammar score which evaluates the sentence's readability. Each of these

two scores ranges from 1(bad) to 5(good).

Table 5 shows that when using lexical features, our system has statistically significantly ($p < 0.05$) higher Grammar value and content importance value than the CRF and the leaves only system. When no lexical features are used, default system can achieve statistically significantly ($p < 0.01$) higher results than the CRF and the leaves only system.

We can see that using the expanded parse tree performs better than using the leaves only, especially when lexical features are not used. In addition, we observe that our proposed compression method is more generalizable than the CRF-based model. When our system does not use lexical features in the leaves, it achieves better performance than the CRF-based model. This is important since such a model is more robust and may be used in multiple domains, whereas a model relying on lexical information may suffer more from domain mismatch. From the table we can see our proposed tree based compression method consistently has better linguistic quality. On the other hand, the CRF compression model is the most computationally efficient one among these three compression methods. It is about 200 times faster than our model using the expanded parse tree. Table 6 shows some examples using different methods.

System	C Rate(%)	Uni-F1	Rel-F1	Gram	Imp
Using lexical features					
CRF	79.98	0.80	0.51	3.9	4.0
ILP(I)	80.54	0.79	0.57	4.0	4.2
ILP(II)	79.90	0.80	0.57	4.2	4.4
No lexical features					
CRF	77.75	0.78	0.51	3.35	3.5
ILP(I)	77.77	0.78	0.56	3.7	3.9
ILP(II)	77.78	0.80	0.58	4.1	4.2

Table 5: Sentence compression results: effect of lexical features and expanded parse tree. ILP(I) represents the system using only bottom nodes in constituent parse tree. ILP(II) is our system. Imp means the content importance value.

6 Conclusion

In this paper, we propose a discriminative ILP sentence compression model based on the expanded constituent parse tree, which aims to improve the linguistic quality of the compressed sentences in the summarization task. Linguistically motivated constraints are incorporated to improve the sentence quality. We conduct experiments on the TAC 2008 and 2011 summarization data sets and show that by incorporating this sentence compression model, our summarization system can yield significant performance gain in linguistic quality without losing much ROUGE results. The analysis of the compression module also demonstrates its competitiveness, in particular the better linguistic quality and less reliance on lexical cues.

Using lexical features

Abstract

In this study, we analyzed the effects of applying different levels of stemming approaches such as fixed-length word truncation and morphological analysis for multi-document summarization (MDS) on Turkish, which is an agglutinative and morphologically rich language. We constructed a manually annotated MDS data set, and to our best knowledge, reported the first results on Turkish MDS. Our results show that a simple fixed-length word truncation approach performs slightly better than no stemming, whereas applying complex morphological analysis does not improve Turkish MDS.

1 Introduction

Automatic text summarization has gained more importance with the enormous growth and easy availability of the Internet. It is now possible to reach extensive and continuously growing amount of resources. However, this situation brings its own challenges such as finding the relevant documents, and absorbing a large quantity of relevant information (Gupta and Lehal, 2010). The goal of multi-document summarization (MDS) is to automatically create a summary of a set of documents about the same topic without losing the important information. Several approaches for MDS have been proposed in the last decade. However, most of them have only been applied to a relatively small set of languages, mostly English, and recently also to languages like Chinese, Romanian, Arabic, and Spanish (Giannakopoulos, 2013).

Previous studies have shown that methods proposed for languages like English do not generally work well for morphologically rich languages like Finnish, Turkish, and Czech, and additional methods considering the morphological structures of these languages are needed (Eryiğit et al., 2008). For instance, Turkish is an agglutinative language where root words can take many derivational and inflectional affixes. This feature results in a very high number of different word surface forms, and eventually leads to the data sparseness problem. Hakkani-Tür et al. (2000) analyzed the number of unique terms for Turkish and English and showed that the term count for Turkish is three times more than English for a corpus of 1M words.

There are only a few studies for text summarization on Turkish, all of which are about single-document summarization (Altan, 2004; Çığır et al., 2009; Özsoy et al., 2010; Güran et al., 2010; Güran et al., 2011). Some of these studies applied morphological analysis methods, but none of them analyzed their effects in detail.

To our best knowledge, this paper reports the first multi-document summarization study for Turkish. We used LexRank as the main summarization algorithm (Erkan and Radev, 2004), applied and analyzed different levels of stemming methods such as complex morphological analysis and fixed-length word truncation. We also created the first manually annotated MDS data set for Turkish, which has been made publicly available for future studies.

The rest of the paper is organized as follows. Section 2 presents the related work on MDS, as well as on the applications of morphological analysis on Turkish for different Natural Language Processing (NLP) and Information Retrieval (IR) problems. In Section 3, we provide a very brief introduction to the Turkish morphology and present the stemming methods that we evaluated. The details about the created data set and our experimental setup are presented in Section 4. We present and discuss the results in Section 5, and conclude in Section 6.

2 Related Work

A large number of methods have been proposed for multi-document summarization in the last 10-15 years (e.g. (Erkan and Radev, 2004; Shen and Li, 2010; Christensen et al., 2013)). While most of these approaches have only been applied to English, summarization data sets and systems for other languages like Chinese, Romanian, and Arabic have also been proposed in the recent years (Giannakopoulos, 2013).

Previous studies on automatic summarization for Turkish only tackled the problem of single-document summarization (SDS). Altan (2004) and Çığır et al. (2009) proposed feature-based approaches for Turkish SDS, whereas Özsoy et al. (2010) and Güran et al. (2010) used Latent Semantic Analysis (LSA) based methods. Güran et al. (2011) applied non-negative ma-

trix factorization (NMF) and used consecutive words detection as a preprocessing step.

The effect of morphological analysis for Turkish was analyzed in detail for Information Retrieval (Can et al., 2008) and Text Categorization (Akkuş and Çakıcı, 2013). Can et al. (2008) showed that using fixed-length truncation methods perform similarly to lemmatization-based stemming for information retrieval. Akkuş and Çakıcı (2013) obtained better results for text categorization with fixed-length word truncation rather than complex morphological analysis, but the difference was not significant. For other morphologically rich languages, there is a case study on Greek by Galiotou et al. (2013). They applied different stemming algorithms and showed that stemming on Greek texts improves the summarization performance.

3 Methodology

This section contains detailed information about the application of different levels of morphological features during the summarization process. Before diving into the details, we provide a very brief description of the morphological structure of the Turkish language.

3.1 Turkish Morphology

Turkish is an agglutinative language with a productive morphology. Root words can take one or more derivational and inflectional affixes; therefore, a root can be seen in a large number of different word forms. Another issue is the morphological ambiguity, where a word can have more than one morphological parse.

Table 1 shows an example list of different word forms for the stem "gör" (to see). All the words in the table have the same root, but the different suffixes lead to different surface forms which may have similar or different meanings. When the surface forms of these words are used in a summarization system, they will be regarded as totally different words. However, if a morphological analysis method is applied to the sentences before giving them to the summarization system, words with similar meanings can match during the sentence similarity calculations.

3.2 Stemming Policies

In this section, we explain the different stemming methods that we investigated.

Raw: In this method, we take the surface forms of words, without applying any stemming.

Root: This method takes the most simple unit of a word, namely the root form. For example, in Table 1, the words "gören", "görüşün", and "görüşmelerin" have the same root (gör), so they will match during sentence similarity calculations.

Deriv: Using the Root method may oversimplify words because some words that are derived from the same root may have irrelevant meanings. In the above example, "görüşler" and "gören" have different meanings, but they have the same root (gör). In order to solve this oversimplification issue, we propose to preserve derivational affixes, and only remove the inflectional affixes from the words. In this method, "görüşler" and "gören" will not match because when we remove only the inflectional affixes, they become "görüş" and "gören". On the other hand, the words "görüşler" and "görüşün" will match because their Deriv forms are the same, which is "görüş".

Prefix: In Turkish, affixes almost always occur as suffixes, not prefixes. Additionally, applying morphological analysis methods is a time consuming process, and may become an overhead for online applications. Therefore, a fixed-length simplification method is also tried, since it is both a fast method and can help match similar words by taking the first n characters of words which have lengths larger than n.

As the summarization algorithm, we used LexRank (Erkan and Radev, 2004), which is a salient graph-based method that achieves promising results for MDS. In LexRank, first a sentence connectivity graph is constructed based on the cosine similarities between sentences, and then the PageRank (Page et al., 1999) algorithm is used to find the most important sentences.

4 Experimental Setup

4.1 Data Set

One of the greatest challenges for MDS studies in Turkish is that there does not exist a manually annotated data set. In this study, we have collected and manually

annotated a Turkish MDS data set, which is publicly available for future studies[1].

In order to match the standards for MDS data sets, we tried to follow the specifications of the DUC 2004 data set. Our data set consists of 21 clusters, each consisting of around 10 documents. We selected 21 different topics from different domains (e.g., politics, economics, sports, social, daily, and technology), and selected 10 documents on average for each topic. The documents were obtained from the websites of various news sources. The average number of words per document is 337, and the average number of letters in a word is 6.84.

For manual annotation, we divided the 21 clusters into three groups and sent them to three annotators different from the authors. We required the human summaries not to exceed 120 words for the summary of each cluster.

4.2 Tools

4.2.1 Turkish Morphological Analysis

In order to perform different levels of morphological analysis on documents, we used a two-level morphological analyzer (Oflazer, 1994) and a perceptron-based morphological disambiguator (Sak et al., 2007), which is trained with a corpus of about $750,000$ tokens from news articles. The accuracy of the disambiguator has been reported as 96% (Sak et al., 2007). The Root and Deriv forms of words were generated from the disambiguator output.

4.2.2 MEAD Summarization Toolkit

We used MEAD (Radev et al., 2004), which is an open-source toolkit created for extractive MDS, in our experiments. MEAD handles all the necessary processes to generate a summary document (e.g., sentence ranking, selection, re-ordering, and etc.).

We used the LexRank implementation that comes with MEAD as a feature, together with the Centroid and Position features (each feature is equally weighted). We forced the generated summaries not to exceed 120 words. However, we define the following exception in order to preserve the readability and the grammaticality of the generated summary. For a candidate sentence S having n words, if the absolute difference between the threshold (which is 120) and the summary length including sentence S (say N_w) is less than the absolute difference between the threshold and the summary length excluding sentence S (say N_{wo}), and if N_w is less than 132 (which is $120*1.1$), we allow the summary to exceed the threshold and add sentence S as the last summary sentence.

We used term frequency (tf) based cosine similarity as the similarity measure during the sentence selection step. We also required sentence length to be between 6 and 50 words (which we found empirically) in order to increase the readability of the summaries. The reason behind applying this filtering is that very short sentences generally do not contain much information to become a summary sentence, whereas very long sentences decrease the readability and fill a significant percentage of the summary limit.

4.2.3 ROUGE

For evaluation, we used ROUGE, which is a standard metric for automated evaluation of summaries based on n-gram co-occurrence. We used ROUGE-1 (based on uni-grams), ROUGE-2 (based on bi-grams), and ROUGE-W (based on longest common sub-sequence weighted by length) in our experiments. Among these, ROUGE-1 has been shown to agree with human judges the most (Lin and Hovy, 2003), so we give importance to it while interpreting the results.

5 Evaluation and Results

We ran MEAD with the proposed stemming policies using different levels of cosine similarity threshold values to analyze the effect of the similarity threshold on the summarization performance. After the sentences are ranked using the LexRank method, the similarity threshold is used to decide whether to include a sentence to the summary. A sentence is not included to the summary, if its similarity to a previously picked sentence is larger than the similarity threshold.

In our preliminary experiments, we used the default similarity threshold 0.7, which was found empirically by the MEAD developers for English. However, it produced poor results on the Turkish data set.

Policy	ROUGE-1	ROUGE-2	ROUGE-W
Prefix10	**0.438**	0.194	**0.197**
Prefix12	0.433	**0.197**	0.195
Prefix9	0.432	0.194	0.194
Prefix4	0.432	0.178	0.190
Prefix7	0.431	0.189	0.190
Prefix5	0.431	0.183	0.190
Prefix6	0.430	0.185	0.189
Raw	0.428	0.189	0.191
Deriv	0.428	0.178	0.188
Prefix8	0.427	0.187	0.188
Prefix11	0.427	0.190	0.193
Root	0.420	0.186	0.185

Table 2: Best scores for different policies

Figure 1 shows the F-1 scores for the ROUGE-1 metric for policies with different thresholds. After the threshold exceeds 0.5, the performances for all policies start to decrease, so we don't report the values here to make the chart more readable. In general, Raw and Prefix10 (taking the first 10 letters of the words) achieve better performances with lower threshold values, whereas Root and Deriv operate better with relatively higher threshold values. As we stated earlier, in Turkish, words with similar meanings can occur in

[1]The data set can be retrieved from the following github repository: https://github.com/manuyavuz/TurkishMDSDataSet_alpha

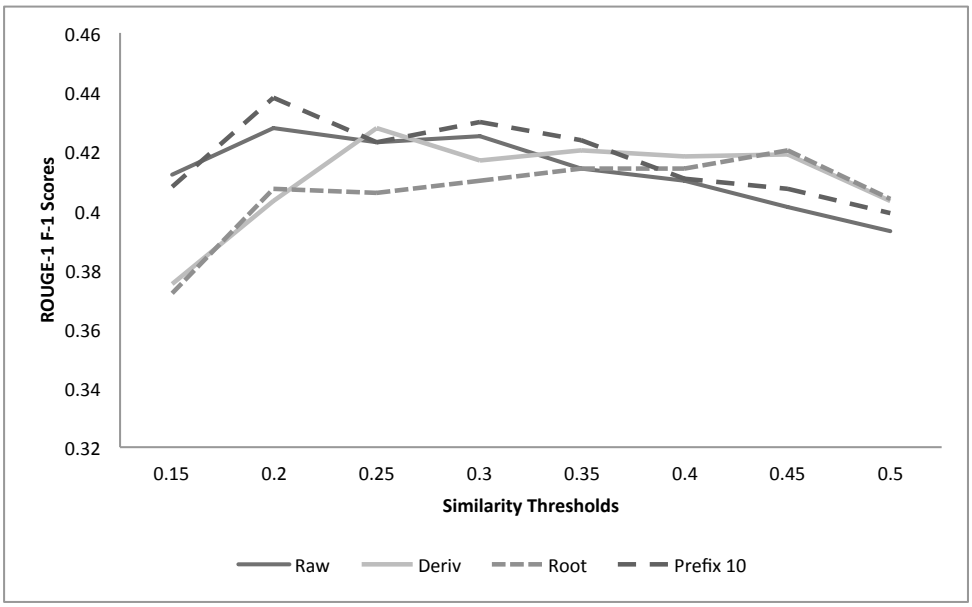

Figure 1: F-1 scores for different similarity threshold values

text with different surface forms due to their inflections. Such words can not be matched during similarity computation if morphological analysis is not performed. Therefore, using higher similarity threshold values cause very similar sentences to occur together in the summaries, and eventually, result in poor scores.

Table 2 shows the best scores obtained by each policy. The Prefix policy generally outperforms the Raw policy. The Prefix10 policy achieves the best ROUGE-1 score. On the other hand, the policies that apply complex morphological analysis (i.e. Root and Deriv) are not able to outperform the simple Prefix and Raw policies. The Deriv policy performs similarly to the Raw and Prefix policies, whereas the Root policy obtains the lowest ROUGE-1 score.

5.1 Discussion

The results show that using a simple fixed-length prefix policy outperforms all other methods, and applying complex morphological analysis does not improve Turkish MDS. The poor performance of the Root policy is somewhat expected due to the fact that, if we preserve only the roots of the words, we lose the semantic differences among the surface forms provided by the derivational affixes. On the other hand, the reason behind the observation that Deriv and Raw obtain similar performances is not obvious.

In order to further analyze this observation, we used an entropy based measure, which is calculated as shown below, to quantify the homogeneity of the clusters in the data set in terms of the variety of the surface forms corresponding to the Deriv forms of each word in the cluster. We first compute the entropy for each Deriv form in a cluster. The entropy of a Deriv form is lower, if it occurs with fewer different surface forms in the cluster. The entropy of a cluster is computed by summing the entropies of the Deriv forms in the cluster and dividing the sum by the number of words in the cluster (i.e. N).

$$D_{Deriv_i} = \{t \mid t\ inflected\ from\ Deriv\ i\}$$

$$H(Deriv_i) = \sum_{t \in D_{Deriv_i}} p(t) \log p(t)$$

$$H(C) = \sum_i \frac{H(Deriv_i)}{N}$$

To compare with the data set clusters, we generated random document clusters by randomly selecting 10 different clusters and then randomly selecting one document from each selected cluster. The average entropy value for the data set clusters and the random clusters were 4.99 and 7.58, respectively. Due to this significant difference, we can hypothesize that the documents about the same topic show a more homogeneous structure. In other words, a Deriv form is usually seen in the same surface form in a cluster of documents which are about the same topic. Therefore, the Deriv policy and the Raw policy achieve similar results for summarizing documents about the same topic.

During evaluation, we ran ROUGE with the Deriv versions of the human summaries and the system summaries in order to match semantically similar words having different surface forms. We also experimented with ROUGE using the Raw versions, but the results followed very similar patterns, so those results were not reported.

6 Conclusion

In this paper, we reported the first steps for a multi-document summarization system for Turkish. A manually annotated data set has been constructed from news

articles, and made publicly available for future studies. We utilized the LexRank summarization algorithm, and analyzed the effects of different stemming policies for Turkish MDS. Our results show that simple fixed-length truncation methods with high limits (such as taking the first 10 letters) improves summarization scores. In contrast to our expectation, using morphological analysis does not enhance Turkish MDS, possibly due to the homogeneousness of the documents in a cluster to be summarized. As future work, we plan to extend the data set with more clusters and more reference summaries, as well as to develop sentence compression methods for Turkish MDS.

Acknowledgments

We would like to thank Ferhat Aydın for his contributions during the data set corpus collection and annotation process. We would also like to thank Burak Sivrikaya and Serkan Bugur for their help in generating the human summaries for the data set.

Abstract

The ability to learn from user interactions can give systems access to unprecedented amounts of knowledge. This is evident in search engines, recommender systems, and electronic commerce, and it can be the key to solving other knowledge intensive tasks. However, extracting the knowledge conveyed by user interactions is less straightforward than standard machine learning, since it requires learning systems that explicitly account for human decision making, human motivation, and human abilities.

In this talk, I argue that the design space of such interactive learning systems encompasses not only the machine learning algorithm itself, but also the design of the interaction under an appropriate model of user behavior. To this effect, the talk explores how integrating microeconomic models of human behavior into the learning process leads to new interaction models and their associated learning algorithms, leading to systems that have provable guarantees and that perform robustly in practice.

About the Speaker

Thorsten Joachims is a Professor in the Department of Computer Science and the Department of Information Science at Cornell University. His research interests center on a synthesis of theory and system building in machine learning, with applications in information access, language technology, and recommendation. His past research focused on support vector machines, text classification, structured output prediction, convex optimization, learning to rank, learning with preferences, and learning from implicit feedback. In 2001, he finished his dissertation advised by Prof. Katharina Morik at the University of Dortmund. From there he also received his Diploma in Computer Science in 1997. Between 2000 and 2001 he worked as a PostDoc at the GMD Institute for Autonomous Intelligent Systems. From 1994 to 1996 he was a visiting scholar with Prof. Tom Mitchell at Carnegie Mellon University.

Abstract

We provide a comparative study between neural word representations and traditional vector spaces based on co-occurrence counts, in a number of compositional tasks. We use three different semantic spaces and implement seven tensor-based compositional models, which we then test (together with simpler additive and multiplicative approaches) in tasks involving verb disambiguation and sentence similarity. To check their scalability, we additionally evaluate the spaces using simple compositional methods on larger-scale tasks with less constrained language: paraphrase detection and dialogue act tagging. In the more constrained tasks, co-occurrence vectors are competitive, although choice of compositional method is important; on the larger-scale tasks, they are outperformed by neural word embeddings, which show robust, stable performance across the tasks.

1 Introduction

Neural word embeddings (Bengio et al., 2006; Collobert and Weston, 2008; Mikolov et al., 2013a) have received much attention in the distributional semantics community, and have shown state-of-the-art performance in many natural language processing tasks. While they have been compared with co-occurrence based models in simple similarity tasks at the word level (Levy et al., 2014; Baroni et al., 2014), we are aware of only one work that attempts a comparison of the two approaches in compositional settings (Blacoe and Lapata, 2012), and this is limited to additive and multiplicative composition, compared against composition via a neural autoencoder.

The purpose of this paper is to provide a more complete picture regarding the potential of neural word embeddings in compositional tasks, and meaningfully compare them with the traditional distributional approach based on co-occurrence counts. We are especially interested in investigating the performance of neural word vectors in compositional models involving general mathematical composition operators, rather than in the more task- or domain-specific deep-learning compositional settings they have generally been used with so far (for example, by Socher et al. (2012), Kalchbrenner and Blunsom (2013) and many others).

In particular, this is the first large-scale study to date that applies neural word representations in tensor-based compositional distributional models of meaning similar to those formalized by Coecke et al. (2010). We test a range of implementations based on this framework, together with additive and multiplicative approaches (Mitchell and Lapata, 2008), in a variety of different tasks. Specifically, we use the verb disambiguation task of Grefenstette and Sadrzadeh (2011a) and the transitive sentence similarity task of Kartsaklis and Sadrzadeh (2014) as small-scale focused experiments on pre-defined sentence structures. Additionally, we evaluate our vector spaces on paraphrase detection (using the Microsoft Research Paraphrase Corpus of Dolan et al. (2005)) and dialogue act tagging using the Switchboard Corpus (see e.g. (Stolcke et al., 2000)).

In all of the above tasks, we compare the neural word embeddings of Mikolov et al. (2013a) with two vector spaces both based on co-occurrence counts and produced by standard distributional techniques, as described in detail below. The general picture we get from the results is that in almost all cases the neural vectors are more effective than the traditional approaches.

We proceed as follows: Section 2 provides a concise introduction to distributional word representations in natural language processing. Section

3 takes a closer look to the subject of compositionality in vector space models of meaning and describes the range of compositional operators examined here. In Section 4 we provide details about the vector spaces used in the experiments. Our experimental work is described in detail in Section 5, and the results are discussed in Section 6. Finally, Section 7 provides conclusions.

2 Meaning representation

There are several approaches to the representation of word, phrase and sentence meaning. As natural languages are highly creative and it is very rare to see the same sentence twice, any practical approach dealing with large text segments must be *compositional*, constructing the meaning of phrases and sentences from their constituent parts. The ideal method would therefore express not only the similarity in meaning between those constituent parts, but also between the results of their composition, and do this in ways which fit with linguistic structure and generalisations thereof.

Formal semantics Formal approaches to the semantics of natural language have long built upon the classical idea of compositionality – that the meaning of a sentence is a function of the meanings of its parts (Frege, 1892). In compositional type-logical approaches, predicate-argument structures representing phrases and sentences are built from their constituent parts by β-reduction within the lambda calculus framework (Montague, 1970): for example, given a representation of *John* as $john'$ and *sleeps* as $\lambda x.sleep'(x)$, the meaning of the sentence "John sleeps" can be constructed as $\lambda x.sleep'(x)(john') = sleep'(john')$. Given a suitable pairing between words and semantic representations of them, this method can produce structured sentential representations with broad coverage and good generalisability (see e.g. (Bos, 2008)). The above logical approach is extremely powerful because it can capture complex aspects of meaning such as quantifiers and their interaction (see e.g. (Copestake et al., 2005)), and enables inference using well studied and developed logical methods (see e.g. (Bos and Gabsdil, 2000)).

Distributional hypothesis However, such formal approaches are less able to express *similarity* in meaning. We would like to capture the intuition that while *John* and *Mary* are distinct, they are rather similar to each other (both of them are humans) and dissimilar to words such as *dog*, *pavement* or *idea*. The same applies at the phrase and sentence level: "dogs chase cats" is similar in meaning to "hounds pursue kittens", but less so to "cats chase dogs" (despite the lexical overlap).

Distributional methods provide a way to address this problem. By representing words and phrases as vectors or tensors in a (usually highly dimensional) vector space, one can express similarity in meaning via a suitable distance metric within that space (usually cosine distance); furthermore, composition can be modelled via suitable linear-algebraic operations.

Co-occurrence-based word representations One way to produce such vectorial representations is to directly exploit Harris (1954)'s intuition that semantically similar words tend to appear in similar contexts. We can construct a vector space in which the dimensions correspond to contexts, usually taken to be words as well. The word vector components can then be calculated from the frequency with which a word has co-occurred with the corresponding contexts in a window of words, with a predefined length.

Table 1 shows 5 3-dimensional vectors for the words *Mary*, *John*, *girl*, *boy* and *idea*. The words *philosophy*, *book* and *school* signify vector space dimensions. As the vector for *John* is closer to *Mary* than it is to *idea* in the vector space—a direct consequence of the fact that *John*'s contexts are similar to *Mary*'s and dissimilar to *idea*'s—we can infer that *John* is semantically more similar to *Mary* than to *idea*.

Many variants of this approach exist: performance on word similarity tasks has been shown to be improved by replacing raw counts with weighted values (e.g. mutual information)—see (Turney et al., 2010) and below for discussion, and (Kiela and Clark, 2014) for a detailed comparison.

	philosophy	book	school
Mary	0	10	22
John	4	60	59
girl	0	19	93
boy	0	12	164
idea	10	47	39

Table 1: Word co-occurrence frequencies extracted from the BNC (Leech et al., 1994).

Neural word embeddings Deep learning techniques exploit the distributional hypothesis differently. Instead of relying on observed co-occurrence frequencies, a neural language model is trained to maximise some objective function related to e.g. the probability of observing the surrounding words in some context (Mikolov et al., 2013b):

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t) \qquad (1)$$

Optimizing the above function, for example, produces vectors which maximise the conditional probability of observing words in a context around the target word w_t, where c is the size of the training window, and $w_1 w_2, \cdots w_T$ a sequence of words forming a training instance. Therefore, the resulting vectors will capture the distributional intuition and can express degrees of lexical similarity.

This method has an obvious advantage compared to co-occurrence method: since now the context is *predicted*, the model in principle can be much more robust in data sparsity problems, which is always an important issue for co-occurrence word spaces. Additionally, neural vectors have also proven successful in other tasks (Mikolov et al., 2013c), since they seem to encode not only attributional similarity (the degree to which similar words are close to each other), but also relational similarity (Turney, 2006). For example, it is possible to extract the singular:plural relation (*apple*:*apples*, *car*:*cars*) using vector subtraction:

$$\overrightarrow{apple} - \overrightarrow{apples} \approx \overrightarrow{car} - \overrightarrow{cars}$$

Perhaps even more importantly, semantic relationships are preserved in a very intuitive way:

$$\overrightarrow{king} - \overrightarrow{man} \approx \overrightarrow{queen} - \overrightarrow{woman}$$

allowing the formation of analogy queries similar to $\overrightarrow{king} - \overrightarrow{man} + \overrightarrow{woman} = ?$, obtaining $\overrightarrow{queen}$ as the result.[1]

Both neural and co-occurrence-based approaches have advantages over classical formal approaches in their ability to capture lexical semantics and degrees of similarity; their success at extending this to the sentence level and to more complex semantic phenomena, though, depends on their applicability within compositional models, which is the subject of the next section.

3 Compositional models

Compositional distributional models represent meaning of a sequence of words by a vector, obtained by combining meaning vectors of the words within the sequence using some vector composition operation. In a general classification of these models, one can distinguish between three broad cases: simplistic models which combine word vectors irrespective of their order or relation to one another, models which exploit linear word order, and models which use grammatical structure.

The first approach combines word vectors by vector addition or point-wise multiplication (Mitchell and Lapata, 2008)—as this is independent of word order, it cannot capture the difference between the two sentences "dogs chase cats" and "cats chase dogs". The second approach has generally been implemented using some form of deep learning, and captures word order, but not by necessarily caring about the grammatical structure of the sentence. Here, one works by recursively building and combining vectors for subsequences of words within the sentence using e.g. autoencoders (Socher et al., 2012) or convolutional filters (Kalchbrenner et al., 2014). We do not consider this approach in this paper. This is because, as mentioned in the introduction, their vectors and composition operators are task-specific. These are trained directly to achieve specific objectives in certain pre-determined tasks. We are interested in vector and composition operators that work for *any* compositional task, and which can be combined with results in linguistics and formal semantics to provide generalisable models that can canonically extend to complex semantic phenomena. The third (i.e. the grammatical) approach promises a way to achieve this, and has been instantiated in various ways in the work of Baroni and Zamparelli (2010),Grefenstette and Sadrzadeh (2011a), and Kartsaklis et al. (2012).

General framework Formally, we can specify the vector representation of a word sequence $w_1 w_2 \cdots w_n$ as the vector $\overrightarrow{s} = \overrightarrow{w_1} \star \overrightarrow{w_2} \star \cdots \star \overrightarrow{w_n}$, where $\star$ is a vector operator, such as addition $+$, point-wise multiplication $\odot$, tensor product $\otimes$, or matrix multiplication $\times$.

[1] Levy et al. (2014) improved Mikolov et al. (2013c)'s method of retrieving relational similarities by changing the underlying objective function.

In the simplest compositional models (the first approach described above), $\star$ is $+$ or $\odot$, e.g. see (Mitchell and Lapata, 2008). Grammar-based compositional models (the third approach) are based on a generalisation of the notion of vectors, known as *tensors*. Whereas a vector $\overrightarrow{v}$ is an element of an atomic vector space V, a tensor $\overline{z}$ is an element of a tensor space $V \otimes W \otimes \cdots \otimes Z$. The number of tensored spaces is referred to by the *order* of the space. Using a general duality theorem from multi-linear algebra (Bourbaki, 1989), it follows that tensors are in one-one correspondence with multi-linear maps, that is we have:

$$\overline{z} \in V \otimes W \otimes \cdots \otimes Z \;\cong\; f_{\overline{z}} \colon V \to W \to \cdots \to Z$$

In such a tensor-based formalism, meanings of nouns are vectors and meanings of predicates such as adjectives and verbs are tensors. Meaning of a string of words is obtained by applying the compositions of multi-linear map duals of the tensors to the vectors. For the sake of demonstration, take the case of an intransitive sentence "Sbj Verb"; the meaning of the subject is a vector $\overrightarrow{\text{Sbj}} \in V$ and the meaning of the intransitive verb is a tensor $\overline{\text{Verb}} \in V \otimes W$. Meaning of the sentence is obtained by applying $f_{\overline{Verb}}$ to $\overrightarrow{\text{Sbj}}$, as follows:

$$\overrightarrow{\text{Sbj Verb}} = f_{\overline{Verb}}(\overrightarrow{\text{Sbj}})$$

By tensor-map duality, the above becomes equivalent to the following, where composition has now become the familiar notion of matrix multiplication, that is $\star$ is $\times$:

$$\overline{\text{Verb}} \times \overrightarrow{\text{Sbj}}$$

In general and for words with tensors of order higher than two, $\star$ becomes a generalisation of $\times$, referred to by *tensor contraction*, see e.g. Kartsaklis and Sadrzadeh (2013). Since the creation and manipulation of tensors of order higher than 2 is difficult, one can work with simplified versions of tensors, faithful to their underlying mathematical basis; these have found intuitive interpretations, e.g. see Grefenstette and Sadrzadeh (2011a), Kartsaklis and Sadrzadeh (2014). In such cases, $\star$ becomes a combination of a range of operations such as $\times$, $\otimes$, $\odot$, and $+$.

Specific models In the current paper we will experiment with a variety of models. In Table 2, we present these models in terms of their composition operators and a reference to the main paper in which each model was introduced. For the simple compositional models the sentence is a string of any number of words; for the grammar-based models, we consider simple transitive sentences "Sbj Verb Obj" and introduce the following abbreviations for the concrete method used to build a tensor for the verb:

1. $\overline{\text{Verb}}$ is a verb matrix computed using the formula $\sum_i \overrightarrow{\text{Sbj}_i} \otimes \overrightarrow{\text{Obj}_i}$, where $\overrightarrow{\text{Sbj}_i}$ and $\overrightarrow{\text{Obj}_i}$ are the subjects and objects of the verb across the corpus. These models are referred to by *relational* (Grefenstette and Sadrzadeh, 2011a); they are generalisations of predicate semantics of transitive verbs, from pairs of individuals to pairs of vectors. The models reduce the order 3 tensor of a transitive verb to an order 2 tensor (i.e. a matrix).

2. $\widetilde{\text{Verb}}$ is a verb matrix computed using the formula $\overrightarrow{\text{Verb}} \otimes \overrightarrow{\text{Verb}}$, where $\overrightarrow{\text{Verb}}$ is the distributional vector of the verb. These models are referred to by *Kronecker*, which is the term sometimes used to denote the outer product of tensors (Grefenstette and Sadrzadeh, 2011b). This models also reduces the order 3 tensor of a transitive verb to an order 2 tensor.

3. The models of the last five lines of the table use the so-called *Frobenius* operators from categorical compositional distributional semantics (Kartsaklis et al., 2012) to expand the relational matrices of verbs from order 2 to order 3. The expansion is obtained by either copying the dimension of the subject into the space provided by the third tensor, hence referred to by *Copy-Sbj*, or copying the dimension of the object in that space, hence referred to by *Copy-Obj*; furthermore, we can take addition, multiplication, or outer product of these, which are referred to by *Frobenius-Add*, *Frobenius-Mult*, and *Frobenius-Outer* (Kartsaklis and Sadrzadeh, 2014).

4 Semantic word spaces

Co-occurrence-based vector space instantiations have received a lot of attention from the scientific community (refer to (Kiela and Clark, 2014; Polajnar and Clark, 2014) for recent studies). We instantiate two co-occurrence-based vectors spaces with different underlying corpora and weighting schemes.

Method	Sentence	Linear algebraic formula	Reference
Addition	$w_1 w_2 \cdots w_n$	$\overrightarrow{w_1} + \overrightarrow{w_2} + \cdots + \overrightarrow{w_n}$	Mitchell and Lapata (2008)
Multiplication	$w_1 w_2 \cdots w_n$	$\overrightarrow{w_1} \odot \overrightarrow{w_2} \odot \cdots \odot \overrightarrow{w_n}$	Mitchell and Lapata (2008)
Relational	Sbj Verb Obj	$\overline{\text{Verb}} \odot (\overrightarrow{\text{Sbj}} \otimes \overrightarrow{\text{Obj}})$	Grefenstette and Sadrzadeh (2011a)
Kronecker	Sbj Verb Obj	$\widetilde{\text{Verb}} \odot (\overrightarrow{\text{Sbj}} \otimes \overrightarrow{\text{Obj}})$	Grefenstette and Sadrzadeh (2011b)
Copy object	Sbj Verb Obj	$\overrightarrow{\text{Sbj}} \odot (\overline{\text{Verb}} \times \overrightarrow{\text{Obj}})$	Kartsaklis et al. (2012)
Copy subject	Sbj Verb Obj	$\overrightarrow{\text{Obj}} \odot (\overline{\text{Verb}}^{\mathsf{T}} \times \overrightarrow{\text{Sbj}})$	Kartsaklis et al. (2012)
Frob. add.	Sbj Verb Obj	$(\overrightarrow{\text{Sbj}} \odot (\overline{\text{Verb}} \times \overrightarrow{\text{Obj}})) + (\overrightarrow{\text{Obj}} \odot (\overline{\text{Verb}}^{\mathsf{T}} \times \overrightarrow{\text{Sbj}}))$	Kartsaklis and Sadrzadeh (2014)
Frob. mult.	Sbj Verb Obj	$(\overrightarrow{\text{Sbj}} \odot (\overline{\text{Verb}} \times \overrightarrow{\text{Obj}})) \odot (\overrightarrow{\text{Obj}} \odot (\overline{\text{Verb}}^{\mathsf{T}} \times \overrightarrow{\text{Sbj}}))$	Kartsaklis and Sadrzadeh (2014)
Frob. outer	Sbj Verb Obj	$(\overrightarrow{\text{Sbj}} \odot (\overline{\text{Verb}} \times \overrightarrow{\text{Obj}})) \otimes (\overrightarrow{\text{Obj}} \odot (\overline{\text{Verb}}^{\mathsf{T}} \times \overrightarrow{\text{Sbj}}))$	Kartsaklis and Sadrzadeh (2014)

Table 2: Compositional methods.

GS11 Our first word space is based on a typical configuration that has been used in the past extensively for compositional distributional models (see below for details), so it will serve as a useful baseline for the current work. In this vector space, the co-occurrence counts are extracted from the British National Corpus (BNC) (Leech et al., 1994). As basis words, we use the most frequent nouns, verbs, adjectives and adverbs (POS tags `SUBST`, `VERB`, `ADJ` and `ADV` in the BNC XML distribution[2]). The vector space is lemmatized, that is, it contains only "canonical" forms of words.

In order to weight the raw co-occurrence counts, we use positive point-wise mutual information (PPMI). The component value for a target word t and a context word c is given by:

$$\text{PPMI}(t, c) = \max\left(0, \log \frac{p(c|t)}{p(c)}\right)$$

where $p(c|t)$ is the probability of word c given t in a symmetric window of length 5 and $p(c)$ is the probability of c overall.

Vector spaces based on point-wise mutual information (or variants thereof) have been successfully applied in various distributional and compositional tasks; see e.g. Grefenstette and Sadrzadeh (2011a), Mitchell and Lapata (2008), Levy et al. (2014) for details. PPMI has been shown to achieve state-of-the-art results (Levy et al., 2014) and is suggested by the review of Kiela and Clark (2014). Our use here of the BNC as a corpus and the window length of 5 is based on previous use and better performance of these parameters in a number of compositional experiments (Grefenstette and Sadrzadeh, 2011a; Grefenstette and Sadrzadeh, 2011b; Mitchell and Lapata, 2008; Kartsaklis et al., 2012).

KS14 In this variation, we train a vector space from the ukWaC corpus[3] (Ferraresi et al., 2008), originally using as a basis the 2,000 content words with the highest frequency (but excluding a list of stop words as well as the 50 most frequent content words since they exhibit low information content). The vector space is again lemmatized. As context we consider a 5-word window from either side of the target word, while as our weighting scheme we use local mutual information (i.e. point-wise mutual information multiplied by raw counts). In a further step, the vector space was normalized and projected onto a 300-dimensional space using singular value decomposition (SVD).

In general, dimensionality reduction produces more compact word representations that are robust against potential noise in the corpus (Landauer and Dumais, 1997; Schütze, 1997). SVD has been shown to perform well on a variety of tasks similar to ours (Baroni and Zamparelli, 2010; Kartsaklis and Sadrzadeh, 2014).

Neural word embeddings (NWE) For our neural setting, we used the skip-gram model of Mikolov et al. (2013b) trained with negative sampling. The specific implementation that was tested in our experiments was a 300-dimensional vector space learned from the Google News corpus and provided by the `word2vec`[4] toolkit. Furthermore, the `gensim` library (Řehůřek and Sojka, 2010) was used for accessing the vectors. On the contrary with the previously described co-

[2] `http://www.natcorp.ox.ac.uk/`

[3] `http://wacky.sslmit.unibo.it/`

[4] `https://code.google.com/p/word2vec/`

occurrence vector spaces, this version is *not* lemmatized.

The negative sampling method improves the objective function of Equation 1 by introducing negative examples to the training algorithm. Assume that the probability of a specific (c, t) pair of words (where t is a target word and c another word in the same context with t), coming from the training data, is denoted as $p(D = 1|c, t)$. The objective function is then expressed as follows:

$$\prod_{(c,t)\in D} p(D = 1|c, t) \quad (2)$$

That is, the goal is to set the model parameters in a way that maximizes the probability of all observations coming from the training data. Assume now that D' is a set of randomly selected incorrect (c', t') pairs that do not occur in D, then Equation 2 above can be recasted in the following way:

$$\prod_{(c,t)\in D} p(D = 1|c, t) \prod_{(c',t')\in D'} p(D = 0|c', t') \quad (3)$$

In other words, the model tries to distinguish a target word t from random draws that come from a noise distribution. In the implementation we used for our experiments, c is always selected from a 5-word window around t. More details about the negative sampling approach can be found in (Mikolov et al., 2013b); the note of Goldberg and Levy (2014) also provides an intuitive explanation of the underlying setting.

5 Experiments

Our experiments explore the use of the vector spaces above, together with the compositional operators described in Section 3, in a range of tasks all of which require semantic composition: verb sense disambiguation; sentence similarity; paraphrasing; and dialogue act tagging.

5.1 Disambiguation

We use the transitive verb disambiguation dataset described in Grefenstette and Sadrzadeh (2011a)[5]. This dataset consists of ambiguous transitive verbs together with their arguments, landmark verbs that identify one of the verb senses, and human judgements that specify how similar is the disambiguated sense of the verb in the given context to one of the landmarks. This is similar to the intransitive dataset described in (Mitchell and Lapata, 2008). Consider the sentence "system meets specification"; here, *meets* is the ambiguous transitive verb, and *system* and *specification* are its arguments in this context. Possible landmarks for *meet* are *satisfy* and *visit*; for this sentence, the human judgements show that the disambiguated meaning of the verb is more similar to the landmark *satisfy* and less similar to *visit*.

The task is to estimate the similarity of the sense of a verb in a context with a given landmark. To get our similarity measures, we compose the verb with its arguments using one of our compositional models; we do the same for the landmark and then compute the cosine similarity of the two vectors. We evaluate the performance by averaging the human judgements for the same verb, argument and landmark entries, and calculating the Spearman's correlation between the average values and the cosine scores. As a baseline, we compare this with the correlation produced by using only the verb vector, without composing it with its arguments.

Table 3 shows the results of the experiment. NWE *copy-object* composition yields the best correlation with the human judgements, and top performance across all vector spaces and models with a Spearman ρ of 0.456. For the KS14 space, the best result comes from *Frobenius outer* (0.350),

Method	GS11	KS14	NWE
Verb only	0.212	0.325	0.107
Addition	0.103	0.275	0.149
Multiplication	0.348	0.041	0.095
Kronecker	0.304	0.176	0.117
Relational	0.285	0.341	0.362
Copy subject	0.089	0.317	0.131
Copy object	0.334	0.331	**0.456**
Frobenius add.	0.261	0.344	0.359
Frobenius mult.	0.233	0.341	0.239
Frobenius outer	0.284	0.350	0.375

Table 3: Spearman ρ correlations of models with human judgements for the word sense disambiguation task. The best result (NWE Copy object) outperforms the nearest co-occurrence-based competitor (KS14 Frobenius outer) with a statistically significant difference ($p < 0.05$, t-test).

[5]This and the sentence similarity dataset are available at `http://www.cs.ox.ac.uk/activities/compdistmeaning/`

while the best operator for the GS11 space is *point-wise multiplication* (0.348).

For simple point-wise composition, only multiplicative GS11 and additive NWE improve over their corresponding verb-only baselines (but both perform worse than the KS14 baseline). With tensor-based composition in co-occurrence based spaces, *copy subject* yields lower results than the corresponding baselines. Other composition methods, except *Kronecker* for KS14, improve over the verb-only baselines. Finally we should note that, despite the small training corpus, the GS11 vector space performs comparatively well: for instance, *Kronecker* model improves the previously reported score of 0.28 (Grefenstette and Sadrzadeh, 2011b).

5.2 Sentence similarity

In this experiment we use the transitive sentence similarity dataset described in Kartsaklis and Sadrzadeh (2014). The dataset consists of transitive sentence pairs and a human similarity judgement[6]. The task is to estimate a similarity measure between two sentences. As in the disambiguation task, we first compose word vectors to obtain sentence vectors, then compute cosine similarity of them. We average the human judgements for identical sentence pairs to compute a correlation with cosine scores.

Table 4 shows the results. Again, the best performing vector space is KS14, but this time with *addition*: the Spearman ρ correlation score with averaged human judgements is 0.732. Addition was the means for the other vector spaces to achieve top performance as well: GS11 and NWE got 0.682 and 0.689 respectively.

None of the models in tensor-based composition outperformed addition. KS14 performs worse with tensor-based methods here than in the other vector spaces. However, GS11 and NWE, except *copy subject* for both of them and *Frobenius multiplication* for NWE, improved over their verb-only baselines.

5.3 Paraphrasing

In this experiment we evaluate our vector spaces on a mainstream paraphrase detection task.

[6]The textual content of this dataset is the same as that of (Kartsaklis and Sadrzadeh, 2013), the difference is that the dataset of (Kartsaklis and Sadrzadeh, 2014) has updated human judgements whereas the previous dataset used the original annotations of the intransitive dataset of (Mitchell and Lapata, 2010).

Method	**GS11**	**KS14**	**NWE**
Verb only	0.491	0.602	0.561
Addition	0.682	**0.732**	0.689
Multiplication	0.597	0.321	0.341
Kronecker	0.581	0.408	0.561
Relational	0.558	0.437	0.618
Copy subject	0.370	0.448	0.405
Copy object	0.571	0.306	0.655
Frobenius add.	0.566	0.460	0.585
Frobenius mult.	0.525	0.226	0.387
Frobenius outer	0.560	0.439	0.622

Table 4: Results for sentence similarity. There is no statistically significant difference between KS14 addition and NWE addition (the second best result).

Specifically, we get classification results on the Microsoft Research Paraphrase Corpus paraphrase corpus (Dolan et al., 2005) working in the following way: we construct vectors for the sentences of each pair; if the cosine similarity between the two sentence vectors exceeds a certain threshold, the pair is classified as a paraphrase, otherwise as not a paraphrase. For this experiment and that of Section 5.4 below, we investigate only the addition and point-wise multiplication compositional models, since at their current stage of development tensor-based models can only efficiently handle sentences of fixed structure. Nevertheless, the simple point-wise compositional models still allow for a direct comparison of the vector spaces, which is the main goal of this paper.

For each vector space and model, a number of different thresholds were tested on the first 2000 pairs of the training set, which we used as a development set; in each case, the best-performed threshold was selected for a *single* run of our "classifier" on the test set (1726 pairs). Additionally, we evaluate the NWE model with a lemmatized version of the corpus, so that the experimental setup is maximally similar for all vector spaces. The results are shown in the first part of Table 5.

Additive NWE gives the highest performance, with both lemmatized and un-lemmatized versions outperforming the GS11 and KS14 spaces. In the un-lemmatized case, the accuracy of our simple "classifier" (0.73) is close to state-of-the-art range. The state-of-the art result (0.77 accuracy

	Baseline		Co-occurrence				Neural word embeddings			
			GS11		KS14		Unlemmatized		Lemmatized	
Model	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score
MSR addition	0.65	0.75	0.62	0.79	0.70	0.80	**0.73**	**0.82**	0.72	0.81
MSR multiplication			0.52	0.58	**0.66**	**0.80**	0.42	0.34	0.41	0.36
SWDA addition	0.60	0.58	0.35	0.35	0.40	0.35	**0.63**	**0.60**	0.44	0.40
SWDA multiplication			0.32	0.16	0.39	0.33	**0.58**	**0.53**	0.43	0.38

Table 5: Results for paraphrase detection (MSR) and dialog act tagging (SWDA) tasks. All top results significantly outperform corresponding nearest competitors (for accuracy): $p < 0.05$, χ^2 test.

and 0.84 F-score[7]) by the time of this writing has been obtained using 8 machine translation metrics and three constituent classifiers (Madnani et al., 2012).

The multiplicative model gives lower results than the additive model across all vector spaces. The KS14 vector space shows the steadiest performance, with a drop in accuracy of only 0.04 and no drop in F-score, while for the GS11 and NWE spaces both accuracy and F-score experienced drops by more than 0.20.

5.4 Dialogue act tagging

As our last experiment, we evaluate the word spaces on a dialogue act tagging task (Stolcke et al., 2000) over the Switchboard corpus (Godfrey et al., 1992). Switchboard is a collection of approximately 2500 dialogs over a telephone line by 500 speakers from the U.S. on predefined topics.[8]

The experiment pipeline follows (Milajevs and Purver, 2014). The input utterances are preprocessed so that the parts of interrupted utterances are concatenated (Webb et al., 2005). Disfluency markers and commas are removed from the utterance raw texts. For GS11 and KS14 the utterance tokens are POS-tagged and lemmatized; for NWE, we test the vectors in both a lemmatized and an un-lemmatized version of the corpus.[9] We split the training and testing utterances as suggested by Stolcke et al. (2000). Utterance vectors are then obtained as in the previous experiments; they are reduced to 50 dimensions using SVD and a k-nearest-neighbour classifier is trained on these reduced utterance vectors (the 5 closest neighbours by Euclidean distance are retrieved to make a classification decision). The results are shown in the second part of Table 5.

Un-lemmatized NWE *addition* gave the best accuracy (0.63) and F-score (0.60) (averaged over tag classes), i.e. similar results to (Milajevs and Purver, 2014)—although note that the dimensionality of our NWE vectors is 10 times lower than theirs. *Multiplicative* NWE outperformed the corresponding model in (Milajevs and Purver, 2014). In general, addition consistently outperforms multiplication for all the models. Lemmatization dramatically lowers tagging accuracy: the lemmatized GS11, KS14 and NWE models perform much worse than un-lemmatized NWE, suggesting that morphological features are important for this task.

6 Discussion

Previous comparisons of co-occurrence-based and neural word vector representations vary widely in their conclusions. While Baroni et al. (2014) conclude that "context-predicting models obtain a thorough and resounding victory against their count-based counterparts", this seems to contradict, at least at the first consideration, the more conservative conclusion of Levy et al. (2014) that "analogy recovery is not restricted to neural word embeddings [...] a similar amount of relational similarities can be recovered from traditional distributional word representations" and the findings of Blacoe and Lapata (2012) that "shallow approaches are as good as more computationally intensive alternatives" on phrase similarity and paraphrase detection tasks.

It seems clear that neural word embeddings have an advantage when used in tasks for which they have been trained; our main questions here are whether they outperform co-occurrence based alternatives across the board; and which approach lends itself better to composition using general mathematical operators. To partially an-

[7] F-scores use the standard definition $F = 2(precision * recall)/(precision + recall)$.

[8] The dataset and a Python interface to it are available at `http://compprag.christopherpotts.net/swda.html`

[9] We use `WordNetLemmatizer` of the NLTK library (Bird, 2006).

swer this question, we can compare model behaviour against the baselines in *isolation*.

For the disambiguation and sentence similarity tasks the baseline is the similarity between verbs only, ignoring the context—see above. For the paraphrase task, we take the global vector-based similarity reported in (Mihalcea et al., 2006): 0.65 accuracy and 0.75 F-score. For the dialogue act tagging task the baseline is the accuracy of the bag-of-unigrams model in (Milajevs and Purver, 2014): 0.60.

Sections 5.1 and 5.2 show that although the best choice of vector representation might vary, for small-scale tasks all methods give fairly competitive results. The choice of compositional operator seems to be more important and more task-specific: while a tensor-based operation (Frobenius copy-object) performs best for verb disambiguation, the best result for sentence similarity is achieved by a simple additive model, with all other compositional methods behaving worse than the verb-only baseline in the KS14 case. GS11 and NWE, on the other hand, outperform their baselines with a number of compositional methods, although both of them achieve lower performance than KS14 overall.

Based on only small-scale experiment results, one could conclude that there is little significant difference between the two ways of obtaining vectors. GS11 and NWE show similar behaviour in comparison to their baselines, while it is possible to tune a co-occurrence based vector space (KS14) and obtain the best result. Large scale tasks reveal another pattern: the GS11 vector space, which behaves stably on the small scale, drags behind the KS14 and NWE spaces in the paraphrase detection task. In addition, NWE consistently yields best results. Finally, only the NWE space was able to provide adequate results on the dialogue act tagging task. Table 6 summarizes model performance with regard to baselines.

Task	**GS11**	**KS14**	**NWE**
Disambiguation	+	+	**+**
Sentence similarity	+	**−**	+
Paraphrase	−	+	**+**
Dialog act tagging	−	−	**+**

Table 6: Summary of vector space performance against baselines. General improvement (cases where more than a half of the models perform better) and decrease with regard to a corresponding baseline is respectively marked by + and −. A bold value means that the model gave the best result in the task.

7 Conclusion

In this work we compared the performance of two co-occurrence-based semantic spaces with vectors learned by a neural network in compositional settings. We carried out two small-scale tasks (word sense disambiguation and sentence similarity) and two large-scale tasks (paraphrase detection and dialogue act tagging).

On small-scale tasks, where the sentence structures are predefined and relatively constrained, NWE gives better or similar results to count-based vectors. Tensor-based composition does not always outperform simple compositional operators, but for most of the cases gives results within the same range.

On large-scale tasks, neural vectors are more successful than the co-occurrence based alternatives. However, this study does not reveal whether this is because of their neural nature, or just because they are trained on a larger amount of data.

The question of whether neural vectors outperform co-occurrence vectors therefore requires further detailed comparison to be entirely resolved; our experiments suggest that this is indeed the case in large-scale tasks, but the difference in size and nature of the original corpora may be a confounding factor. In any case, it is clear that the neural vectors of `word2vec` package perform steadily off-the-shelf across a large variety of tasks. The size of the vector space (3 million words) and the available code-base that simplifies the access to the vectors, makes this set a good and safe choice for experiments in the future. Of course, even better performances can be achieved by training neural language models specifically for a given task (see e.g. Kalchbrenner et al. (2014)).

The choice of compositional operator (tensor-based or a simple point-wise operation) depends strongly on the task and dataset: tensor-based composition performed best with the verb disambiguation task, where the verb senses depend strongly on the arguments of the verb. However, it seems to depend less on the nature of the vectors itself: in the disambiguation task, tensor-based

composition proved best for both co-occurrence-based and neural vectors; in the sentence similarity task, where point-wise operators proved best, this was again true across vector spaces.

Opinion Mining with Deep Recurrent Neural Networks

Ozan İrsoy and **Claire Cardie**

Cornell University
Ithaca, NY, 14853, USA
oirsoy, cardie@cs.cornell.edu

Abstract

Recurrent neural networks (RNNs) are connectionist models of sequential data that are naturally applicable to the analysis of natural language. Recently, "depth in space" — as an orthogonal notion to "depth in time" — in RNNs has been investigated by stacking multiple layers of RNNs and shown empirically to bring a temporal hierarchy to the architecture. In this work we apply these *deep RNNs* to the task of opinion expression extraction formulated as a token-level sequence-labeling task. Experimental results show that deep, narrow RNNs outperform traditional shallow, wide RNNs with the same number of parameters. Furthermore, our approach outperforms previous CRF-based baselines, including the state-of-the-art semi-Markov CRF model, and does so without access to the powerful opinion lexicons and syntactic features relied upon by the semi-CRF, as well as without the standard layer-by-layer pre-training typically required of RNN architectures.

1 Introduction

Fine-grained opinion analysis aims to detect the subjective expressions in a text (e.g. "hate") and to characterize their intensity (e.g. strong) and sentiment (e.g. negative) as well as to identify the opinion holder (the entity expressing the opinion) and the target, or topic, of the opinion (i.e. what the opinion is about) (Wiebe et al., 2005). Fine-grained opinion analysis is important for a variety of NLP tasks including opinion-oriented question answering and opinion summarization. As a result, it has been studied extensively in recent years.

In this work, we focus on the detection of opinion expressions — both *direct subjective expressions* (DSEs) and *expressive subjective expressions* (ESEs) as defined in Wiebe et al. (2005). DSEs consist of explicit mentions of private states or speech events expressing private states; and ESEs consist of expressions that indicate sentiment, emotion, etc., without explicitly conveying them. An example sentence shown in Table 1 in which the DSE "has refused to make any statements" explicitly expresses an opinion holder's attitude and the ESE "as usual" indirectly expresses the attitude of the writer.

The	committee	,	as	usual	,	has
O	O	O	B_ESE	I_ESE	O	B_DSE
refused	to	make	any	statements	.	
I_DSE	I_DSE	I_DSE	I_DSE	I_DSE	O	

Table 1: An example sentence with labels

Opinion extraction has often been tackled as a sequence labeling problem in previous work (e.g. Choi et al. (2005)). This approach views a sentence as a sequence of tokens labeled using the conventional BIO tagging scheme: B indicates the beginning of an opinion-related expression, I is used for tokens inside the opinion-related expression, and O indicates tokens outside any opinion-related class. The example sentence in Table 1 shows the appropriate tags in the BIO scheme. For instance, the ESE "as usual" results in the tags B_ESE for "as" and I_ESE for "usual".

Variants of **conditional random field (CRF)** approaches have been successfully applied to opinion expression extraction using this token-based view (Choi et al., 2005; Breck et al., 2007): the state-of-the-art approach is the semiCRF, which relaxes the Markovian assumption inherent to CRFs and operates at the phrase level rather than the token level, allowing the incorporation of phrase-level features (Yang and Cardie, 2012). The success of the CRF- and semiCRF-based approaches, however, hinges critically on access to an appropriate feature set, typically based on constituent and dependency parse trees, manually crafted opinion lexicons, named entity taggers and other preprocessing components (see Yang and Cardie (2012) for an up-to-date list).

Distributed representation learners provide a different approach to learning in which latent features are modeled as distributed dense vectors of hidden layers. A **recurrent neural network (RNN)** is one such learner that can operate on sequential data of variable length, which means it can also be applied as a sequence labeler. Moreover, **bidirectional RNNs** incorporate information from preceding as well as following tokens (Schuster and Paliwal, 1997) while recent advances in word embedding induction (Collobert and Weston, 2008; Mnih and Hinton, 2007; Mikolov et

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 720–728,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

al., 2013; Turian et al., 2010) have enabled more effective training of RNNs by allowing a lower dimensional dense input representation and hence, more compact networks (Mikolov et al., 2010; Mesnil et al., 2013). Finally, **deep recurrent networks**, a type of RNN with multiple stacked hidden layers, are shown to naturally employ a temporal hierarchy with multiple layers operating at different time scales (Hermans and Schrauwen, 2013): lower levels capture short term interactions among words; higher layers reflect interpretations aggregated over longer spans of text. When applied to natural language sentences, such hierarchies might better model the multi-scale language effects that are emblematic of natural languages, as suggested by previous results (Hermans and Schrauwen, 2013).

Motivated by the recent success of deep architectures in general and deep recurrent networks in particular, we explore an application of **deep bidirectional RNNs** — henceforth **deep RNNs** — to the task of opinion expression extraction. For both DSE and ESE detection, we show that such models outperform conventional, shallow (uni- and bidirectional) RNNs as well as previous CRF-based state-of-the-art baselines, including the semiCRF model.

In the rest of the paper we discuss related work (Section 2) and describe the architecture and training methods for recurrent neural networks (RNNs), bidirectional RNNs, and deep (bidirectional) RNNs (Section 3). We present experiments using a standard corpus for fine-grained opinion extraction in Section 4.

2 Related Work

Opinion extraction. Early work on fine-grained opinion extraction focused on recognizing subjective phrases (Wilson et al., 2005; Munson et al., 2005). Breck et al. (2007), for example, formulated the problem as a token-level sequence-labeling problem and apply a CRF-based approach, which significantly outperformed previous baselines. Choi et al. (2005) extended the sequential prediction approach to jointly identify opinion holders; Choi and Cardie (2010) jointly detected polarity and intensity along with the opinion expression. Reranking approaches have also been explored to improve the performance of a single sequence labeler (Johansson and Moschitti, 2010; Johansson and Moschitti, 2011). More recent work relaxes the Markovian assumption of CRFs to capture phrase-level interactions, significantly improving upon the token-level labeling approach (Yang and Cardie, 2012). In particular, Yang and Cardie (2013) propose a joint inference model to jointly detect opinion expressions, opinion holders and targets, as well as the relations among them, outperforming previous pipelined approaches.

Deep learning. Recurrent neural networks (Elman, 1990) constitute one important class of naturally deep architecture that has been applied to many sequential prediction tasks. In the context of NLP, recurrent neural networks view a sentence as a sequence of tokens and have been successfully applied to tasks such as language modeling (Mikolov et al., 2011) and spoken language understanding (Mesnil et al., 2013). Since classical recurrent neural networks only incorporate information from the past (i.e. preceding tokens), **bidirectional** variants have been proposed to incorporate information from both the past and the future (i.e. subsequent tokens) (Schuster and Paliwal, 1997). Bidirectionality is especially useful for NLP tasks, since information provided by the following tokens is generally helpful (and sometimes essential) when making a decision on the current token.

Stacked recurrent neural networks have been proposed as a way of constructing *deep* RNNs (Schmidhuber, 1992; El Hihi and Bengio, 1995). Careful empirical investigation of this architecture showed that multiple layers in the stack can operate at different time scales (Hermans and Schrauwen, 2013). Pascanu et al. (2013) explore other ways of constructing deep RNNs that are orthogonal to the concept of stacking layers on top of each other. In this work, we focus on the *stacking* notion of depth.

3 Methodology

This section describes the architecture and training methods for the deep bidirectional recurrent networks that we propose for the task of opinion expression mining. Recurrent neural networks are presented in 3.1, bidirectionality is introduced in 3.2, and deep bidirectional RNNs, in 3.3.

3.1 Recurrent Neural Networks

A recurrent neural network (Elman, 1990) is a class of neural network that has recurrent connections, which allow a form of memory. This makes them applicable for sequential prediction tasks with arbitrary spatio-temporal dimensions. Thus, their structure fits many NLP tasks, when the interpretation of a single sentence is viewed as analyzing a sequence of tokens. In this work, we focus our attention on only Elman-type networks (Elman, 1990).

In an **Elman-type network**, the hidden layer h_t at time step t is computed from a nonlinear transformation of the current input layer x_t and the previous hidden layer h_{t-1}. Then, the final output y_t is computed using the hidden layer h_t. One can interpret h_t as an intermediate representation summarizing the past, which is used to make a final decision on the current input.

More formally, given a sequence of vectors $\{x_t\}_{t=1..T}$, an Elman-type RNN operates by computing the following memory and output sequences:

$$h_t = f(Wx_t + Vh_{t-1} + b) \quad (1)$$

$$y_t = g(Uh_t + c) \quad (2)$$

where f is a nonlinear function, such as the sigmoid function and g is the output nonlinearity, such as the

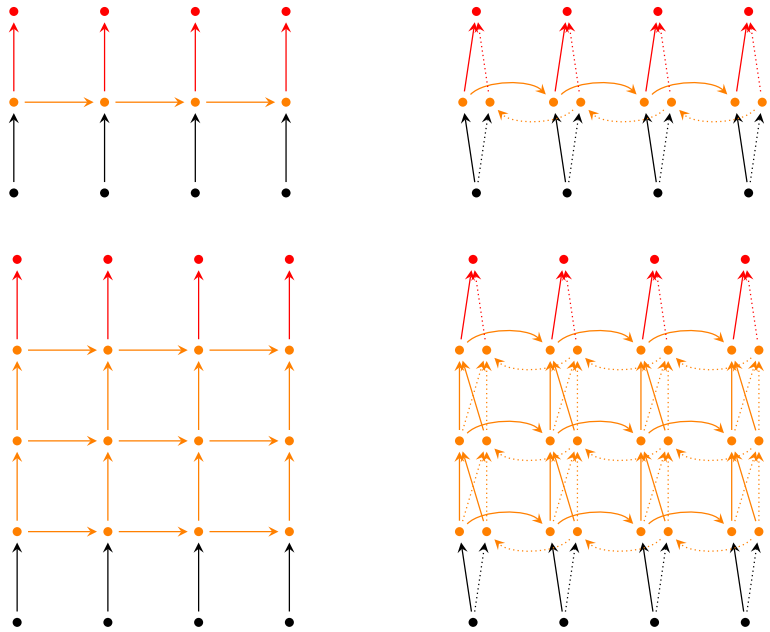

Figure 1: Recurrent neural networks. Each black, orange and red node denotes an input, hidden or output layer, respectively. Solid and dotted lines denote the connections of forward and backward layers, respectively. Top: Shallow unidirectional (left) and bidirectional (right) RNN. Bottom: 3-layer deep unidirectional (left) and bidirectional (right) RNN.

softmax function. W and V are weight matrices between the input and hidden layer, and among the hidden units themselves (connecting the previous intermediate representation to the current one), respectively, while U is the output weight matrix. b and c are bias vectors connected to hidden and output units, respectively. As a base case for the recursion in Equation 1, h_0 is assumed to be 0.

Training an RNN can be done by optimizing a discriminative objective (e.g. the cross entropy for classification tasks) with a gradient-based method. Backpropagation through time can be used to efficiently compute the gradients (Werbos, 1990). This method is essentially equivalent to unfolding the network in time and using backpropagation as in feedforward neural networks, while sharing the connection weights across different time steps. The Elman-style RNN is shown in Figure 1, top left.

3.2 Bidirectionality

Observe that with the above definition of RNNs, we have information only about the past, when making a decision on x_t. This is limiting for most NLP tasks. As a simple example, consider the two sentences: "I did not accept his suggestion" and "I did not go to the rodeo". The first has a DSE phrase ("did not accept") and the second does not. However, any such RNN will assign the same labels for the words "did" and "not" in both sentences, since the preceding sequences (past) are the same: the Elman-style unidirectional RNNs lack the representational power to model this task. A simple way to work around this problem is to include a fixed-size future context around a single input vector (token). However, this approach requires tuning the context size, and ignores future information from outside of the context window. Another way to incorporate information about the future is to add bidirectionality to the architecture, referred as the **bidirectional RNN** (Schuster and Paliwal, 1997):

$$\overrightarrow{h}_t = f(\overrightarrow{W}x_t + \overrightarrow{V}\overrightarrow{h}_{t-1} + \overrightarrow{b}) \quad (3)$$

$$\overleftarrow{h}_t = f(\overleftarrow{W}x_t + \overleftarrow{V}\overleftarrow{h}_{t+1} + \overleftarrow{b}) \quad (4)$$

$$y_t = g(U_{\rightarrow}\overrightarrow{h}_t + U_{\leftarrow}\overleftarrow{h}_t + c) \quad (5)$$

where $\overrightarrow{W}$, $\overrightarrow{V}$ and $\overrightarrow{b}$ are the forward weight matrices and bias vector as before; $\overleftarrow{W}$, $\overleftarrow{V}$ and $\overleftarrow{b}$ are their backward counterparts; $U_{\rightarrow}$, $U_{\leftarrow}$ are the output matrices; and c is the output bias.[1] Again, we assume $\overrightarrow{h}_0 = \overleftarrow{h}_{T+1} = 0$. In this setting $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ can be interpreted as a summary of the past, and the future, respectively, around the time step t. When we make a decision on an input vector, we employ the two intermediate representations $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ of the past and

[1] As a convention, we adopt the following notation throughout the paper: Superscript arrows for vectors disambiguate between forward and backward representations. Superscript arrows for matrices denote the resulting vector representations (connection outputs), and subscript arrows for matrices denote incoming vector representations (connection inputs). We omit subscripts when there is no ambiguity.

the future. (See Figure 1, top right.) Therefore in the bidirectional case, we have perfect information about the sequence (ignoring the practical difficulties about capturing long term dependencies, caused by vanishing gradients), whereas the classical Elman-type network uses only partial information as described above.

Note that the forward and backward parts of the network are independent of each other until the output layer when they are combined. This means that during training, after backpropagating the error terms from the output layer to the forward and backward hidden layers, the two parts can be thought of as separate, and each trained with the classical backpropagation through time (Werbos, 1990).

3.3 Depth in Space

Recurrent neural networks are often characterized as having *depth in time*: when unfolded, they are equivalent to feedforward neural networks with as many hidden layers as the number tokens in the input sequence (with shared connections across multiple layers of time). However, this notion of depth likely does not involve hierarchical processing of the data: across different time steps, we repeatedly apply the same transformation to compute the memory contribution of the input (W), to compute the response value from the current memory (U) and to compute the next memory vector from the previous one (V). Therefore, assuming the input vectors $\{x_t\}$ together lie in the same representation space, as do the output vectors $\{y_t\}$, hidden representations $\{h_t\}$ lie in the same space as well. As a result, they do not necessarily become more and more abstract, hierarchical representations of one another as we traverse in time. However in the more conventional, *stacked* deep learners (e.g. deep feedforward nets), an important benefit of depth is the hierarchy among hidden representations: every hidden layer conceptually lies in a different representation space, and constitutes a more abstract and higher-level representation of the input (Bengio, 2009).

In order to address these concerns, we investigate deep RNNs, which are constructed by stacking Elman-type RNNs on top of each other (Hermans and Schrauwen, 2013). Intuitively, every layer of the deep RNN treats the memory sequence of the previous layer as the input sequence, and computes its own memory representation.

More formally, we have:

$$\overrightarrow{h}_t^{(i)} = f(\overrightarrow{W}_{\rightarrow}^{(i)} \overrightarrow{h}_t^{(i-1)} + \overrightarrow{W}_{\leftarrow}^{(i)} \overleftarrow{h}_t^{(i-1)} + \overrightarrow{V}^{(i)} \overrightarrow{h}_{t-1}^{(i)} + \overrightarrow{b}^{(i)}) \quad (6)$$

$$\overleftarrow{h}_t^{(i)} = f(\overleftarrow{W}_{\rightarrow}^{(i)} \overrightarrow{h}_t^{(i-1)} + \overleftarrow{W}_{\leftarrow}^{(i)} \overleftarrow{h}_t^{(i-1)} + \overleftarrow{V}^{(i)} \overleftarrow{h}_{t+1}^{(i)} + \overleftarrow{b}^{(i)}) \quad (7)$$

when $i > 1$ and

$$\overrightarrow{h}_t^{(1)} = f(\overrightarrow{W}^{(1)} x_t + \overrightarrow{V}^{(1)} \overrightarrow{h}_{t-1}^{(1)} + \overrightarrow{b}^{(1)}) \quad (8)$$

$$\overleftarrow{h}_t^{(1)} = f(\overleftarrow{W}^{(1)} x_t + \overleftarrow{V}^{(1)} \overleftarrow{h}_{t+1}^{(1)} + \overleftarrow{b}^{(1)}) \quad (9)$$

Importantly, note that both forward and backward representations are employed when computing the forward and backward memory of the next layer.

Two alternatives for the output layer computations are to employ all memory layers or only the last. In this work we adopt the second approach:

$$y_t = g(U_{\rightarrow} \overrightarrow{h}_t^{(L)} + U_{\leftarrow} \overleftarrow{h}_t^{(L)} + c) \quad (10)$$

where L is the number of layers. Intuitively, connecting the output layer to only the last hidden layer forces the architecture to capture enough high-level information at the final layer for producing the appropriate output-layer decision.

Training a deep RNN can be conceptualized as interleaved applications of the conventional backpropagation across multiple layers, and backpropagation through time within a single layer.

The unidirectional and bidirectional deep RNNs are depicted in the bottom half of Figure 1.

Hypotheses. In general, we expected that the deep RNNs would show the most improvement over shallow RNNS for ESEs — phrases that implicitly convey subjectivity. Existing research has shown that these are harder to identify than direct expressions of subjectivity (DSEs): they are variable in length and involve terms that, in many (or most) contexts, are neutral with respect to sentiment and subjectivity. As a result, models that do a better job interpreting the context should be better at disambiguating subjective vs. non-subjective uses of phrases involving common words (e.g. "as usual", "in fact"). Whether or not deep RNNs would be powerful enough to outperform the state-of-the-art semiCRF was unclear, especially if the semiCRF is given access to the distributed word representations (embeddings) employed by the deep RNNs. In addition, the semiCRF has access to parse tree information and opinion lexicons, neither of which is available to the deep RNNs.

4 Experiments

Activation Units. We employ the standard softmax activation for the output layer: $g(x) = e^{x_i} / \sum_j e^{x_j}$. For the hidden layers we use the rectifier linear activation: $f(x) = \max\{0, x\}$. Experimentally, rectifier activation gives better performance, faster convergence, and sparse representations. Previous work also reported good results when training deep neural networks using rectifiers, without a pretraining step (Glorot et al., 2011).

Data. We use the MPQA 1.2 corpus (Wiebe et al., 2005) (535 news articles, 11,111 sentences) that is manually annotated with both DSEs and ESEs at the phrase level. As in previous work, we separate 135 documents as a development set and employ 10-fold CV over the remaining 400 documents. The development set is used during cross validation to do model selection.

Table 3: Experimental evaluation of RNNs for ESE extraction

Evaluation Metrics. We use precision, recall and F-measure for performance evaluation. Since the boundaries of expressions are hard to define even for human annotators (Wiebe et al., 2005), we use two soft notions of the measures: *Binary Overlap* counts every overlapping match between a predicted and true expression as correct (Breck et al., 2007; Yang and Cardie, 2012), and *Proportional Overlap* imparts a partial correctness, proportional to the overlapping amount, to each match (Johansson and Moschitti, 2010; Yang and Cardie, 2012). All statistical comparisons are done using a two-sided paired t-test with a confidence level of $\alpha = .05$.

Baselines (CRF and SEMICRF). As baselines, we use the CRF-based method of Breck et al. (2007) and the SEMICRF-based method of Yang and Cardie (2012), which is the state-of-the-art in opinion expression extraction. Features that the baselines use are words, part-of-speech tags and membership in a manually constructed opinion lexicon (within a [-1, +1] context window). Since SEMICRF relaxes the Markovian assumption and operates at the segment-level instead of the token-level, it also has access to parse trees of sentences to generate candidate segments (Yang and Cardie, 2012).

Word Vectors (+VEC). We also include versions of the baselines that have access to pre-trained word vectors. In particular, CRF+VEC employs word vectors as continuous features per every token. Since SEMICRF has phrase-level rather than word-level features, we simply take the mean of every word vector for a phrase-level vector representation for SEMICRF+VEC as suggested in Mikolov et al. (2013).

In all of our experiments, we keep the word vectors fixed (i.e. do not finetune) to reduce the degree of freedom of our models. We use the publicly available 300-dimensional word vectors of Mikolov et al. (2013), trained on part of the Google News dataset ($\sim$100B words). Preliminary experiments with other word vector representations such as Collobert-Weston (2008) embeddings or HLBL (Mnih and Hinton, 2007) provided poorer results ($\sim -3\%$ difference in proportional and binary F1).

Regularizer. We do not employ any regularization for smaller networks ($\sim$24,000 parameters) because we have not observed strong overfitting (i.e. the difference between training and test performance is small). Larger networks are regularized with the recently proposed dropout technique (Hinton et al., 2012): we randomly set entries of hidden representations to 0 with a probability called the dropout rate, which is tuned over the development set. Dropout prevents learned

features from co-adapting, and it has been reported to yield good results when training deep neural networks (Krizhevsky et al., 2012; Dahl et al., 2013).

Network Training. We use the standard multiclass cross-entropy as the objective function when training the neural networks. We use stochastic gradient descent with momentum with a fixed learning rate (.005) and a fixed momentum rate (.7). We update weights after minibatches of 80 sentences. We run 200 epochs for training. Weights are initialized from small random uniform noise. We experiment with networks of various sizes, however we have the same number of hidden units across multiple forward and backward hidden layers of a single RNN. We do not employ a pre-training step; deep architectures are trained with the supervised error signal, even though the output layer is connected to only the final hidden layer. With these configurations, every architecture successfully converges without any oscillatory behavior. Additionally, we employ early stopping for the neural networks: out of all iterations, the model with the best development set performance (Proportional F1) is selected as the final model to be evaluated.

4.1 Results and Discussion

Bidirectional vs. Unidirectional. Although our focus is on bidirectional RNNs, we first confirm that the SHALLOW bidirectional RNN outperforms a (shallow) unidirectional RNN for both DSE and ESE recognition. To make the comparison fair, each network has the same number of total parameters: we use 65 hidden units for the unidirectional, and 36 for the bidirectional network, respectively. Results are as expected: the bidirectional RNN obtains higher F1 scores than the unidirectional RNN — 63.83 vs. 60.35 (proportional overlap) and 69.62 vs. 68.31 (binary overlap) for DSEs; 54.22 vs. 51.51 (proportional) and 65.44 vs. 63.65 (binary) for ESEs. All differences are statistically significant at the 0.05 level. Thus, we will not include comparisons to the unidirectional RNNs in the remaining experiments.

Adding Depth. Next, we quantitatively investigate the effects of adding depth to RNNs. Tables 2 and 3 show the evaluation of RNNs of various depths and sizes. In both tables, the first group networks have approximately 24,000 parameters and the second group networks have approximately 200,000 parameters. Since all RNNs within a group have approximately the same number of parameters, they grow narrower as they get deeper. Within each group, bold shows the best result with an asterisk denoting statistically indistinguishable performance with respect to the best. As noted above, all statistical comparisons use a two-sided paired t-test with a confidence level of $\alpha = .05$.

In both DSE and ESE detection and for larger networks (bottom set of results), 3-layer RNNs provide the best results. For smaller networks (top set of results), 2, 3 and 4-layer RNNs show equally good performance for certain sizes and metrics and, in general, adding additional layers degrades performance. This could be related to how we train the architectures as well as to the decrease in width of the networks. In general, we observe a trend of increasing performance as we increase the number of layers, until a certain depth.

deepRNNs vs. (semi)CRF. Table 4 shows comparison of the best deep RNNs to the previous best results in the literature. In terms of F-measure, DEEP RNN performs best for both DSE and ESE detection, achieving a new state-of-the-art performance for the more strict proportional overlap measure, which is harder to improve upon than the binary evaluation metric. SEMICRF, with its very high recall, performs comparably to the DEEP RNN on the binary metric. Note that RNNs do not have access to any features other than word vectors.

In general, CRFs exhibit high precision but low recall (CRFs have the best precision on both DSE and ESE detection) while SEMICRFs exhibit a high recall, low precision performance. Compared to SEMICRF, the DEEP RNNs produce an even higher recall but sometimes lower precision for ESE detection. This suggests that the methods are complementary, and can

potentially be even more powerful when combined in an ensemble method.

Word vectors. Word vectors help CRFs on both precision and recall on both tasks. However, SEMICRFs become more conservative with word vectors, producing higher precision and lower recall on both tasks. This sometimes hurts overall F-measure.

Among the (SEMI)CRF-based methods, SEMICRF obtains the highest F1 score for DSEs and for ESEs using the softer metric; SEMICRF+VEC performs best for ESEs according to the stricter proportional overlap measure.

Network size. Finally, we observe that even small networks (such as 4-layer deep RNN for DSE and 2-layer deep RNN for ESE) outperform conventional CRFs. This suggests that with the help of good word vectors, we can train compact but powerful sequential neural models.

When examining the output, we see some systematic differences between the previously top-performing SEMICRF and the RNN-based models. (See Figure 2.) First, SEMICRF often identifies excessively long subjective phrases as in Example 1. Here, none of the models exactly matches the gold standard, but the RNNs are much closer. And all three models appear to have identified an ESE that was mistakenly omitted by the human annotator — "obviously". At the same time, the SEMICRF sometimes entirely misses subjective expressions that the RNNs identify — this seems to occur when there are no clear indications of sentiment in the subjective expression. The latter can be seen in Examples 2 and 3, in which the SEMICRF does not identify "but equally", "would have to be based on evidence", "not yet", and "not enough".

We also observe evidence of the power of the DEEPRNN over the SHALLOWRNN in Examples 4 and 5. (See Figure 3.) In contrast to Figure 2, Figure 3 distinguishes subjective expressions that are (correctly) assigned an initial Begin label from those that consist only of Inside labels[2] — the latter are shown in ALL CAPS and indicate some degree of confusion in the model that produced them. In Example 4, SHALLOWRNN exhibits *some* evidence for each ESE — it labels one or more tokens as Inside an ESE ("any" and "time"). But it does not explicitly tag the beginning of the ESE. DEEPRNN does better, identifying the first ESE in its entirety ("in any case") and identifying more words as being Inside the second ESE ("it is high time). A similar situation occurs in Example 5.

5 Conclusion

In this paper we have explored an application of deep recurrent neural networks to the task of sentence-level opinion expression extraction. We empirically evaluated deep RNNs against conventional, shallow RNNs that have only a single hidden layer. We also compared our models with previous (semi)CRF-based approaches.

Experiments showed that deep RNNs outperformed shallow RNNs on both DSE and ESE extrac-

[2]Sequences of I's are decoded as the associated DSE or ESE even though they lack the initial B.

tion. Furthermore, deep RNNs outperformed previous (semi)CRF baselines, achieving new state-of-the-art results for fine-grained on opinion expression extraction.

We have trained our deep networks without any pre-training and with only the last hidden layer connected to the output layer. One potential future direction is to explore the effects of pre-training on the architecture. Pre-training might help to exploit the additional representational power available in deeper networks. Another direction is to investigate the impact of fine-tuning the word vectors during supervised training. Additionally, alternative notions of depth that are orthogonal to stacking, as in Pascanu et al. (2013) can be investigated for this task.

The Inside-Outside Recursive Neural Network model for Dependency Parsing

Phong Le and **Willem Zuidema**

University of Amsterdam, the Netherlands
{p.le,zuidema}@uva.nl

Abstract

We propose the first implementation of an infinite-order generative dependency model. The model is based on a new recursive neural network architecture, the Inside-Outside Recursive Neural Network. This architecture allows information to flow not only bottom-up, as in traditional recursive neural networks, but also top-down. This is achieved by computing content as well as context representations for any constituent, and letting these representations interact. Experimental results on the English section of the Universal Dependency Treebank show that the infinite-order model achieves a perplexity seven times lower than the traditional third-order model using counting, and tends to choose more accurate parses in k-best lists. In addition, reranking with this model achieves state-of-the-art unlabelled attachment scores and unlabelled exact match scores.

1 Introduction

Estimating probability distributions is the core issue in modern, data-driven natural language processing methods. Because of the traditional definition of discrete probability

$$Pr(A) \equiv \frac{\text{the number of times A occurs}}{\text{the size of event space}}$$

counting has become a standard method to tackle the problem. When data are sparse, smoothing techniques are needed to adjust counts for non-observed or rare events. However, successful use of those techniques has turned out to be an art. For instance, much skill and expertise is required to create reasonable reduction lists for back-off, and to avoid impractically large count tables, which store events and their counts.

An alternative to counting for estimating probability distributions is to use neural networks. Thanks to recent advances in deep learning, this approach has recently started to look very promising again, with state-of-the-art results in sentiment analysis (Socher et al., 2013), language modelling (Mikolov et al., 2010), and other tasks. The Mikolov et al. (2010) work, in particular, demonstrates the advantage of neural-network-based approaches over counting-based approaches in language modelling: it shows that recurrent neural networks are capable of capturing long histories efficiently and surpass standard n-gram techniques (e.g., Kneser-Ney smoothed 5-gram).

In this paper, keeping in mind the success of these models, we compare the two approaches. Complementing recent work that focused on such a comparison for the case of finding appropriate word vectors (Baroni et al., 2014), we focus here on models that involve more complex, hierarchical structures. Starting with existing generative models that use counting to estimate probability distributions over constituency and dependency parses (e.g., Eisner (1996b), Collins (2003)), we develop an alternative based on recursive neural networks. This is a non-trivial task because, to our knowledge, no existing neural network architecture can be used in this way. For instance, classic recurrent neural networks (Elman, 1990) unfold to left-branching trees, and are not able to process arbitrarily shaped parse trees that the counting approaches are applied to. Recursive neural networks (Socher et al., 2010) and extensions (Socher et al., 2012; Le et al., 2013), on the other hand, do work with trees of arbitrary shape, but process them in a bottom-up manner. The probabilities we need to estimate are, in contrast, defined by top-down generative models, or by models that require information flows in both directions (e.g., the probability of generating a node depends on the whole fragment rooted at its just-generated sis-

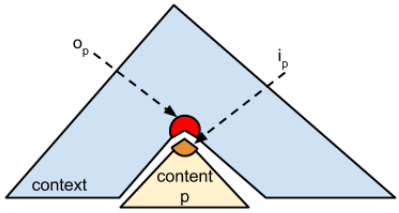

Figure 1: Inner ($\mathbf{i}_p$) and outer ($\mathbf{o}_p$) representations at the node that covers constituent p. They are vectorial representations of p's content and context, respectively.

ter).

To tackle this problem, we propose a new architecture: the Inside-Outside Recursive Neural Network (IORNN) in which information can flow not only bottom-up but also top-down, inward and outward. The crucial innovation in our architecture is that every node in a hierarchical structure is associated with two vectors: one vector, the *inner representation*, representing the content under that node, and another vector, the *outer representation*, representing its context (see Figure 1). Inner representations can be computed bottom-up; outer representations, in turn, can be computed top-down. This allows information to flow in any direction, depending on the application, and makes the IORNN a natural tool for estimating probabilities in tree-based generative models.

We demonstrate the use of the IORNN by applying it to an ∞-order generative dependency model which is impractical for counting due to the problem of data sparsity. Counting, instead, is used to estimate a third-order generative model as in Sangati et al. (2009) and Hayashi et al. (2011). Our experimental results show that our new model not only achieves a seven times lower perplexity than the third-order model, but also tends to choose more accurate candidates in k-best lists. In addition, reranking with this model achieves state-of-the-art scores on the task of supervised dependency parsing.

The outline of the paper is following. Firstly, we give an introduction to Eisner's generative model in Section 2. Then, we present the third-order model using counting in Section 3, and propose the IORNN in Section 4. Finally, in Section 5 we show our experimental results.

2 Eisner's Generative Model

Eisner (1996b) proposed a generative model for dependency parsing. The generation process is top-down: starting at the ROOT, it generates left dependents and then right dependents for the ROOT. After that, it generates left dependents and right dependents for each of ROOT's dependents. The process recursively continues until there is no further dependent to generate. The whole process is captured in the following formula

$$P(T(H)) = \prod_{l=1}^{L} P\left(H_l^L | \mathcal{C}_{H_l^L}\right) P\left(T(H_l^L)\right) \times \prod_{r=1}^{R} P\left(H_r^R | \mathcal{C}_{H_r^R}\right) P\left(T(H_r^R)\right) \quad (1)$$

where H is the current head, $T(N)$ is the fragment of the dependency parse rooted in N, and $\mathcal{C}_N$ is the context in which N is generated. H^L, H^R are respectively H's left dependents and right dependents, plus EOC (End-Of-Children), a special token to indicate that there are no more dependents to generate. Thus, $P(T(ROOT))$ is the probability of generating the entire dependency structure T. We refer to $\langle H_l^L, \mathcal{C}_{H_l^L}\rangle$, $\langle H_r^R, \mathcal{C}_{H_r^R}\rangle$ as "events", and $\langle \mathcal{C}_{H_l^L}\rangle$, $\langle \mathcal{C}_{H_r^R}\rangle$ as "conditioning contexts".

In order to avoid the problem of data sparsity, the conditioning context in which a dependent D is generated should capture only part of the fragment generated so far. Based on the amount of information that contexts hold, we can define the *order* of a generative model (see Hayashi et al. (2011, Table 3) for examples)

- first-order: $\mathcal{C}_D^1$ contains the head H,
- second-order: $\mathcal{C}_D^2$ contains H and the just-generated sibling S,
- third-order: $\mathcal{C}_D^3$ contains H, S, the sibling S' before S (tri-sibling); or H, S and the grand-head G (the head of H) (grandsibling) (the fragment enclosed in the blue doted contour in Figure 2),
- ∞-order: $\mathcal{C}_D^\infty$ contains all of D's ancestors, theirs siblings, and its generated siblings (the fragment enclosed in the red dashed contour in Figure 2).

In the original models (Eisner, 1996a), each dependent D is a 4-tuple $\langle dist, w, c, t\rangle$

- $dist(H, D)$ the distance between D and its head H, represented as one of the four ranges 1, 2, 3-6, 7-∞.

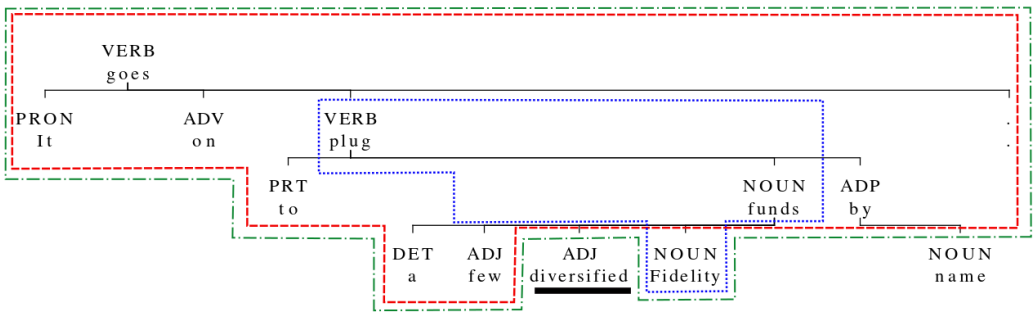

Figure 2: Example of different orders of context of "diversified". The blue dotted shape corresponds to the third-order outward context, while the red dashed shape corresponds to the ∞-order left-to-right context. The green dot-dashed shape corresponds to the context to compute the outer representation.

- $\underline{word}(D)$ the lowercase version of the word of D,
- $\underline{cap}(D)$ the capitalisation feature of the word of D (all letters are lowercase, all letters are uppercase, the first letter is uppercase, the first letter is lowercase),
- $\underline{tag}(D)$ the POS-tag of D,

Here, to make the dependency complete, $\underline{deprel}(D)$, the dependency relation of D (e.g., SBJ, DEP), is also taken into account.

3 Third-order Model with Counting

The third-order model we suggest is similar to the grandsibling model proposed by Sangati et al. (2009) and Hayashi et al. (2011). It defines the probability of generating a dependent $D = \langle dist, d, w, c, t \rangle$ as the product of the distance-based probability and the probabilities of generating each of its components (d, t, w, c, denoting dependency relation, POS-tag, word and capitalisation feature, respectively). Each of these probabilities is smoothed using back-off according to the given reduction lists (as explained below).

$$
\begin{aligned}
&P(D|\mathcal{C}_D) \\
&= P(dist(H,D), dwct(D)|H,S,G,dir) \\
&= P(d(D)|H,S,G,dir) \\
&\quad \text{reduction list: } \left\{\begin{array}{|l|}\hline tw(H),tw(S),tw(G),dir \\ \hline tw(H),tw(S),t(G),dir \\ \hline \left\{\begin{array}{l} tw(H),t(S),t(G),dir \\ t(H),tw(S),t(G),dir \end{array}\right. \\ \hline t(H),t(S),t(G),dir \\ \hline \end{array}\right. \\
&\times P(t(D)|d(D),H,S,G,dir) \\
&\quad \text{reduction list: } \left\{\begin{array}{|l|}\hline d(D),dtw(H),t(S),dir \\ \hline d(D),d(H),t(S),dir \\ \hline d(D),d(D),dir \\ \hline \end{array}\right. \\
&\times P(w(D)|dt(D),H,S,G,dir) \\
&\quad \text{reduction list: } \left\{\begin{array}{|l|}\hline dtw(H),t(S),dir \\ \hline dt(H),t(S),dir \\ \hline \end{array}\right. \\
&\times P(c(D)|dtw(D),H,S,G,dir) \\
&\quad \text{reduction list: } \left\{\begin{array}{|l|}\hline tw(D),d(H),dir \\ \hline tw(D),dir \\ \hline \end{array}\right. \\
&\times P(dist(H,D)|dtwc(D),H,S,G,dir) \qquad (2) \\
&\quad \text{reduction list: } \left\{\begin{array}{|l|}\hline dtw(D),dt(H),t(S),dir \\ \hline dt(D),dt(H),t(S),dir \\ \hline \end{array}\right.
\end{aligned}
$$

The reason for generating the dependency relation first is based on the similarity between relation/dependent and role/filler: we generate a role and then choose a filler for that role.

Back-off The back-off parameters are identical to Eisner (1996b). To estimate the probability $P(A|context)$ given a reduction list $L = (l_1, l_2, ..., l_n)$ of $context$, let

$$
p_i = \begin{cases} \frac{count(A,l_i)+0.005}{count(l_i)+0.5} & \text{if } i = n \\ \frac{count(A,l_i)+3p_{i+1}}{count(l_i)+3} & \text{otherwise} \end{cases}
$$

then $P(A|context) = p_1$.

4 The Inside-Outside Recursive Neural Network

In this section, we first describe the Recursive Neural Network architecture of Socher et al. (2010) and then propose an extension we call the Inside-Outside Recursive Neural Network (IORNN). The IORNN is a general architecture for trees, which works with tree-based generative models including those employed by Eisner (1996b) and Collins (2003). We then explain how to apply the IORNN to the ∞-order model. Note that for the present paper we are only concerned with the problem of computing the probability of

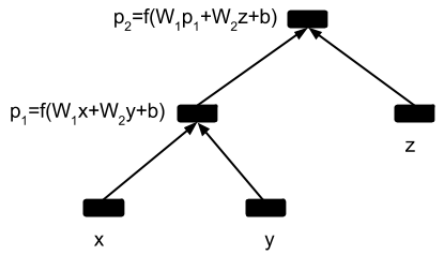

Figure 3: Recursive Neural Network (RNN).

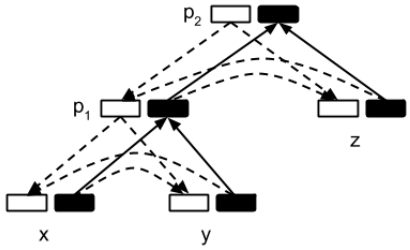

Figure 4: Inside-Outside Recursive Neural Network (IORNN). Black rectangles correspond to inner representations, white rectangles correspond to outer representations.

a tree; we assume an independently given parser is available to assign a syntactic structure, or multiple candidate structures, to an input string.

4.1 Recursive Neural Network

The architecture we propose can best be understood as an extension of the Recursive Neural Networks (RNNs) proposed by Socher et al. (2010), that we mentioned above. In order to see how an RNN works, consider the following example. Assume that there is a constituent with parse tree $(p_2\ (p_1\ x\ y)\ z)$ (Figure 3), and that $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathbb{R}^n$ are the (inner) representations of the three words x, y and z, respectively. We use a neural network which consists of a weight matrix $\mathbf{W}_1 \in \mathbb{R}^{n \times n}$ for left children and a weight matrix $\mathbf{W}_2 \in \mathbb{R}^{n \times n}$ for right children to compute the vector for a parent node in a bottom up manner. Thus, we compute p_1 as follows

$$\mathbf{p}_1 = f(\mathbf{W}_1\mathbf{x} + \mathbf{W}_2\mathbf{y} + \mathbf{b})$$

where $\mathbf{b}$ is a bias vector and f is an activation function (e.g., *tanh* or *logistic*). Having computed p_1, we can then move one level up in the hierarchy and compute p_2:

$$\mathbf{p}_2 = f(\mathbf{W}_1\mathbf{p}_1 + \mathbf{W}_2\mathbf{z} + \mathbf{b})$$

This process is continued until we reach the root node. The RNN thus computes a single vector for each node p in the tree, representing the *content* under that node. It has in common with logical semantics that representations for compounds (here *xyz*) are computed by recursively applying a composition function to meaning representations of the parts. It is difficult to characterise the expressivity of the resulting system in logical terms, but recent work suggests it is surprisingly powerful (e.g., Kanerva (2009)).

4.2 IORNN

We extend the RNN-architecture by adding a second vector to each node, representing the *context* of the node, shown as white rectangles in figure 4. The job of this second vector, the outer representation, is to summarize all information about the context of node p so that we can either predict its content (i.e., predict an inner representation), or pass on this information to the daughters of p (i.e., compute outer representations of these daughters). Outer representations thus allow information to flow top-down.

We explain the operation of the resulting *Inside-Outside Recursive Neural Network* in terms of the same example parse tree $(p_2\ (p_1\ x\ y)\ z)$ (see Figure 4). Each node u in the syntactic tree carries two vectors $\mathbf{o}_u$ and $\mathbf{i}_u$, the outer representation and inner representation of the constituent that is covered by the node.

Computing inner representations Inner representations are computed from the bottom up. We assume for every word w an inner representation $\mathbf{i}_w \in \mathbb{R}^n$. The inner representation of a non-terminal node, say p_1, is given by

$$\mathbf{i}_{p_1} = f(\mathbf{W}_1^i\mathbf{i}_x + \mathbf{W}_2^i\mathbf{i}_y + \mathbf{b}^i)$$

where $\mathbf{W}_1^i, \mathbf{W}_2^i$ are $n \times n$ real matrices, $\mathbf{b}^i$ is a bias vector, and f is an activation function, e.g. $tanh$. (This is the same as the computation of non-terminal vectors in the RNNs.) The inner representation of a parent node is thus a function of the inner representations of its children.

Computing outer representations Outer representations are computed from the top down. For a node which is not the root, say p_1, the outer repre-

sentation is given by

$$\mathbf{o}_{p_1} = g(\mathbf{W}_1^o \mathbf{o}_{p_2} + \mathbf{W}_2^o \mathbf{i}_z + \mathbf{b}^o)$$

where $\mathbf{W}_1^o, \mathbf{W}_2^o$ are $n \times n$ real matrices, $\mathbf{b}^o$ is a bias vector, and g is an activation function. The outer representation of a node is thus a function of the outer representation of its parent and the inner representation of its sisters.

If there is information about the external context of the utterance that is being processed, this information determines the outer representation of the root node $\mathbf{o}_{root}$. In our first experiments reported here, no such information was assumed to be available. In this case, a random value $\mathbf{o}_\emptyset$ is chosen at initialisation and assigned to the root nodes of all utterances; this value is then adjusted by the learning process discussed below.

Training Training the IORNN is to minimise an objective function $J(\theta)$ which depends on the purpose of usage where θ is the set of parameters. To do so, we compute the gradient $\partial J/\partial\theta$ and apply the gradient descent method. The gradient is effectively computed thanks to back-propagation through structure (Goller and Küchler, 1996). Following Socher et al. (2013), we use AdaGrad (Duchi et al., 2011) to update the parameters.

4.3 The ∞-order Model with IORNN

The RNN and IORNN are defined for context-free trees. To apply the IORNN architecture to dependency parses we need to adapt the definitions somewhat. In particular, in the generative dependency model, every step in the generative story involves the decision to generate a specific word while the span of the subtree that this word will dominate only becomes clear when all dependents are generated. We therefore introduce *partial outer representation* as a representation of the current context of a word in the generative process, and compute the final outer representation only when all its siblings have been generated.

Consider an example of head h and its dependents x, y (we ignore directions for simplicity) in Figure 5. Assume that we are in the state in the generative process where the generation of h is complete, i.e. we know its inner and outer representations $\mathbf{i}_h$ and $\mathbf{o}_h$. Now, when generating h's first dependent x (see Figure 5-a), we first compute x's *partial* outer representation (representing its context at this stage in the process), which is a function of the outer representation of the head (representing the head's context) and the inner representation of the head (representing the content of the head word):

$$\bar{\mathbf{o}}_1 = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{b}_o)$$

where $\mathbf{W}_{hi}, \mathbf{W}_{ho}$ are $n \times n$ real matrices, $\mathbf{b}_o$ is a bias vector, f is an activation function.

With the context of the first dependent determined, we can proceed and generate its content. For this purpose, we assume a separate weight matrix $\mathbf{W}$, trained (as explained below) to predict a specific word given a (partial) outer representation. To compute a proper probability for word x, we use the softmax function:

$$softmax(x, \bar{\mathbf{o}}_1) = \frac{e^{u(x,\bar{\mathbf{o}}_1)}}{\sum_{w \in V} e^{u(w,\bar{\mathbf{o}}_1)}}$$

where $\left[u(w_1, \bar{\mathbf{o}}_1), ..., u(w_{|V|}, \bar{\mathbf{o}}_1)\right]^T = \mathbf{W}\bar{\mathbf{o}}_1 + \mathbf{b}$ and V is the set of all possible dependents.

Note that since $\mathbf{o}_h$, the outer representation of h, represents the entire dependency structure generated up to that point, $\bar{\mathbf{o}}_1$ is a vectorial representation of the ∞-order context generating the first dependent (like the fragment enclosed in the red dashed contour in Figure 2). The softmax function thus estimates the probability $P(D = x|\mathcal{C}_D^\infty)$.

The next step, now that x is generated, is to compute the partial outer representation for the second dependent (see Figure 5-b)

$$\bar{\mathbf{o}}_2 = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{W}_{dr(x)}\mathbf{i}_x + \mathbf{b}_o)$$

where $\mathbf{W}_{dr(x)}$ is a $n \times n$ real matrix specific for the dependency relation of x with h.

Next y is generated (using the softmax function above), and the partial outer representation for the third dependent (see Figure 5-c) is computed:

$$\bar{\mathbf{o}}_3 = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \frac{1}{2}\left(\mathbf{W}_{dr(x)}\mathbf{i}_x + \mathbf{W}_{dr(y)}\mathbf{i}_y\right) + \mathbf{b}_o)$$

Since the third dependent is the End-of-Children symbol (EOC), the process of generating dependents for h stops. We can then return to x and y to replace the partial outer representations with complete outer representations[1] (see

[1] According to the IORNN architecture, to compute the outer representation of a node, the inner representations of the whole fragments rooting at its sisters must be taken into account. Here, we replace the inner representation of a fragment by the inner representation of its root since the meaning of a phrase is often dominated by the meaning of its head.

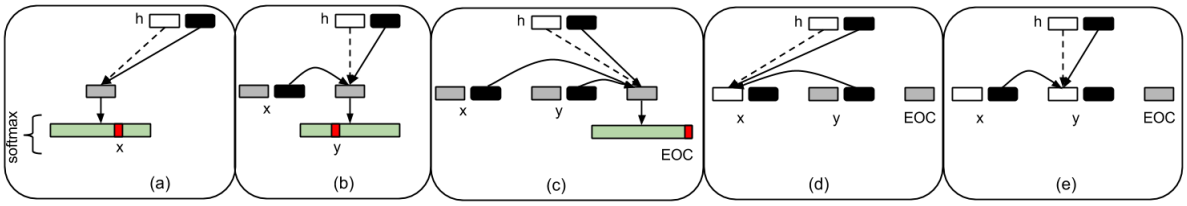

Figure 5: Example of applying IORNN to dependency parsing. Black, grey, white boxes are respectively inner, partial outer, and outer representations. For simplicity, only links related to the current computation are drawn (see text).

Figure 5-d,e):

$$\mathbf{o}_x = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{W}_{dr(y)}\mathbf{i}_y + \mathbf{b}_o)$$
$$\mathbf{o}_y = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{W}_{dr(x)}\mathbf{i}_x + \mathbf{b}_o)$$

In general, if u is the first dependent of h then

$$\bar{\mathbf{o}}_u = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{b}_o)$$

otherwise

$$\bar{\mathbf{o}}_u = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{b}_o + \frac{1}{|\bar{\mathcal{S}}(u)|}\sum_{v\in\bar{\mathcal{S}}(u)}\mathbf{W}_{dr(v)}\mathbf{i}_v)$$

where $\bar{\mathcal{S}}(u)$ is the set of u's sisters generated before it. And, if u is the only dependent of h (ignoring EOC) then

$$\mathbf{o}_u = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{b}_o)$$

otherwise

$$\mathbf{o}_u = f(\mathbf{W}_{hi}\mathbf{i}_h + \mathbf{W}_{ho}\mathbf{o}_h + \mathbf{b}_o + \frac{1}{|\mathcal{S}(u)|}\sum_{v\in\mathcal{S}(u)}\mathbf{W}_{dr(v)}\mathbf{i}_v)$$

where $\mathcal{S}(u)$ is the set of u's sisters.

We then continue this process to generate dependents for x and y until the process stops.

Inner Representations In the calculation of the probability of generating a word, described above, we assumed inner representations of all possible words to be given. These are, in fact, themselves a function of vector representations for the words (in our case, the word vectors are initially borrowed from Collobert et al. (2011)), the POS-tags and capitalisation features. That is, the inner representation at a node h is given by:

$$\mathbf{i}_h = f\left(\mathbf{W}_w\mathbf{w}_h + \mathbf{W}_p\mathbf{p}_h + \mathbf{W}_c\mathbf{c}_h\right)$$

where $\mathbf{W}_w \in R^{n\times d_w}$, $\mathbf{W}_p \in R^{n\times d_p}$, $\mathbf{W}_c \in R^{n\times d_c}$, $\mathbf{w}_h$ is the word vector of h, and $\mathbf{p}_h, \mathbf{c}_h$ are respectively binary vectors representing the POS-tag and capitalisation feature of h.

Training Training this IORNN is to minimise the following objective function which is the regularised cross-entropy

$$J(\theta) = -\frac{1}{m}\sum_{T\in\mathcal{D}}\sum_{w\in T}\log(P(w|\bar{\mathbf{o}}_w)) + \frac{1}{2}\left(\lambda_W\|\theta_W\|^2 + \lambda_L\|\theta_L\|^2\right)$$

where $\mathcal{D}$ is the set of training dependency parses, m is the number of dependents; θ_W, θ_L are the weight matrix set and the word embeddings ($\theta = (\theta_W, \theta_L)$); λ_W, λ_L are regularisation hyper-parameters.

Implementation We decompose a dependent D into four features: dependency relation, POS-tag, lowercase version of word, capitalisation feature of word. We then factorise $P(D|\mathcal{C}_D^\infty)$ similarly to Section 3, where each component is estimated by a softmax function.

5 Experiments

In our experiments, we convert the Penn Treebank to dependencies using the Universal dependency annotation (McDonald et al., 2013)[2]; this yields a dependency tree corpus we label PTB-U. In order to compare with other systems, we also experiment with an alternative conversion using the head rules of Yamada and Matsumoto (2003)[3]; this yields a dependency tree corpus we label PTB-YM. Sections 2-21 are used for training, section 22 for development, and section 23 for testing. For the PTB-U, the gold POS-tags are used. For the PTB-YM, the development and test sets are tagged by the Stanford POS-tagger[4] trained on the whole

	Perplexity
3rd-order model	1736.73
∞-order model	**236.58**

Table 1: Perplexities of the two models on PTB-U-22.

training data, whereas 10-way jackknifing is used to generate tags for the training set.

The vocabulary for both models, the third-order model and the ∞-order model, is taken as a list of words occurring more than two times in the training data. All other words are labelled 'UNKNOWN' and every digit is replaced by '0'. For the IORNN used by the ∞-order model, we set $n = 200$, and define f as the $tanh$ activation function. We initialise it with the 50-dim word embeddings from Collobert et al. (2011) and train it with the learning rate 0.1, $\lambda_W = 10^{-4}, \lambda_L = 10^{-10}$.

5.1 Perplexity

We firstly evaluate the two models on PTB-U-22 using the perplexity-per-word metric

$$ppl(P) = 2^{-\frac{1}{N}\sum_{T\in\mathcal{D}}\log_2 P(T)}$$

where $\mathcal{D}$ is a set of dependency parses, N is the total number of words. It is worth noting that, the better P estimates the true distribution P^* of $\mathcal{D}$, the lower its perplexity is. Because Eisner's model with the $dist(H, D)$ feature (Equation 2) is leaky (the model allocates some probability to events that can never legally arise), this feature is discarded (only in this experiment).

Table 1 shows results. The perplexity of the third-order model is more than seven times higher than the ∞-order model. This reflects the fact that data sparsity is more problematic for counting than for the IORNN.

To investigate why the perplexity of the third-order model is so high, we compute the percentages of events extracted from the development set appearing more than twice in the training set. Events are grouped according to the reduction lists in Equation 2 (see Table 2). We can see that reductions at level 0 (the finest) for dependency relations and words seriously suffer from data sparsity: more than half of the events occur less than three times, or not at all, in the training data. We thus conclude that counting-based models heavily rely on carefully designed reduction lists for back-off.

back-off level	d	t	w	c
0	47.4	61.6	43.7	87.7
1	69.8	98.4	77.8	97.3
2	76.0, 89.5	99.7		
3	97.9			
total	76.1	86.6	60.7	92.5

Table 2: Percentages of events extracted from PTB-U-22 appearing more than twice in the training set. Events are grouped according to the reduction lists in Equation 2. d, t, w, c stand for dependency relation, POS-tag, word, and capitalisation feature.

5.2 Reranking

In the second experiment, we evaluate the two models in the reranking framework proposed by Sangati et al. (2009) on PTB-U. We used the MSTParser (with the 2nd-order feature mode) (McDonald et al., 2005) to generate k-best lists. Two evaluation metrics are labelled attachment score (LAS) and unlabelled attachment score (UAS), *including* punctuation.

Rerankers Given $\mathcal{D}(S)$, a k-best list of parses of a sentence S, we define the *generative* reranker

$$T^* = \arg\max_{T\in\mathcal{D}(S)} P(T(ROOT))$$

which is identical to Sangati et al. (2009). Moreover, as in many mixture-model-based approaches, we define the *mixture* reranker as a combination of the generative model and the MST discriminative model (Hayashi et al., 2011)

$$T^* = \arg\max_{T\in\mathcal{D}(S)} \alpha \log P(T(ROOT)) + (1-\alpha)s(S,T)$$

where $s(S, T)$ is the score given by the MSTParser, and $\alpha \in [0, 1]$.

Results Figure 6 shows UASs of the generative reranker on the development set. The MSTParser achieves 92.32% and the Oracle achieve 96.23% when $k = 10$. With the third-order model, the generative reranker performs better than the MSTParser when $k < 6$ and the maximum improvement is 0.17%. Meanwhile, with the ∞-order model, the generative reranker always gains higher UASs than the MSTParser, and with $k = 6$, the difference reaches 0.7%. Figure 7 shows UASs of the mixture reranker on the same set. α is optimised by searching with the step-size 0.005. Unsurprisingly, we observe improvements over the

generative reranker as the mixture reranker can combine the advantages of the two models.

Table 3 shows scores of the two rerankers on the test set with the parameters tuned on the development set. Both the rerankers, either using third-order or ∞-order models, outperform the MSTParser. The fact that both gain higher improvements with the ∞-order model suggests that the IORNN surpasses counting.

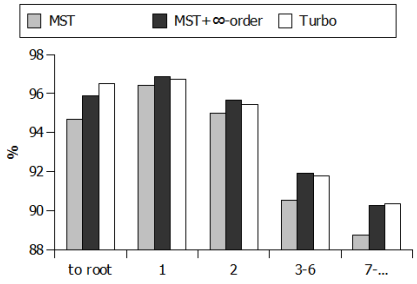

Figure 9: F1-scores of binned HEAD distance (PTB-U-23).

5.3 Comparison with other systems

We first compare the mixture reranker using the ∞-order model against the state-of-the-art dependency parser TurboParser (with the full mode) (Martins et al., 2013) on PTB-U-23. Table 4 shows LASs and UASs. When taking labels into account, the TurboParser outperforms the reranker. But without counting labels, the two systems perform comparably, and when ignoring punctuation the reranker even outperforms the TurboParser. This pattern is also observed when the exact match metrics are used (see Table 4). This is due to the fact that the TurboParser performs significantly better than the MSTParser, which generates k-best lists for the reranker, in labelling: the former achieves 96.03% label accuracy score whereas the latter achieves 94.92%.

One remarkable point is that reranking with the ∞-order model helps to improve the exact match scores 4% - 6.4% (see Table 4). Because the exact match scores correlate with the ability to handle global structures, we conclude that the IORNN is able to capture ∞-order contexts. Figure 8 shows distributions of correct-head accuracy over CPOS-tags and Figure 9 shows F1-scores of binned HEAD distance. Reranking with the ∞-order model is clearly helpful for all CPOS-tags and dependent-to-head distances, except a minor decrease on PRT.

We compare the reranker against other systems on PTB-YM-23 using the UAS metric ignoring punctuation (as the standard evaluation for English) (see Table 5). Our system performs slightly better than many state-of-the-art systems such as Martins et al. (2013) (a.k.a. TurboParser), Zhang and McDonald (2012), Koo and Collins (2010). It outperforms Hayashi et al. (2011) which is a reranker using a combination of third-order generative models with a variational model learnt

	LAS (w/o punc)	UAS (w/o punc)	LEM (w/o punc)	UEM (w/o punc)
MSTParser	89.97 (90.54)	91.99 (92.82)	32.37 (34.19)	42.80 (45.24)
w. ∞-order ($k = 9$)	91.02 (91.51)	**93.08** (**93.84**)	37.58 (39.16)	**49.17** (**51.53**)
TurboParser	**91.56** (**92.02**)	93.05 (93.70)	**40.65** (**41.72**)	48.05 (49.83)

Table 4: Comparison with the TurboParser on PTB-U-23. LEM and UEM are respectively the labelled exact match score and unlabelled exact match score metrics. The numbers in brackets are scores computed excluding punctuation.

on the fly; performs equally with Hayashi et al. (2013) which is a discriminative reranker using the stacked technique; and slightly worse than Bohnet and Kuhn (2012), who develop a hybrid transition-based and graphical-based approach.

6 Related Work

Using neural networks to process trees was first proposed by Pollack (1990) in the Recursive Autoassociative Memory model which was used for unsupervised learning. Socher et al. (2010) later introduced the Recursive Neural Network architecture for supervised learning tasks such as syntactic parsing and sentiment analysis (Socher et al., 2013). Our IORNN is an extension of the RNN: the former can process trees not only bottom-up like the latter but also top-down.

Elman (1990) invented the simple recurrent neural network (SRNN) architecture which is capable of capturing very long histories. Mikolov et al. (2010) then applied it to language modelling and gained state-of-the-art results, outperforming the the standard n-gram techniques such as Kneser-Ney smoothed 5-gram. Our IORNN architecture for dependency parsing bears a resemblance to the SRNN in the sense that it can also capture long 'histories' in context representations (i.e., outer representations in our terminology). Moreover, the IORNN can be seen as a generalization of the SRNN since a left-branching tree is equivalent to a chain and vice versa.

The idea of letting parsing decisions depend on arbitrarily long derivation histories is also explored in Borensztajn and Zuidema (2011) and is related to parsing frameworks that allow arbitrarily large elementary trees (e.g., Scha (1990), O'Donnell et al. (2009), Sangati and Zuidema (2011), and van Cranenburgh and Bod (2013)).

Titov and Henderson (2007) were the first proposing to use deep networks for dependency parsing. They introduced a transition-based generative dependency model using incremental sigmoid belief networks and applied beam pruning for searching best trees. Differing from them, our work uses the IORNN architecture to rescore k-best candidates generated by an independent

graph-based parser, namely the MSTParser.

Reranking k-best lists was introduced by Collins and Koo (2005) and Charniak and Johnson (2005). Their rerankers are discriminative and for constituent parsing. Sangati et al. (2009) proposed to use a third-order generative model for reranking k-best lists of dependency parses. Hayashi et al. (2011) then followed this idea but combined generative models with a variational model learnt on the fly to rerank forests. In this paper, we also followed Sangati et al. (2009)'s idea but used an ∞-order generative model, which has never been used before.

7 Conclusion

In this paper, we proposed a new neural network architecture, the Inside-Outside Recursive Neural Network, that can process trees both bottom-up and top-down. The key idea is to extend the RNN such that every node in the tree has two vectors associated with it: an inner representation for its content, and an outer representation for its context. Inner and outer representations of any constituent can be computed simultaneously and interact with each other. This way, information can flow top-down, bottom-up, inward and outward. Thanks to this property, by applying the IORNN to dependency parses, we have shown that using an ∞-order generative model for dependency parsing, which has never been done before, is practical.

Our experimental results on the English section of the Universal Dependency Treebanks show that the ∞-order generative model approximates the true dependency distribution better than the traditional third-order model using counting, and tends to choose more accurate parses in k-best lists. In addition, reranking with this model even outperforms the state-of-the-art TurboParser on unlabelled score metrics.

A Fast and Accurate Dependency Parser using Neural Networks

Abstract

Almost all current dependency parsers classify based on millions of sparse indicator features. Not only do these features generalize poorly, but the cost of feature computation restricts parsing speed significantly. In this work, we propose a novel way of learning a neural network classifier for use in a greedy, transition-based dependency parser. Because this classifier learns and uses just a small number of dense features, it can work very fast, while achieving an about 2% improvement in unlabeled and labeled attachment scores on both English and Chinese datasets. Concretely, our parser is able to parse more than 1000 sentences per second at 92.2% unlabeled attachment score on the English Penn Treebank.

1 Introduction

In recent years, enormous parsing success has been achieved by the use of feature-based discriminative dependency parsers (Kübler et al., 2009). In particular, for practical applications, the speed of the subclass of transition-based dependency parsers has been very appealing.

However, these parsers are not perfect. First, from a statistical perspective, these parsers suffer from the use of millions of mainly poorly estimated feature weights. While in aggregate both lexicalized features and higher-order interaction term features are very important in improving the performance of these systems, nevertheless, there is insufficient data to correctly weight most such features. For this reason, techniques for introducing higher-support features such as word class features have also been very successful in improving parsing performance (Koo et al., 2008). Second, almost all existing parsers rely on a manually designed set of feature templates, which require a lot of expertise and are usually incomplete. Third, the use of many feature templates cause a less studied problem: in modern dependency parsers, most of the runtime is consumed not by the core parsing algorithm but in the feature extraction step (He et al., 2013). For instance, Bohnet (2010) reports that his baseline parser spends 99% of its time doing feature extraction, despite that being done in standard efficient ways.

In this work, we address all of these problems by using dense features in place of the sparse indicator features. This is inspired by the recent success of distributed word representations in many NLP tasks, e.g., POS tagging (Collobert et al., 2011), machine translation (Devlin et al., 2014), and constituency parsing (Socher et al., 2013). Low-dimensional, dense word embeddings can effectively alleviate sparsity by sharing statistical strength between similar words, and can provide us a good starting point to construct features of words and their interactions.

Nevertheless, there remain challenging problems of how to encode all the available information from the configuration and how to model higher-order features based on the dense representations. In this paper, we train a neural network classifier to make parsing decisions within a transition-based dependency parser. The neural network learns compact dense vector representations of words, part-of-speech (POS) tags, and dependency labels. This results in a fast, compact classifier, which uses only 200 learned dense features while yielding good gains in parsing accuracy and speed on two languages (English and Chinese) and two different dependency representations (CoNLL and Stanford dependencies). The main contributions of this work are: (i) showing the usefulness of dense representations that are learned within the parsing task, (ii) developing a neural network architecture that gives good accuracy and speed, and (iii) introducing a novel acti-

vation function for the neural network that better captures higher-order interaction features.

2 Transition-based Dependency Parsing

Transition-based dependency parsing aims to predict a transition sequence from an initial configuration to some terminal configuration, which derives a target dependency parse tree, as shown in Figure 1. In this paper, we examine only greedy parsing, which uses a classifier to predict the correct transition based on features extracted from the configuration. This class of parsers is of great interest because of their efficiency, although they tend to perform slightly worse than the search-based parsers because of subsequent error propagation. However, our greedy parser can achieve comparable accuracy with a very good speed.[1]

As the basis of our parser, we employ the **arc-standard** system (Nivre, 2004), one of the most popular transition systems. In the arc-standard system, a *configuration* $c = (s, b, A)$ consists of a *stack* s, a *buffer* b, and a set of *dependency arcs* A. The initial configuration for a sentence $w_1, \ldots, w_n$ is $s = [\texttt{ROOT}], b = [w_1, \ldots, w_n], A = \emptyset$. A configuration c is terminal if the buffer is empty and the stack contains the single node `ROOT`, and the parse tree is given by A_c. Denoting s_i $(i = 1, 2, \ldots)$ as the i^{th} top element on the stack, and b_i $(i = 1, 2, \ldots)$ as the i^{th} element on the buffer, the arc-standard system defines three types of transitions:

- `LEFT-ARC`(l): adds an arc $s_1 \rightarrow s_2$ with label l and removes s_2 from the stack. Precondition: $|s| \geq 2$.
- `RIGHT-ARC`(l): adds an arc $s_2 \rightarrow s_1$ with label l and removes s_1 from the stack. Precondition: $|s| \geq 2$.
- `SHIFT`: moves b_1 from the buffer to the stack. Precondition: $|b| \geq 1$.

In the labeled version of parsing, there are in total $|\mathcal{T}| = 2N_l + 1$ transitions, where N_l is number of different arc labels. Figure 1 illustrates an example of one transition sequence from the initial configuration to a terminal one.

The essential goal of a greedy parser is to predict a correct transition from $\mathcal{T}$, based on one given configuration. Information that can be obtained from one configuration includes: (1) all the words and their corresponding POS tags (e.g., `has` / `VBZ`); (2) the head of a word and its label (e.g., `nsubj`, `dobj`) if applicable; (3) the position of a word on the stack/buffer or whether it has already been removed from the stack.

Single-word features (9)	
$s_1.w$; $s_1.t$; $s_1.wt$; $s_2.w$; $s_2.t$;	
$s_2.wt$; $b_1.w$; $b_1.t$; $b_1.wt$	
Word-pair features (8)	
$s_1.wt \circ s_2.wt$; $s_1.wt \circ s_2.w$; $s_1.wts_2.t$;	
$s_1.w \circ s_2.wt$; $s_1.t \circ s_2.wt$; $s_1.w \circ s_2.w$	
$s_1.t \circ s_2.t$; $s_1.t \circ b_1.t$	
Three-word feaures (8)	
$s_2.t \circ s_1.t \circ b_1.t$; $s_2.t \circ s_1.t \circ lc_1(s_1).t$;	
$s_2.t \circ s_1.t \circ rc_1(s_1).t$; $s_2.t \circ s_1.t \circ lc_1(s_2).t$;	
$s_2.t \circ s_1.t \circ rc_1(s_2).t$; $s_2.t \circ s_1.w \circ rc_1(s_2).t$;	
$s_2.t \circ s_1.w \circ lc_1(s_1).t$; $s_2.t \circ s_1.w \circ b_1.t$	

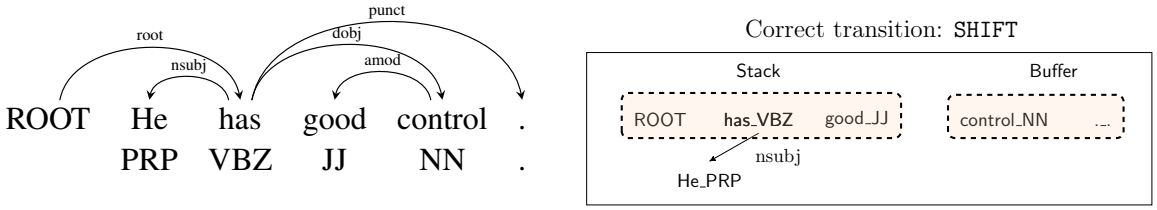
Table 1: The feature templates used for analysis. $lc_1(s_i)$ and $rc_1(s_i)$ denote the leftmost and rightmost children of s_i, w denotes word, t denotes POS tag.

Conventional approaches extract indicator features such as the conjunction of $1 \sim 3$ elements from the stack/buffer using their words, POS tags or arc labels. Table 1 lists a typical set of feature templates chosen from the ones of (Huang et al., 2009; Zhang and Nivre, 2011).[2] These features suffer from the following problems:

- **Sparsity**. The features, especially lexicalized features are highly sparse, and this is a common problem in many NLP tasks. The situation is severe in dependency parsing, because it depends critically on word-to-word interactions and thus the high-order features. To give a better understanding, we perform a feature analysis using the features in Table 1 on the English Penn Treebank (CoNLL representations). The results given in Table 2 demonstrate that: (1) lexicalized features are indispensable; (2) Not only are the word-pair features (especially s_1 and s_2) vital for predictions, the three-word conjunctions (e.g., $\{s_2, s_1, b_1\}$, $\{s_2, lc_1(s_1), s_1\}$) are also very important.

[1] Additionally, our parser can be naturally incorporated with beam search, but we leave this to future work.

[2] We exclude sophisticated features using labels, distance, valency and third-order features in this analysis, but we will include all of them in the final evaluation.



Transition	Stack	Buffer	A

Features	UAS
All features in Table 1	88.0
single-word & word-pair features	82.7
only single-word features	76.9
excluding all lexicalized features	81.5

Table 2: Performance of different feature sets. UAS: unlabeled attachment score.

- **Incompleteness**. Incompleteness is an unavoidable issue in all existing feature templates. Because even with expertise and manual handling involved, they still do not include the conjunction of every useful word combination. For example, the conjunction of s_1 and b_2 is omitted in almost all commonly used feature templates, however it could indicate that we cannot perform a RIGHT-ARC action if there is an arc from s_1 to b_2.
- **Expensive feature computation**. The feature generation of indicator features is generally expensive — we have to concatenate some words, POS tags, or arc labels for generating feature strings, and look them up in a huge table containing several millions of features. In our experiments, more than 95% of the time is consumed by feature computation during the parsing process.

So far, we have discussed preliminaries of transition-based dependency parsing and existing problems of sparse indicator features. In the following sections, we will elaborate our neural network model for learning dense features along with experimental evaluations that prove its efficiency.

3 Neural Network Based Parser

In this section, we first present our neural network model and its main components. Later, we give details of training and speedup of parsing process.

3.1 Model

Figure 2 describes our neural network architecture. First, as usual word embeddings, we represent each word as a d-dimensional vector $e_i^w \in \mathbb{R}^d$ and the full embedding matrix is $E^w \in \mathbb{R}^{d\times N_w}$ where N_w is the dictionary size. Meanwhile, we also map POS tags and arc labels to a d-dimensional vector space, where $e_i^t, e_j^l \in \mathbb{R}^d$ are the representations of i^{th} POS tag and j^{th} arc label. Correspondingly, the POS and label embedding matrices are $E^t \in \mathbb{R}^{d\times N_t}$ and $E^l \in \mathbb{R}^{d\times N_l}$ where N_t and N_l are the number of distinct POS tags and arc labels.

We choose a set of elements based on the stack / buffer positions for each type of information (word, POS or label), which might be useful for our predictions. We denote the sets as S^w, S^t, S^l respectively. For example, given the configuration in Figure 2 and $S^t =$

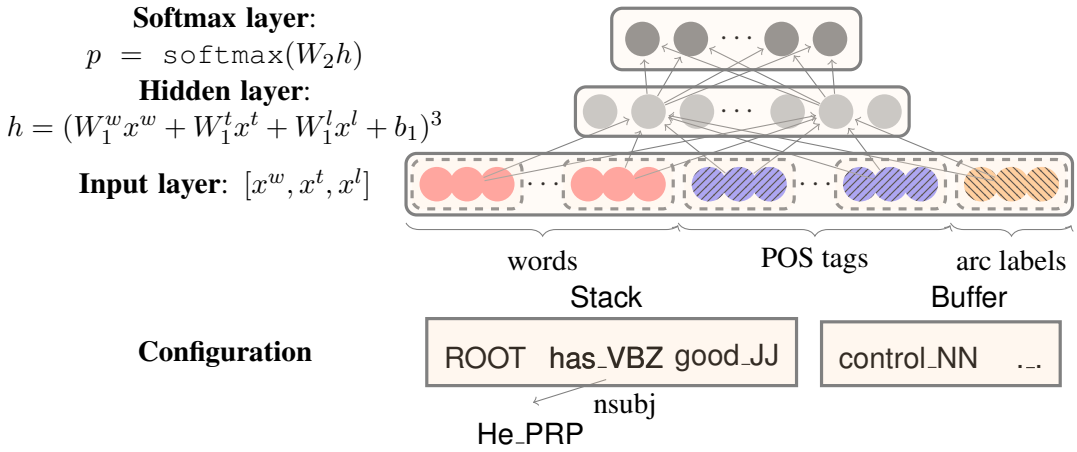

Figure 2: Our neural network architecture.

$\{lc_1(s_2).t, s_2.t, rc_1(s_2).t, s_1.t\}$, we will extract PRP, VBZ, NULL, JJ in order. Here we use a special token NULL to represent a non-existent element.

We build a standard neural network with one hidden layer, where the corresponding embeddings of our chosen elements from S^w, S^t, S^l will be added to the input layer. Denoting n_w, n_t, n_l as the number of chosen elements of each type, we add $x^w = [e^w_{w_1}; e^w_{w_2}; \dots e^w_{w_{n_w}}]$ to the input layer, where $S^w = \{w_1, \dots, w_{n_w}\}$. Similarly, we add the POS tag features x^t and arc label features x^l to the input layer.

We map the input layer to a hidden layer with d_h nodes through a **cube activation function**:

$$h = (W_1^w x^w + W_1^t x^t + W_1^l x^l + b_1)^3$$

where $W_1^w \in \mathbb{R}^{d_h \times (d \cdot n_w)}$, $W_1^t \in \mathbb{R}^{d_h \times (d \cdot n_t)}$, $W_1^l \in \mathbb{R}^{d_h \times (d \cdot n_l)}$, and $b_1 \in \mathbb{R}^{d_h}$ is the bias.

A softmax layer is finally added on the top of the hidden layer for modeling multi-class probabilities $p = \texttt{softmax}(W_2 h)$, where $W_2 \in \mathbb{R}^{|\mathcal{T}| \times d_h}$.

POS and label embeddings

To our best knowledge, this is the first attempt to introduce POS tag and arc label embeddings instead of discrete representations.

Although the POS tags $\mathcal{P}$ = {NN, NNP, NNS, DT, JJ, ...} (for English) and arc labels $\mathcal{L}$ = {amod, tmod, nsubj, csubj, dobj, ...} (for Stanford Dependencies on English) are relatively small discrete sets, they still exhibit many semantical similarities like words. For example, NN (singular noun) should be closer to NNS (plural noun) than DT (determiner), and amod (adjective modifier) should be closer to num (numeric modifier) than nsubj (nominal subject). We expect these semantic meanings to be effectively captured by the dense representations.

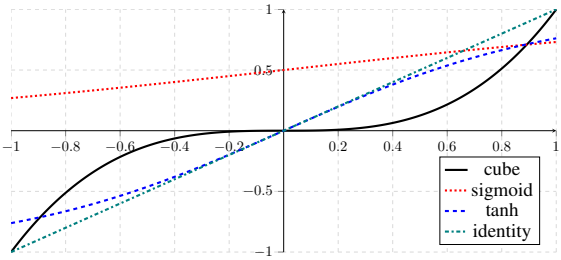

Figure 3: Different activation functions used in neural networks.

Cube activation function

As stated above, we introduce a novel activation function: cube $g(x) = x^3$ in our model instead of the commonly used tanh or sigmoid functions (Figure 3).

Intuitively, every hidden unit is computed by a (non-linear) mapping on a weighted sum of input units plus a bias. Using $g(x) = x^3$ can model the product terms of $x_i x_j x_k$ for any three different elements at the input layer directly:

$$g(w_1 x_1 + \dots + w_m x_m + b) = \sum_{i,j,k} (w_i w_j w_k) x_i x_j x_k + \sum_{i,j} b(w_i w_j) x_i x_j \dots$$

In our case, x_i, x_j, x_k could come from different dimensions of three embeddings. We believe that this better captures the interaction of three ele-

ments, which is a very desired property of dependency parsing.

Experimental results also verify the success of the cube activation function empirically (see more comparisons in Section 4). However, the expressive power of this activation function is still open to investigate theoretically.

The choice of S^w, S^t, S^l

Following (Zhang and Nivre, 2011), we pick a rich set of elements for our final parser. In detail, S^w contains $n_w = 18$ elements: (1) The top 3 words on the stack and buffer: $s_1, s_2, s_3, b_1, b_2, b_3$; (2) The first and second leftmost / rightmost children of the top two words on the stack: $lc_1(s_i), rc_1(s_i), lc_2(s_i), rc_2(s_i),\ i = 1, 2$. (3) The leftmost of leftmost / rightmost of rightmost children of the top two words on the stack: $lc_1(lc_1(s_i)), rc_1(rc_1(s_i)), i = 1, 2$.

We use the corresponding POS tags for S^t ($n_t = 18$), and the corresponding arc labels of words excluding those 6 words on the stack/buffer for S_l ($n_l = 12$). A good advantage of our parser is that we can add a rich set of elements cheaply, instead of hand-crafting many more indicator features.

3.2 Training

We first generate training examples $\{(c_i, t_i)\}_{i=1}^m$ from the training sentences and their gold parse trees using a "shortest stack" oracle which always prefers $\texttt{LEFT-ARC}_l$ over $\texttt{SHIFT}$, where c_i is a configuration, $t_i \in \mathcal{T}$ is the oracle transition.

The final training objective is to minimize the cross-entropy loss, plus a l_2-regularization term:

$$L(\theta) = -\sum_i \log p_{t_i} + \frac{\lambda}{2}\|\theta\|^2$$

where θ is the set of all parameters $\{W_1^w, W_1^t, W_1^l, b_1, W_2, E^w, E^t, E^l\}$. A slight variation is that we compute the softmax probabilities only among the feasible transitions in practice.

For initialization of parameters, we use pre-trained word embeddings to initialize E^w and use random initialization within $(-0.01, 0.01)$ for E^t and E^l. Concretely, we use the pre-trained word embeddings from (Collobert et al., 2011) for English (#dictionary = 130,000, coverage = 72.7%), and our trained 50-dimensional `word2vec` embeddings (Mikolov et al., 2013) on Wikipedia and Gigaword corpus for Chinese (#dictionary = 285,791, coverage = 79.0%). We will also compare with random initialization of E^w in Section 4. The training error derivatives will be back-propagated to these embeddings during the training process.

We use mini-batched AdaGrad (Duchi et al., 2011) for optimization and also apply a dropout (Hinton et al., 2012) with 0.5 rate. The parameters which achieve the best unlabeled attachment score on the development set will be chosen for final evaluation.

3.3 Parsing

We perform greedy decoding in parsing. At each step, we extract all the corresponding word, POS and label embeddings from the current configuration c, compute the hidden layer $h(c) \in \mathbb{R}^{d_h}$, and pick the transition with the highest score: $t = \arg\max_{t \text{ is feasible}} W_2(t, \cdot)h(c)$, and then execute $c \rightarrow t(c)$.

Comparing with indicator features, our parser does not need to compute conjunction features and look them up in a huge feature table, and thus greatly reduces feature generation time. Instead, it involves many matrix addition and multiplication operations. To further speed up the parsing time, we apply a **pre-computation** trick, similar to (Devlin et al., 2014). For each position chosen from S^w, we pre-compute matrix multiplications for most top frequent $10,000$ words. Thus, computing the hidden layer only requires looking up the table for these frequent words, and adding the d_h-dimensional vector. Similarly, we also pre-compute matrix computations for all positions and all POS tags and arc labels. We only use this optimization in the neural network parser, but it is only feasible for a parser like the neural network parser which uses a small number of features. In practice, this pre-computation step increases the speed of our parser $8 \sim 10$ times.

4 Experiments

4.1 Datasets

We conduct our experiments on the English Penn Treebank (PTB) and the Chinese Penn Treebank (CTB) datasets.

For English, we follow the standard splits of `PTB3`, using sections 2-21 for training, section 22 as development set and 23 as test set. We adopt two different dependency representations: CoNLL Syntactic Dependencies (CD) (Johansson

Dataset	#Train	#Dev	#Test	#words (N_w)	#POS (N_t)	#labels (N_l)	projective (%)
PTB: CD	39,832	1,700	2,416	44,352	45	17	99.4
PTB: SD	39,832	1,700	2,416	44,389	45	45	99.9
CTB	16,091	803	1,910	34,577	35	12	100.0

Table 3: Data Statistics. "Projective" is the percentage of projective trees on the training set.

and Nugues, 2007) using the LTH Constituent-to-Dependency Conversion Tool[3] and Stanford Basic Dependencies (SD) (de Marneffe et al., 2006) using the Stanford parser v3.3.0.[4] The POS tags are assigned using Stanford POS tagger (Toutanova et al., 2003) with ten-way jackknifing of the training data (accuracy $\approx 97.3\%$).

For Chinese, we adopt the same split of `CTB5` as described in (Zhang and Clark, 2008). Dependencies are converted using the Penn2Malt tool[5] with the head-finding rules of (Zhang and Clark, 2008). And following (Zhang and Clark, 2008; Zhang and Nivre, 2011), we use gold segmentation and POS tags for the input.

Table 3 gives statistics of the three datasets.[6] In particular, over 99% of the trees are projective in all datasets.

4.2 Results

The following hyper-parameters are used in all experiments: embedding size $d = 50$, hidden layer size $h = 200$, regularization parameter $\lambda = 10^{-8}$, initial learning rate of Adagrad $\alpha = 0.01$.

To situate the performance of our parser, we first make a comparison with our own implementation of greedy arc-eager and arc-standard parsers. These parsers are trained with structured averaged perceptron using the "early-update" strategy. The feature templates of (Zhang and Nivre, 2011) are used for the arc-eager system, and they are also adapted to the arc-standard system.[7]

Furthermore, we also compare our parser with two popular, off-the-shelf parsers: MaltParser — a greedy transition-based dependency parser (Nivre et al., 2006),[8] and MSTParser — a first-order graph-based parser (McDonald and Pereira, 2006).[9] In this comparison, for MaltParser, we select `stackproj` (arc-standard) and `nivreeager` (arc-eager) as parsing algorithms, and liblinear (Fan et al., 2008) for optimization.[10] For MSTParser, we use default options.

On all datasets, we report unlabeled attachment scores (UAS) and labeled attachment scores (LAS) and punctuation is excluded in all evaluation metrics.[11] Our parser and the baseline arc-standard and arc-eager parsers are all implemented in Java. The parsing speeds are measured on an Intel Core i7 2.7GHz CPU with 16GB RAM and the runtime does not include pre-computation or parameter loading time.

Table 4, Table 5 and Table 6 show the comparison of accuracy and parsing speed on PTB (CoNLL dependencies), PTB (Stanford dependencies) and CTB respectively.

Parser	Dev		Test		Speed
	UAS	LAS	UAS	LAS	(sent/s)
standard	89.9	88.7	89.7	88.3	51
eager	90.3	89.2	89.9	88.6	63
Malt:sp	90.0	88.8	89.9	88.5	560
Malt:eager	90.1	88.9	90.1	88.7	535
MSTParser	92.1	90.8	**92.0**	90.5	12
Our parser	**92.2**	**91.0**	**92.0**	**90.7**	**1013**

Table 4: Accuracy and parsing speed on PTB + CoNLL dependencies.

Clearly, our parser is superior in terms of both accuracy and speed. Comparing with the baselines of arc-eager and arc-standard parsers, our parser achieves around 2% improvement in UAS and LAS on all datasets, while running about 20 times faster.

It is worth noting that the efficiency of our

[9] http://www.seas.upenn.edu/ strctlrn/MSTParser/MSTParser.html

[10] We do not compare with libsvm optimization, which is known to be sightly more accurate, but orders of magnitude slower (Kong and Smith, 2014).

[11] A token is a punctuation if its gold POS tag is {" " : , .} for English and `PU` for Chinese.

Parser	Dev		Test		Speed
	UAS	LAS	UAS	LAS	(sent/s)
standard	90.2	87.8	89.4	87.3	26
eager	89.8	87.4	89.6	87.4	34
Malt:sp	89.8	87.2	89.3	86.9	469
Malt:eager	89.6	86.9	89.4	86.8	448
MSTParser	91.4	88.1	90.7	87.6	10
Our parser	**92.0**	**89.7**	**91.8**	**89.6**	**654**

Table 5: Accuracy and parsing speed on PTB + Stanford dependencies.

Parser	Dev		Test		Speed
	UAS	LAS	UAS	LAS	(sent/s)
standard	82.4	80.9	82.7	81.2	72
eager	81.1	79.7	80.3	78.7	80
Malt:sp	82.4	80.5	82.4	80.6	420
Malt:eager	81.2	79.3	80.2	78.4	393
MSTParser	**84.0**	82.1	83.0	81.2	6
Our parser	**84.0**	**82.4**	**83.9**	**82.4**	**936**

Table 6: Accuracy and parsing speed on CTB.

parser even surpasses MaltParser using liblinear, which is known to be highly optimized, while our parser achieves much better accuracy.

Also, despite the fact that the graph-based MSTParser achieves a similar result to ours on PTB (CoNLL dependencies), our parser is nearly 100 times faster. In particular, our transition-based parser has a great advantage in LAS, especially for the fine-grained label set of Stanford dependencies.

4.3 Effects of Parser Components

Herein, we examine components that account for the performance of our parser.

Cube activation function

We compare our `cube` activation function (x^3) with two widely used non-linear functions: `tanh` ($\frac{e^x-e^{-x}}{e^x+e^{-x}}$), `sigmoid` ($\frac{1}{1+e^{-x}}$), and also the `identity` function (x), as shown in Figure 4 (left).

In short, `cube` outperforms all other activation functions significantly and `identity` works the worst. Concretely, `cube` can achieve $0.8\% \sim 1.2\%$ improvement in UAS over `tanh` and other functions, thus verifying the effectiveness of the cube activation function empirically.

Initialization of pre-trained word embeddings

We further analyze the influence of using pre-trained word embeddings for initialization. Figure 4 (middle) shows that using pre-trained word embeddings can obtain around 0.7% improvement on PTB and 1.7% improvement on CTB, compared with using random initialization within $(-0.01, 0.01)$. On the one hand, the pre-trained word embeddings of Chinese appear more useful than those of English; on the other hand, our model is still able to achieve comparable accuracy without the help of pre-trained word embeddings.

POS tag and arc label embeddings

As shown in Figure 4 (right), POS embeddings yield around 1.7% improvement on PTB and nearly 10% improvement on CTB and the label embeddings yield a much smaller 0.3% and 1.4% improvement respectively.

However, we can obtain little gain from label embeddings when the POS embeddings are present. This may be because the POS tags of two tokens already capture most of the label information between them.

4.4 Model Analysis

Last but not least, we will examine the parameters we have learned, and hope to investigate what these dense features capture. We use the weights learned from the English Penn Treebank using Stanford dependencies for analysis.

What do E^t, E^l capture?

We first introduced E^t and E^l as the dense representations of all POS tags and arc labels, and we wonder whether these embeddings could carry some semantic information.

Figure 5 presents t-SNE visualizations (van der Maaten and Hinton, 2008) of these embeddings. It clearly shows that these embeddings effectively exhibit the similarities between POS tags or arc labels. For instance, the three adjective POS tags `JJ`, `JJR`, `JJS` have very close embeddings, and also the three labels representing clausal complements `acomp`, `ccomp`, `xcomp` are grouped together.

Since these embeddings can effectively encode the semantic regularities, we believe that they can be also used as alternative features of POS tags (or arc labels) in other NLP tasks, and help boost the performance.

What do W_1^w, W_1^t, W_1^l capture?

Knowing that E^t and E^l (as well as the word embeddings E^w) can capture semantic information very well, next we hope to investigate what each feature in the hidden layer has really learned.

Since we currently only have $h = 200$ learned dense features, we wonder if it is sufficient to learn the word conjunctions as sparse indicator features, or even more. We examine the weights $W_1^w(k, \cdot) \in \mathbb{R}^{d \cdot n_w}$, $W_1^t(k, \cdot) \in \mathbb{R}^{d \cdot n_t}$, $W_1^l(k, \cdot) \in \mathbb{R}^{d \cdot n_l}$ for each hidden unit k, and reshape them to $d \times n_t$, $d \times n_w$, $d \times n_l$ matrices, such that the weights of each column corresponds to the embeddings of one specific element (e.g., $s_1.t$).

We pick the weights with absolute value > 0.2, and visualize them for each feature. Figure 6 gives the visualization of three sampled features, and it exhibits many interesting phenomena:

- Different features have varied distributions of the weights. However, most of the discriminative weights come from W_1^t (the middle zone in Figure 6), and this further justifies the importance of POS tags in dependency parsing.
- We carefully examine many of the $h = 200$ features, and find that they actually encode very different views of information. For the three sampled features in Figure 6, the largest weights are dominated by:
  - Feature 1: $s_1.t, s_2.t, lc(s_1).t.$
  - Feautre 2: $rc(s_1).t, s_1.t, b_1.t.$
  - Feature 3: $s_1.t, s_1.w, lc(s_1).t, lc(s_1).l.$

  These features all seem very plausible, as observed in the experiments on indicator feature systems. Thus our model is able to automatically identify the most useful information for predictions, instead of hand-crafting them as indicator features.
- More importantly, we can extract features regarding the conjunctions of more than 3 elements easily, and also those not presented in the indicator feature systems. For example, the 3rd feature above captures the conjunction of words and POS tags of s_1, the tag of its leftmost child, and also the label between them, while this information is not encoded in the original feature templates of (Zhang and Nivre, 2011).

5 Related Work

There have been several lines of earlier work in using neural networks for parsing which have points of overlap but also major differences from our work here. One big difference is that much early work uses localist one-hot word representations rather than the distributed representations of modern work. (Mayberry III and Miikkulainen, 1999) explored a shift reduce constituency parser with one-hot word representations and did subsequent parsing work in (Mayberry III and Miikkulainen, 2005).

(Henderson, 2004) was the first to attempt to use neural networks in a broad-coverage Penn Treebank parser, using a simple synchrony network to predict parse decisions in a constituency parser. More recently, (Titov and Henderson, 2007) applied Incremental Sigmoid Belief Networks to constituency parsing and then (Garg and Henderson, 2011) extended this work to transition-based dependency parsers using a Temporal Restricted Boltzman Machine. These are very different neural network architectures, and are much less scalable and in practice a restricted vocabulary was used to make the architecture practical.

There have been a number of recent uses of deep learning for constituency parsing (Collobert, 2011; Socher et al., 2013). (Socher et al., 2014) has also built models over dependency representations but this work has not attempted to learn neural networks for dependency parsing.

Most recently, (Stenetorp, 2013) attempted to build recursive neural networks for transition-based dependency parsing, however the empirical performance of his model is still unsatisfactory.

6 Conclusion

We have presented a novel dependency parser using neural networks. Experimental evaluations show that our parser outperforms other greedy parsers using sparse indicator features in both accuracy and speed. This is achieved by representing all words, POS tags and arc labels as dense vectors, and modeling their interactions through a novel cube activation function. Our model only relies on dense features, and is able to automatically learn the most useful feature conjunctions for making predictions.

An interesting line of future work is to combine our neural network based classifier with search-based models to further improve accuracy. Also,

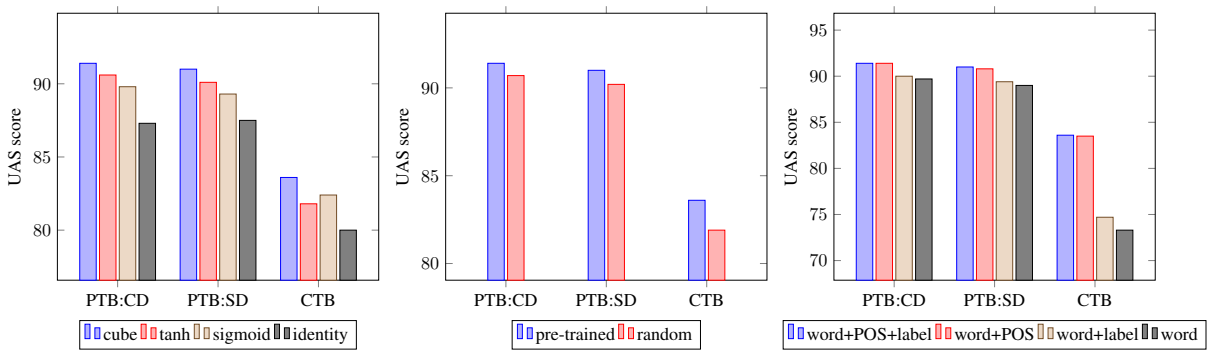

Figure 4: Effects of different parser components. Left: comparison of different activation functions. Middle: comparison of pre-trained word vectors and random initialization. Right: effects of POS and label embeddings.

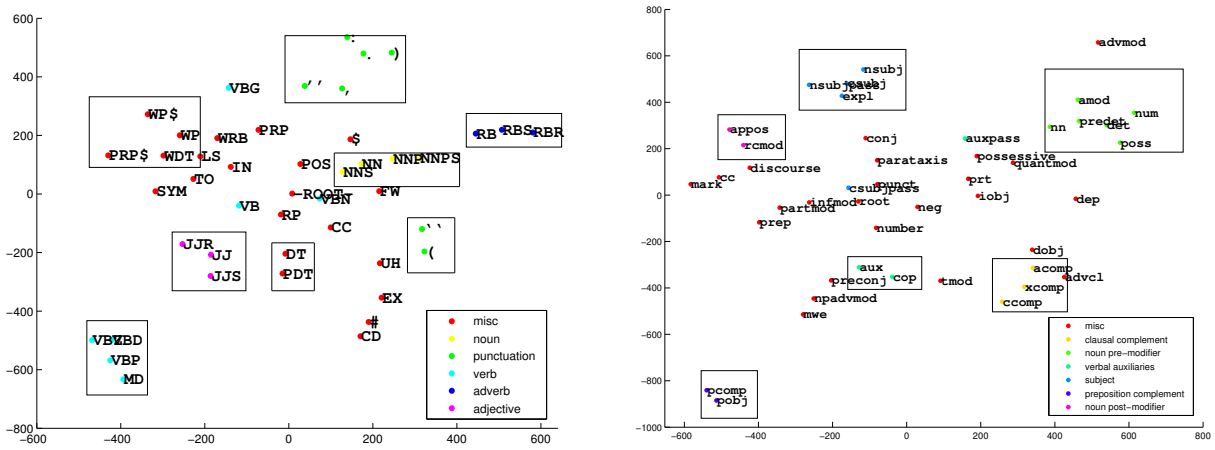

Figure 5: t-SNE visualization of POS and label embeddings.

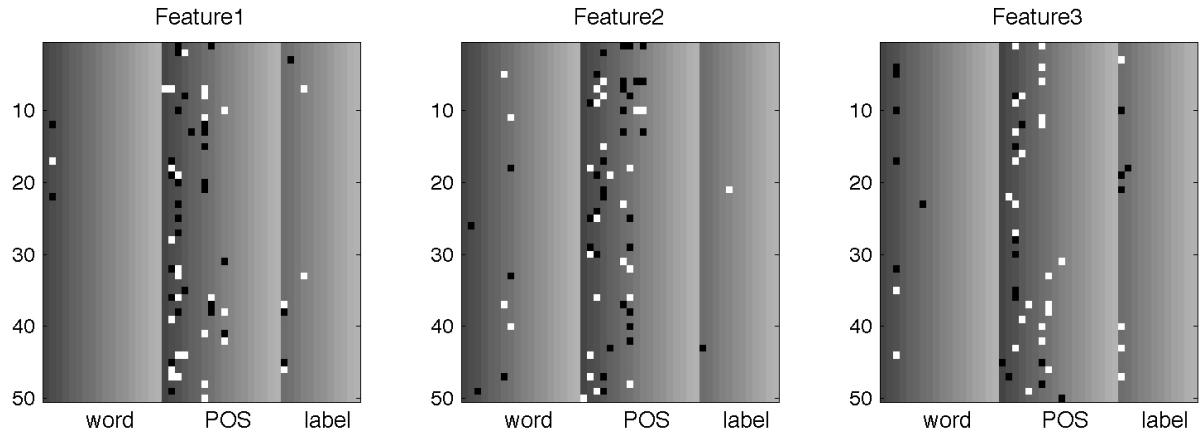

Figure 6: Three sampled features. In each feature, each row denotes a dimension of embeddings and each column denotes a chosen element, e.g., $s_1.t$ or $lc(s_1).w$, and the parameters are divided into 3 zones, corresponding to $W_1^w(k,:)$ (left), $W_1^t(k,:)$ (middle) and $W_1^l(k,:)$ (right). White and black dots denote the most positive weights and most negative weights respectively.

there is still room for improvement in our architecture, such as better capturing word conjunctions, or adding richer features (e.g., distance, valency).

Why are You Taking this Stance? Identifying and Classifying Reasons in Ideological Debates

Kazi Saidul Hasan and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{saidul,vince}@hlt.utdallas.edu

Abstract

Recent years have seen a surge of interest in stance classification in online debates. Oftentimes, however, it is important to determine not only the stance expressed by an author in her debate posts, but also the reasons behind her supporting or opposing the issue under debate. We therefore examine the new task of reason classification in this paper. Given the close interplay between stance classification and reason classification, we design computational models for examining how automatically computed stance information can be profitably exploited for reason classification. Experiments on our reason-annotated corpus of ideological debate posts from four domains demonstrate that sophisticated models of stances and reasons can indeed yield more accurate reason and stance classification results than their simpler counterparts.

1 Introduction

In recent years, researchers have begun exploring new opinion mining tasks. One such task is *debate stance classification* (SC): given a post written for a *two-sided* topic discussed in an online debate forum, determine which of the two sides (i.e., *for* or *against*) its author is taking (Agrawal et al., 2003; Thomas et al., 2006; Bansal et al., 2008; Somasundaran and Wiebe, 2009; Burfoot et al., 2011; Hasan and Ng, 2013b). For example, the author of the post shown in Figure 1 is pro-abortion.

Oftentimes, however, it is important to determine not only the author's stance expressed in her debate posts, but also the reasons why she supports or opposes the issue under debate. Intuitively, given a debate topic such as *"Should abortion be banned?"* or *"Do you support Obamacare?"*, it should not be difficult for us to come up with a set of reasons people typically use to back up their stances. Given a set of reasons associated with each stance in an online debate, the goal of *post-level reason classification* is to identify those reason(s) an author uses to back up her stance in her debate post. A more challenging version of this task is *sentence-level reason classification*, where the goal is to identify not only the reason(s) an author uses in her post, but also the sentence(s) in the post that the author uses to describe each of her reasons. For example, the author of the post shown in Figure 1 mentions two reasons why she supports abortion, namely *it's a woman's right to abort* and *unwanted babies are threat to their parents' future*, which are mentioned in the first and third sentences in the post respectively.

> [I feel that abortion should remain legal, or rather, parents should have the power to make the decision themselves and not face any legal hindrance of any form.][1] Let us take a look from the social perspective. [If parents cannot afford to provide for the child, or if the family is facing financial constraints, it is understandable that abortion can remain as one of the options.][2]
>
> **Reason 1:** Woman's right to abort
> **Reason 2:** Unwanted babies are threat to their parents' future

Figure 1: A sample post on abortion annotated with reasons.

Our goal in this paper is to examine post- and sentence-level reason classification (RC) in *ideological debates*. Many online debaters use emotional languages, which may involve sarcasm and insults, to express their points, thereby making RC and SC in ideological debates potentially more challenging than that in other debate settings such as congressional debates and company-internal discussions (Walker et al., 2012).

Besides examining the new task of RC in ideological debates, we believe that our work makes three contributions. First, we propose to address post-level RC by means of sentence-level RC by

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 751–762,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

(1) determining the reason(s) associated with each of its sentences (if any), and then (2) taking the union of the set of reasons associated with all of its sentences to be the set of reasons associated with the post. We hypothesize that this sentence-based approach, which exploits a training set in which each sentence in a post is labeled with its reason, would achieve better performance than a *multi-label* text classification approach to post-level RC, which learns to determine the subset of reasons a post contains directly from a training set in which each post is labeled with the corresponding set of reasons. In other words, we hypothesize that we could achieve better results for post-level RC by learning from *sentence-level* than from *post-level* reason annotations, as sentence-level reason annotations can enable a learning algorithm to accurately attribute an annotated reason to a particular portion of a post.

Second, we propose *stance-supported* RC systems, hypothesizing that *automatically computed* stance information can be profitably exploited for RC. Since we are exploiting automatically computed (and thus potentially noisy) stance information, we hypothesize that the effectiveness of such information would depend in part on the way it is exploited in RC systems. As a result, we introduce a set of stance-supported models for RC, starting with simple pipeline models and then moving on to joint models with increasing sophistication. Note that exploiting stance information by no means guarantees that RC performance will improve, as an incorrect determination of stance could lead to an incorrect identification of reasons. Hence, one of our goals is to examine how to model stances and reasons so that RC can benefit from stance information.

Finally, since progress on RC is hindered in part by the lack of an annotated corpus, we make our reason-annotated dataset publicly available.[1] To our knowledge, this will be the first publicly available corpus for sentence- and post-level RC.

2 Corpus and Annotation

We collected debate posts from four popular *domains*, Abortion (ABO), Gay Rights (GAY), Obama (OBA), and Marijuana (MAR), from an online debate forum[2]. All debates are two-sided, so each post receives one of two *stance labels*, *for* or *against*, depending on whether the author of the post *supports* or *opposes* abortion, gay rights, Obama, or the legalization of marijuana respectively. A post's stance label is given by its author.

Note that each post belongs to a *thread*, which is a tree with one or more nodes such that (1) each node corresponds to a debate post, and (2) a post y_i is the parent of another post y_j if y_j is a reply to y_i. Given a thread, we generate *post sequences*, each of which is a path from the root of the thread to one of its leaves. Hence, a post sequence is an ordered set of posts such that each post is a reply to its immediately preceding post in the sequence. Table 2a shows the statistics of the four stance-labeled datasets.

While the debate posts contain the stance labels given by their authors, they are not annotated with reasons. As part of our study of RC, we annotate each post with the reasons it gives for its stance. Our annotation procedure is composed of three steps. First, two human annotators independently examined each post and identified the reasons authors present to support their stances (i.e., *for* and *against*) in each domain. Second, they discussed and agreed on the reasons identified for each domain. Third, they independently annotated the text of each post with reason labels from the post's domain. To do this, they labeled each sentence of a post with the set of reasons the author expressed in that sentence. Any sentence that does not belong to any reason class was assigned the NONE class.

After the annotators completed the aforementioned steps, they were asked to collapse all the reason classes that occur in less than 2% of the sentences annotated with non-NONE classes into the OTHER class. In other words, all the sentences that were originally annotated with one of these infrequent reason classes will now be labeled as OTHER. Our decision to merge infrequent classes is motivated by two observations. First, from a practical point of view, infrequent reasons do not carry much weight. Second, from a modeling perspective, it is often not worth increasing model complexity by handling infrequent classes. The resulting set of reason classes for each domain is shown in Table 1.

A closer examination of the resulting annotations reveals that approximately 3% of the sentences received multiple reason labels. Again, to avoid the complexity of modeling multi-labeled

Domain	Stance	Reason classes
ABO	*for*	[F1] Abortion is a woman's right (26%); [F2] Rape victims need it to be legal (7%); [F3] A fetus is not human (38%); [F4] Mother's life in danger (5%); [F5] Unwanted babies are ill-treated by parents (8%); [F6] Birth control fails at times (3%); [F7] Abortion is not murder (3%); [F8] Mother is not healthy/financially solvent (4%); [F9] Others (6%)
	against	[A1] Put baby up for adoption (9%); [A2] Abortion kills a life (29%); [A3] An unborn baby is a human and has the right to live (40%); [A4] Be willing to have the baby if you have sex (14%); [A5] Abortion is harmful for women (5%); [A6] Others (3%)
GAY	*for*	[F1] Gay marriage is like any other marriage (14%); [F2] Gay people should have the same rights as straight people (36%); [F3] Gay parents can adopt and ensure a happy life for a baby (10%); [F4] People are born gay (18%); [F5] Religion should not be used against gay rights (11%); [F6] Others (11%)
	against	[A1] Religion does not permit gay marriages (18%); [A2] Gay marriages are not normal/against nature (39%); [A3] Gay parents can not raise kids properly (11%); [A4] Gay people have problems and create social issues (16%); [A5] Others (16%)
OBA	*for*	[F1] Fixed the economy (21%); [F2] Ending the wars (7%); [F3] Better than the republican candidates (25%); [F4] Makes good decisions/policies (8%); [F5] Has qualities of a good leader (14%); [F6] Ensured better healthcare (8%); [F7] Executed effective foreign policies (6%); [F8] Created more jobs (4%); [F9] Others (7%)
	against	[A1] Destroyed our economy (26%); [A2] Wars are still on (11%); [A3] Unemployment rate is high (5%); [A4] Healthcare bill is a failure(9%); [A5] Poor decision-maker (7%); [A6] We have better republicans than Obama (5%); [A7] Not eligible as a leader (20%); [A8] Ineffective foreign policies (4%); [A9] Others (13%)
MAR	*for*	[F1] Not addictive (23%); [F2] Used as a medicine (11%); [F3] Legalized marijuana can be controlled and regulated by the government (33%); [F4] Prohibition violates human rights (15%); [F5] Does not cause any damage to our bodies (6%); [F6] Others (12%)
	against	[A1] Damages our bodies (23%); [A2] Responsible for brain damage (22%); [A3] If legalized, people will use marijuana and other drugs more (12%); [A4] Causes crime (9%); [A5] Highly addictive (17%); [A6] Others (17%)

Table 1: Reason classes and their percentages in the corresponding stance for each domain.

sentences given their rarity, we asked each annotator to pick the reason that was highlighted the most in each multi-labeled sentence.

Inter-annotator agreement scores at the sentence level and the post level, expressed in terms of Cohen's Kappa (Carletta, 1996), are shown in Table 2b. Given that the majority of sentences were labeled as NONE, we avoid inflating agreement by *not* considering the sentences labeled with NONE by both annotators when computing Kappa. As we can see, we achieved substantial post-level agreement and high sentence-level agreement.

The major source of inter-annotator disagreement for all four datasets stems from the fact that in many cases, the annotators, while agreeing on the reason class, differ on how long the text span for a reason should be. This hurts sentence-level agreement but not post-level agreement, since the latter only concerns *whether* a reason was mentioned in a post, and explains why the sentence-level agreement scores are lower than the corresponding post-level scores. Minor sources of disagreement arise from the facts that (1) the annotators selected different reason labels for some of the multi-labeled sentences, and (2) they tend to disagree in some cases where authors use sarcasm to present a reason. Each case of disagreement is resolved through discussion among the annotators.

3 Baseline RC System

Our baseline system uses a maximum entropy (MaxEnt) classifier to determine whether a reason is expressed in a post and/or its sentence(s). We create one training instance for each sentence in each post in the training set, using the reason label as its class label. We represent each instance using five types of features, as described below.

N-gram features. We encode each unigram and bigram collected from the training sentences as a

binary feature indicating the n-gram's presence or absence in a given sentence.

Dependency-based features. To capture the inter-word relationships that n-grams may not, we employ the dependency-based features previously used for stance classification in Anand et al. (2011). These features have three variants. In the first variant, the pair of arguments involved in each dependency relation extracted by a dependency parser is used as a feature. The second variant is the same as the first except that the head (i.e., the first argument in a relation) is replaced by its part-of-speech tag. The features in the third variant, the topic-opinion features, are created by replacing each sentiment-bearing word in features of the first two types with its corresponding polarity label (i.e., + or −).

Frame-semantic features. While dependency-based features capture the syntactic dependencies, frame-semantic features encode the semantic representation of the concepts in a sentence. Following our previous work on stance classification (Hasan and Ng, 2013c), we employ three types of features computed based on the frame-semantic parse of each sentence in a post obtained from SEMAFOR (Das et al., 2010). *Frame-word interaction* features encode whether two words appear in different elements of the same frame. Hence, each frame-word interaction feature consists of (1) the name of the frame f from which it is created, and (2) an unordered word pair in which the words are taken from two frame elements of f. A *frame-pair* feature is represented as a word pair corresponding to the names of two frames and encodes whether the target word of the first frame appears within an element of the second frame. Finally, *frame n-gram* features are a variant of word n-grams. For each word n-gram in the sentence, a frame n-gram feature is created by replacing one or more words in the word n-gram with the name of the frame or the frame element in which the word appears. A detailed description of these features can be found in Hasan and Ng (2013c).

Quotation features. We employ two quotation features. *IsQuote* is a binary feature that indicates whether a sentence is a quote or not (i.e., whether it appeared in its parent post in the post sequence). Note that if an instance is a quote from a previous post, it is unlikely that it represents a reason the author is presenting to support her argument. Instead, the author may have quoted this before stating her counter-argument. *FollowsQuote* is a binary feature that indicates whether a sentence follows a sentence for which the *IsQuote* feature value is *true*. Intuitively, a sentence following a quote is likely to present a counter-argument.

Positional feature. We split each post into four parts (such that each part contains roughly the same number of sentences) and create one positional feature that encodes which part of the post contains a given sentence. This feature is motivated by our observations on the training data that (1) reasons are more likely to appear in the second half of a post and (2) on average more than one-third of the reasons appear in the last quarter of a post.

After training, we can apply the resulting RC system to classify the test instances, which are generated in the same way as the training instances. Once the sentences of a test post are classified, we simply assume its post-level reason labels to be the set of reason labels assigned by the classifier to its sentences.

4 Stance-Supported RC Systems

In this section, we propose a set of systems for RC. Unlike the baseline RC system, these RC systems are *stance-supported*, enabling us to explore how different ways of modeling automatically computed stances and reasons can improve RC classification. Below we present our systems in increasing order of modeling sophistication.

4.1 Pipeline Systems

We examine two pipeline systems, P1 and P2. Given a set of test posts, both systems first determine the stance of each post and then apply a stance-specific *reason classifier* to each of them.

More specifically, both P1 and P2 employ two stance-specific reason classifiers: one is trained on all the posts labeled as *for* and the other is trained on all the posts labeled as *against*. Each stance-specific reason classifier is trained using MaxEnt on the same feature set as that of the Baseline RC system. It computes for a particular stance s the probability $P(r|s,t)$, where r is a reason label and t is a sentence in a test post p.

P1 and P2 differ only with respect to the SC model used to stance-label each post. In P1, the stance s of a post p is determined by applying to p a stance classifier that computes $P(s|p)$. To train the classifier, we employ MaxEnt. Each train-

ing instance corresponds to a training post and is represented by all but the quotation and positional features used to train the Baseline RC system, since these two feature types are sentence-based rather than post-based. After training, the resulting classifier can be used to stance-label a post independently of the other posts.

In P2, on the other hand, we recast SC as a sequence labeling task. In other words, we train a SC model that assumes as input a post sequence and outputs a stance sequence, with one stance label for each post in the input post sequence. This choice is motivated by an observation we made previously (Hasan and Ng, 2013a): since each post in a sequence is a reply to the preceding post, we could exploit their dependencies by determining their stance labels together.[3]

As our sequence learner, we employ a maximum entropy Markov model (MEMM) (McCallum et al., 2000). Given an input post sequence $P_S = (p_1, p_2, \ldots, p_n)$, the MEMM finds the most probable stance sequence $S = (s_1, s_2, \ldots, s_n)$ by computing $P(S|P_S)$, where:

$$P(S|P_S) = \prod_{k=1}^{n} P(s_k|s_{k-1}, p_k) \qquad (1)$$

This probability can be computed efficiently via dynamic programming (DP), using a modified version of the Viterbi algorithm (Viterbi, 1967).

There is a caveat, however. Recall that the post sequences are generated from a thread. Since a test post may appear in more than one sequence, different occurrences of it may be assigned different stance labels by the MEMM. To determine the final stance label for the post, we average the probabilities assigned to the *for* stance over all its occurrences; if the average is ≥ 0.5, then its final label is *for*; otherwise, its label is *against*.

4.2 System based on Joint Inference

One weakness of the pipeline systems is that errors may propagate from the SC system to the RC system. If the stance of a post is incorrectly labeled, its reasons will also be incorrectly labeled.

To avoid this problem, we employ joint inference. Specifically, we first train a SC system and a RC system independently of each other. We employ the Baseline as our RC system, since this is the only RC system that is not stance-specific. For the SC system, we employ P2.

Since the SC system and the RC system are trained independently of each other, their outputs may not be consistent. For instance, an inconsistency arises if a post is labeled as *for* but one or more of its reasons are associated with the opposing stance. In fact, an inconsistency can arise in the output of the RC system alone: reasons associated with both stances may be assigned by the RC systems to different sentences of a given post.

To enforce consistency, we apply integer linear programming (ILP) (Roth and Yih, 2004). We formulate one ILP program for each debate post. Each ILP program contains two post-stance variables (x_{for} and $x_{against}$) and $|T| * |L_R|$ reason variables (i.e., one indicator variable $z_{t,r}$ for each reason class r and each sentence t), where $|T|$ is the number of sentences in the post and $|L_R|$ is the number of reason labels. Our objective is to maximize the linear combination of these variables and their corresponding probabilities assigned by their respective classifiers (see (2) below) subject to two types of constraints, the *integrity* constraints and the *post-reason* constraints. The integrity constraints ensure that each post is assigned exactly one stance and each sentence in a post is assigned exactly one reason class (see the two equality constraints in (3)). The post-reason constraints ensure consistency between the predictions made by the SC and the RC systems. Specifically, (1) if there is at least one reason supporting the *for* stance, the post must be assigned a *for* label; and (2) a *for* post must have at least one *for* reason. These constraints are defined for the *against* label as well (see the constraints in (4)).

Maximize:

$$\sum_{s \in L_S} a_s x_s + \frac{1}{|T|} \sum_{t=1}^{|T|} \sum_{r \in L_R} b_{t,r} z_{t,r} \qquad (2)$$

subject to:

$$\sum_{s \in L_S} x_s = 1, \ \forall\, t \sum_{r \in L_R} z_{t,r} = 1,$$
$$x_s \in \{0,\ 1\},\ z_{t,r} \in \{0,\ 1\} \qquad (3)$$

$$\forall\, t \ \ x_s \geq z_{t,r},\ \sum_{t=1}^{|T|} z_{t,r} \geq x_s \qquad (4)$$

[3] While we could similarly recast the problem of assigning reasons to the sentences in a post as a sequence learning task, we did not pursue this idea further because preliminary experiments indicated that sequence learning for RC was ineffective: there is little, if any, dependency between the reason labels in consecutive sentences.

Note that (1) a_s and $b_{t,r}$ are two sets of probabilities assigned by the SC and RC systems respectively; (2) L_S and L_R denote the set of stance labels and reason labels respectively; and (3) the fraction $\frac{1}{|T|}$ ensures that both classifiers are contributing equally to the objective function.

4.3 Systems based on Joint Learning

Another way to avoid the error propagation problem in pipeline systems is to perform joint learning. In joint learning, the two tasks, SC and RC, are learned jointly. Below we propose three joint models in increasing level of sophistication.

J1 is a joint model that, given a test post p, finds the stance label s and the reason label for each of the sentences that together maximize the probability $P(R_p, s|p)$, where $R_p = (r_1, r_2, \ldots, r_n)$ is the sequence of reason labels with r_i $(1 \leq i \leq n)$ being the reason label assigned to t_i, the i-th sentence in p. Using Chain Rule,

$$\begin{aligned} P(R_p, s|p) &= P(s|p)P(R_p|s, p) \\ &= P(s|p)\prod_{i=1}^{n} P(r_i|s, t_i) \end{aligned} \tag{5}$$

Hence, $P(R_p, s|p)$ can be computed by using the stance-specific RC classifier and the SC classifier employed in P1.

The second joint model, J2, is the same as J1, except that we recast SC as a sequence labeling task. As before, we employ MEMM to learn how to predict stance sequences. Given a post sequence $P_S = (p_1, p_2, \ldots, p_n)$, J2 finds the stance sequence $S = (s_1, s_2, \ldots, s_n)$ and reasons $R = (R_1, R_2, \ldots, R_n)$ that jointly maximize $P(R, S|P_S)$. Note that R_i is the sequence of reason labels assigned to the sentences in post i.

The R and S that jointly maximize $P(R, S|P_S)$ can be found efficiently via DP, using a modified version of the Viterbi algorithm. Unlike in P2, in J2 the decoding process is slightly more complicated because we have to take into account R_i. Below we show the recursive definitions used to compute the entries in the DP table, where $v_k(h)$ is the (k,h)-th entry of the table; $P(h|p)$ is provided by the MaxEnt stance classifier used in P1; $P(h|j, p)$ is provided by the MEMM stance classifier used in P2; $P(r_i^{max}|h, t_i)$ is provided by the stance-specific reason classifier used in the pipeline systems; and r_i^{max} is the reason label for sentence t_i that has the highest probability according to the reason classifier.

Base case:

$$v_1(h) = P(h|p)\prod_{i=1}^{n} P(r_i^{max}|h, t_i) \tag{6}$$

Recursive definition:

$$v_k(h) = \max_j v_{k-1}(j)P(h|j, p)\prod_{i=1}^{n} P(r_i^{max}|h, t_i) \tag{7}$$

To motivate our third joint model, J3, we make the following observation. Recall that a post in a post sequence is a reply to its preceding post. An inspection of the training data reveals that in many cases, a reply is a rebuttal to the preceding post, where an author attempts to argue why the points or reasons raised in the preceding post are wrong and then provides her reasons for the opposing stance. Motivated by this observation, we hypothesize that the reasons mentioned in the preceding post could be useful for predicting the reasons in the current post. However, none of the models we have presented so far makes use of the reasons predicted for the preceding post.

This motivates the design of J3, which we build on top of J2. Specifically, to incorporate the reason labels predicted for the preceding post in a post sequence, we augment the feature set of the stance-specific reason classifiers with a set of *reason features*, with one binary feature for each reason. The value of a reason feature is 1 if and only if the corresponding reason is predicted to be present in the preceding post. Hence, in J3, we can apply the same DP equations we used in J2 except that the set of features used by the reason classifier is augmented with the reason features.

5 Evaluation

While our primary goal is to evaluate the RC systems introduced in the previous section, we are also interested in whether SC performance can improve when SC is jointly modeled with RC. More specifically, our evaluation is driven by the following question: will RC performance and SC performance improve as we employ more sophisticated methods for modeling reasons and stances? Before showing the results, we describe the metrics for evaluating RC and SC systems.

System	ABO			GAY			OBA			MAR		
	Stance	Reason		Stance	Reason		Stance	Reason		Stance	Reason	
		Sentence	Post		Sentence	Post		Sentence	Post		Sentence	Post
Baseline	–	32.7	45.0	–	23.3	40.5	–	19.5	31.5	–	28.7	44.2

Table 3: SC accuracies and RC F-scores for our five-fold cross-validation experiments.

5.1 Experimental Setup

We express SC results in terms of *accuracy* (i.e., the percentage of test posts labeled with the correct stance) and RC results in terms of *F-score* micro-averaged over all reason classes except the NONE class. For each RC system, we report its sentence-level RC score and post-level RC score, which are computed over sentences and posts respectively. As mentioned at the end of Section 3, the set of post-level reason labels of a given post is automatically obtained by taking the union of the set of reason labels assigned to each of its sentences. Hence, a reason classifier will be rewarded as long as it can predict, for any sentence in a test post, a reason label that the annotators assigned to some sentence in the same post.

We obtain these scores via five-fold cross-validation experiments. During fold partition, all posts that are in the same post sequence are assigned to the same fold. All reason and stance classifiers are domain-specific, meaning that each of them is trained on sentences/posts from exactly one domain and is applied to classify sentences/posts from the same domain. We use the Stanford maximum entropy classifier[4] for classification and solve ILP programs using *lpsolve*[5].

5.2 Results and Discussion

Results are shown in Table 3. Each row corresponds to one of our seven RC systems, showing its SC accuracy as well as its sentence- and post-level RC F-scores for each domain.

Let us begin by discussing the RC results. **First**, P1 and P2 significantly beat the Baseline on all four domains by an average of 1.4 and 3.1 points at the sentence level and by an average of 2.3 and 3.8 points at the post level respectively.[6] These results show that stance information can indeed be profitably used for RC even if it is incorporated into RC systems in a simple manner. **Second**, improving SC through sequence learning can improve RC: the systems in which SC is recast as sequence labeling (P2 and J2) perform significantly better than the corresponding systems that do not (P1 and J1). **Third**, ILP significantly beats P2 on two domains (ABO and GAY) and achieves the same level of performance as P2 on the remaining domains. These results suggest that joint inference is no worse (and sometimes even better) than pipeline learning as far as exploiting stance information for RC is concerned. **Fourth**, the systems trained via joint learning (J1 and J2) beat their corresponding pipeline counterparts (P1 and P2) on all four domains, significantly so by an average of 2.3 and 2.5 points at the sentence level and by an average of 2.0 and 2.6 points at the post level respectively, suggesting that joint learning is indeed a better way to incorporate stance information than pipeline learning. **Finally**, J3, the joint system that exploits reasons predicted for the previous post, significantly beats J2, the system on which it is built, by 1.6 and 1.8 points at the sentence level and by 1.7 and 1.3 points at the post level for ABO and GAY respectively. It also yields small, statistically insignificant, improvements (0.6 points at the sentence level and 0.6–0.9 points at the post level) for the remaining two domains. These results suggest that the reasons predicted for the previous post indeed provide useful information for predicting the current post's reasons.

Overall, these results are consistent with our hy-

[4] http://nlp.stanford.edu/software/classifier.shtml

[5] http://sourceforge.net/projects/lpsolve/

[6] All significance tests are paired t-tests ($p < 0.05$).

pothesis that the usefulness of stance information depends in part on the way it is exploited, and that RC performance increases as we employ more sophisticated methods for modeling reasons and stances. Our best system, J3, significantly beats the Baseline by an average of 6.7 and 7.5 points at the sentence and post levels respectively.

As mentioned earlier, a secondary goal of this work is to determine whether joint modeling can improve SC as well. For that reason, we compare the performances of the best pipeline model (P2) and the best joint model (J3) on each domain. We find that in terms of SC accuracy, J3 is significantly better than P2 on ABO and GAY, and yields slightly, though insignificantly, better performance on the remaining two domains. In other words, our results suggest that joint modeling of SC and RC has a positive impact on SC performance on all domains, and the impact can sometimes be large enough to yield significantly better results.

5.3 Further Comparison

We hypothesized in the introduction that the sentence-based approach to post-level RC would yield better performance than the multi-label text classification approach. In Section 5.2, we presented results of the sentence-based approach to RC. So, to test this hypothesis, we next evaluate the multi-label text classification approach to RC.

Recall that the multi-label text classification approach assumes the following setup. Given a set of training posts where each post is multi-labeled with the set of reasons it contains, the goal is to train a system to determine the set of reasons a test post contains. Hence, unlike in the sentence-based approach, in this approach no sentence-level reason annotations are exploited during training.

We implement this approach by recasting multi-label text classification as n binary text classification tasks, where n is the number of reason classes for a domain. In the binary classification task for predicting reason i, we train a binary classifier c_i using the one-versus-all training scheme. Specifically, to train c_i, we create one training instance for each post p in the training set, labeling it as positive if and only if p contains reason i. Note that if i is a minority reason, the class distribution of the resulting training set will be highly skewed towards the negatives, which will in turn cause the resulting MaxEnt classifier to be biased towards predicting a test instance as negative.

To address this problem, we adjust the classification thresholds associated with the binary classifiers. Recall that a test instance is classified as positive by a binary classifier if and only if its probability of belonging to the positive class is above the classification threshold used. Hence, adjusting the threshold amounts to adjusting the number of test instances classified as positive, thus addressing the bias problem mentioned above. Specifically, we adjust the thresholds of the classifiers as follows. We train the binary classifiers to optimize the overall F-score by jointly tuning their classification thresholds on 25% of the training data reserved for development purposes. Since computing the exact solution to this optimization problem is computationally expensive, we employ a local search algorithm that changes the value of one threshold at a time to optimize F-score while keeping the remaining thresholds fixed. During testing, classifier c_i will classify a test instance as positive if its probability of belonging to the positive class is above the corresponding threshold.

We apply this multi-label text classification approach to obtain post-level RC scores for the Baseline, P1 and P2. Note that since P1 and P2 are pipeline systems, the binary classifiers they use to predict a test post's reasons depend on the post's predicted stance. Specifically, if a test post is predicted to have a positive (negative) stance, then only the reason classifiers associated with the positive (negative) stance will be used to predict the reasons it contains. On the other hand, this approach cannot be used in combination with ILP or the joint models to produce post-level RC scores: they all require a reason classifier trained on reason-annotated *sentences*, which are not available in the multi-label text classification approach.

Post-level RC results of the Baseline and the two pipeline systems, P1 and P2, obtained via this multi-label text classification approach are shown in Table 4. These scores are significantly lower than the corresponding scores in Table 3 by 3.2, 2.9, and 3.1 points for the Baseline, P1, and P2 respectively, when averaged over the four domains. They confirm our hypothesis that the sentence-based approach to post-level RC is indeed better than its multi-class text classification counterpart.

5.4 Error Analysis

To get a better understanding of our best-performing RC system (J3), we examine its major

System	ABO	GAY	OBA	MAR
Baseline	39.8	37.9	30.1	40.8
P1	41.5	41.0	31.7	44.7
P2	43.3	42.6	32.0	46.3

Table 4: Post-level RC F-scores obtained via the multi-class text classification approach.

sources of error in this subsection.

For the four domains, 75–83% of the errors can be attributed to the system's inability to decide whether a sentence describes a reason or not. Specifically, in 51–54% of the erroneous cases, a reason sentence is misclassified as NONE. On the other hand, 23–30% of the cases are concerned with assigning a reason label to a NONE sentence. The remaining 17–25% of the errors concern mislabeling a reason sentence with the wrong reason.

A closer examination of the errors reveals that they resulted primarily from (1) the lack of access to background knowledge, (2) the failure to process complex discourse structures, and (3) the failure to process sarcastic statements and rhetorical questions. We present two examples for each of these three major sources of error from the ABO and OBA domains in Table 5. In each example, we show their predicted (P) and gold (G) labels.

Lack of access to background knowledge. Consider the first example for ABO in Table 5. Our system misclassifies this sentence in part because it lacks the background knowledge that "genetic code" is one of the characteristics of life and a fetus having it means a fetus has life (A3). Similarly, the system cannot determine the reason for the first OBA example without the knowledge that "deficit spending" is a term related to the economy and that increasing it is bad (A1). We believe some of these relations can be extracted from lexical knowledge bases such as YAGO2 (Suchanek et al., 2007), Freebase (Bollacker et al., 2008), and BabelNet (Navigli and Ponzetto, 2012).

Failure to process complex discourse structures. Our system misclassifies the second example for ABO in part because the first part of the sentence (i.e., *Sure, the fetus has the potential to one day be a person*) expresses a meaning that is completely inverted by the second part. Such complex discourse structures often lead to classification errors even for sentences whose interpretation requires no background knowledge. We believe that this problem can be addressed in part by a better understanding of the structure of a discourse, particularly the relation between two discourse segments, using a discourse parser.

Failure to process sarcastic statements and rhetorical questions. Owing to the nature of our dataset (i.e., debate posts), many errors arise from sentences containing sarcasm and/or rhetorical questions. This is especially a problem in long post sequences, where authors frequently restate their opponents' positions, sometimes ironically. A first step towards handling these errors would therefore be to identify sentences containing sarcasm and/or rhetorical questions.

6 Related Work

In this section, we discuss related work in the areas of document-level RC, argument recognition, textual entailment in online debates, argumentation mining, and sentiment analysis.

Document-level reason classification. Persing and Ng (2009) apply a multi-label text classification approach to document-level RC of aviation safety incident reports. Given a set of pre-defined reasons, their RC system seeks to identify the reasons that can explain why the incident described in a given report occurred. Their work is different from ours in at least two respects. First, while our posts occur in post sequences (which can be profitably exploited in RC, for example, as in J3), their incident reports were written independently of each other. Second, they do not perform sentence-level RC, as the lack of sentence-level reason annotations in their dataset prevented them from training a sentence-level reason classifier.

Argument recognition. Boltužić and Šnajder (2014) propose a multi-class classification task called *argument recognition* in online discussions. Given a post and a reason for a particular domain, the task is to predict the extent to which the author of the post supports or opposes the reason as measured on a five-point ordinal scale ranging from "explicitly supports" to "explicitly opposes". Hence, unlike RC, argument recognition focuses on the *magnitude* rather than the *existence* of a post-reason relationship. In addition, Boltužić and Šnajder focus on post-level (rather than sentence-level) classification and employ perfect (rather than predicted) stance information.

Textual entailment in online debates. Given the title of a debate and a post written in response to it, this task seeks to detect arguments in

Domain	Background knowledge			Complex discourse structure			Sarcasm/rhetorical questions		
	Example	P	G	Example	P	G	Example	P	G
ABO	Science does agree that the fetus has an individual genetic code and fits into the biological definition of life.	NONE	A3	Sure, the fetus has the potential to one day be a person, but right now it is not.	NONE	F3	So are there enough homes for 50,000,000 babies?	F9	F5
OBA	Democrats have increased deficit spending by 2 trillion dollars over 2 years.	NONE	A1	Bush raised the debt by two billion for the wars, Obama has outspent that in a week.	A2	A1	I agree, Bush put us in debt for the next 100 years, so we can blame Obama forever.	NONE	F3

Table 5: Examples of the major sources of error. P and G stand for predicted tag and gold tag respectively.

the post that entail or contradict the title (Cabrio and Villata, 2012). Hence, this task is concerned with *identifying* text segments that correspond to rationales without a predefined set of rationales, whereas RC is concerned with both *identifying* text segments and *classifying* them based on a given set of reasons.

Argumentation mining. The goal of this task is to extract the argumentative structure of a document. Researchers have proposed approaches to mine the structure of scientific papers (Teufel and Moens, 2000; Teufel, 2001), product reviews (Villalba and Saint-Dizier, 2012; Wyner et al., 2012), newspaper articles (Feng and Hirst, 2011), and legal documents (Brüninghaus and Ashley, 2005; Wyner et al., 2010; Palau and Moens, 2011; Ashley and Walker, 2013). A major difference between this task and RC is that the argument types refer to generic structural cues, textual patterns etc., whereas our reason classes refer to the specific reasons an author may mention to support her stance in a domain. For instance, in the case of a scientific article, the argument types correspond to general background, description of the paper's or some other papers' approach, objective, contrastive and/or comparative comments, etc. (Teufel and Moens, 2000). The argument types for legal documents refer to legal factors which are either pro-plaintiff or pro-defendant (Brüninghaus and Ashley, 2005). For instance, for trade secret law cases, factors such as *Waiver-of-Confidentiality* and *Disclosure-in-Public-Forum* refer to certain facts strengthening the claim of one of the sides participating in a case.

Sentiment analysis. RC resembles certain tasks in sentiment analysis. One such task is pro and con reason classification in reviews (Kim and Hovy, 2006), where sentences containing opinions as well as reasons justifying the opinions are to be extracted and classified as PRO, CON, or NONE. Hence, this task focuses on categorizing sentences into coarse-grained, high-level groups (e.g., PRO vs. CON, POSITIVE vs. NEGATIVE), but does not attempt to subcategorize the PRO and CON classes into fine-grained reason classes, unlike RC. Somewhat similar to the PRO and CON sentence classification task is the task of determining the *relevance* of a sentence in a review for polarity classification. Zaidan et al. (2007) coined the term *rationale* to refer to any subjective textual content that contains evidence supporting the author's opinion or stance. These rationales, however, may not always contain reasons. For instance, a sentence that mentions that the author likes a product is a rationale, but it does not contain any reason for her liking it. Methods have been proposed for automatically identifying rationales (e.g., Yessenalina et al. (2010), Trivedi and Eisenstein (2013)) and distinguishing subjective from objective materials in a review (e.g., Pang and Lee (2004), Wiebe and Riloff (2005), McDonald et al. (2007), Zhao et al. (2008)). Note that in all these attempts, the end goal is not to classify sentences, but to employ the results of sentence classification to improve a higher-level task, such as sentiment classification.

7 Conclusion

We examined the new task of reason classification. We exploited stance information for reason classification, proposing systems of varying complexity for modeling stances and reasons. Experiments on our reason-annotated corpus of ideological debate posts from four domains demonstrate that sophisticated models of stances and reasons can indeed yield more accurate reason and stance classification results than their simpler counterparts. Nevertheless, reason classification remains a challenging task: the best post-level F-scores are in the low 50s. By making our corpus publicly available, we hope to stimulate further research on this task.

Chinese Zero Pronoun Resolution: An Unsupervised Probabilistic Model Rivaling Supervised Resolvers

Chen Chen and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{yzcchen,vince}@hlt.utdallas.edu

Abstract

State-of-the-art Chinese zero pronoun resolution systems are supervised, thus relying on training data containing manually resolved zero pronouns. To eliminate the reliance on annotated data, we present a generative model for unsupervised Chinese zero pronoun resolution. At the core of our model is a novel hypothesis: a probabilistic pronoun resolver trained on overt pronouns in an unsupervised manner can be used to resolve zero pronouns. Experiments demonstrate that our unsupervised model rivals its state-of-the-art supervised counterparts in performance when resolving the Chinese zero pronouns in the OntoNotes corpus.

1 Introduction

A zero pronoun (ZP) is a gap in a sentence that is found when a phonetically null form is used to refer to a real-world entity. An anaphoric zero pronoun (AZP) is a ZP that corefers with one or more preceding noun phrases (NPs) in the associated text. Below is an example taken from the Chinese TreeBank (CTB), where the ZP (denoted as *pro*) refers to 俄罗斯 (Russia).

[俄罗斯] 作为米洛舍夫维奇一贯的支持者，*pro* 曾经提出调停这场政治危机。

([Russia] is a consistent supporter of Milošević, *pro* has proposed to mediate the political crisis.)

As we can see, ZPs lack grammatical attributes that are useful for overt pronoun resolution such as NUMBER and GENDER. This makes ZP resolution more challenging than overt pronoun resolution.

Automatic ZP resolution is typically composed of two steps. The first step, AZP identification, involves extracting ZPs that are anaphoric. The second step, AZP resolution, aims to identify an antecedent of an AZP. State-of-the-art ZP resolvers have tackled both of these steps in a supervised manner, training a classifier for AZP identification and another one for AZP resolution (e.g., Zhao and Ng (2007), Chen and Ng (2013)).

In this paper, we focus on the second task, AZP resolution, designing a model that assumes as input the AZPs in a document and resolves each of them. Note that the task of AZP resolution alone is by no means easy: even when gold-standard AZPs are given, state-of-the-art supervised resolvers can only achieve an F-score of 47.7% for *resolving* Chinese AZPs (Chen and Ng, 2013). For the sake of completeness, we will evaluate our AZP resolution model using both gold-standard AZPs as well as AZPs automatically identified by a rule-based approach that we propose in this paper.

Our contribution lies in the proposal of the first *unsupervised* probabilistic model for AZP resolution that rivals its supervised counterparts in performance when evaluated on the Chinese portion of the OntoNotes 5.0 corpus. Its main advantage is that it does not require training data with manually resolved AZPs. This, together with the fact that its underlying generative process is not language-dependent, enables it to be applied to languages where such annotated data is not readily available. At its core is a novel hypothesis: we can apply a probabilistic pronoun resolution model trained on *overt* pronouns in an *unsupervised* manner to resolve *zero* pronouns. Motivated by Cherry and Bergsma's (2005) and Charniak and Elsner's (2009) work on unsupervised English pronoun resolution, we train our unsupervised resolver on Chinese overt pronouns using the Expectation-Maximization (EM) algorithm (Dempster et al., 1977).

2 Related Work

Chinese ZP resolution. Early approaches to Chinese ZP resolution are *rule-based*. Converse (2006) applied Hobbs' algorithm (Hobbs,

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 763–774,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

1978) to resolve the ZPs in the CTB documents. Yeh and Chen (2007) hand-engineered a set of rules for ZP resolution based on Centering Theory (Grosz et al., 1995).

In contrast, virtually all recent approaches to this task are based on *supervised* learning. Zhao and Ng (2007) are the first to employ a supervised learning approach to Chinese ZP resolution. They trained an AZP resolver by employing syntactic and positional features in combination with a decision tree learner. Unlike Zhao and Ng, Kong and Zhou (2010) employed context-sensitive convolution tree kernels (Zhou et al., 2008) in their resolver to model syntactic information. More recently, we extended Zhao and Ng's feature set with novel features that encode the context surrounding a ZP and its candidate antecedents, and exploited the coreference links between ZPs as bridges to find textually distant antecedents for ZPs (Chen and Ng, 2013).

ZP resolution for other languages. There have been rule-based and supervised machine learning approaches for resolving ZPs in other languages. For example, to resolve ZPs in Spanish texts, Ferrández and Peral (2000) proposed a set of handcrafted rules that encode preferences for candidate antecedents. In addition, supervised approaches have been extensively employed to resolve ZPs in Korean (e.g., Han (2006)), Japanese (e.g., Seki et al. (2002), Isozaki and Hirao (2003), Iida et al. (2006; 2007), Imamura et al. (2009), Iida and Poesio (2011), Sasano and Kurohashi (2011)), and Italian (e.g., Iida and Poesio (2011)).

3 Chinese Overt Pronouns

Since our approach relies heavily on Chinese *overt* pronouns, in this section we introduce them by describing their four grammatical attributes, namely NUMBER, GENDER, PERSON and ANIMACY. NUMBER has two values, *singular* and *plural*. GENDER has three values, *neuter*, *masculine* and *feminine*. PERSON has three values, *first*, *second* and *third*. Finally, ANIMACY has two values, *animate* and *inanimate*.

We exploit ten personal pronouns that have well-defined grammatical attribute values, namely 你 (singular you), 我 (I), 他 (he), 她 (she), 它 (it), 你们 (plural you), 我们 (we), 他们 (masculine they), 她们 (feminine they), and 它们 (impersonal they). As can be seen in Table 1, each of them can be uniquely identified using these four attributes.

Pronouns	NUMBER	GENDER	PERSON	ANIMACY
我 (I)	singular	neuter	first	animate
你 (you)	singular	neuter	second	animate
他 (he)	singular	masculine	third	animate
她 (she)	singular	feminine	third	animate
它 (it)	singular	neuter	third	inanimate
你们 (you)	plural	neuter	second	animate
我们 (we)	plural	neuter	first	animate
他们 (they)	plural	masculine	third	animate
她们 (they)	plural	feminine	third	animate
它们 (they)	plural	neuter	third	inanimate

Table 1: Attribute values of Chinese overt pronouns.

4 The Generative Model

4.1 Notation

Let p be an overt pronoun in PR, the set of the 10 overt pronouns described in Section 3. C, the set of candidate antecedents of p, contains all and only those maximal or modifier NPs that precede p in the associated text and are at most two sentences away from it.[1] k is the context surrounding p as well as every candidate antecedent c in C; k_c is the context surrounding p and candidate antecedent c; and l is a binary variable indicating whether c is the correct antecedent of p. The set $A = \{Num, Gen, Per, Ani\}$ has four elements, which correspond to NUMBER, GENDER, PERSON and ANIMACY respectively. a is an attribute in A. Finally, p_a and c_a are the attribute values of p and c with respect to a respectively.

4.2 Training

Our model estimates $P(p, k, c, l)$, the probability of seeing (1) the overt pronoun p; (2) the context k surrounding p and its candidate antecedents; (3) a candidate antecedent c of p; and (4) whether c is the correct antecedent of p. Since we estimate this probability from a raw, unannotated corpus, we are effectively treating p, k, and c as observed data and l as hidden data.

Owing to the presence of hidden data, we estimate the model parameters using the EM algorithm. Specifically, we use EM to iteratively estimate the model parameters from data in which each overt pronoun is labeled with the probability it corefers with each of its candidate antecedents and apply the resulting model to re-label each overt pronoun with the probability it corefers with each of its candidate antecedents. Below we describe

[1] Only 8% of the overt pronouns in our corpus, the Chinese portion of the OntoNotes 5.0 corpus, do not have any antecedent in the preceding two sentences.

the details of the E-step and the M-step.

4.2.1 E-Step

The goal of the E-step is to compute $P(l{=}1|p,k,c)$, the probability that a candidate antecedent c is the correct antecedent of p given context k. Assuming that exactly one of the p's candidate antecedents is its correct antecedent, we can rewrite $P(l{=}1|p,k,c)$ as follows:

$$P(l{=}1|p,k,c) = \frac{P(p,k,c,l{=}1)}{\sum_{c' \in C} P(p,k,c',l{=}1)} \quad (1)$$

Applying Chain Rule, we can rewrite $P(p,k,c,l{=}1)$ as follows:

$$\begin{aligned} P(p,k,c,l{=}1) = P(p|k,c,l{=}1) * P(l{=}1|k,c) \\ * P(c|k) * P(k) \end{aligned} \quad (2)$$

Next, given $l = 1$ (i.e., c is the antecedent of p), we assume that we can generate p from c without looking at the context.[2] Then we represent p using its grammatical attributes A. We further assume that p's value with respect to attribute $a \in A$ is independent of the value of each of its remaining attributes given the antecedent's value with respect to a. So we can rewrite $P(p|k,c,l{=}1)$ as follows:

$$\begin{aligned} & P(p|k,c,l{=}1) \approx P(p|c,l{=}1) \\ \approx\ & P(p_{Num}, p_{Gen}, p_{Per}, p_{Ani}|c,l{=}1) \\ \approx\ & \prod_{a \in A} P(p_a|c_a,l{=}1) \end{aligned} \quad (3)$$

Moreover, we assume that (1) given p and c's context, the probability of c being the antecedent of p is not affected by the context of the other candidate antecedents; and (2) k_c is sufficient for determining whether c is the antecedent of p. So,

$$P(l{=}1|k,c) \approx P(l{=}1|k_c,c) \approx P(l{=}1|k_c) \quad (4)$$

Furthermore, we assume that given context k, each candidate antecedent of p is generated with equal probability. In other words,

$$P(c|k) \approx P(c'|k) \ \ \forall\, c, c' \in C \quad (5)$$

Given Equations (2), (3), (4) and (5), we can rewrite $P(l{=}1|p,k,c)$ as:

$$\begin{aligned} P(l{=}1|p,k,c) &= \frac{P(p,k,c,l{=}1)}{\sum_{c' \in C} P(p,k,c',l{=}1)} \\ &\approx \frac{\prod_{a \in A} P(p_a|c_a,l{=}1) * P(l{=}1|k_c)}{\sum_{c' \in C} \prod_{a \in A} P(p_a|c'_a,l{=}1) * P(l{=}1|k_{c'})} \end{aligned} \quad (6)$$

[2] This assumption is reasonable because it is fairly easy to determine which pronoun can be used to refer to a given NP.

As we can see from Equation (6), our model has two groups of parameters, namely $P(p_a|c_a,l{=}1)$ and $P(l{=}1|k_c)$. Since we have four grammatical attributes, $P(p_a|c_a,l{=}1)$ contains four sets of parameters, with one set per attribute. Using Equation (6) and the current parameter estimates, we can compute $P(l{=}1|p,k,c)$.

Two points deserve mention before we describe the M-step. First, we estimate $P(l{=}1|p,k,c)$ from all and only those overt pronouns $p \in PR$ that are surface or deep subjects in their corresponding sentences. This condition is motivated by our observation that 99.56% of the ZPs in our evaluation corpus (i.e., OntoNotes 5.0) are surface or deep subjects. In other words, we impose this condition so that we can focus our efforts on learning a model for resolving overt pronouns that are subjects. This is by no means a limitation of our model: if we were given a corpus in which many ZPs occur as grammatical objects, we could similarly train another model on overt objects. Second, since in the E-step we attempt to probabilistically label every overt pronoun p that satisfies the condition above, our model is effectively making the simplifying assumption that every overt pronoun is anaphoric. This is clearly an overly simplistic assumption. One way to relax this assumption, which we leave as future work, is to first identify those pronouns that are anaphoric and then use EM to estimate the joint probability only from the anaphoric pronouns.

4.2.2 M-Step

Given $P(l{=}1|p,k,c)$, the goal of the M-step is to (re)estimate the model parameters, $P(p_a|c_a,l{=}1)$ and $P(l{=}1|k_c)$, using maximum likelihood estimation. Specifically, $P(p_a|c_a,l{=}1)$ is estimated as follows:

$$P(p_a|c_a,l{=}1) = \frac{Count(p_a,c_a,l{=}1) + \theta}{Count(c_a,l{=}1) + \theta * |a|} \quad (7)$$

where $Count(c_a,l{=}1)$ is the expected number of times c has attribute value c_a when it is the antecedent of p; $|a|$ is the number of possible values of attribute a; θ is the Laplace smoothing parameter, which we set to 1; and $Count(p_a,c_a,l{=}1)$ is the expected number of times p has attribute value p_a when its antecedent c has attribute value c_a. Given attribute values p'_a and c'_a, we compute

$Count(p'_a, c'_a, l{=}1)$ as follows:

$$Count(p'_a, c'_a, l{=}1) = \sum_{p,c:p_a=p'_a,c_a=c'_a} P(l{=}1|p,k,c) \quad (8)$$

Similarly, $P(l{=}1|k_c)$ is estimated as follows:

$$P(l{=}1|k_c) = \frac{Count(k_c, l{=}1) + \theta}{Count(k_c) + \theta * 2} \quad (9)$$

where $Count(k_c)$ is the number of times k_c appears in the training data, and $Count(k_c, l{=}1)$ is the expected number of times k_c is the context surrounding a pronoun and its antecedent c. Given context k'_c, we compute $Count(k'_c, l{=}1)$ as follows:

$$Count(k'_c, l{=}1) = \sum_{k:k_c=k'_c} P(l{=}1|p,k,c) \quad (10)$$

To start the induction process, we initialize all parameters with uniform values. Specifically, $P(p_a|c_a, l{=}1)$ is set to $\frac{1}{|a|}$, and $P(l{=}1|k_c)$ is set to 0.5. Then we iteratively run the E-step and the M-step until convergence.

There are two important questions we have not addressed. First, how can we compute the four attribute values of a candidate antecedent (i.e., c_a for each attribute a), which we need to estimate $P(p_a|c_a, l{=}1)$? Second, what features should we use to represent context k_c, which we need to estimate $P(l{=}1|k_c)$? We defer the discussion of these questions to Sections 5 and 6.

4.3 Inference

After training, we can apply the resulting model to resolve AZPs. Given an AZP z, we determine its antecedent as follows:

$$(\hat{c}, \hat{p}) = \underset{c \in C,\ p \in PR}{\arg\max}\ P(l{=}1|p,k,c) \quad (11)$$

where PR is our set of 10 Chinese overt pronouns and C is the set of candidate antecedents of z. In other words, we apply Formula (11) to each AZP z, searching for the candidate antecedent c and overt pronoun p that maximize $P(l{=}1|p,k,c)$ when p is used to fill the ZP gap left behind by z. The c that results in the maximum probability value over all overt pronouns in PR is chosen as the antecedent of z. In essence, since the model is trained on overt pronouns but is applied to ZPs, we have to exhaustively fill the ZP's gap under consideration with each of the 10 overt pronouns in PR during inference.

Although we can now apply our generative model to resolve AZPs, the resolution procedure can be improved further. The improvement is motivated by a problem we observed previously (Chen and Ng, 2013): an AZP and its closest antecedent can sometimes be far away from each other, thus making it difficult to correctly resolve the AZP. To address this problem, we employ the following resolution procedure in our experiments. Given a test document, we process its AZPs in a left-to-right manner. As soon as we resolve an AZP to a preceding NP c, we fill the corresponding AZP's gap with c. Hence, when we process an AZP z, all of its preceding AZPs in the associated text have been resolved, with their gaps filled by the NPs they are resolved to. To resolve z, we create test instances between z and its candidate antecedents in the same way as described before. The only difference is that the set of candidate antecedents of z may now include those NPs that are used to fill the gaps of the AZPs resolved so far. In other words, this incremental resolution procedure may increase the number of candidate antecedents of each AZP z. Some of these additional candidate antecedents are closer to z than the original candidate antecedents, thereby facilitating the resolution of z. If the model resolves z to the additional candidate antecedent that fills the gap left behind by, say, AZP z', we postprocess the output by resolving z to the NP that z' is resolved to.[3]

5 Attributes of Candidate Antecedents

In this section, we describe how we determine the four grammatical attribute values (NUMBER, GENDER, PERSON and ANIMACY) of a candidate antecedent c, as they are used to represent c when estimating $P(p_a|c_a, l{=}1)$ for each attribute a.

5.1 ANIMACY

We determine the ANIMACY of a candidate antecedent c heuristically. Specifically, we first check the NP type of c. If c is a pronoun, we look up its ANIMACY in Table 1. If c is a named entity, there are two cases to consider: if c is a *person*[4], we label it as *animate*; otherwise, we label it as *inanimate*. If c is a common noun, we look up the ANIMACY of its head noun in an automatically

[3] This postprocessing step is needed because the additional candidate antecedents are only gap fillers.

[4] A detailed description of our named entity recognizer can be found in Chen and Ng (2014).

constructed word list WL. If the head noun is not in WL, we set its ANIMACY to *unknown*.

Our method for constructing WL is motivated by an observation of measure words in Chinese: some of them only modify *inanimate* nouns while others only modify *animate* nouns. For example, the nouns modified by the measure word 张 are always *inanimate*, as in 一张纸 (one piece of paper). On the other hand, the nouns modified by the measure word 位 are always *animate*, as in 一位工人 (one worker).

Given this observation, we first define two lists, M_{ani} and M_{inani}. M_{ani} is a list of measure words that can only modify *animate* nouns. M_{inani} is a list of measure words that can only modify *inanimate* nouns.[5] There exists a special measure word in Chinese, 个, which can be used to modify most of the common nouns regardless of their ANIMACY. As a result, we remove 个 from both lists. After constructing M_{ani} and M_{inani}, we (1) parse the Chinese Gigaword corpus (Parker et al., 2009), which contains 4,370,600 documents, using an efficient dependency parser, ctbparser[6] (Qian et al., 2010), and then (2) collect all pairs of words (m, n), where m is a measure word, n is a common noun, and there is a NMOD dependency relation between m and n. Finally, we determine the ANIMACY of a given common noun n as follows. First, we retrieve all of the pairs containing n. Then, we sum over all occurrences of m in M_{ani} (call the sum C_{ani}), as well as all occurrences of m in M_{inani} (call the sum C_{inani}). If $C_{ani} > C_{inani}$, we label this common noun as *animate*; otherwise, we label it as *inanimate*.

Table 2 shows the learned values of $P(p_{Ani}|c_{Ani}, l{=}1)$. These results are consistent with our intuition: an animate (inanimate) pronoun is more likely to be generated from an animate (inanimate) antecedent than from an inanimate (animate) antecedent. Note that animate pronouns are more likely to be generated than inanimate pronouns regardless of the antecedent's ANIMACY. This can be attributed to the fact that 94.6% of the pronouns in our corpus are animate.

5.2 GENDER

We determine the GENDER of a candidate antecedent c as follows. If c is a pronoun, we look up its GENDER in Table 1. Otherwise, we determine its GENDER based on its ANIMACY. Specifically, if c is *inanimate*, we set its GENDER to *neuter*. Otherwise, we determine its gender by looking up a gender word list constructed by Bergsma and Lin's (2006) approach. If the word is not in the list, we set its GENDER to *masculine* by default.

Antecedent \ Pronoun	animate	inanimate
animate	0.999	0.001
inanimate	0.858	0.142
unknown	0.945	0.055

Table 2: Learned values of $P(p_{Ani}|c_{Ani}, l{=}1)$.

Next, we describe how the aforementioned gender word list is constructed. Following Bergsma and Lin (2006), we define a *dependency path* as the sequence of non-terminal nodes and dependency labels between two potentially coreferent entities in a dependency parse tree. From the parsed Chinese Gigaword corpus, we first collect every dependency path that connects two pronouns. For each path P collected, we compute $CL(P)$, the coreference likelihood of P, as follows:

$$CL(P) = \frac{N_I(P)}{N_I(P) + N_D(P)} \qquad (12)$$

where $N_I(P)$ is the number of times P connects two identical pronouns, and $N_D(P)$ is the number of times it connects two different pronouns. Assuming that two identical pronouns in a sentence are coreferent (Bergsma and Lin, 2006), we can see that the larger a path's CL value is, the more likely it is that the two NPs it connects are coreferent. To ensure that we have dependency paths that are strongly indicative of coreference relations, we consider a dependency path P a *coreferent path* if and only if $CL(P) > 0.8$.

Given these coreferent paths, we can compute the GENDER of a noun n as follows. First, we compute (1) $N_M(n)$, the number of coreferent paths connecting n with a *masculine* pronoun; and (2) $N_F(n)$, the number of coreferent paths connecting n with a *feminine* pronoun. Then, if $N_F(n) > N_M(n)$, we set n's gender to *feminine*; otherwise, we set it to *masculine*.

Table 3 shows the learned values of $P(p_{Gen}|c_{Gen}, l{=}1)$. These results are consistent with our intuition: a pronoun is a lot more likely to be generated from an antecedent with the same GENDER than one with a different GENDER.

[5] We create these two lists with the help of this page: http://chinesenotes.com/ref_measure_words.htm

[6] http://code.google.com/p/ctbparser/

Antecedent \ Pronoun	neuter	feminine	masculine
neuter	0.864	0.018	0.117
feminine	0.065	0.930	0.005
masculine	0.130	0.041	0.828

Table 3: Learned values of $P(p_{Gen}|c_{Gen}, l{=}1)$.

Antecedent \ Pronoun	singular	plural
singular	0.861	0.139
plural	0.26	0.74

Table 4: Learned values of $P(p_{Num}|c_{Num}, l{=}1)$.

5.3 NUMBER

When computing the NUMBER of a candidate antecedent in English, Charniak and Elsner (2009) rely on part-of-speech information. For example, NN and NNP denote singular nouns, whereas NNS and NNPS denote plural nouns. However, Chinese part-of-speech tags do not provide such information. Hence, we need a different method for finding the NUMBER of a candidate antecedent c in Chinese. If c is a pronoun, we look up its NUMBER in Table 1. If c is a named entity, its NUMBER is *singular*. If c is a common noun, we infer its NUMBER from its string: if the string ends with 们 or is modified by a quantity word (e.g., 一些, 许多), c is *plural*; otherwise, c is *singular*.

Table 4 shows the learned values of $P(p_{Num}|c_{Num}, l{=}1)$. These results are consistent with our intuition: a pronoun is more likely to be generated from an antecedent with the same NUMBER than one with a different NUMBER.

5.4 PERSON

Finally, we compute the PERSON of a candidate antecedent c. Similar to Charniak and Elsner (2009), we set 我 (I) and 我们 (we) to *first* person, 你 (singular you) and 你们 (plural you) to *second* person, and everything else to *third* person. We estimate two sets of probabilities $P(p_{Per}|c_{Per}, l{=}1)$, one where p and c are from the same speaker, and the other where they are from different speakers.[7] This is based on our observation that $P(p_{Per}|c_{Per}, l{=}1)$ could be very different in these two cases.

[7]We employ a simple heuristic to identify the speaker of NPs occurring in direct speech: we assume that the speaker is the subject of the speech's reporting verb. So for example, we identify *Jack* as the speaker of *This book* in the sentence *"This book is good," Jack said.*

Antecedent \ Pronoun	first	second	third
first	0.856	0.119	0.025
second	0.219	0.766	0.016
third	0.289	0.077	0.634

Table 5: Learned values of $P(p_{Per}|c_{Per}, l{=}1)$ (same speaker).

Antecedent \ Pronoun	first	second	third
first	0.417	0.525	0.057
second	0.75	0.23	0.02
third	0.437	0.229	0.334

Table 6: Learned values of $P(p_{Per}|c_{Per}, l{=}1)$ (different speakers).

Tables 5 and 6 show the learned values of these two sets of probabilities. These results are consistent with our intuition. In the same-speaker case, a pronoun is a lot more likely to be generated from an antecedent with the same speaker than one with a different speaker. In the different-speaker case, a first (second) person pronoun is most likely to be generated from a second (first) person pronoun.

6 Context Features

To fully specify our model, we need to describe how to represent k_c, which is needed to compute $P(l{=}1|k_c)$. Recall that k_c encodes the context surrounding candidate antecedent c and the associated pronoun p. As described below, we represent k_c using eight features, some of which are motivated by previous work on supervised AZP resolution (e.g., Zhao and Ng (2007), Chen and Ng (2013)). Note that (1) all but feature 1 are computed based on syntactic parse trees, and (2) features 2, 3, 6, and 8 are ternary-valued features.

1. the sentence distance between c and p;
2. whether the node spanning c has an ancestor NP node; if so, whether this NP node is a descendant of c's lowest ancestor IP node;
3. whether the node spanning c has an ancestor VP node; if so, whether this VP node is a descendant of c's lowest ancestor IP node;
4. whether vp has an ancestor NP node, where vp is the VP node spanning the VP that follows p;
5. whether vp has an ancestor VP node;

	Training	Test
Documents	1,391	172
Sentences	36,487	6,083
Words	756,063	110,034
Overt Subject Pronouns	13,418	–
AZPs	–	1,713

Table 7: Statistics on the training and test sets.

6. whether p is the first word of a sentence; if not, whether p is the first word of an IP clause;
7. whether c is a subject whose governing verb is lexically identical to the verb governing p;
8. whether c is the closest candidate antecedent with subject grammatical role and is semantically compatible with p's governing verb; if not, whether c is the first semantically compatible candidate antecedent[8].

Our approach to determine semantic compatibility (in feature 8) resembles Kehler et al.'s (2004) and Yang et al.'s (2005) methods for computing selectional preferences. Specifically, for each verb and each noun that serves as a subject in Chinese Gigaword, we compute their mutual information (MI). Now, given a pronoun p and a candidate antecedent c in the training/test corpus, we retrieve the MI value of c and p's governing verb. We then consider them semantically compatible if and only if their MI value is greater than zero.

7 Evaluation

7.1 Experimental Setup

Datasets. We employ the Chinese portion of the OntoNotes 5.0 corpus that was used in the official CoNLL-2012 shared task (Pradhan et al., 2012). In the CoNLL-2012 data, the training set and development set contain ZP coreference annotations, but the test set does not. Therefore, we train our models on the training set and perform evaluation on the development set. Statistics on the datasets are shown in Table 7. The documents in these datasets come from six sources, namely Broadcast News (BN), Newswire (NW), Broadcast Conversation (BC), Telephone Conversation (TC), Web Blog (WB) and Magazine (MZ).

[8] We sort the candidate antecedents of p as follows. We first consider the subject candidate antecedents in the same sentence as p from right to left, then the other candidate antecedents in the same sentence from right to left. Next, we consider the candidate antecedents in the previous sentence, also preferring candidates that are subjects, but in left-to-right order. Finally, we consider the candidate antecedents two sentences back, following the subject-first, left-to-right order.

Evaluation measures. We express the results of ZP resolution in terms of recall (R), precision (P) and F-score (F).

Evaluation settings. Following Chen and Ng (2013), we evaluate our model in three settings. In Setting 1, we assume the availability of gold syntactic parse trees and gold AZPs. In Setting 2, we employ gold syntactic parse trees and system (i.e., automatically identified) AZPs. Finally, in Setting 3, we employ system syntactic parse trees and system AZPs. The gold and system syntactic parse trees, as well as the gold AZPs, are obtained from the CoNLL-2012 shared task dataset, while the system AZPs are identified by the rule-based approach described in the Appendix.[9] Since our AZP identification approach does not rely on any labeled data, we are effectively evaluating an end-to-end unsupervised AZP resolver in Setting 3.

7.2 Results

Baseline systems. We employ seven resolvers as baseline systems. To gauge the difficulty of the task, we employ four simple rule-based resolvers, which resolve an AZP z to (1) the candidate antecedent closest to z (Baseline 1); (2) the subject NP closest to z (Baseline 2); (3) the closest candidate antecedent that is semantically compatible with z (Baseline 3); and (4) the first candidate antecedent that is semantically compatible with z, where the candidate antecedents are visited according to the order described in Footnote 8 (Baseline 4). These four baselines allow us to study the role of (1) recency, (2) salience, (3) recency combined with semantic compatibility, and (4) salience combined with semantic compatibility in AZP resolution respectively. The remaining three baselines are state-of-the-art supervised AZP resolvers, which include our own resolver (Chen and Ng, 2013) as well as our re-implementations of Zhao and Ng's (2007) resolver and Kong and Zhou's (2010) resolver.

The test set results of these seven baseline resolvers when evaluated under the three aforementioned evaluation settings are shown in Table 8. The system AZPs employed by the rule-based resolvers are obtained using our rule-based

[9] One may wonder why we do not train a supervised system for identifying AZPs and instead experiment with a rule-based AZP identification system. The reason is that employing labeled data defeats the whole purpose of having an unsupervised AZP resolution model: if annotated data is available for training an AZP identification system, the same data can be used to train an AZP resolution system.

Table 9: AZP resolution results of the best baseline and our unsupervised model on the test set.

AZP identification system. On the other hand, since our supervised resolvers are meant to be re-implementations of existing resolvers, we follow previous work and let them employ a supervised AZP identification system. In particular, we employ the one described in Chen and Ng (2013).

Several observations can be made about these results. First, among the rule-based resolvers, Baseline 4 achieves the best performance, outperforming Baselines 1, 2, and 3 by 12.9%, 1.5%, and 10.8% in F-score respectively when averaged over the three evaluation settings. From their relative performance, which remains the same in the three settings, we can conclude that as far as AZP resolution is concerned, (1) salience plays a greater role than recency; and (2) semantic compatibility is useful. Second, among the supervised baselines, our supervised resolver (Chen and Ng, 2013) achieves the best performance, outperforming Zhao and Ng's resolver and Kong and Zhou's resolver by 3.9% and 2.0% in F-score respectively when averaged over the three evaluation settings. Finally, comparing the rule-based resolvers and the learning-based resolvers, we can see that the best rule-based baseline (Baseline 4) performs even better than Zhao and Ng's resolver and Kong and Zhou's resolver.

In the rest of this subsection, we will compare our unsupervised model against the best baseline, Chen and Ng's (2013) supervised resolver.

Our model. Results of the best baseline and our model on the entire test set and each of the six sources are shown in Table 9. As we can see, our model achieves the same overall F-score as the best baseline under all three settings, despite the fact that it is unsupervised. In fact, our model even outperforms the best baseline on NW, WB and BN in Setting 1, NW, WB, BN and BC in Setting 2, and NW, WB and BC in Setting 3.

It is worth mentioning that while the two resolvers achieved the same overall performance, their outputs differ a lot from each other. Specifically, the two models only agree on the antecedents of 55% of the AZPs in Setting 1.[10]

7.3 Ablation Experiments

Impact of $P(p_a|c_a, l{=}1)$ and $P(l{=}1|k_c)$. Recall that our model is composed of five probability terms, $P(p_a|c_a, l{=}1)$ for each of the four grammatical attributes and $P(l{=}1|k_c)$, the context probability. To investigate the contribution of context and each attribute to overall performance, we conduct ablation experiments. Specifically, in each ablation experiment, we remove exactly one probability term from the model and retrain it.

[10]Note that it is difficult to directly compare the outputs produced under Settings 2 and 3: the AZPs identified by the best baseline are quite different from those identified by our rule-based system, as can be inferred from the AZP identification results in Table 12.

System	Setting 1			Setting 3		
	R	P	F	R	P	F
Full model	47.5	47.9	47.7	19.9	12.9	15.7
− NUMBER	47.5	47.9	47.7	19.7	12.8	15.5
− GENDER	44.5	45.0	44.7	19.2	12.5	15.1
− PERSON	45.2	45.6	45.4	19.1	12.4	15.1
− ANIMACY	45.1	45.5	45.3	19.1	12.4	15.1
− Context Features	32.9	33.1	33.0	15.2	9.8	11.9

Table 10: Probability term ablation results.

Ablation results under Settings 1 and 3 are shown in Table 10. As we can see, under Setting 1, after NUMBER is ablated, performance does not drop. We attribute this to the fact that almost all candidate antecedents are *singular*. On the other hand, when we ablate any of the remaining three attributes, performance drops significantly by 2.3−3.0% in overall F-score.[11] Similar trends can be observed with respect to Setting 3: after NUMBER is ablated, performance only decreases by 0.2%, while ablating any of the other three attributes results in a drop of 0.6%.

Results after ablating context are shown in the last row of Table 10. As we can see, the F-score drops significantly by 14.7% and 3.8% under Settings 1 and 3 respectively. These results illustrate the importance of context features in our model.

Context feature ablation. Recall that we employed eight context features to encode the relationship between a pronoun and a candidate antecedent. To determine the relative contribution of these eight features to overall performance, we conduct ablation experiments under Settings 1 and 3. In these ablation experiments, all four grammatical attributes are retained in the model.

Ablation results are shown in rows 2−9 of Table 11. To facilitate comparison, the F-score of the model in which all eight context features are used is shown in row 1. As we can see, feature 8 (the rule-based feature) is the most useful feature: its removal causes the F-scores of our resolver to drop significantly by 6.4% under Setting 1 and 1.5% under Setting 3.

7.4 Error Analysis

To gain additional insights into our full model, we examine its major sources of error below. To focus on errors attributable to AZP resolution, we analyze our full model under Setting 1.

Specifically, we randomly select 100 AZPs that our model incorrectly resolves under Setting 1.

[11] All significance tests are paired t-tests, with $p < 0.05$.

System	Setting 1			Setting 3

Table 11: Context feature ablation results.

We found that 17 errors are attributable to discourse disfluency, lack of background knowledge and subject detection, while the remaining 83 errors can be divided into three types:

Failure to recognize the topics of a document. Our model incorrectly resolves 32 AZPs that are coreferent with NPs corresponding to the topics of the associated documents. Consider the following example:

[八里乡] 位于台北盆地西北端。行政区隶属于台北县，*pro* 为台北县廿九个乡镇市之一。
([Bali Town] is located in the Northwest of Taipei Basin. Its administrative area is affiliated with Taipei County, *pro* is one of Taipei County's 29 towns and cities.)[12]

The model incorrectly resolves the AZP *pro* to 行政区 (Its administrative area). The reason is that the correct antecedent, 八里乡 (Bali Town), is far from *pro*: there are five candidate antecedents between *pro* and 八里乡 (Bali Town). Note, however, that it is easy for a human to resolve *pro* to 八里乡 (Bali Town) because the whole passage is discussing 八里乡 (Bali Town). Hence, to correctly handle such cases, one may construct a topic model over the passage and assign each candidate antecedent a prior probability so that the resulting system favors the selection of candidates representing the topics as antecedents.

Errors in computing semantic compatibility. This type of error contributes to 28 of the incorrectly resolved AZPs. When computing semantic compatibility in our model, we only consider the mutual information between a candidate antecedent and the pronoun's governing verb, but in some cases, additional context needs to be taken into account. Consider the following example:

[12] The pronoun *Its* in the phrase *Its administrative area* is inserted into the English translation for the sake of grammaticality and correct understanding of the sentence. The corresponding Chinese phrase does not contain any pronoun.

[一支海军陆战队] 杀死了约 [24 名手无寸铁的伊拉克人]，*pro* 包括妇女和六名儿童。
([Marines] killed about [24 unarmed Iraqis], *pro* include women and six children.)

There are two candidate antecedents in this example, 一支海军陆战队 (Marines) and 24 名手无寸铁的伊拉克人 (24 unarmed Iraqis), which we denote as c_1 and c_2 respectively. The correct antecedent of *pro* is c_2 , while our model wrongly resolves *pro* to c_1. Note that both c_1 and c_2 are compatible with the AZP's governing verb 包括 (include). However, if the object of the governing verb, i.e., 妇女和六名儿童 (women and six children), were also considered, the model could determine that c_1 is not compatible with the object while c_2 is, and then correctly resolve *pro* to c_2.

Failure to recognize and exploit semantically similar sentences. This type of error contributes to 23 wrongly resolved AZPs. Recall that an AZP is omitted for brevity, so the sentence it appears in often expresses similar meaning to an earlier sentence. However, our model fails to handle such cases. Consider the following example:

[指挥部和突进的部队] 之间也会失去联络。..... *pro* 就联络不上了。
([The command and the onrush of troops] lost connection with each other. ... *pro* cannot connect with each other.)

The above example shows two sentences that are separated by some other sentences. The AZP under consideration is in the last sentence, while the first sentence contains the correct antecedent 指挥部和突进的部队 (the command and the onrush troops), denoted as c_1. Our model fails to resolve *pro* to c_1, because there are many competing candidate antecedents between c_1 and AZP. However, if our model were aware of the similarity between the constructions appearing after c_1 and *pro*, i.e., 之间也会失去联络 (lost connection with each other) and 就联络不上了 (cannot connect with each other), then it might be able to correctly resolve the AZP.

8 Conclusion

We proposed an unsupervised model for Chinese zero pronoun resolution, investigating the novel hypothesis that an unsupervised probabilistic resolver trained on overt pronouns can be applied to resolve ZPs. To our knowledge, this is the first unsupervised probabilistic model for this task. Experiments on the OntoNotes 5.0 corpus showed that our unsupervised model rivaled its state-of-the-art supervised counterparts in performance.

Appendix: Automatic AZP Identification

Our automatic AZP identification system employs an ordered set of rules. The first rule is a positive rule that aims to extract as many *candidate* AZPs as possible. It is followed by seven negative rules that aim to improve precision by filtering out erroneous candidate AZPs. Below we first describe the rules and then evaluate this rule-based system.

Rule 1. Add candidate AZP z if it occurs before the leftmost word spanned by a VP node vp.

Rule 2. Remove z if its associated vp is in a coordinate structure or modified by an adverbial node.

Rule 3. Remove z if the parent of its associated vp node is not an IP node.

Rule 4. Remove z if its associated vp has a NP or QP node as an ancestor.

Rule 5. Remove z if one of the left sibling nodes of vp is NP, QP, IP or ICP.

Rule 6. Remove z if (1) z does not begin a sentence, (2) the highest node whose spanning word sequence ends with the left non-comma neighbor word of z is either NP, QP or IP, and (3) the parent of this node is VP.

Systems	Gold Parses			System Parses		
	R	P	F	R	P	F
Rule-based	72.4	42.3	53.4	42.3	26.8	32.8
Supervised	50.6	55.1	52.8	30.8	34.4	32.5

Table 12: AZP identification results on the test set.

Rule 7. Remove z if vp's lowest IP ancestor has (1) a VP node as its parent and (2) a VV node as its left sibling.

Rule 8. Remove z if it begins a document.

To gauge the performance of our rule-based AZP identification system, we compare it with our supervised AZP identification system (Chen and Ng, 2013). Results of the two systems on our test set are shown in Table 12. As we can see, the F-scores achieved by the rule-based system is comparable to those of the supervised system.

Unsupervised Sentence Enhancement for Automatic Summarization

Abstract

We present *sentence enhancement* as a novel technique for text-to-text generation in abstractive summarization. Compared to extraction or previous approaches to sentence fusion, sentence enhancement increases the range of possible summary sentences by allowing the combination of dependency subtrees from any sentence from the source text. Our experiments indicate that our approach yields summary sentences that are competitive with a sentence fusion baseline in terms of content quality, but better in terms of grammaticality, and that the benefit of sentence enhancement relies crucially on an event coreference resolution algorithm using distributional semantics. We also consider how text-to-text generation approaches to summarization can be extended beyond the source text by examining how human summary writers incorporate source-text-external elements into their summary sentences.

1 Introduction

Sentence fusion is the technique of merging several input sentences into one output sentence while retaining the important content (Barzilay and McKeown, 2005; Filippova and Strube, 2008; Thadani and McKeown, 2013). For example, the input sentences in Figure 1 may be fused into one output sentence.

As a text-to-text generation technique, sentence fusion is attractive because it provides an avenue for moving beyond sentence extraction in automatic summarization, while not requiring deep semantic analysis beyond, say, a dependency parser and lexical semantic resources.

Input: *Bil Mar Foods Co., a meat processor owned by Sara Lee, announced a recall of certain* ***lots of hot dogs and packaged meat****.*
Input: ***The outbreak led to the recall on Tuesday of*** *15 million pounds of hot dogs and cold cuts* ***produced at the Bil Mar Foods plant.***
Output: *The outbreak led to the recall on Tuesday of lots of hot dogs and packaged meats produced at the Bil Mar Foods plant.*

Figure 1: An example of fusing two input sentences into an output sentence. The sections of the input sentences that are retained in the output are shown in bold.

The overall trajectory pursued in the field can be characterized as a move away from local contexts relying heavily on the original source text towards more global contexts involving reformulation of the text. Whereas sentence extraction and sentence compression (Knight and Marcu, 2000, for example) involve taking one sentence and perhaps removing parts of it, traditional sentence fusion involves reformulating a small number of relatively similar sentences in order to take the union or intersection of the information present therein.

In this paper, we move further along this path in the following ways. First, we present **sentence enhancement** as a novel technique which extends sentence fusion by combining the subtrees of many sentences into the output sentence, rather than just a few. Doing so allows relevant information from sentences that are not similar to the original input sentences to be added during fusion. As

Figure 2: An example of sentence enhancement, in which parts of dissimilar sentences are incorporated into the output sentence.

shown in Figure 2, the phrase *of food-borne illness* can be added to the previous output sentence, despite originating in a source text sentence that is quite different overall.

Elsner and Santhanam (2011) proposed a supervised method to fuse disparate sentences, which takes as input a small number of sentences with compatible information that have been manually identified by editors of articles. By contrast, our algorithm is unsupervised, and tackles the problem of identifying compatible event mergers in the entire source text using an event coreference module. Our method outperforms a previous syntax-based sentence fusion baseline on measures of summary content quality and grammaticality.

Second, we analyze how text-to-text generation systems may make use of text that is not in the source text itself, but in articles on a related topic in the same domain. By examining the parts of human-written summaries that are not found in the source text, we find that using in-domain text allows summary writers to more precisely express some target semantic content, but that more sophisticated computational semantic techniques will be required to enable automatic systems to likewise do so.

A more general argument of this paper is that the apparent dichotomy between text-to-text generation and semantics-to-text generation can be resolved by viewing them simply as having different starting points towards the same end goal of precise and wide-coverage NLG. The statistical generation techniques developed by the text-to-text generation community have been successful in many domains. Yet the results of our experiments and studies demonstrate the following: as text-to-text generation techniques move beyond using local contexts towards more dramatic reformulations of the kind that human writers perform, more semantic analysis will be needed in order to ensure that the reformulations preserve the inferences that can be drawn from the input text.

2 Related Work

A relatively large body of work exists in sentence compression (Knight and Marcu, 2000; McDonald, 2006; Galley and McKeown, 2007; Cohn and Lapata, 2008; Clarke and Lapata, 2008, inter alia), and sentence fusion (Barzilay and McKeown, 2005; Marsi and Krahmer, 2005; Filippova and Strube, 2008; Filippova, 2010; Thadani and McKeown, 2013). Unlike this work, our sentence enhancement algorithm considers the entire source text and is not limited to the initial input sentences. Few previous papers focus on combining the content of diverse sentences into one output sentence. Wan et al. (2008) propose sentence augmentation by identifying "seed" words in a single original sentence, then adding information from auxiliary sentences based on word co-occurrence counts. Elsner and Santhanam (2011) investigate the idea of fusing disparate sentences with a supervised algorithm, as discussed above.

Previous studies on cut-and-paste summarization (Jing and McKeown, 2000; Saggion and Lapalme, 2002) investigate the operations that human summarizers perform on the source text in order to produce the summary text. Our previous work argued that current extractive systems rely too heavily on notions of information centrality (Cheung and Penn, 2013). This paper extends this work by identifying specific linguistic factors correlated with the use of source-text-external elements.

3 A Sentence Enhancement Algorithm

The basic steps in our sentence expansion algorithm are as follows: (1) clustering to identify initial input sentences, (2) sentence graph creation, (3) sentence graph expansion, (4) tree generation, and (5) linearization.

At a high level, our method for sentence enhancement is inspired by the syntactic sentence fusion approach of Filippova and Strube (2008) (henceforth, F&S) originally developed for German, in that it operates over the dependency parses of a small number of input sentences to produce an output sentence which fuses parts of the in-

put sentences. We adopt the same assumption as F&S that these initial **core sentences** have a high degree of similarity with each other, and should form the core of a new sentence to be generated (Step 1). While fusion from highly disparate input sentences is possible, Elsner and Santhanam (2011) showed how difficult it is to do so correctly, even where such cases are manually identified. We thus aim for a more targeted type of fusion initially. Next, the dependency trees of the core sentences are fused into an intermediate **sentence graph** (Step 2), a directed acyclic graph from which the final sentence will be generated (Steps 4 and 5). We will compare against our implementation of F&S, adapted to English.

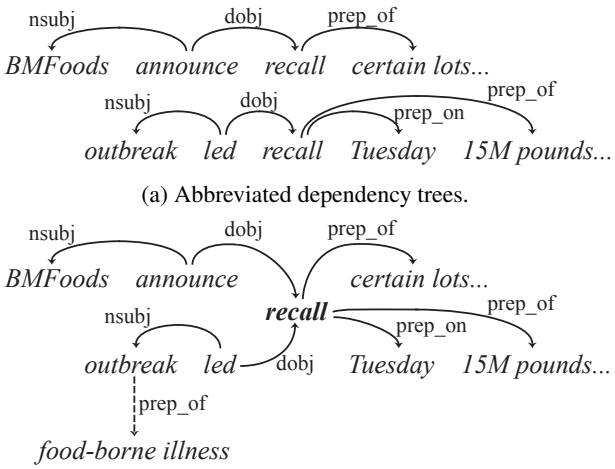
However, unlike F&S or other previous approaches to sentence fusion, the sentence enhancement algorithm may also avail itself of the dependency parses of all of the other sentences in the source text, which expands the range of possible sentences that may be produced. This is accomplished by expanding the sentence graph with parts of these sentences (Step 3). One important issue here is that the expansion must be modulated by an event coreference component to ensure that the merging of information from different points in the source text is valid and does not result in incorrect or nonsensical inferences.

3.1 Core sentence identification

To generate the core sentence clusters, we first identify clusters of similar sentences, then rank the clusters according to their salience. The top cluster in the source text is then selected to be the input to the sentence fusion algorithms.

Sentence alignment is performed by complete-link agglomerative clustering, which requires a measure of similarity between sentences and a stopping criterion. We define the similarity between two sentences to be the standard cosine similarity between the lemmata of the sentences, weighted by IDF and excluding stopwords, and clustering is run until a similarity threshold of 0.5 is reached. Since complete-link clustering prefers small coherent clusters and we select the top-scoring cluster in each document collection, the method is somewhat robust to different choices of the stopping threshold.

The clusters are scored according to the signature term method of Lin and Hovy (2000), which assigns an importance score to each term according to how much more often it appears in the source text compared to some irrelevant background text using a log likelihood ratio. Specifically, the score of a cluster is equal to the sum of the importance scores of the set of lemmata in the cluster.



(a) Abbreviated dependency trees.

(b) Sentence graph after merging the nodes with lemma *recall* (in bold), and expanding the node *outbreak* (dashed outgoing edge).

Figure 3: An example of the input dependency trees for sentence graph creation and expansion, using the input sentences of Figure 1.

3.2 Sentence graph creation

After core sentence identification, the next step is to align the nodes of the dependency trees of the core input sentences in order to create the initial sentence graph. The input to this step is the collapsed dependency tree representations of the core sentences produced by the Stanford parser[1]. In this representation, preposition nodes are collapsed into the label of the dependency edge between the functor of the prepositional phrase and the prepositional object. Chains of conjuncts are also split, and each argument is attached to the parent. In addition, auxiliary verbs, negation particles, and noun-phrase-internal elements[2] are collapsed into their parent nodes. Figure 3a shows the abbreviated dependency representations of the input sentences from Figure 1.

Then, a sentence graph is created by merging nodes that share a common lemma and part-of-

[1] As part of the CoreNLP suite: `http://nlp.stanford.edu/software/corenlp.shtml`

[2] As indicated by the dependency edge label *nn*.

speech tag. In addition, we allow synonyms to be merged, defined as being in the same WordNet synset. Merging is blocked if the word is a stop word, which includes function words as well as a number of very common verbs (e.g., *be*, *have*, *do*). Throughout the sentence graph creation and expansion process, the algorithm disallows the addition of edges that would result in a cycle in the graph.

3.3 Sentence graph expansion

The initial sentence graph is expanded by merging in subtrees from dependency parses of non-core sentences drawn from the source text. First, expansion candidates are identified for each node in the sentence graph by finding all of the dependency edges in the source text from non-core sentences in which the governor of the edge shares the same lemma and POS tag as the node in the sentence graph.

Then, these candidate edges are pruned according to two heuristics. The first is to keep only one candidate edge of each dependency relation type according to the edge that has the highest informativeness score (Section 3.4.1), with ties being broken according to which edge has a subtree with a fewer number of nodes. The second is to perform event coreference in order to prune away those candidate edges which are unlikely to be describing the same event as the core sentences, as explained in the next section. Finally, any remaining candidate edges are fused into the sentence graph, and the subtree rooted at the dependent of the candidate edge is added to the sentence graph as well. See Figure 3b for an example of sentence graph creation and expansion.

3.3.1 Event coreference

One problem of sentence fusion is that the different inputs of the fusion may not refer to the same event, resulting in an incorrect merging of information, as would be the case in the following example:

S1: *Officers pled not guilty but **risked** 25 years to life.*

S2: *Officers recklessly engaged in conduct which seriously **risked** the lives of others.*

Here, the first usage of *risk* refers to the potential sentence imposed if the officers are convicted in a trial, whereas the second refers to the potential harm caused by the officer.

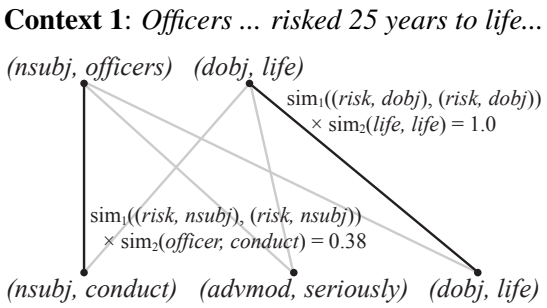


Figure 4: Event coreference resolution as a maximum-weight bipartite graph matching problem. All the nodes share the predicate *risk*.

In order to ensure that sentence enhancement does not lead to the merging of such incompatible events, we designed a simple method to approximate event coreference resolution that does not require event coreference labels. This method is based on the intuition that different mentions of an event should contain many of the same participants. Thus, by measuring the similarity of the arguments and the syntactic contexts between the node in the sentence graph and the candidate edge, we can have a measure of the likelihood that they refer to the same event.

We would be interested in integrating existing event coreference resolution systems into this step in the future, such as the unsupervised method of Bejan and Harabagiu (2010). Existing event coreference systems tend to focus on cases with different heads (e.g., *X kicked Y*, then *Y was injured*), which could increase the possibilities for sentence enhancement, if the event coreference module is sufficiently accurate. However, since our method currently only merges identical heads, we require a more fine-grained method based on distributional measures of similarity.

We measure the similarity of these syntactic contexts by aligning the arguments in the syntactic contexts and computing the similarity of the aligned arguments. These problems can be jointly solved as a maximum-weight bipartite graph matching problem (Figure 4). Formally, let a syntactic context be a list of dependency triples (h, r, a), consisting of a governor or head node h and a dependent argument a in the dependency relation r, where head node h is fixed across each

element of the list. Then, each of the two input syntactic contexts forms one of the two disjoint sets in a complete weighted bipartite graph where each node corresponds to one dependency triple. We define the edge weights according to the similarities of the edge's incident nodes; i.e., between two dependency triples (h_1, r_1, a_1) and (h_2, r_2, a_2). We also decompose the similarity into the similarities between the head and relation types ((h_1, r_1) and (h_2, r_2)), and between the arguments (a_1 and a_2). The edge weight function is thus:

$$\text{sim}((h_1, r_1, a_1), (h_2, r_2, a_2)) = \text{sim}_1((h_1, r_1), (h_2, r_2)) \times \text{sim}_2(a_1, a_2), \quad (1)$$

where sim_1 and sim_2 are binary functions that represent the similarities between governor-relation pairs and dependents, respectively. We train models of distributional semantics using a large background corpus; namely, the Annotated Gigaword corpus (Napoles et al., 2012). For sim_1, we create a vector of counts of the arguments that are seen filling each (h, r) pair, and define the similarity between two such pairs to be the cosine similarity between their argument vectors. For sim_2, we create a basic vector-space representation of a word d according to words that are found in the context of word d within a five-word context window, and likewise compute the cosine similarity between the word vectors. These methods of computing distributional similarity are well attested in lexical semantics for measuring the relatedness of words and syntactic structures (Turney and Pantel, 2010), and similar methods have been applied in text-to-text generation by Ganitkevitch et al. (2012), though the focus of that work is to use paraphrase information thus learned to improve sentence compression.

The resulting graph matching problem is solved using the NetworkX package for Python[3]. The final similarity score is an average of the similarity scores from Equation 1 that participate in the selected matching, weighted by the product of the IDF scores of the dependent nodes of each edge. This final score is used as a threshold that candidate contexts from the source text must meet in order to be eligible for being merged into the sentence graph. This threshold was tuned by cross-validation, and can remain constant, although retuning to different domains (a weakly supervised alternative) is likely to be beneficial.

[3] http://networkx.github.io/

3.4 Tree generation

The next major step of the algorithm is to extract an output dependency tree from the expanded sentence graph. We formulate this as an integer linear program, in which variables correspond to edges of the sentence graph, and a solution to the linear program determines the structure of an output dependency tree. We use ILOG CPLEX to solve all of the integer linear programs in our experiments.

A good dependency tree must at once express the salient or important information present in the input text as well as be grammatically correct and of a manageable length. These desiderata are encoded into the linear program as constraints or as part of the objective function.

3.4.1 Objective function

We designed an objective function that considers the importance of the words and syntactic relations that are selected as well as accounts for redundancy in the output sentence. Let X be the set of variables in the program, and let each variable in X take the form $x_{h,r,a}$, a binary variable that represents whether an edge in the sentence graph from a head node with lemma h to an argument with lemma a in relation r is selected. For a lexicon Σ, our objective function is:

$$\max \sum_{w \in \Sigma} \max_{x_{h,r,a} \in X \, s.t. \, a = w} (x_{h,r,w} \cdot P(r|h) \cdot I(w)), \quad (2)$$

where $P(r|h)$ is the probability that head h projects the dependency relation r, and $I(w)$ is the informativeness score for word w as defined by Clarke and Lapata (2008). This formulation encourages the selection of words that are informative according to $I(w)$ and syntactic relations that are probable. The inner $\max$ function for each w in the lexicon encourages non-redundancy, as each word may only contribute once to the objective value. This function can be rewritten into a form compatible with a standard linear program by the addition of auxiliary variables and constraints. For more details of how this and other aspects of the linear program are implemented, see the supplementary document.

3.4.2 Constraints

Well-formedness constraints, taken directly from F&S, ensure that the set of selected edges pro-

duces a tree. Another constraint limits the number of content nodes in the tree to 11, which corresponds to the average number of content nodes in human-written summary sentences in the data set. Syntactic constraints aim to ensure grammaticality of the output sentence. In addition to the constraint proposed by F&S regarding subordinating conjunctions, we propose two other ones. The first ensures that a nominal or adjectival predicate must be selected with a copular construction at the top level of a non-finite clause. The second ensures that transitive verbs retain both of their complements in the output[4]. Semantic constraints ensure that only noun phrases of sufficiently high similarity which are not in a hyperonym-hyponym or holonym-meronym relation with each other may be joined by coordination.

3.5 Linearization

The final step of our method is to linearize the dependency tree from the previous step into the final sequence of words. We implemented our own linearization method to take advantage of the ordering information can be inferred from the original source text sentences.

Our linearization algorithm proceeds top-down from the root of the dependency tree to the leaves. At each node of the tree, linearization consists of realizing the previously collapsed elements such as prepositions, determiners and noun compound elements, then ordering the dependent nodes with respect to the root node and each other. Restoring the collapsed elements is accomplished by simple heuristics. For example, prepositions and determiners precede their accompanying noun phrase.

The dependent nodes are ordered by a sorting algorithm, where the order between two syntactic relations and dependent nodes (r_1, a_1) and (r_2, a_2) is determined as follows. First, if a_1 and a_2 originated from the same source text sentence, then they are ordered according to their order of appearance in the source text. Otherwise, we consider the probability $P(r_1 \text{ precedes } r_2)$, and order a_1 before a_2 iff $P(r_1 \text{ precedes } r_2) > 0.5$. This distribution, $P(r_1 \text{ precedes } r_2)$, is estimated by counting and normalizing the order of the relation types in the source text corpus. For the purposes of ordering, the governor node is treated as if it were a dependent node with a special syntactic relation label *self*. This algorithm always produces an output ordering with a projective dependency tree, which is a reasonable assumption for English.

[4]We did not experiment with changing the grammatical voice in the output tree, such as introducing a passive construction if only a direct object is selected, but this is one possible extension of the algorithm.

4 Experiments

4.1 Method

Recent approaches to sentence fusion have often been evaluated as isolated components. For example, F&S evaluate the output sentences by asking human judges to rate the sentences' informativeness and grammaticality according to a 1–5 Likert scale rating. Thadani and McKeown (2013) combine grammaticality ratings with an automatic evaluation which compares the system output against gold-standard sentences drawn from summarization data sets. However, this evaluation setting still does not reflect the utility of sentence fusion in summarization, because the input sentences come from human-written summaries rather than the original source text.

We adopt a more realistic setting of using sentence fusion in automatic summarization by drawing the input or core sentences automatically from the source text, then evaluating the output of the fusion and expansion algorithm directly as one-sentence summaries according to standard summarization evaluation measures of content quality.

Data preparation. Our experiments are conducted on the TAC 2010 and TAC 2011 Guided Summarization corpus (Owczarzak and Dang, 2010), on the initial summarization task. Each document cluster is summarized by one sentence, generated from an initial cluster of core sentences as described in Section 3.1.

Evaluation measures. We evaluate summary content quality using the word-overlap measures ROUGE-1 and ROUGE-2, as is standard in the summarization community. We also measure the quality of sentences at a syntactic or shallow semantic level that operates at the level of dependency triples by a measure that we call **Pyramid BE**. Specifically, we extract all of the dependency triples of the form $t = (h, r, a)$ from the sentence under evaluation and the gold-standard summaries, where h and a are the lemmata of the head and the argument, and r is the syntactic relation, normalized for grammatical voice and excluding the collapsed edges which are mostly noun-phrase-internal elements and grammatical

Method	Pyramid BE	ROUGE-1	ROUGE-2	Log Likelihood	Oracle Pyramid BE
Fusion (F&S)	10.61	**10.07**	**2.15**	-159.31	28.00
Expansion	8.82	9.41	1.82	-157.46	52.97
+Event coref	**11.00**	9.76	1.93	**-156.20**	40.30

Table 1: Results of the sentence enhancement and fusion experiments.

particles. Then, we perform a matching between the set of triples in the sentence under evaluation and in a reference summary following the Transformed BE method of Tratz and Hovy (2008) with the *total* weighting scheme. This matching is performed between the sentence and every gold-standard summary, and the maximum of these scores is taken. This score is then divided by the maximum score that is achievable using the number of triples present in the input sentence, as inspired by the Pyramid method. This denominator is more appropriate than the one used in Transformed BE, which is designed for the case where the evaluated summary and the reference summaries are of comparable length.

For grammaticality, we parse the output sentences using the Stanford parser[5], and use the log likelihood of the most likely parse of the sentence as a coarse estimate of grammaticality. Parse log likelihoods have been shown to be useful in determining grammaticality (Wagner et al., 2009), and many of the problems associated with using it do not apply in our evaluation, because our sentences have a fixed number of content nodes, and contain similar content. While we could have conducted a user study to elicit Likert-scale grammaticality judgements, such results are difficult to interpret and the scores depend heavily on the set of judges and the precise evaluation setting, as is the case for sentence compression (Napoles et al., 2011).

4.2 Results and discussion

As shown in Table 1, sentence enhancement with coreference outperforms the sentence fusion algorithm of F&S in terms of the Pyramid BE measure and the baseline expansion algorithm, though only the latter difference is statistically significant ($p = 0.019$[6]). In terms of the ROUGE word overlap measures, fusion achieves a better performance, but it only outperforms the expansion baseline significantly (ROUGE-1: $p = 0.021$, ROUGE-2: $p = 0.012$). Note that the ROUGE scores are low because they involve comparing a one-sentence summary against a paragraph-long gold standard. The average log likelihood result suggests that sentence enhancement with event coreference produces sentences that are more grammatical than traditional fusion does, and this difference is statistically significant ($p = 0.044$). These results show that sentence enhancement with event coreference is competitive with a strong previous sentence fusion method in terms of content, despite having to combine information from more diverse sentences. This does not come at the expense of grammaticality; in fact, it seems that having a greater possible range of output sentences may even improve the grammaticality of the output sentences.

Oracle score. To examine the potential of sentence enhancement, we computed an oracle score that provides an upper bound to the best possible sentence that may be extracted from the sentence graph. First, we ranked all of dependency triples found in each gold-standard summary by their score (i.e., the number of gold-standard summaries they appear in). Then, we took the highest scoring triples from this ranking that are found in the sentence graph until the length limit was reached, and divided by the Pyramid-based denominator as above[7]. The oracle score is the maximum of these scores over the gold-standard summaries. The resulting oracle scores are shown in the rightmost column of Table 1. While it is no surprise that the oracle score improves after the sentence graph is expanded, the large increase in the oracle score indicates the potential of sentence enhancement for generating high-quality summary sentences.

[5]The likelihoods are obtained by the PCFG model of CoreNLP version 1.3.2. We experimented with the Berkeley parser (Petrov et al., 2006) as well, with similar results that favour the sentence enhancement with event coreference method, but because the parser failed to parse a number of cases, we do not report those results here.

[6]All statistical significance results in this section are for Wilcoxon signed-rank tests.

[7]There is no guarantee that these dependency triples form a tree structure. Hence, this is an upper bound.

Grammaticality. There is still room for improvement in the grammaticality of the generated sentences, which will require modelling contexts larger than individual predicates and their arguments. Consider the following output of the sentence enhancement with event coreference system:

(3) *The government has launched an investigation into Soeharto's wealth by the Attorney General's office on the wealth of former government officials.*

This sentence suffers from coherence problems because two pieces of information are duplicated. The first is the subject of the investigation, which is expressed by two prepositional objects of *investigation* with the prepositions *into* and *on*. The second, more subtle incoherence concerns the body that is responsible for the investigation, which is expressed both by the subject of *launch* (***The government*** *has launched an investigation*), and the *by*-prepositional object of *investigation* (an investigation ... ***by the Attorney General's office***). Clearly, a model that makes fewer independence assumptions about the relation between different edges in the sentence graph is needed.

5 A Study of Source-External Elements

The sentence enhancement algorithm presented above demonstrates that it is possible to use the entire source text to produce an informative sentence. Yet it is still limited by the particular predicates and dependency relations that are found in the source. The next step towards developing abstractive systems that exhibit human-like behaviour is to try to incorporate elements into the summary that are not found in the source text at all.

Despite its apparent difficulty, there is reason to be hopeful for text-to-text generation techniques even in such a scenario. In particular, we showed in earlier work that almost all of the **caseframes**, or pairs of governors and relations, in human-written summaries can be found in the source text or in a small set of additional related articles that belong to the same domain as the source text (e.g., natural disasters) (Cheung and Penn, 2013). What that study lacks, however, is a detailed analysis of the factors surrounding why human summary writers use non-source-text elements in their summaries, and how these may be automatically identified in the in-domain text. In this section, we supply such an analysis and provide evidence that human summary writers actually do incorporate elements external to the source text for a reason, namely, that these elements are more specific to the semantic content that they wish to convey. We also identify a number of features that may be useful for automatically determining the appropriateness of these in-domain elements in a summary.

5.1 Method

We performed our analysis on the predicates present in text, such as *kill* and *computer*. We also analyzed predicate-relation pairs (**PR pairs**) such as $(kill, nsubj)$ or $(computer, amod)$. This choice is similar to the caseframes used by Cheung and Penn (2013), and we similarly apply transformations to normalize for grammatical voice and other syntactic alternations, but we consider PR pairs of all relation types, unlike caseframes, which only consider verb complements and prepositional objects. PR pairs are extracted from the preprocessed corpus. We use the TAC 2010 Guided Summarization data set for our analyses, which we organize into two sub-studies. In the provenance study, we divide the PR pairs in human-written summaries according to whether they are found in the source text (**source-internal**) or not (**source-external**). In the domain study, we divide in-domain but source-external predicate-relation pairs according to whether they are used in a human-written summary (**gold-standard**) or not (**non-gold-standard**).

5.2 Provenance Study

In the first study, we compare the characteristics of gold-standard predicates and PR pairs according to their provenance; that is, are they found in the source text itself? The question that we try to answer is why human summarizers need to look beyond the source text at all when writing their summaries. We will provide evidence that they do so because they can find predicates that are more appropriate to the content that is being expressed according to two quantitative measures.

Predicate provenance. Source-external PR pairs may be external to the source text for two reasons. Either the predicate (i.e., the actual word) is found in the source text, but the dependency relation (i.e., the semantic predication that holds between the predicate and its arguments) is not found with that particular predicate, or the

	Average freq (millions)
Source-internal	1.77 (1.57, 2.08)
Source-external	1.15 (0.99, 1.50)

(a) The average predicate frequency of source-internal vs. source-external gold-standard predicates in an external corpus.

	Arg entropy
Source-internal	7.94 (7.90, 7.97)
Source-external	7.42 (7.37, 7.48)

(b) The average argument entropy of source-internal vs. source-external PR pairs in bits.

Table 2: Results of the provenance study. 95% confidence intervals are estimated by the bootstrap method and indicated in parentheses.

predicate itself may be external to the source text altogether. If the former is true, then a generalized version of the sentence enhancement algorithm presented in this paper could in principle capture these PR-pairs. We thus compute the proportion of source-external PR pairs where the predicate already exists in the source text.

We find that 2413 of the 4745 source-external PR pairs, or 51% have a predicate that can be found in the source text. This indicates that an extension of the sentence enhancement with event coreference approach presented in this paper could capture a substantial portion of the source-external PR pairs in its hypothesis space already.

Predicate frequency. What factors then can account for the remaining predicates that are not found in the source text at all? The first such factor we identify is the frequency of the predicates. Here, we take frequency to be the number of occurrences of the predicate in an external corpus; namely the Annotated Gigaword, which gives us a proxy for the specificity or informativeness of a word. In this comparison, we take the set of predicates in human-written summaries, divide them according to whether they are found in the source text or not, and then look up their frequency of appearance in the Annotated Gigaword corpus.

As Table 2a shows, the predicates that are not found in the source text consist of significantly less frequent words on average (Wilcoxon rank-sums test, $p < 10^{-17}$). This suggests that human summary writers are motivated to use source-external predicates, because they are able to find a more informative or apposite predicate than the ones that are available in the source text.

Entropy of argument distribution. Another measure of the informativeness or appropriateness of a predicate is to examine the range of arguments that it tends to take. A more generic word would be expected to take a wider range of arguments, whereas a more particular word would take a narrower range of arguments, for example those of a specific entity type. We formalize this notion by measuring the entropy of the distribution of arguments that a predicate-relation pair takes as observed in Annotated Gigaword. Given frequency statistics $f(h, r, a)$ of predicate head h taking an argument word a in relation r, we define the argument distribution of predicate-relation pair (h, r) as:

$$P(a|h, r) = f(h, r, a) / \sum_{a'} f(h, r, a') \quad (4)$$

We then compute the entropy of $P(a|h, r)$ for the gold-standard predicate-relation pairs, and compare the average argument entropies of the source-internal and the source-external subsets.

Table 2b shows the result of this comparison. Source-external PR pairs exhibit a lower average argument entropy, taking a narrower range of possible arguments. Together these two findings indicate that human summary writers look beyond the source text not just for the sake of diversity or to avoid copying the source text; they do so because they can find predicates that more specifically convey some desired semantic content.

5.3 Domain study

The second study examines how to distinguish those source-external predicates and PR pairs in in-domain articles that are used in a summary from those that are not. For this study, we rely on the topic category divisions in the TAC 2010 data set, and define the in-domain text to be the documents that belong to the same topic category as the target document cluster (but not including the target document cluster itself). This study demonstrates the importance of better semantic understanding for developing a text-to-text generation system that uses in-domain text, and identifies potentially useful features for training such a system.

Nearest neighbour similarity. In the event-coreference step of the sentence enhancement algorithm, we relied on distributional semantics to

	N	NN sim
GS	2202	0.493 (0.486, 0.501)
Non-GS	789K	0.443 (0.442, 0.443)

(a) Average similarity of gold-standard (GS) and non-gold-standard (non-GS) PR pairs to the nearest neighbour in the source text.

	N	Freq. (millions)	Fecundity
GS	1568	2.44 (2.05, 2.94)	21.6 (20.8, 22.5)
non-GS	268K	0.85 (0.83, 0.87)	6.43 (6.41, 6.47)

(b) Average frequency and fecundity of GS and non-GS predicates in an external corpus. The differences are statistically significant ($p < 10^{-10}$).

Table 3: Results of the domain study. 95% confidence intervals are given in parentheses.

measure the similarity of arguments. Here, we examine how well distributional similarity determines the appropriateness of a source-external PR pair in a summary. Specifically, we measure its similarity to the nearest PR pair in the source text. To determine the similarity between two PR pairs, we compute the cosine similarity between their vector representations. The vector representation of a PR pair is the concatenation of a context vector for the predicate itself and a selectional preferences vector for the PR pair; that is, the vector of counts with elements $f(h, r, a)$ for fixed h and r. These vectors are trained from the Annotated Gigaword corpus.

The average nearest-neighbour similarities of PR pairs are shown in Table 3a. While the difference between the gold-standard and non-gold-standard PR pairs is indeed statistically significant, the magnitude of the difference is not large. This illustrates the challenge of mining source-external text for abstractive summarization, and demonstrates the need for a more structured or detailed semantic representation in order to determine the PR pairs that would be appropriate. In other words, the kind of simple event coreference method based solely on distributional semantics that we used in Section 3.3.1 is unlikely to be sufficient when moving beyond the source text.

Frequency and fecundity. We also explore several features that would be relevant to identifying predicates in in-domain text that are used in the automatic summary. This is a difficult problem, as less than 0.6% of such predicates are actually used in the source text. As a first step, we consider several simple measures of the frequency and characteristics of the predicates.

The first measure that we compute is the average predicate frequency of the gold-standard and non-gold-standard predicates in an external corpus, as in Section 5.2. A second, related measure is to compute the number of possible relations that may occur with a given predicate. We call this measure the **fecundity** of a predicate. Both of these are computed with respect to the external Annotated Gigaword corpus, as before.

As shown in Table 3b, there is a dramatic difference in both measures between gold-standard and non-gold-standard predicates in in-domain articles. Gold-standard predicates tend to be more common words compared to non-gold-standard ones. This result is not in conflict with the result in the provenance study that source-external predicates are less common words. Rather, it is a reminder that the background frequencies of the predicates matter, and must be considered together with the semantic appropriateness of the candidate word.

6 Conclusions

This paper introduced sentence enhancement as a method to incorporate information from multiple points in the source text into one output sentence in a fashion that is more flexible than previous sentence fusion algorithms. Our results show that sentence enhancement improves the content and grammaticality of summary sentences compared to previous syntax-based sentence fusion approaches. Then, we presented studies on the components of human-written summaries that are external to the source text. Our analyses suggest that human summary writers look beyond the source text to find predicates and relations that more precisely express some target semantic content, and that more sophisticated semantic techniques are needed in order to exploit in-domain articles for text-to-text generation in summarization.

Abstract

In this paper we introduce a new game to crowd-source natural language referring expressions. By designing a two player game, we can both collect and verify referring expressions directly within the game. To date, the game has produced a dataset containing 130,525 expressions, referring to 96,654 distinct objects, in 19,894 photographs of natural scenes. This dataset is larger and more varied than previous REG datasets and allows us to study referring expressions in real-world scenes. We provide an in depth analysis of the resulting dataset. Based on our findings, we design a new optimization based model for generating referring expressions and perform experimental evaluations on 3 test sets.

1 Introduction

Much of everyday language and discourse concerns the visual world around us, making understanding the relationship between objects in the physical world and language describing those objects an important challenge problem for AI. From robotics, to image search, to situated language learning, and natural language grounding, there are a number of research areas that would benefit from a better understanding of how people refer to physical entities in the world.

Recent advances in automatic computer vision methods have started to make technologies for recognizing thousands of object categories a near reality (Perronnin et al., 2012; Deng et al., 2012; Deng et al., 2010; Krizhevsky et al., 2012). As a result, there has been a spurt of recent work trying to estimate higher level semantics, including exciting efforts to automatically produce natural language descriptions of images and video (Farhadi et al., 2010; Kulkarni et al., 2011; Yang et al., 2011; Ordonez et al., 2011; Kuznetsova et al., 2012; Feng and Lapata, 2013). Common challenges encountered in these pursuits include the fact that descriptions can be highly task dependent, open-ended, and difficult to evaluate automatically.

Therefore, we look at the related, but more focused problem of referring expression generation (REG). Previous work on REG has made significant progress toward understanding how people generate expressions to refer to objects (a recent survey of techniques is provided in Krahmer and van Deemter (2012)). In this paper, we study the relatively unexplored setting of how people refer to objects in *complex photographs of real-world cluttered scenes*. One initial stumbling block to examining this scenario is lack of existing relevant datasets, as previous collections for studying REG have used relatively focused domains such as graphics generated objects (van Deemter et al., 2006; Viethen and Dale, 2008), crafts (Mitchell et al., 2010), or small everyday (home and office) objects arrayed on a simple background (Mitchell et al., 2013a; FitzGerald et al., 2013).

In this paper, we collect a new large-scale corpus, currently containing 130,525 expressions, referring to 96,654 distinct objects, in 19,894 photographs of real world scenes. Some examples from our dataset are shown in Figure 5. To construct this corpus efficiently, we design a new two player referring expression game (ReferItGame) to crowd-source the data collection. Popularized by efforts like the ESP game (von Ahn and Dabbish, 2004) and Peekaboom (von Ahn et al., 2006b), Human Computation based games can be an effective way to engage users and collect large amounts of data inexpensively. Two player games can also automate verification of human provided annotations.

Our resulting corpus is both more real-world and much bigger than previous datasets, allowing

us to examine referring expression generation in a new setting at large scale. To understand and quantify this new dataset, we perform an extensive set of analyses. One significant difference from previous work is that we study how referring expressions vary for different categories. We find that an object's category greatly influences the types of attributes used in their referring expression (e.g. people use color words to describe cars more often than mountains). Additionally, we find that references to an object are sometimes made with respect to other nearby objects, e.g. "the ball to left of the man". Interestingly, the types of reference objects (i.e. "the man") used in referring expressions is also biased toward some categories. Finally, we find that the word used to refer to the object category itself displays consistencies across people. This notion is related to ideas of entry-level categories from Psychology (Rosch, 1978).

Given these findings, we propose an optimization model for generating referring expressions that jointly selects which attributes to include in the expression, and what attribute values to generate. This model incorporates both visual models for selecting attribute-values and object category specific priors. Experimental evaluations indicate that our proposed model produces reasonable results for REG.

In summary, contributions of our paper include:

- A two player online game to collect and verify natural language referring expressions.
- A new large-scale dataset containing natural language expressions referring to objects in photographs of real world scenes.
- Analyses of the collected dataset, including studying category-specific variations in referring expressions.
- An optimization based model to generate referring expressions for objects in real-world scenes with experimental evaluations on three labeled test sets.

The rest of the paper is organized as follows. First we outline related work from the vision and language communities (§2). Then we describe our online game for collecting referring expressions (§3) and provide an analysis of our new ReferItGame Dataset (§4). Finally, we present and evaluate our model for generating referring expressions (§5) and discuss conclusions and future work (§6).

2 Related Work

Referring Expression Generation: There has been a long history of research on understanding how people generate referring expressions, dating back to the 1970s (Winograd, 1972). One common approach is the Incremental Algorithm (Dale and Reiter, 1995; Dale and Reiter, 2000) which uses logical expressions for generation. Much work in REG follows the Gricean maxims (Grice, 1975) which provide principles for how people will behave in conversation.

Recently, there has been progress examining other aspects of the referring expression problem such as understanding what types of attributes are used (Mitchell et al., 2013a), modeling variations between speakers (Viethen and Dale, 2010; Viethen et al., 2013; Van Deemter et al., 2012; Mitchell et al., 2013b), incorporating visual classifiers (Mitchell et al., 2011), producing algorithms to refer to object sets (Ren et al., 2010; FitzGerald et al., 2013), or examining impoverished perception REG (Fang et al., 2013). A good survey of work in this area is provided in Krahmer and van Deemter (2012). We build on past work, extending models to generate attributes jointly in a category specific framework.

Referring Expression Datasets: Some initial datasets in REG used graphics engines to produce images of objects (van Deemter et al., 2006; Viethen and Dale, 2008). Recently more realistic datasets have been introduced, consisting of craft objects like pipecleaners, ribbons, and feathers (Mitchell et al., 2010), or everyday home and office objects such as staplers, combs, or rulers (Mitchell et al., 2013a), arrayed on a simple background. These datasets helped moved referring expression generation research into the domain of real world objects. We seek to further these pursuits by constructing a dataset of natural objects in photographs of the real world.

Image & Video Description Generation: Recent research on automatic image description has followed two main directions. Retrieval based methods (Aker and Gaizauskas, 2010; Farhadi et al., 2010; Ordonez et al., 2011; Feng and Lapata, 2010; Feng and Lapata, 2013) retrieve existing captions or phrases to describe a query image. Bottom up methods (Kulkarni et al., 2011; Yang et al., 2011; Yao et al., 2010) rely on visual classifiers to first recognize image content and then construct captions from scratch, perhaps with some

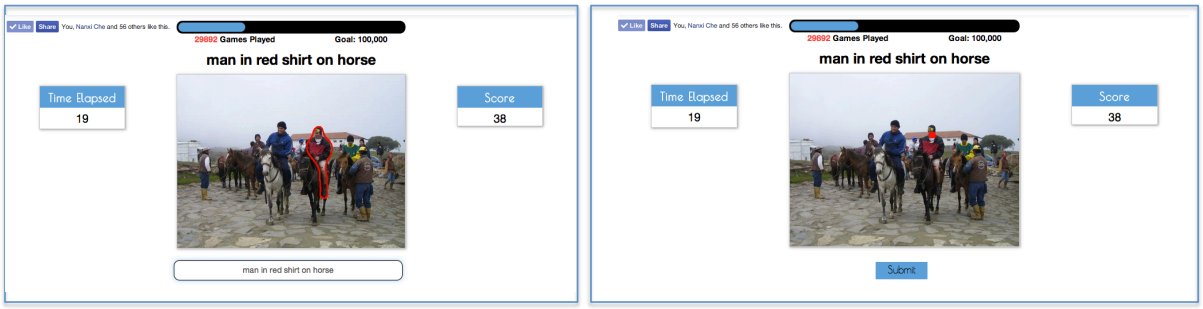

Figure 1: An example game. Player 1 (*left*) sees an image with an object outlined in red (the man) and provides a referring expression for the object ("man in red shirt on horse"). Player 2 (*right*) sees the image and the expression from Player 1 and must localize the correct object by clicking on it (click indicated by the red square). Elapsed time and current scores are also provided.

input from natural language statistics. Very recently, these ideas have been extended to produce descriptions for videos (Guadarrama et al., 2013; Barbu et al., 2012). Like these methods, we generate descriptions for natural scenes, but focus on referring to particular objects rather than providing an overall description of an image or video.

Human Computation Games: Games can be a useful tool for collecting large amounts of labeled data quickly. Human Computation Games were first introduced by Luis von Ahn in the ESP game (von Ahn and Dabbish, 2004) for image labeling, and later extended to segment objects (von Ahn et al., 2006b), collect common-sense knowledge (von Ahn et al., 2006a), or disambiguate words (Seemakurty et al., 2010). Recently, crowd games have also been introduced into the computer vision community for tasks like fine grained category recognition (Deng et al., 2013). These games can be released publicly on the web or used on Mechanical Turk to enhance and encourage turker participation (Deng et al., 2013). Inspired by the success of previous games, we create a game to collect and verify natural language expressions referring to objects in natural scenes.

3 Referring Expression Game (ReferItGame)

In this section we describe our referring expression game (ReferItGame*), a simple two player game where players alternate between generating expressions referring to objects in images of natural scenes, and clicking on the locations of described objects. An example game is shown in Figure 1.

*Available online at http://referitgame.com

3.1 Game Play

Player 1: is shown an image with an object outlined in red and provided with a text box in which to write a referring expression. *Player 2:* is shown the same image and the referring expression written by Player 1 and must click on the location of the described object (note, Player 2 does not see the object segmentation). If Player 2 clicks on the correct object, then both players receive game points and the Player 1 and Player 2 roles swap for the next image. If Player 2 does not click on the correct object then no points are received and the players remain in their current roles.

This provides us with referring expressions for our dataset and verification that the expressions are valid since they led to correct object localizations. Expressions written for games where the object was not correctly localized are kept and released with the dataset for future study, but are not included in our final dataset analyses or statistics. A game timer encourages players to write expressions quickly, resulting in more natural expressions. Also, IP addresses are filtered to prevent people from simultaneously playing both roles.

3.2 Playing Against the Computer

To promote engagement, we implement a single player version of the game. When a player connects, if there is another player online then the two people are paired. If there are currently no other available players, then the person plays a "canned" game against the computer. If at any point another person connects, the canned game ends and the player is paired with the new person.

To implement canned games we seed the game with 5000 pre-recorded referring expression games (5 referring expressions and resulting clicks

for each of 1000 objects) collected using Amazon's Mechanical Turk service. Implementing an automated version of Player 1 is simple; we just show the person one of the pre-collected referring expressions and they click as usual.

Automating the role of Player 2 is a bit more complicated. In this case, we compare the person's written expression against the pre-recorded expressions for the same object. For this comparison we use a parser to lemmatize the words in an expression and then compute cosine similarity between expressions with a bag of words representation. Based on this measure the closest matching expression is determined. If there is no similarity between the newly generated expression and the canned expressions, the expression is deemed incorrect and a random click location (outside of the object) is generated. If there is a successful match with a previously generated expression, then the canned click from the most similar pre-recorded game is used. More complex similarities could be used, but since we require real-time performance in our game setting we use this simple implementation which works well for our expressions.

4 ReferItGame Dataset

In this section we describe the ReferItGame dataset[†], including images and labels, processing the dataset, and analysis of the collection.

4.1 Images and Labels

We build our dataset of referring expressions on top of the ImageCLEF IAPR image retrieval dataset (Grubinger et al., 2006). This dataset is a collection of 20,000 images available free of charge without copyright restrictions, depicting a variety of aspects of everyday life, from sports, to animals, to cities, and landscapes. Crucial for our purposes, the SAIAPR TC-12 expansion (Escalante et al., 2010) includes segmentations of each image into regions indicating the locations of constituent objects. 238 different object categories are labeled, including animals, people, buildings, objects, and background elements like grass or sky. This provides us with information regarding object category, object location, and object size, as well as the location and categories of other objects present in the same image.

[†] Available at http://tamaraberg.com/referitgame

4.2 Collecting the Dataset

From the ImageCLEF dataset, we created a total of over 100k distinct games (one per object labeled in the dataset). For the games we imposed an ordering to allow for collecting the most interesting expressions first. Initially we prioritized games for objects in images with multiple objects of the same category. Once these games were completed, we prioritized ordering based on object category to include a comprehensive range of objects. Finally, after successfully collecting referring expressions from the prioritized games, we posted games for the remaining objects. In order to evaluate consistency of expression generation across people, we also include a probability of repeating previously played games during collection.

To date, we have collected 130,525 successfully completed games. This includes 10,431 canned games (a person playing against the computer, not including the initial seed set) and 120,094 real games (two people playing). 96,654 distinct objects from 19,984 photographs are represented in the dataset. This covers almost all of the objects present in the IAPR corpus. The remaining objects from the collection were either too small or too ambiguous to result in successful games.

For data collection, we posted the game online for anyone on the web to play and encouraged participation through social media and the survey section of reddit. In this manner we collected over 4 thousand referring expressions over a period of 3 weeks. To speed up data collection, we also posted the game on Mechanical Turk. Turkers were paid upon completion of 10 correct games (games where Player 2 clicks on the correct object of interest). Turkers were pre-screened to have approval ratings above 80% and to be located in the US for language consistency.

4.3 Processing the Dataset

Because of the size of the dataset, hand annotation of all referring expressions is prohibitive. Therefore, similar to past work (FitzGerald et al., 2013), we design an automatic method to pre-process the expressions and extract object and attribute mentions. These automatically processed expressions are used only for analysis and model training. We also fully hand label portions of the dataset for evaluation (§5.2).

By examining the expressions in the collected dataset, we define a set of attributes with broad

$$
\begin{aligned}
S &::= subject\_word \\
color\_word' &::= rel(S, color\_word)_{color\_word'=color\_word} \mid \\
&\quad prep\_in(S, color\_word)_{color\_word'=color\_word} \\
size\_word' &::= rel(S, size\_word)_{size\_word'=size\_word} \\
abs\_loc\_word' &::= rel(S, abs\_loc\_word)_{\ abs\_loc\_word'=abs\_loc\_word} \mid \\
&\quad prep\_on(S, orientation\_word) \wedge \neg prep\_of(S, \_)_{abs\_loc\_word'=on+orientation\_word} \\
rel\_loc\_word' &::= RL \\

&\quad prep\_to(S, orientation\_word) \wedge prep\_of(S, object\_word)_{\ RL=to\_orientation\_word} \mid \\
&\quad prep\_at(S, orientation\_word) \wedge prep\_of(S, object\_word)_{\ RL=at\_orientation\_word} \\
generic\_word' &::= amod(S, generic\_word)
\end{aligned}
$$

Figure 2: Templates for parsing attributes from referring expressions (§4.3).

coverage of the attribute types used in the referring expressions. We define the set of attributes for a referring expression as a 7-tuple $R = \{r_1, r_2, r_3, r_4, r_5, r_6, r_7\}$:

- r_1 is an entry-level category attribute,
- r_2 is a color attribute,
- r_3 is a size attribute,
- r_4 is an absolute location attribute,
- r_5 is a relative location relation attribute,
- r_6 is a relative location object attribute,
- r_7 is a generic attribute,

Color and *size* attributes refer to the object color (e.g. "blue") and object size (e.g. "tiny") respectively. *Absolute location* refers to the location of the object in the image (e.g. "top of the image"). *Relative location relation* and *relative location object* attributes allow for referring expressions that localize the object with respect to another object in the picture (e.g. "the car to the left of the tree"). *Generic attributes* cover all less frequently observed attribute types (e.g. "wooden" or "round").

The *entry-level category attribute* is related to the concept of entry-level categories first proposed by Psychologists in the 1970s (Rosch, 1978) and recently explored in visual recognition (Ordonez et al., 2013). The idea of entry-level categories is that an object can belong to many different categories; an indigo bunting is an oscine, a bird, a vertebrate, a chordate, and so on. But, a person looking at a picture of one would probably call it a bird (unless they are very familiar with ornithology). Therefore, we include this attribute to capture how people name object categories in referring expressions.

Parsing the referring expressions: We parse the expressions using the most recent version of the StanfordCoreNLP parser (Socher et al., 2013). We begin by traversing the parse tree in a breadth-first manner and selecting the head noun of the sentence to determine the object of the referring expression, denoted as $subject\_word$. We pre-define a dictionary of attribute-values ($color\_word$, $size\_word$, $abs\_location\_word$, $rel\_location\_word$) for each of the attributes based on the observed data using a combination of POS-tagging and manual labeling.

We then apply a template-based approach on the collapsed dependency relations to recover the set of attributes (the main template rules are shown in Figure 2). The relationship rel indicates any linguistic binary relationship between the subject word S and another word, including the $amod$ relationship. $Orientation\_word$ captures the words like left, right, top and bottom. For $generic\_word$ we consider any modifier words other than those captured by our other attributes (color, size, location).

Using this template-based parser we can for instance parse the following expression: "Red flower on top of pedestal". The first rule would match the $prep(S, color\_word)$ relation, effectively recovering the attribute $color\_word'$ as "red". The second rule would match the $prep\_on(S, orientation\_word) \wedge prep\_of(S, object\_word)$ relations, recovering rel_loc_word' as "on top of " and $object\_word$ as "pedestal".

The accuracy of our parser based processing is 91%. This was evaluated on 4,500 expressions

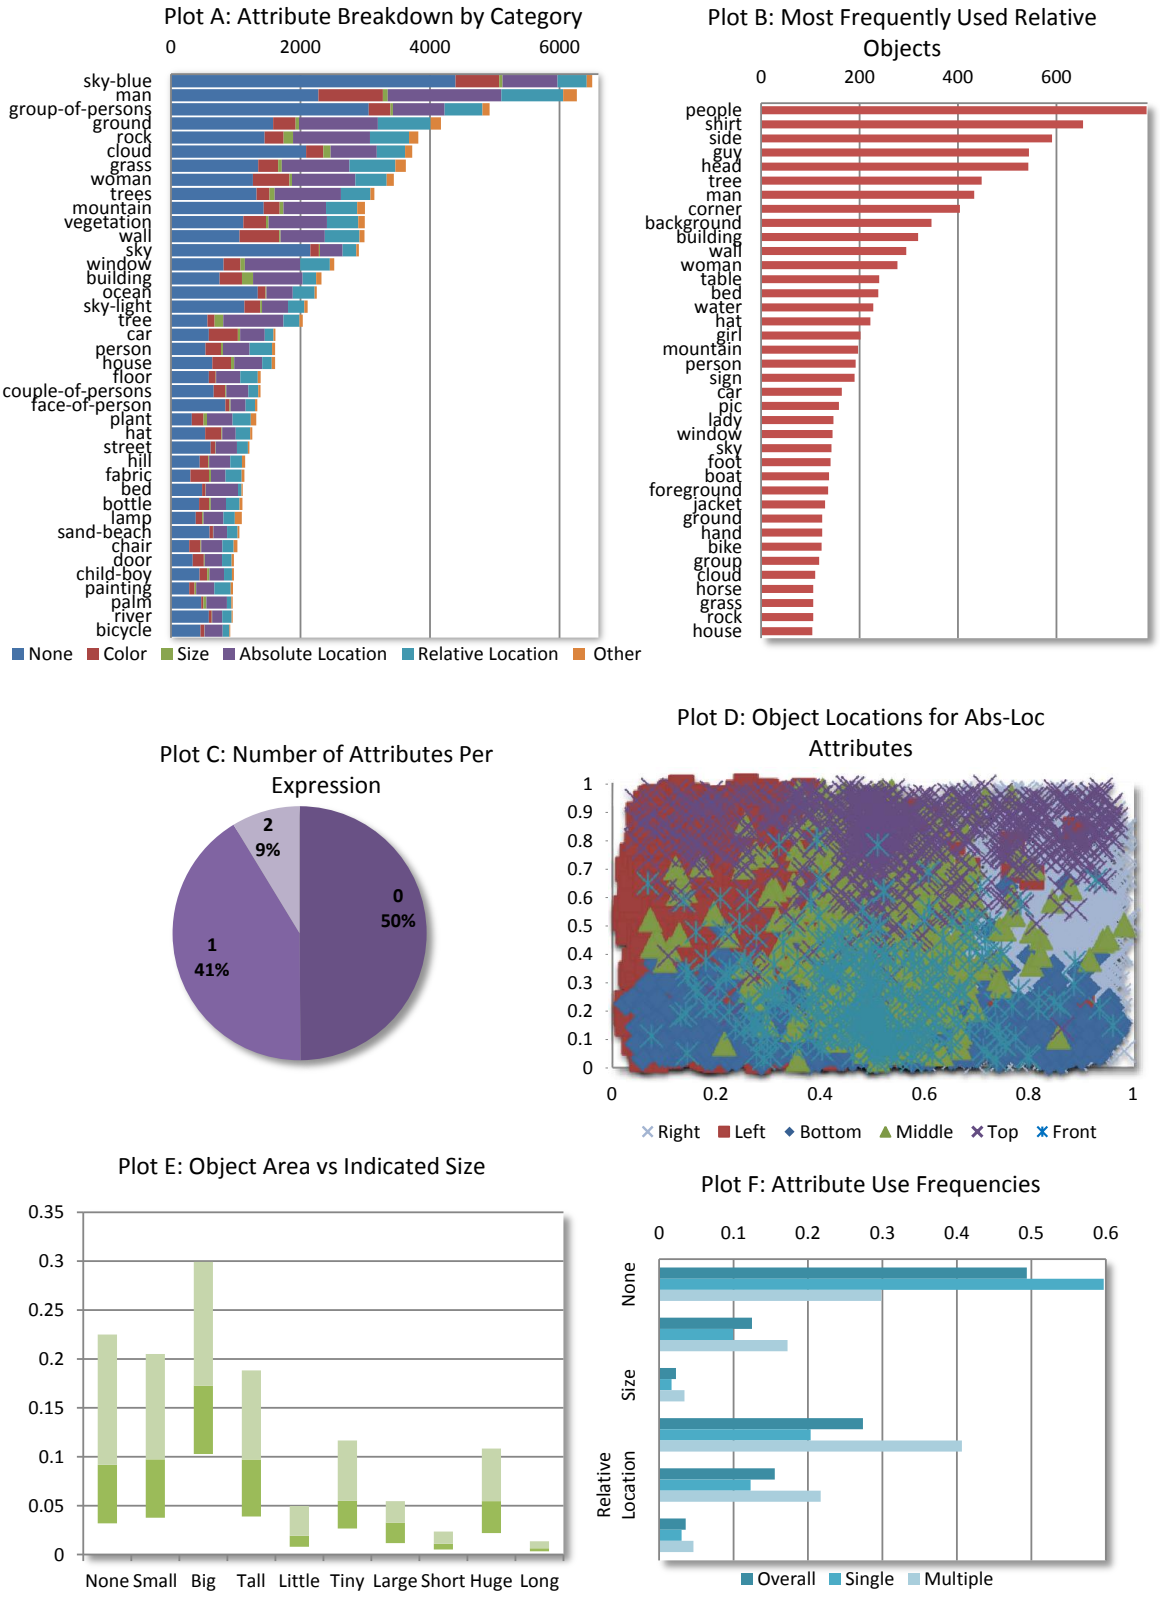

Figure 3: Analyses of the ReferItGame Dataset. **Plot A** shows frequency and attribute occurrence for common object categories. **Plot B** shows objects frequently used as reference points, ie "to the left of the man". **Plot C** shows frequencies of using 0, 1 or 2 attributes within the same expression. **Plot D** shows object locations vs location words used. **Plot E** shows normalized object size vs size words used (bars show 1^{st} through 3^{rd} quartiles). **Plot F** shows the frequency of usage of each attribute type for images containing either a *single* instance of the object category or *multiple* instances of the category.

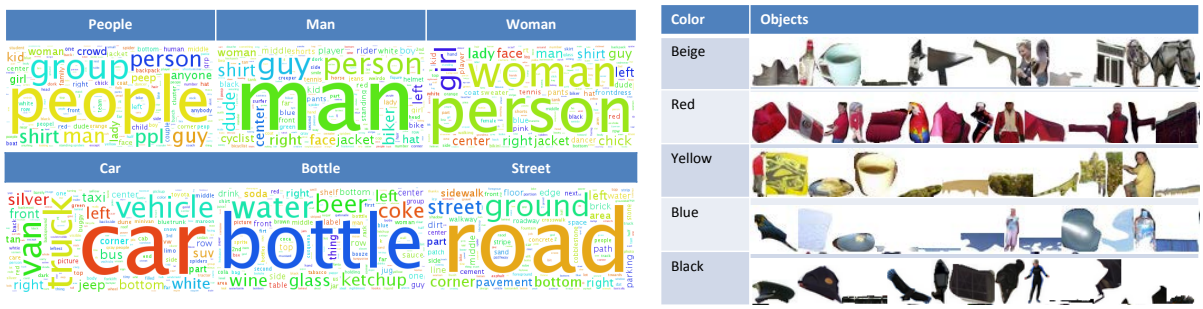

Figure 4: **Left:** Tag clouds showing entry-Level category words used in referring expressions to name various object categories, with word size indicating frequency. For example, this indicates that "streets" are often called "road", sometimes "ground", sometimes "roadway", etc. **Right:** example objects predicted to portray some of our color attribute values. Note sometimes our color predictor is quite accurate, and sometimes it makes mistakes (see the man in a red shirt predicted as "yellow").

that were manually parsed by a human annotator.

4.4 Dataset Analysis

In the resulting dataset, we have a range of coverage over objects. For 10,304 of the objects we have 2 or more referring expressions while for the rest of the objects we have collected only one expression. This creates a dataset that emphasizes breadth while also containing enough data to study speaker variation.

Multiple attribute analyses are provided in Figure 3. We find that most expressions use 0, 1, or 2 attributes (in addition to the entry-level attribute object word), with very few expressions containing more than 2 attributes (frequencies are shown in Fig 3c). We also examine what types of attributes are used most frequently, according to object category in Fig 3a, and when associated with single or multiple occurrences of the same object category in an image in Fig 3f. The frequency of attribute usage in images containing multiple objects of the same type increases for all types, compared to single object occurrences. Perhaps more interestingly, the use of different attributes is highly category dependent. People use more attribute words overall to describe some categories, like "man", "woman", or "plant", and the distribution of attribute types also varies by category. For example, color attributes are used more frequently for categories like "car" or "woman" than for categories like "sky" or "rock".

We also examine which objects are most frequently used as points of reference, e.g.,"the chair next to the *man*" in Fig 3b. We observe that people and some background categories like "tree" or "wall" are often used to help localize objects in referring expressions. Additionally, we provide plots showing the relationship between object location in the image and use of absolute location words, Fig 3d, as well as size words vs object area, Fig 3e.

Finally, we study entry-level category attribute-values to understand how people name objects in referring expressions. Tag clouds indicating the frequencies of words used to name various object categories are provided in Fig 4 (left). Objects like "street" are usually referred to as "road", but sometimes they are called "ground", "roadway", etc. "Bottles" are usually called "bottle", but sometimes referred to as "coke" or "beer". Interestingly, "man" is usually called "man" while "woman" is most often called "person" in the referring expressions.

5 Generating Referring Expressions

In this section we describe our proposed generation model and provide experimental evaluations on three test sets.

5.1 Generation Model

Given an input tuple $I = \{P, S\}$, where P is a target object and S is a scene (image containing multiple objects), our goal is to generate an output referring expression, R. For instance, the representation R for the referring expression: *The big old white cabin beside the tree* would be $R = \{cabin, white, big, \varnothing, beside, tree, old\}$.

To generate referring expressions we construct vocabularies V_{r_i} with candidate values for each attribute $r_i \in R$, where attribute vocabulary V_{r_i} contains the set of words observed in our parsed referring expressions for attribute r_i plus an additional

Image	Human Expressions	Generated Expressions

Figure 5: Example results, including human generated expressions, baseline and full model generated expressions. For some images the model does well at mimicking human expressions (left). For others it does not generate the correct attributes (right).

ε value indicating that the attribute should be omitted from the referring expression entirely.

In this way, our framework can jointly determine which attributes to include in the expression (e.g.,"size" and "color") and what attribute values to generate (e.g.,"small" and "blue") from the list of all possible values. We enforce a constraint to always include an "entry-level category" attribute (e.g. "boy") so that we always generate a word referring to the object.

We pose our problem as an optimization where we map a tuple $\{P, S\}$ to a referring expression R^* as:

$$R^* = \underset{R}{\text{argmax}} E(R, P, S) \quad \text{s. t. } f_i(R) \leq b_i \tag{1}$$

Where the objective function E is decomposed as:

$$E(R,P,S) = \alpha \sum_{i=2}^{6} \phi_i(r_i, P, S) + \beta \sum_{i=1}^{7} \psi_i(r_i, type(P)) + \sum_{i>j} \psi_{i,j}(r_i, r_j) \tag{2}$$

Where ϕ_i is the compatibility function between an attribute-value for r_i and the properties of the observed scene S and object P (described in §5.1.1). The terms ψ_i and $\psi_{i,j}$ are unary and pairwise priors computed based on observed co-occurrence statistics of attribute-values for r_i with categories (where $type(P)$ denotes the type or category of an object) and between pairs of attribute-values (described in §5.1.2). Attributes r_1 and r_7 are modeled only in the priors since we do not have visual models for these attributes.

The constraints $f_i(R) \leq b_i$ are restricted to be linear constraints and are used to impose hard constraints on the solution. The first such constraint is used to control the verbosity (length) of the generated referring expression using a constraint function that imposes a minimum attribute length requirement by restricting the number of entries r_i that can take value ε in the solution.

$$\sum_i \mathbb{1}[r_i = \varepsilon] \leq 7 - \gamma(P, S) \tag{3}$$

Where $\mathbb{1}[.]$ is the indicator function and $\gamma(P, S)$ is a term that allows us to change the length requirement based on the object and scene (so that images with a larger number of objects of the same type have a larger length requirement).

Finally we add hard constraints such that $r_5 = \varepsilon \iff r_6 = \varepsilon$, so that relative location and relative object attributes are produced together.

5.1.1 Content-based potentials

Potentials ϕ_i are defined for attributes r_2 to r_6. Attribute r_7 represents a variety of different attributes, e.g. material or shape attributes, but we lack sufficient data to train visual models for these infrequent attribute terms. Therefore, we model these attributes using only prior statistics-based potentials (§5.1.2). Visual recognition models for recognizing entry-level object categories

could also be incorporated for modeling r_1, but we leave this as future work.

Color attribute:

$$\phi_2(r_2 = c_k, P, S) = sim(hist_{c_k}, hist(P))$$

Where $hist(P)$ is the HSV color histogram of the object P. We compute similarity sim using cosine similarity, and $hist_{c_k}$ is the mean histogram of all objects in our training data that were referred to with color attribute-value $c_k \in V_{r_2}$.

Size attribute:

$$\phi_3(r_3 = s_k, P, S) = \frac{1}{\sigma_{s_k}\sqrt{2\pi}} e^{-\left(size(P)-\mu_{s_k}\right)^2 / 2\sigma_{s_k}^2}$$

Where $size(P)$ is the size of object P normalized by image size. We model the probabilities of each size word $s_k \in V_{r_3}$ as a Gaussian learned on our training set.

Absolute-location attribute:

$$\phi_4(r_4 = a_k, P, S) = \frac{1}{\sqrt{(2\pi)^n |\Sigma_{a_k}|}} e^{-\frac{1}{2}(loc(P)-\mu_{a_k})^T \Sigma_{a_k}{}^{-1} (loc(P)-\mu_{a_k})}$$

Where $loc(P)$ are the 2-dimensional coordinates of the object P normalized to be $\in [0-1]$. Parameters μ_{a_k} and Σ_{a_k} are estimated from training data for each absolute location word $a_k \in V_{r_4}$.

Relative-location and Relative object:

$$\phi_5(r_5 = l_k, P, S) = \mathbb{1}[l_k = \varepsilon] \cdot g(count(type(P), S))$$

If there are a larger number of objects of the same type in the image we find that the probability of using a relative-location-object increases (e.g., "the car to the right of the man"). For images where P was the only object of that category type, the probability of using a relative-location-object is 0.12. This increases to 0.22 when there were two objects of the same type and further increases to 0.26 for additional objects of the same type. Therefore, we model the probability of selecting relative location value $l_k \in V_{r_5}$ as a function g, where $count(type(P), S)$ counts the number of objects in the scene S of the same category type as the object P.

$$\phi_6(r_6 = o_k, P, S) = \mathbb{1}[o_k \in objectsnear(location(P), S)]$$

The above expression filters out potential relative objects $o_k \in V_{r_6}$ that are not located in sufficient proximity to object P or are not present in the image at all.

5.1.2 Prior statistics-based potentials

Prior statistics-based potentials are modeled for all of the attributes r_1 - r_7. Note that these potentials do not depend on specific attribute-values but only on the given object category $type(P)$.

Unary prior potentials ψ_i are defined as:

$$\psi_i(r_i, type(P)) = \frac{\sum_{j=1}^{|D|} \mathbb{1}[(r_i^{(j)} \neq \epsilon) \wedge (type(P^{(j)}) = type(P))]}{\sum_{j=1}^{|D|} \mathbb{1}[type(P^{(j)}) = type(P)]} + \frac{\sum_{j=1}^{|D|} \mathbb{1}[r_i^{(j)} \neq \epsilon]}{|D|} + \lambda$$

Where $D = \{P^{(j)}, S^{(j)}, R^{(j)}\}$ is our training dataset and λ is a small additive smoothing term. The two terms in the above expression represent *category-specific* counts and *global* counts of the number of times a given attribute r_i was output in a referring expression in training data. Pairwise prior potentials $\psi_{i,j}$ are defined as:

$$\sum_{i<j} \psi_{i,j}(r_i, r_j) = \sum_{i<j} \psi_{i,j}^{(1)}(r_i, r_j) + \psi_{5,6}^{(2)}(r_5, r_6)$$

$$\psi_{i,j}^{(1)}(r_i, r_j) = \begin{cases} 1 & \text{if } r_i = r_j = \varepsilon \\ C + \lambda & o.w. \end{cases}$$

$$\psi_{5,6}^{(2)}(r_5 = a, r_6 = b) = \frac{\sum_{t=1}^{|D|} \mathbb{1}[(r_5^{(t)} = a) \wedge (r_6^{(t)} = b)]}{|D|}$$

where $C = \frac{\sum_{t=1}^{|D|} \mathbb{1}[(r_i^{(t)} \neq \epsilon) \wedge (r_j^{(t)} \neq \epsilon)]}{|D|}$. The pairwise potential $\psi_{i,j}^{(1)}$ captures the pairwise statistics of how frequently people use pairs of attribute types.

SOURCE	PREC(%)	RECALL(%)
Baseline - A	27.92	43.27
Full Model - A	**36.28**	**53.44**
Baseline - B	29.87	50.57
Full Model - B	**36.68**	**59.80**
Baseline - C	28.85	37.41
Full Model - C	**37.73**	**48.54**

Table 1: Baseline Model & Full Model performance on the three test sets (A,B,C).

For instance how frequently people use both color and size attributes to refer to an object. The pairwise potential $\psi_{i,j}^{(2)}$ produces a cohesion score between relative-location words and relative-object words based on global dataset statistics.

5.2 Experiments

We implement the proposed model using commercial binary integer linear programming software (IBM ILOG CPLEX). This requires introducing a set of indicator variables for each of our multi-valued attributes and another set of indicator variables to model pairwise interactions between our variables, as well as incorporating additional consistency constraints between variables. Model parameters (α and β) are tuned on data randomly sampled from the training set.

Test Sets: We evaluate our model on three test sets, each containing 500 objects. For each object in the test sets we collect 3 referring expressions using the ReferItGame and manually label the attributes mentioned in each expression. We find human agreement to be 72.31% on our dataset (where we measure agreement as mean matching accuracy of attribute values for pairs of users across images in our test sets). The three test sets are created to evaluate different aspects of our data.

Test Set A contains objects sampled randomly from the entire dataset. This test set is meant to closely resemble the full dataset distribution. The goal of the other two test sets is to sample expressions for "interesting" objects. We first identify categories that are mainly related to background content elements, e.g. "sky, ground, floor, sand, sidewalk, etc". We consider these categories to be potentially less interesting for study than categories like people, animals, cars, etc. *Test Set B* contains objects sampled from the most frequently occurring object categories in the dataset, selected to contain a balanced number of objects from each category, excluding the less interesting categories. *Test Set C* contains objects sampled from images that contain at least 2 objects of the same category, excluding the less interesting categories.

Results: *Qualitative examples* are shown in Fig 5 comparing our results to the human produced expressions. For some images (left) we do quite well at predicting the correct attributes and values. For others we do less well (right). We also show example objects predicted for some color words in Fig 4 (right). We see that our model can fail in several ways, such as generating the wrong attribute-value due to inaccurate predictions by visual models or selecting incorrect attributes to include in the generated expression.

Quantitative results: precision and recall measures for the 3 test sets are reported in Table 1, including evaluation of a baseline version of our model which incorporates only the prior potentials (§5.1.2) without any content based estimates. We see that our model performs reasonably on both measures, and outperforms the baseline by a large margin on all test sets, with highest performance on the broadly sampled interesting category test set. Note that our problem is somewhat different than traditional REG where the input is often attribute-value pairs and the task is to select which pairs to include in the expression. Our goal is to jointly select which attributes to include and what values to predict from a list of all possible values for the attribute.

6 Conclusions & Future Work

In this paper we have introduced a new game to crowd-source referring expressions for objects in natural scenes. We have used this game to produce a new large-scale dataset with analysis. We have also proposed an optimization based model for REG and performed experimental evaluations. Future work includes developing fully automatic visual recognition methods for REG in real world scenes, and incorporating linguistically inspired models for entry-level category prediction.

Acknowledgments

This work was funded by NSF Awards #1417991 and #1444234. M.M. was supported by the Stony Brook Simons Summer Research Program for High School students. We also thank Alex Berg for many helpful discussions.

Abstract

We propose an unsupervised approach to constructing templates from a large collection of semantic category names, and use the templates as the semantic representation of categories. The main challenge is that many terms have multiple meanings, resulting in a lot of wrong templates. Statistical data and semantic knowledge are extracted from a web corpus to improve template generation. A nonlinear scoring function is proposed and demonstrated to be effective. Experiments show that our approach achieves significantly better results than baseline methods. As an immediate application, we apply the extracted templates to the cleaning of a category collection and see promising results (precision improved from 81% to 89%).

1 Introduction

A semantic category is a collection of items sharing common semantic properties. For example, all cities in Germany form a semantic category named "city in Germany" or "German city". In Wikipedia, the category names of an entity are manually edited and displayed at the end of the page for the entity. There have been quite a lot of approaches (Hearst, 1992; Pantel and Ravichandran, 2004; Van Durme and Pasca, 2008; Zhang et al., 2011) in the literature to automatically extracting category names and instances (also called is-a or hypernymy relations) from the web.

Most existing work simply treats a category name as a text string containing one or multiple words, without caring about its internal structure. In this paper, we explore the *semantic* structure of category names (or simply called "categories"). For example, both "CEO of General Motors" and "CEO of Yahoo" have structure "CEO of [company]". We call such a structure a *category template*. Taking a large collection of open-domain categories as input, we construct a list of *category templates* and build a mapping from categories to templates. Figure 1 shows some example semantic categories and their corresponding templates.

Templates can be treated as additional features of semantic categories. The new features can be exploited to improve some upper-layer applications like web search and question answering. In addition, by linking categories to templates, it is possible (for a computer program) to infer the semantic meaning of the categories. For example in Figure 1, from the two templates linking to category "symptom of insulin deficiency", it is reasonable to interpret the category as: "a symptom of a medical condition called insulin deficiency which is about the deficiency of one type of hormone called insulin." In this way, our knowledge about a category can go beyond a simple string and its member entities. An immediate application of templates is removing invalid category names from a noisy category collection. Promising results are observed for this application in our experiments.

An intuitive approach to this task (i.e., extracting templates from a collection of category names)

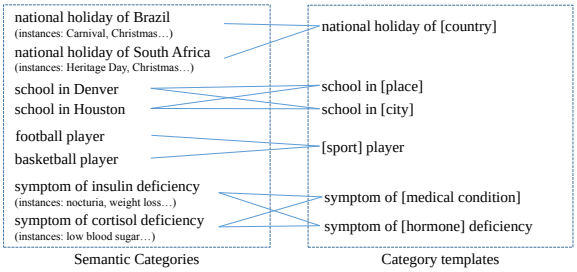

Figure 1: Examples of semantic categories and their corresponding templates.

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 799–809,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

contains two stages: category labeling, and template scoring.

Category labeling: Divide a category name into multiple segments and replace some key segments with its hypernyms. As an example, assume "CEO of Delphinus" is divided to three segments "CEO + of + Delphinus"; and the last segment (Delphinus) has hypernyms "constellation", "company", etc. By replacing this segment with its hypernyms, we get candidate templates "CEO of [constellation]" (a wrong template), "CEO of [company]", and the like.

Template scoring: Compute the score of each candidate template by aggregating the information obtained in the first phase.

A major challenge here is that many segments (like "Delphinus" in the above example) have multiple meanings. As a result, wrong hypernyms may be adopted to generate incorrect candidate templates (like "CEO of [constellation]"). In this paper, we focus on improving the template scoring stage, with the goal of assigning lower scores to bad templates and larger scores to high-quality ones.

There have been some research efforts (Third, 2012; Fernandez-Breis et al., 2010; Quesada-Martınez et al., 2012) on exploring the structure of category names by building patterns. However, we automatically assign semantic types to the pattern variables (or called arguments) while they do not. For example, our template has the form of "city in [country]" while their patterns are like "city in [X]". More details are given in the related work section.

A similar task is query understanding, including query tagging and query template mining. Query tagging (Li et al., 2009; Reisinger and Pasca, 2011) corresponds to the category labeling stage described above. It is different from template generation because the results are for one query only, without merging the information of all queries to generate the final templates. Category template construction are slightly different from query template construction. First, some useful features such as query click-through is not available in category template construction. Second, categories should be valid natural language phrases, while queries need not. For example, "city Germany" is a query but not a valid category name. We discuss in more details in the related work section.

Our major contributions are as follows.

1) To the best of our knowledge, this is the first work of template generation specifically for categories in unsupervised manner.

2) We extract semantic knowledge and statistical information from a web corpus for improving template generation. Significant performance improvement is obtained in our experiments.

3) We study the characteristics of the scoring function from the viewpoint of probabilistic evidence combination and demonstrate that nonlinear functions are more effective in this task.

4) We employ the output templates to clean our category collection mined from the web, and get apparent quality improvement (precision improved from 81% to 89%).

After discussing related work in Section 2, we define the problem and describe one baseline approach in Section 3. Then we introduce our approach in Section 4. Experimental results are reported and analyzed in Section 5. We conclude the paper in Section 6.

2 Related work

Several kinds of work are related to ours.

Hypernymy relation extraction: Hypernymy relation extraction is an important task in text mining. There have been a lot of efforts (Hearst, 1992; Pantel and Ravichandran, 2004; Van Durme and Pasca, 2008; Zhang et al., 2011) in the literature to extract hypernymy (or is-a) relations from the web. Our target here is not hypernymy extraction, but discovering the semantic structure of hypernyms (or category names).

Category name exploration: Category name patterns are explored and built in some existing research work. Third (2012) proposed to find axiom patterns among category names on an existing ontology. For example, infer axiom pattern "SubClassOf(AB, B)" from "SubClassOf(junior_school school)" and "SubClassOf(domestic_mammal mammal)". Fernandez-Breis et al. (2010) and Quesada-Martınez et al. (2012) proposed to find lexical patterns in category names to define axioms (in medical domain). One example pattern mentioned in their papers is "[X] binding". They need manual intervention to determine what X means. The main difference between the above work and ours is that we automatically assign semantic types to the pattern variables (or called arguments) while they do not.

Template mining for IE: Some research work in information extraction (IE) involves patterns. Yangarber (2003) and Stevenson and Greenwood (2005) proposed to learn patterns which were in the form of [subject, verb, object]. The category names and learned templates in our work are not in this form. Another difference between our work and their work is that, their methods need a supervised name classifer to generate the candidate patterns while our approach is unsupervised. Chambers and Jurafsky (2011) leverage templates to describe an event while the templates in our work are for understanding category names (a kind of short text).

Query tagging/labeling: Some research work in recent years focuses on segmenting web search queries and assigning semantic tags to key segments. Li et al. (2009) and Li (2010) employed CRF (Conditional Random Field) or semi-CRF models for query tagging. A crowdsourcing-assisted method was proposed by Han et al. (2013) for query structure interpretation. These supervised or semi-supervised approaches require much manual annotation effort. Unsupervised methods were proposed by Sarkas et al. (2010) and Reisinger and Pasca (2011). As been discussed in the introduction section, query tagging is only one of the two stages of template generation. The tagging results are for one query only, without aggregating the global information of all queries to generate the final templates.

Query template construction: Some existing work leveraged query templates or patterns for query understanding. A semi-supervised random walk based method was proposed by Agarwal et al. (2010) to generate a ranked templates list which are relevant to a domain of interest. A predefined domain schema and seed information is needed for this method. Pandey and Punera (2012) proposed an unsupervised method based on graphical models to mine query templates. The above methods are either domain-specific (i.e., generating templates for a specific domain), or have some degree of supervision (supervised or semi-supervised). Cheung and Li (2012) proposed an unsupervised method to generate query templates by the aid of knowledge bases. An approach was proposed in (Szpektor et al., 2011) to improve query recommendation via query templates. Query session information (which is not available in our task) is needed in this approach for templates generation. Li et al. (2013) proposed an clustering algorithm to group existing query templates by search intents of users.

Compared to the open-domain unsupervised methods for query template construction, our approach improves on two aspects. First, we propose to incorporate multiple types of semantic knowledge (e.g., term peer similarity and term clusters) to improve template generation. Second, we propose a nonlinear template scoring function which is demonstrated to be more effective.

3 Problem Definition and Analysis

3.1 Problem definition

The goal of this paper is to construct a list of category templates from a collection of open-domain category names.

Input: The input is a collection of category names, which can either be manually compiled (like Wikipedia categories) or be automatically extracted. The categories used in our experiments were automatically mined from the web, by following existing work (Hearst, 1992, Pantel and Ravichandran 2004; Snow et al., 2005; Talukdar et al., 2008; Zhang et al., 2011). Specifically, we applied Hearst patterns (e.g., "NP [,] (such as | including) $\{NP,\}^*$ {and|or} NP") and is-a patterns ("NP (is|are|was|were|being) (a|an|the) NP") to a large corpus containing 3 billion English web pages. As a result, we obtained a term→hypernym bi-partite graph containing 40 million terms, 74 million hypernyms (i.e., category names), and 321 million edges (e.g., one example edge is "Berlin"→"city in Germany", where "Berlin" is a term and "city in Germany" is the corresponding hypernym). Then all the multi-word hypernyms are used as the input category collection.

Output: The output is a list of templates, each having a score indicating how likely it is valid. A template is a multi-word string with one headword and at least one argument. For example, in template "national holiday of [country]", "holiday" is the headword, and "[country]" is the argument. We only consider one-argument templates in this paper, and the case of multiple arguments is left as future work. A template is valid if it is syntactically and semantically correct. "CEO of [constellation]" (wrongly generated from "CEO of Delphinus", "CEO of Aquila", etc.) is not valid because it is semantically unreasonable.

3.2 Baseline approach

An intuitive approach to this task contains two stages: category labeling and template scoring. Figure 2 shows its workflow with simple examples.

3.2.1 Phase-1: Category labeling

At this stage, each category name is automatically segmented and labeled; and some *candidate template tuples* (CTTs) are derived based on the labeling results. This can be done in the following steps.

Category segmentation: Divide each category name into multiple segments (e.g., "holiday of South Africa" to "holiday + of + South Africa"). Each segment is one word or a phrase appearing in an entity dictionary. The dictionary used in this paper is comprised of all Freebase (www.freebase.com) entities.

Segment to hypernym: Find hypernyms for every segment (except for the headword and some trivial segments like prepositions and articles), by referring to a term→hypernym mapping graph. Following most existing query labeling work, we derive the term→hypernym graph from a dump of Freebase. Below are some examples of Freebase types (hypernyms),

German city (id: /location/de_city)

Italian province (id: /location/it_province)

Poem character (id: /book/poem_character)

Book (id: /book/book)

To avoid generating too fine-grained templates like "mayor of [Germany city]" and "mayor of [Italian city]" (semantically "mayor of [city]" is more desirable), we discard type modifiers and map terms to the headwords of Freebase types. For example, "Berlin" is mapped to "city". In this way, we build our basic version of term→hypernym mapping which contains 16.13 million terms and 696 hypernyms. Since "South Africa" is both a country and a book name in Freebase, hypernyms "country", "book", and others are assigned to the segment "South Africa" in this step.

CTT generation: Construct CTTs by choosing one segment (called the *target segment*) each time and replacing the segment with its hypernyms. An CTT is formed by the candidate template (with one argument), the target segment (as an *argument value*), and the tuple score (indicating tuple quality). Below are example CTTs obtained after the last segment of "holiday + of + South Africa" is processed,

U_1: (holiday of [country], South Africa, w_1)

U_2: (holiday of [book], South Africa, w_2)

3.2.2 Phase-2: Template scoring

The main objective of this stage is to merge all the CTTs obtained from the previous stage and to compute a final score for each template. In this stage, the CTTs are first grouped by the first element (i.e., the template string). For example, tuples for "holiday of [country]" may include,

U_1: (holiday of [country], South Africa, w_1)

U_2: (holiday of [country], Brazil, w_2)

U_3: (holiday of [country], Germany, w_3)

...

Then a scoring function is employed to calculate the template score from the tuple scores. Formally, given n tuples $\vec{U}$=(U_1, U_2..., U_n) for a template, the goal is to find a score fusion function $F(\vec{U})$ which yields large values for high-quality templates and small (or zero) values for invalid ones.

Borrowing the idea of TF-IDF from information retrieval, a reasonable scoring function is,

$$F(\vec{U}) = \sum_{i=1}^{n} w_i \cdot IDF(h) \tag{1}$$

where h is the argument type (i.e., the hypernym of the argument value) of each tuple. TF means the "term frequency" and IDF means the "inverse document frequency". An IDF function assigns lower scores to common hypernyms (like person and music track which contain a lot of entities). Let $DF(h)$ be the number of entities having hypernym h, we test two IDF functions in our experiments,

$$\begin{aligned} IDF_1(h) &= log\frac{1+N}{1+DF(h)} \\ IDF_2(h) &= 1/sqrt(DF(h)) \end{aligned} \tag{2}$$

where N is total number of entities in the entity dictionary.

The next problem is estimating tuple score w_i. Please note that there is no weight or score information in the term→hypernym mapping of Freebase. So we have to set w_i to be constant in the baseline,

$$w_i = 1 \tag{3}$$

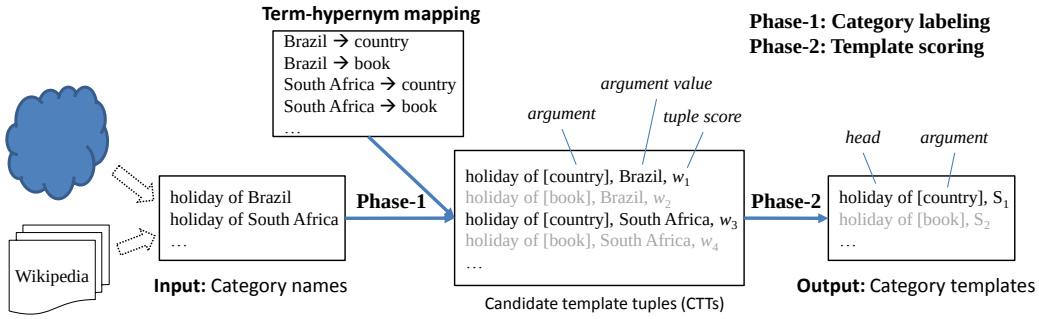

Figure 2: Problem definition and baseline approach.

4 Approach: Enhancing Template Scoring

In our approach, we follow the same framework as in the above baseline approach, and focus on improving the template scoring phase (i.e., phase-2).

We try three techniques: First, a better tuple score w_i is calculated in Section 4.1 by performing statistics on a large corpus. The corpus is a collection of 3 billion web pages crawled in early 2013 by ourselves. During this paper, we use "our web corpus" or "our corpus" to refer to this corpus.

Second, a nonlinear function is adopted in Section 4.2 to replace the baseline tuple fusion function (Formula 1). Third, we extract term peer similarity and term clusters from our corpus and use them as additional semantic knowledge to refine template scores.

4.1 Enhancing tuple scoring

Let's examine the following two template tuples,

U_1: (holiday of [country], South Africa, w_1)

U_2: (holiday of [book], South Africa, w_2)

Intuitively, "South Africa" is more likely to be a country than a book when it appears in text. So for a reasonable tuple scoring formula, we should have $w_1 > w_2$.

The main idea is to automatically calculate the popularity of a hypernym given a term, by referring to a large corpus. Then by adding the popularity information to (the edges of) the term→hypernym graph of Freebase, we obtain a *weighted* term→hypernym graph. The weighted graph is then employed to enhance the estimation of w_i.

For popularity calculation, we apply Hearst patterns (Hearst, 1992) and is-a patterns ("NP (is|are|was|were|being) (a|an|the) NP") to every sentence of our web corpus. For a (term, hypernym) pair, its popularity F is calculated as the number of sentences in which the term and the hypernym co-occur and also follow at least one of the patterns.

For a template tuple U_i with argument type h and argument value v, we test two ways of estimating the tuple score w_i,

$$w_i = \log\left(1 + F(v,h)\right) \tag{4}$$

$$w_i = \frac{F(v,h))}{\lambda + \sum_{h_j \in H} F(v,h_j)} \tag{5}$$

where $F(v,h)$ is the popularity of the (v, h) pair in our corpus, H is the set of all hypernyms for v in the weighted term→hypernym graph. Parameter λ (=1.0 in our experiments) is introduced for smoothing purpose. Note that the second formula is the conditional probability of hypernym h given term v.

Since it is intuitive to estimate tuple scores with their frequencies in a corpus, we treat the approach with the improved w_i as another baseline (our strong baseline).

4.2 Enhancing tuple combination function

Now we study the possibility of improving the tuple combination function (Formula 1), by examining the tuple fusion problem from the viewpoint of probabilistic evidence combination. We first demonstrate that the linear function in Formula 1 corresponds to the conditional independence assumption of the tuples. Then we propose to adopt a series of nonlinear functions for combining tuple scores.

We define the following events:

T: Template T is a valid template;

$\overline{T}$: T is an invalid template;

E_i: The observation of tuple U_i.

Let's compute the posterior odds of event T, given two tuples U_1 and U_2. Assuming E_1 and E_2 are conditionally independent given T or $\overline{T}$, according to the Bayes rule, we have,

$$\begin{aligned}\frac{P(T|E_1,E_2)}{P(\overline{T}|E_1,E_2)} &= \frac{P(E_1,E_2|T)\cdot P(T)}{P(E_1,E_2|\overline{T})\cdot P(\overline{T})} \\ &= \frac{P(E_1|T)}{P(E_1|\overline{T})}\cdot\frac{P(E_2|T)}{P(E_2|\overline{T})}\cdot\frac{P(T)}{P(\overline{T})} \\ = \frac{P(T|E_1)\cdot P(\overline{T})}{P(\overline{T}|E_1)\cdot P(T)}\cdot\frac{P(T|E_2)\cdot P(\overline{T})}{P(\overline{T}|E_2)\cdot P(T)}&\cdot\frac{P(T)}{P(\overline{T})}\end{aligned} \quad (6)$$

Define the log-odds-gain of T given E as,

$$G(T|E) = \log\frac{P(T|E)}{P(\overline{T}|E)} - \log\frac{P(T)}{P(\overline{T})} \quad (7)$$

Here G means the gain of the log-odds of T after E occurs. By combining formulas 6 and 7, we get

$$G(T|E_1,E_2) = G(T|E_1) + G(T|E_2) \quad (8)$$

It is easy to prove that the above conclusion holds true when $n > 2$, i.e.,

$$G(T|E_1,...,E_n) = \sum_{i=1}^{n} G(T|E_i) \quad (9)$$

If we treat $G(T|E_i)$ as the score of template T when only U_i is observed, and $G(T|E_1,...,E_n)$ as the template score after the n tuples are observed, then the above equation means that the combined template score should be the sum of $w_i \cdot IDF(h)$, which is exactly Formula 1. Please keep in mind that Equation 9 is based on the assumption that the tuples are conditional independent. This assumption, however, may not hold in reality. The case of conditional dependence was studied in (Zhang et al., 2011), where a group of nonlinear combination functions were proposed and achieved good performance in their task of hypernymy extraction. We choose p-Norm as our nonlinear fusion functions, as below,

$$F(\vec{U}) = \sqrt[p]{\sum_{i=1}^{n} w_i^p}\cdot IDF(h) \qquad (p>1) \quad (10)$$

where p (=2 in experiments) is a parameter.

Experiments show that the above nonlinear function performs better than the linear function of Formula 1. Let's use an example to show the intuition. Consider a good template "city of [country]" corresponding to CTTs $\vec{U}_A$ and a wrong template "city of [book]" having tuples $\vec{U}_B$. Suppose $|\vec{U}_A| = 200$ (including most countries in the world) and $|\vec{U}_B| = 1000$ (considering that many place names have already been used as book names). We observe that each tuple score corresponding to "city of [country]" is larger than the tuple score corresponding to "city of [book]". For simplicity, we assume each tuple in $\vec{U}_A$ has score 1.0 and each tuple in $\vec{U}_B$ has score 0.2. With the linear and nonlinear (p=2) fusion functions, we can get,

Linear:

$$\begin{aligned}F(\vec{U}_A) &= 200 * 1.0 = 200 \\ F(\vec{U}_B) &= 1000 * 0.2 = 200\end{aligned} \quad (11)$$

Nonlinear:

$$\begin{aligned}F(\vec{U}_A) &= 14.1 \\ F(\vec{U}_B) &= 6.32\end{aligned} \quad (12)$$

In the above settings the nonlinear function yields a much higher score for the good template (than for the invalid template), while the linear one does not.

4.3 Refinement with term similarity and term clusters

The above techniques neglect the similarity among terms, which has a high potential to improve the template scoring process. Intuitively, for a toy set {"city in Brazil", "city in South Africa","city in China", "city in Japan"}, since "Brazil", "South Africa", "China" and "Japan" are very similar to each other and they all have a large probability to be a "country", so we have more confidence that "city in [country]" is a good template. In this section, we propose to leverage the term similarity information to improve the template scoring process.

We start with building a large group of *small* and *overlapped* clusters from our web corpus.

4.3.1 Building term clusters

Term clusters are built in three steps.

Mining term peer similarity: Two terms are peers if they share a common hypernym and they are semantically correlated. For example, "dog" and "cat" should have a high peer similarity score. Following existing work (Hearst, 1992; Kozareva

et al., 2008; Shi et al., 2010; Agirre et al., 2009; Pantel et al., 2009), we built a peer similarity graph containing about 40.5 million nodes and 1.33 billion edges.

Clustering: For each term, choose its top-30 neighbors from the peer similarity graph and run a hierarchical clustering algorithm, resulting in one or multiple clusters. Then we merge highly duplicated clusters. The algorithm is similar to the first part of CBC (Pantel and Lin, 2002), with the difference that a very high merging threshold is adopted here in order to generate small and overlapped clusters. Please note that one term may be included in many clusters.

Assigning top hypernyms: Up to two hypernyms are assigned for each term cluster by majority voting of its member terms, with the aid of the weighted term→hypernym graph of Section 4.1. To be an eligible hypernym for the cluster, it has to be the hypernym of at least 70% of terms in the cluster. The score of each hypernym is the average of the term→hypernym weights over all the member terms.

4.3.2 Template score refinement

With term clusters at hand, now we describe the score refinement procedure for a template T having argument type h and supporting tuples $\vec{U}$=(U_1, U_2..., U_n). Denote $V = \{V_1, V_2, ..., V_n\}$ to be the set of argument values for the tuples (where V_i is the argument value of U_i).

By computing the intersection of V and every term cluster, we can get a distribution of the argument values in the clusters. We find that for a good template like "holiday in [country]", we can often find at least one cluster (one of the country clusters in this example) which has hypernym h and also contains many elements in V. However, for invalid templates like "holiday of [book]", every cluster having hypernym h (="book" here) only contains a few elements in V. Inspired by such an observation, our score refinement algorithm for template T is as follows,

Step-1. Calculating supporting scores: For each term cluster C having hypernym h, compute its supporting score to T as follows:

$$S(C, T) = k(C, V) \cdot w(C, h) \qquad (13)$$

where $k(C, V)$ is the number of elements shared by C and V, and $w(C, h)$ is hypernym score of h to C (computed in the last step of building clusters).

Step-2. Calculating the final template score: Let term cluster C^* has the maximal supporting score to T, the final template score is computed as,

$$S(T) = F(\vec{U}) \cdot S(C^*, T) \qquad (14)$$

where $F(\vec{U})$ is the template score before refinement.

5 Experiments

5.1 Experimental setup

5.1.1 Methods for comparison

We make a comparison among 10 methods.

SC: The method is proposed in (Cheung and Li, 2012) to construct templates from queries. The method firstly represents a query as a matrix based on Freebase data. Then a hierarchical clustering algorithm is employed to group queries having the same structure and meaning. Then an intent summarization algorithm is employed to create templates for each query group.

Base: The linear function in Formula 1 is adopted to combine the tuple scores. We use IDF_2 here because it achieves higher precision than IDF_1 in this setting.

LW: The linear function in Formula 1 is adopted to combine the tuple scores generated by Formula 4. IDF_1 is used rather than IDF_2 for better performance.

LP: The linear function in Formula 1 is adopted to combine the tuple scores generated by Formula 5. IDF_2 is used rather than IDF_1 for better performance.

NLW: The nonlinear fusion function in Formula 10 is used. Other settings are the same as LW.

NLP: The nonlinear fusion function in Formula 10 is used. Other settings are the same as LP.

LW+C, LP+C, NLW+C, NLP+C: All the settings of LW, LP, NLW, NLP respectively, with the refinement technology in Section 4.3 applied.

5.1.2 Data sets, annotation and evaluation metrics

The input category names for experiments are automatically extracted from a web corpus (Section 3.1). Two test-sets are built for evaluation from the output templates of various methods.

Subsets: In order to conveniently compare the performance of different methods, we create 20 sub-collections (called subsets) from the whole input category collection. Each subset contains all

the categories having the same headword (e.g., "symptom of insulin deficiency" and "depression symptom" are in the same subset because they share the same headword "symptom"). To choose the 20 headwords, we first sample 100 at random from the set of all headwords; then manually choose 20 for diversity. The headwords include symptom, school, food, gem, hero, weapon, model, etc. We run the 10 methods on these subsets and sort the output templates by their scores. Top-30 templates from each method on each subset are selected and mixed together for annotation.

Fullset: We run method NLP+C (which has the best performance according to our subsets experiments) on the input categories and sort the output templates by their scores. Then we split the templates into 9 sections according to their ranking position. The sections are: [1∼100], (100∼1K], (1K∼10K], (10K∼100K], (100K,120K], (120K∼140K], (140K∼160K], (160K∼180K], (180K∼200K]. Then 40 templates are randomly chosen from each section and mixed together for annotation.

The selected templates (from subsets and the fullset) are annotated by six annotators, with each template assigned to two annotators. A template is assigned a label of "good", "fair", or "bad" by an annotator. The percentage agreement between the annotators is 80.2%, with kappa 0.624.

For the subset experiments, we adopt Precision@k (k=10,20,30) to evaluate the top templates generated by each method. The scores for "good", "fair", and "bad" are 1, 0.5, and 0. The score of each template is the average annotation score over two annotators (e.g., if a template is annotated "good" by one annotator and "fair" by another, its score is (1.0+0.5)/2=0.75). The evaluation score of a method is the average over the 20 subsets. For the fullset experiments, we report the precision for each section.

5.2 Experimental results

5.2.1 Results for subsets

The results of each method on the 20 subsets are presented in Table 1. A few observations can be made. First, by comparing the performance of baseline-1 (Base) and the methods adopting term→hypernym weight (LW and LP), we can see big performance improvement. The bad performance of baseline-1 is mainly due to the lack of weight (or frequency) information on term→hypernym edges. The results demonstrate that edge scores are critical for generating high quality templates. Manually built semantic resources typically lack such kinds of scores. Therefore, it is very important to enhance them by deriving statistical data from a large corpus. Since it is relatively easy to have the idea of adopting a weighted term→hypernym graph, we treat LW and LP as another (stronger) baseline named baseline-2.

Method		P@10	P@20	P@30
Base (baseline-1)		0.359	0.361	0.358
SC (Cheung and Li, 2012)		0.382	0.366	0.371
Weighted (baseline-2)	LW	0.633	0.582	0.559
	LP	0.771	0.734	0.707
Nonlinear	NLW	0.711	0.671	0.638
	NLP	0.818	0.791	0.765
Term cluster	LW+C	0.813	0.786	0.754
	NLW+C	0.854	0.833	0.808
	LP+C	0.818	0.788	0.778
	NLP+C	0.868	0.839	0.788

Table 1: Performance comparison among the methods on subset.

As the second observation, the results show that the nonlinear methods (NLP and NLW) achieve performance improvement over their linear versions (LW and LP).

Third, let's examine the methods with template scores refined by term similarity and term clusters (LW+C, NLW+C, LP+C, NLP+C). It is shown that the refine-by-cluster technology brings additional performance gains on all the four settings (linear and nonlinear, two different ways of calculating tuple scores). So we can conclude that the peer similarity and term clusters are quite effective in improving template generation.

Fourth, the best performance is achieved when the three techniques (i.e., term→hypernym weight, nonlinear fusion function, and refine-by-cluster) are combined together. For instance, by comparing the P@20 scores of baseline-2 and NLP+C, we see a performance improvement of 14.3% (from 0.734 to 0.839). Therefore every technique studied in this paper has its own merit in template generation.

Finally, by comparing the method SC (Cheung and Li, 2012) with other methods, we can see that SC is slightly better than baseline-1, but has much lower performance than others. The major reason may be that this method did not employ a weighted term→hypernym graph or term peer similarity information in template construction.

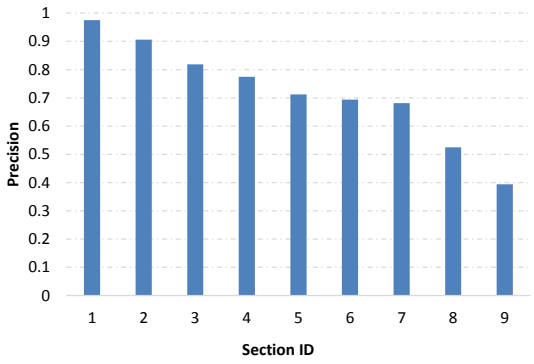

Figure 3: Precision by section in the fullset.

5.2.2 Fullset results

As described in the Section 5.1.2, for the *fullset* experiments, we conduct a section-wise evaluation, selecting 40 templates from each of the 9 sections of the NLP+C results. The results are shown in Figure 3. It can be observed that the precision for each section decreases when the section ID increases. The results indicate the effectiveness of our approach, since it can rank good templates in top sections and bad templates in bottom sections. According to the section-wise precision data, we are able to determine the template score threshold for choosing different numbers of top templates in different applications.

5.2.3 Templates for category collection cleaning

Since our input category collection is automatically constructed from the web, some wrong or invalid category names is inevitably contained. In this subsection, we apply our category templates to clean the category collection. The basic idea is that if a category can match a template, it is more likely to be correct. We compute a new score for every category name H as follows,

$$S_{new}(H) = \log(1 + S(H)) \cdot S(T^*) \qquad (15)$$

where $S(H)$ is the existing category score, determined by its frequency in the corpus. Here $S(T^*)$ is the score of template T^*, the best template (i.e., the template with the highest score) for the category.

Then we re-rank the categories according to their new scores to get a re-ranked category list. We randomly sampled 150 category names from the top 2 million categories of each list (the old list and the new list) and asked annotators to judge the

quality of the categories. The annotation results show that, after re-ranking, the precision increases from 0.81 to 0.89 (i.e., the percent of invalid category names decreases from 19% to 11%).

6 Conclusion

In this paper, we studied the problem of building templates for a large collection of category names. We tested three techniques (tuple scoring by weighted term→hypernym mapping, nonlinear score fusion, refinement by term clusters) and found that all of them are very effective and their combination achieves the best performance. By employing the output templates to clean our category collection mined from the web, we get apparent quality improvement. Future work includes supporting multi-argument templates, disambiguating headwords of category names and applying our approach to general short text template mining.

Acknowledgments

We would like to thank the annotators for their efforts in annotating the templates. Thanks to the anonymous reviewers for their helpful comments and suggestions. This work is supported in part by China National 973 program 2014CB340301 and NSFC grant 61379043.

Abstract

Taxonomies are the backbone of many structured, semantic knowledge resources. Recent works for extracting taxonomic relations from text focused on collecting lexical-syntactic patterns to extract the taxonomic relations by matching the patterns to text. These approaches, however, often show low coverage due to the lack of contextual analysis across sentences. To address this issue, we propose a novel approach that collectively utilizes contextual information of terms in syntactic structures such that if the set of contexts of a term includes most of contexts of another term, a subsumption relation between the two terms is inferred. We apply this method to the task of taxonomy construction from scratch, where we introduce another novel graph-based algorithm for taxonomic structure induction. Our experiment results show that the proposed method is well complementary with previous methods of linguistic pattern matching and significantly improves recall and thus F-measure.

1 Introduction

Taxonomies that are backbone of structured ontology knowledge have been found to be useful for many areas such as question answering (Harabagiu et al., 2003), document clustering (Fodeh et al., 2011) and textual entailment (Geffet and Dagan, 2005). There have been an increasing number of hand-crafted, well-structured taxonomies publicly available, including WordNet (Miller, 1995), OpenCyc (Matuszek et al., 2006), and Freebase (Bollacker et al., 2008). However, the manual curation of those taxonomies is time-consuming and human experts may miss relevant terms. As such, there are still needs to extend existing taxonomies or even to construct new taxonomies from scratch.

The previous methods for identifying taxonomic relations (i.e. is-a relations) from text can be generally classified into two categories: statistical and linguistic approaches. The former includes co-occurrence analysis (Budanitsky, 1999), term subsumption (Fotzo and Gallinari, 2004) and clustering (Wong et al., 2007). The main idea behinds these techniques is that the terms that frequently co-occur may have taxonomic relationships. Such approaches, however, usually suffer from low accuracy, though relatively high coverage, and heavily depend on the choice of feature types and datasets. Most previous methods of the linguistic approach, on the other hand, rely on the lexical-syntactic patterns (e.g. *A is a B*, *A such as B*) (Hearst, 1992). Those patterns can be manually created (Kozareva et al., 2008; Wentao et al., 2012), chosen via automatic bootstrapping (Widdows and Dorow, 2002; Girju et al., 2003) or identified from machine-learned classifiers (Navigli et al., 2011). The pattern matching methods generally achieve high precision, but low coverage due to the lack of contextual analysis across sentences. In this paper, we introduce a novel statistical method and shows that when combined with a pattern matching method, it shows significant performance improvement.

The proposed statistical method, called syntactic contextual subsumption (SCS), compares the syntactic contexts of terms for the taxonomic relation identification, instead of the usage of bag-of-words model by the previous statistical methods. We observe that the terms in taxonomic relations may not occur in the same sentences, but in similar syntactic structures of different sentences, and that the contexts of a specific term are often found in the contexts of a general term but not vice versa. By context of a term, we mean the set of words frequently have a particular syntactic relation (e.g. *Subject-Verb-Object*) with the term in a

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 810–819,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

given corpus. Given two terms, the SCS method collects from the Web pre-defined syntactic relations of each of the terms and checks if the syntactic contexts of a term properly includes that of the other term in order to determine their taxonomic relation. The method scores each taxonomic relation candidate based on the two measures of Web-based evidence and contextual set inclusion, and as such, is able to find implicit subsumption relations between terms across sentences. The SCS shows itself (Section 3.1) to be complementary to linguistic pattern matching.

After the relation identification, the identified taxonomic relations should be integrated into a graph for the task of taxonomy construction from scratch or associated with existing concepts of a given taxonomy via is-a relations (Snow et al., 2006). In this step of taxonomic structure construction, there is a need for pruning incorrect and redundant relations. Previous methods for the pruning task (Kozareva and Hovy, 2010; Velardi et al., 2012) treat the identified taxonomic relations equally, and the pruning task is thus reduced to finding the best trade-off between path length and the connectivity of traversed nodes. This assumption, however, is not always true due to the fact that the identified taxonomic relations may have different confidence values, and the relations with high confidence values can be incorrectly eliminated during the pruning process. We thus propose a novel method for the taxonomy induction by utilizing the evidence scores from the relation identification method and the topological properties of the graph. We show that it can effectively prune redundant edges and remove loops while preserving the correct edges of taxonomy.

We apply the proposed methods of taxonomic relation identification and taxonomy induction to the task of constructing a taxonomy from a given text collection from scratch. The resultant system consists of three modules: Term extraction and filtering (Section 2.1), taxonomic relation identification (Section 2.2), and taxonomy induction (Section 2.3). The outputs of the term extraction/filtering module are used as inputs of the taxonomic relation identification, such that the taxonomic relation identification module checks if there is a taxonomic relation between each pair of terms from the term extraction/filtering module. The taxonomy induction module gets the identified taxonomic relation set as the input, and outputs the final optimal taxonomy by pruning redundant and incorrect relations.

2 Methodology

2.1 Term Extraction and Filtering

The first step to construct taxonomies is to collect candidate terms from text documents in the domain of interest. Like most of linguistic approaches, we use pre-defined linguistic filters to extract candidate terms, including single-word terms and multi-word terms which are noun or noun phrases in sentences. These terms are then preprocessed by removing determiners and lemmatization.

The candidate terms collected are then filtered to select the terms that are most relevant to the domain of interest. Many statistical techniques are developed for the filtering, such as $TF\text{-}IDF$, domain relevance (DR), and domain consensus (DC) (Navigli and Velardi, 2004). DR measures the amount of information that a term t captures within a domain of interest D_i, compared to other contrasting domains (D_j), while DC measures the distributed use of a term t across documents d in a domain D_i. Since three measures have pros and cons, and might be complementary to each other, our term filtering method is thus the linear combination of them:

$$\begin{aligned} TS(t, D_i) = \alpha \times TFIDF(t, D_i) \\ + \beta \times DR(t, D_i) + \gamma \times DC(t, D_i) \end{aligned} \quad (1)$$

We experimented (see Section 3) with different values of α, β and γ, and found that the method shows the best performance when the values for α and β are 0.2 and 0.8 and the value for γ is between 0.15 and 0.35, depending on the size of the domain corpus.

2.2 Taxonomic Relation Identification

In this section, we present three taxonomic relation identification methods which are adopted in our system. First, two methods of string inclusion with WordNet and lexical-syntactic pattern matching, which were commonly used in the literature will be introduced with some modifications. Then, a novel syntactic contextual subsumption method to find implicit relations between terms across sentences by using contextual evidence from syntactic structures and Web data will be proposed. Finally, these three methods will be linearly combined to

Notation	Meaning
$t_1 \gg t_2$	t_1 is a hypernym of t_2
$t_1 \approx t_2$	t_1 semantically equals or is similar to t_2
$t_1 \gg_{WN} t_2$	t_1 is a direct or inherited hypernym of t_2 according to WordNet
$t_1 \approx_{WN} t_2$	t_1 and t_2 belong to the same synset of WordNet

Table 1: Notations

form an integrating solution for taxonomic relation identification. Given two terms t_1 and t_2, Table 1 summarizes important notations used in this paper.

2.2.1 String Inclusion with WordNet (SIWN)

One simple way to check taxonomic relation is to test string inclusion. For example, "terrorist organization" is a hypernym of "foreign terrorist organization", as the former is a substring of the latter. We propose an algorithm to extend the string inclusion test by using WordNet, which will be named SIWN. Given a candidate general term t_g and a candidate specific term t_s, the SIWN algorithm examines t_g from left to right (designating each word in t_g to be examined as w_g) to check if there is any word (w_s) in t_s such that $w_g \approx_{WN} w_s$ or $w_g \gg_{WN} w_s$, and identifies the taxonomic relation between two terms if every word of t_g has a corresponding word in t_s (with at least one $\gg_{WN}$ relation). For example, consider two terms: "suicide attack" and "world trade center self-destruction bombing". Because "attack" $\gg_{WN}$ "bombing" and "suicide" $\approx_{WN}$ "self-destruction", according to SIWN algorithm, we conclude that "suicide attack" is the hypernym of "world trade center self-destruction bombing".

Given two terms t_1 and t_2, the evidence score for SIWN algorithm is calculated as follows:

$$Score_{SIWN}(t_1, t_2) = \begin{cases} 1 & \text{if } t1 \gg t_2 \text{ via SIWN} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

2.2.2 Lexical-syntactic Pattern

Extending the ideas of Kozareva and Hovy (2010) and Navigli et al. (2011), we propose a method of extracting taxonomic relations by matching lexical-syntactic patterns to the Web data.

Definition 1 (Syntactic patterns)**.** *Given two terms t_1 and t_2, Pat(t_1, t_2) is defined as the set of the following patterns:*

- *"t_1 such as t_2"*
- *"t_1, including t_2"*
- *"t_2 is [a|an] t_1"*
- *"t_2 is a [kind|type] of t_1"*
- *"t_2, [and|or] other t_1"*

, where t_1 and t_2 are replaced with actual terms and [a|b] denotes a choice between a and b.

Given candidate general term t_1 and candidate specific term t_2, the lexical-syntactic pattern (LSP) method works as follows:

1. Submit each phrase in *Pat*(t_1, t_2) to a Web search engine as a query. The number of the search results of the query is denoted as *WH*(t_1, t_2).
2. Calculate the following evidence score:

$$Score_{LSP}(t_1, t_2) = \frac{\log(WH(t_1, t_2))}{1 + \log(WH(t_2, t_1))} \quad (3)$$

3. If $Score_{LSP}(t_1, t_2)$ is greater than a threshold value then $t_1 \gg t_2$.

While most lexical-syntactic pattern methods in the literature only consider the value of *WH*(t_1, t_2) in checking $t_1 \gg t_2$ (Wentao et al., 2012), we take into account both *WH*(t_1, t_2) and *WH*(t_2, t_1). The intuition of formula (3) is that if $t1$ is a hypernym of $t2$ then the size of *WH*(t_1, t_2) will be much larger than that of *WH*(t_2, t_1), which means the lexical-syntactic patterns are more applicable for the ordered pair (t_1, t_2) than (t_2, t_1).

2.2.3 Syntactic Contextual Subsumption

The LSP method performs well in recognizing the taxonomic relations between terms in the sentences containing those pre-defined syntactic patterns. This method, however, has a major shortcoming: it cannot derive taxonomic relations between two terms occurring in two different sentences. We thus propose a novel syntactic contextual subsumption (SCS) method which utilizes contextual information of terms in syntactic structure (i.e. *Subject-Verb-Object* in this study) and Web data to infer implicit taxonomic relations

between terms across sentences. Note that the chosen syntactic structure *Subject-Verb-Object* is identical to the definition of non-taxonomic relations in the literature (Buitelaar et al., 2004), where the *Verb* indicate non-taxonomic relations between *Subject* and *Object*. In this subsection, we first present the method to collect those non-taxonomic relations. Then we present in detail the ideas of the SCS method and how we can use it to derive taxonomic relations in practice.

A. Non-taxonomic Relation Identification

Following previous approaches to non-taxonomic relation identification, e.g. (Ciaramita et al., 2005), we use the Stanford parser (Klein and Manning, 2003) to identify the syntactic structures of sentences and extract triples of *(Subject, Verb, Object)*, where *Subject* and *Object* are noun phrases.

We further consider the following issues: First, if a term (or noun phrase) includes a preposition, we remove the prepositional phrase. However, if the headword of a term is a quantitative noun like "lot", "many" or "dozen" and it is modified by the preposition "of", we replace it with the headword of the object of the preposition "of". For example, we can extract the triples $(people, need, food)$ and $(people, like, snow)$ from the following sentences, respectively:

- "People in poor countries need food"
- "A lot of people like snow"

Second, if the object of a verb is in a verb form, we replace it with, if any, the object of the embedded verb. For example, we can extract the triple $(soldier, attack, terrorist)$ from the following sentence:

- "The soldiers continue to attack terrorists"

Third, if a term has a coordinate structure with a conjunction like "and" or "or", we split it into all coordinated noun phrases and duplicate the triple by replacing the term with each of the coordinated noun phrases. For example, we can extract the triples of $R(girl, like, dog)$ and $R(girl, like, cat)$ from the following sentence:

- "The girl likes both dogs and cats"

Given two terms t_1, t_2 and a non-taxonomic relation r, some notations which will be used hereafter are shown below:

- $R(t_1, r, t_2)$: t_1, r, and t_2 have a *(Subject, Verb, Object)* triple.
- $\Theta(t_1, t_2)$: the set of relations r such that there exists $R(t_1, r, t_2)$ or $R(t_2, r, t_1)$.

B. Syntactic Contextual Subsumption Method

The idea of the SCS method derived from the following two observations.

Observation 1. *Given three terms t_1, t_2, t_3, and a non-taxonomic relation r, if we have two triples $R(t_1, r, t_3)$ and $R(t_2, r, t_3)$ (or $R(t_3, r, t_1)$ and $R(t_3, r, t_2)$), t_1 and t_2 may be in taxonomic relation.*

For example, given two triples *R(Al-Qaeda, attack, American)* and *R(Terrorist group, attack, American)*, a taxonomic relation *Terrorist group* $\gg$ *Al-Qaeda* can be induced. However, it is not always guaranteed to induce a taxonomic relations from such a pair of triples, for example from *R(animal, eat, meat)* and *R(animal, eat, grass)*. The second observation introduced hereafter will provide more chance to infer taxonomic relationship.

Definition 2 (Contextual set of a term)**.** *Given a term t_1 and a non-taxonomic relation r, $S(t_1, r, \text{“}subj\text{”})$ denotes the set of terms t_2 such that there exists triple $R(t_1, r, t_2)$. Similarly, $S(t_1, r, \text{“}obj\text{”})$ is the set of terms t_2 such that there exists triple $R(t_2, r, t_1)$.*

Observation 2. *Given two terms t_1, t_2, and a non-taxonomic relation r, if $S(t_1, r, \text{“}subj\text{”})$ mostly contains $S(t_2, r, \text{“}subj\text{”})$ but not vice versa, then most likely t_1 is a hypernym of t_2. Similarly, if $S(t_1, r, \text{“}obj\text{”})$ mostly contains $S(t_2, r, \text{‘}obj\text{”})$ but not vice versa, then most likely t_1 is a hypernym of t_2.*

For example, assume that *S(animal, eat, "subj")* = {*grass, potato, mouse, insects, meat, wild boar, deer, buffalo*} and *S(tiger, eat, "subj")* = {*meat, wild boar, deer, buffalo*}. Since *S(animal, eat, "subj")* properly contains *S(tiger, eat, "subj")*, we can induce *animal* $\gg$ *tiger*.

Based on Observation 2, our strategy to infer taxonomic relations is to first find the contextual set of terms via the evidence of syntactic structures and Web data, and then compute the score of the set inclusion. The detail of the method is presented hereafter.

Definition 3. *Given two terms t_1, t_2 and a non-taxonomic relation r, $C(t_1, t_2, r, \text{“}subj\text{”})$ denotes the number of terms t_3 such that there exists both triples $R(t_1, r, t_3)$ and $R(t_2, r, t_3)$. Similarly, $C(t_1, t_2, r, \text{“}obj\text{”})$ is the number of terms t_3 such that there exists both relations $R(t_3, r, t_1)$ and $R(t_3, r, t_2)$.*

Given the pair of a candidate general term t_1 and a candidate specific term t_2, we extract their non-taxonomic relations from corpora extracted from the Web, and use them to determine the taxonomic relation between t_1 and t_2 as follows:

1. Find from a domain corpus the relation r and type Γ such that:

$$C(t_1, t_2, r, \Gamma) = \max_{\substack{r' \in \Theta(t_1, t_2) \\ \Gamma' \in \{\text{“}subj\text{”}, \text{“}obj\text{”}\}}} C(t_1, t_2, r', \Gamma')$$

2. If type Γ is “subj”, collect the first 1,000 search results of the query “t_1 r” using the Google search engine, designated as $Corpus^{\Gamma}_{t_1}$. In the same way, construct $Corpus^{\Gamma}_{t_2}$ with the query “t_2 r”. If Γ is “obj”, two queries “r t_1” and “r t_2” are submitted instead to collect $Corpus^{\Gamma}_{t_1}$ and $Corpus^{\Gamma}_{t_2}$, respectively.

3. Find the sets of $S(t_1, r, \Gamma)$ and $S(t_2, r, \Gamma)$ from $Corpus^{\Gamma}_{t_1}$ and $Corpus^{\Gamma}_{t_2}$, respectively, using the non-taxonomic relation identification method above.

4. Calculate the following evidence score for SCS method:

$$Score_{SCS} = \left[\frac{|S(t_1, r, \Gamma) \bigcap S(t_2, r, \Gamma)|}{|S(t_2, r, \Gamma)|} + \left(1 - \frac{|S(t_1, r, \Gamma) \bigcap S(t_2, r, \Gamma)|}{|S(t_1, r, \Gamma)|}\right)\right] \times \log(|S(t_1, r, \Gamma)| + |S(t_2, r, \Gamma)|) \quad (4)$$

   The basic idea of the contextual subsumption score in our method is that if t_1 is a hypernym of t_2 then the set $S(t_1, r, \Gamma)$ will mostly contain $S(t_2, r, \Gamma)$ but not vice versa. The intuition of formula (5) is inspired by Jaccard similarity coefficient. We then multiply the score with the log value of total size of two sets to avoid the bias of small set inclusion.

5. If $Score_{SCS}(t_1, t_2)$ is greater than a threshold value, then we have $t1 \gg t2$.

2.2.4 Combined Method

In our study, we linearly combine three methods as follows:

1. For each ordered pair of terms (t_1, t_2) calculate the total evidence score:

$$\begin{aligned} Score(t_1, t_2) = \ & \alpha \times Score_{SIWN}(t_1, t_2) \\ & + \beta \times Score_{LSP}(t_1, t_2) \\ & + \gamma \times Score_{SCS}(t_1, t_2) \end{aligned} \quad (5)$$

2. If $Score(t_1, t_2)$ is greater than a threshold value, then we have $t_1 \gg t_2$.

We experimented with various combinations of values for α, β and γ, and found that the method shows the best performance when the value of α is 0.5, β is between 0.35 and 0.45, and γ is between 0.15 and 0.25, depending on the domain corpus size.

2.3 Taxonomy Induction

The output of the taxonomic relation identification module is a set of taxonomic relations T. In this section, we will introduce a graph-based algorithm (Algorithm 1) to convert this set into an optimal tree-structured taxonomy, as well as to eliminate incorrect and redundant relations. Denote $e(t_1, t_2)$ as an directed edge from t_1 to t_2, the algorithm consists of three steps which will be described hereafter with the corresponding lines in Algorithm 1.

Step 1: Initial hypernym graph creation (line 1 - 16) This step is to construct a connected directed graph from the list of taxonomic relations. The idea is to add each taxonomic relation $t_1 \gg t_2$ as a directed edge from parent node t_1 to child node t_2, and if t_1 does not have any hypernym term, t_1 will become a child node of $ROOT$ node. The result of this step is a connected graph containing all taxonomic relations with the common $ROOT$ node.

Step 2: Edge weighting (line 17) This step is to calculate the weight of each edge in the hypernym graph. Unlike the algorithm of Velardi et al. (2012) and Kozareva and Hovy (2010) where every taxonomic relation is treated equally, we assume the confidence of each taxonomic relation is different, depending on the amount of

Algorithm 1 Taxonomy Induction Algorithm

Input: T : the taxonomic relation set
Output: V: the vertex set of resultant taxonomy;
E: the edge set of resultant taxonomy;

1: Initialize $V = \{ROOT\}$, $E = \emptyset$;
2: **for** each taxonomic relation $(t_1 \gg t_2) \in T$ **do**
3: $E = E \cup \{e(t_1, t_2)\}$
4: **if** $t_1 \notin V$ **then**
5: $V = V \cup \{t_1\}$
6: **end if**
7: **if** $t_2 \notin V$ **then**
8: $V = V \cup \{t_2\}$
9: **end if**
10: **if** $\nexists\, e(t_3, t_1) \in E$ with $t_3 \neq ROOT$ **then**
11: $E = E \cup \{e(ROOT, t_1)\}$
12: **end if**
13: **if** $\exists\, e(ROOT, t_2) \in E$ **then**
14: $E = E \setminus \{e(ROOT, t_2)\}$
15: **end if**
16: **end for**
17: edgeWeighting(V, E);
18: graphPruning(V, E);

evidence it has. Thus, the hypernym graph edges will be weighted as follows:

$$w(e(t_1, t_2)) = \begin{cases} 1 & \text{if } t_1 = ROOT \\ Score(t_1, t_2) & \text{otherwise} \end{cases} \quad (6)$$

Note that the $Score$ value in formula (6) is determined by the taxonomic relation identification process described in Section 2.2.4.

Step 3: Graph pruning (line 18) The hypernym graph generated in Step 1 is not an optimal taxonomy as it may contain many redundant edges or incorrect edges which together form in a loop. In this step, we aim at producing an optimal taxonomy by pruning the graph based on our edge weighting strategy. A maximum spanning tree algorithm, however, cannot be applied as the graph is directed. For this purpose, we apply Edmonds' algorithm (Edmonds, 1967) for finding a maximum optimum branching of a weighted directed graph. Using this algorithm, we can find a subset of the current edge set, which is the optimized taxonomy where every non-root node has in-degree 1 and the sum of the edge weights is maximized. Figure 1 shows an example of the taxonomy induction process.

3 Experiment Results

We evaluated our methods for taxonomy construction against the following text collections of five domains:

- Artificial Intelligence (AI) domain: 4,119 papers extracted from the IJCAI proceedings from 1969 to 2011 and the ACL archives from year 1979 to 2010. The same dataset used in the work of Velardi et al. (2012).
- Terrorism domain: 104 reports of the US state department, titled "Patterns of Global Terrorism (1991-2002)" [1]. A report contains about 1,500 words.
- Animals, Plants and Vehicles domains: Collections of Web pages crawled by using the bootstrapping algorithm described by Kozareva et al. (2008). Navigli et al. (2011) and Kozareva and Hovy (2010) used these datasets to compare their outputs against WordNet sub-hierarchies.

There are two experiments performed in this section: 1) Evaluating the construction of new taxonomies for Terrorism and AI domains, and 2) Comparing our results with the gold-standard WordNet sub-hierarchies. Note that in the experiments, the threshold value we used for $Score_{LSP}$ is 1.9, $Score_{SCS}$ is 1.5 and $Score$ is 2.1.

3.1 Constructing new taxonomies for AI and Terrorism domains

Referential taxonomy structures such as WordNet or OpenCyc are widely used in semantic analytics applications. However, their coverage is limited to common well-known areas, and many specific domains like Terrorism and AI are not well covered in those structures. Therefore, an automatic method which can induce taxonomies for those specific domains from scratch can greatly contribute to the process of knowledge discovery.

First, we applied our taxonomy construction system to the AI domain corpus. We compared the taxonomy constructed by our system with that obtained by Velardi et al. (2012), and show the comparison results in Table 2. Notice that in this comparison, to be fair, we use the same set of terms that was used in (Velardi et al., 2012). The result shows that our approach can extract 9.8%

[1] *http://www.fas.org/irp/threat/terror.htm*

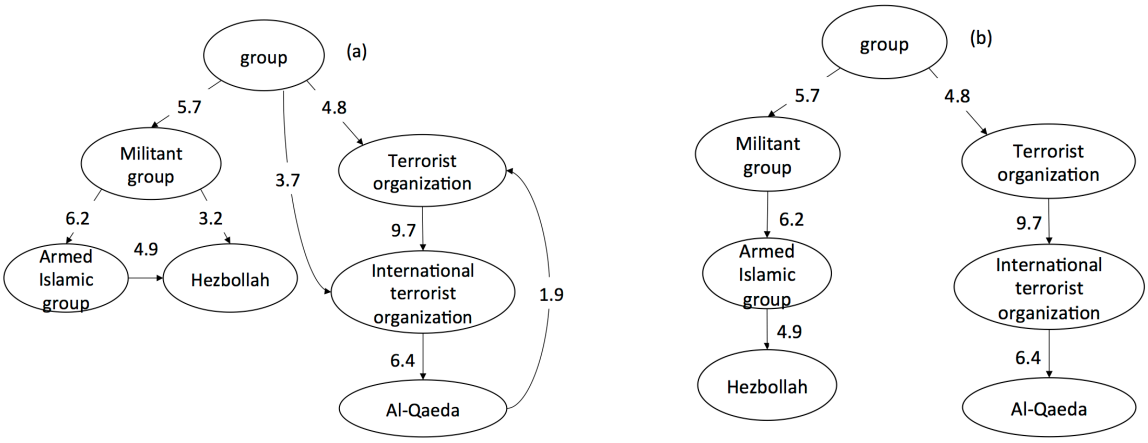

Figure 1: An example of taxonomy induction. (a) Initial weighted hypernym graph. (b) Final optimal taxonomy, where we prune two redundant edges *(group, International terrorist organization)*, *(Militant group, Hezbollah)* and remove the loop by cutting an incorrect edge *(Al-Qaeda, Terrorist organization)*.

more taxonomic relations and achieve 7% better term coverage than Velardi's approach.

	Our system	Velardi's system
#vertex	1839	1675
#edge	1838	1674
Average depth	6.2	6
Max depth	10	10
Term coverage	83%	76%

Table 2: Comparison of our system with (Velardi et al., 2012)

We also applied our system to the Terrorism corpus. The proposed taxonomic relation identification algorithm extracts a total of 976 taxonomic relations, from which the taxonomy induction algorithm builds the optimal taxonomy. The total number of vertices in the taxonomy is 281, and the total number of edges is 280. The average depth of the trees is 3.1, with the maximum depth 6. In addition, term coverage (the ratio of the number of terms in the final optimal trees to the number of terms obtained by the term suggestion/filtering method) is 85%.

To judge the contribution of each of taxonomic relation identification methods described in Section 2.2 to the overall system, we alternately run the system for the AI and Terrorism domains with different combinations of the three methods (i.e. SIWN, LSP, and SCS) as shown in Table 3. Note that we employed only the first two modules of term suggestion/filtering and taxonomic relation identification except the last module of taxonomy induction for this experiment. Table 3 shows the number of the taxonomic relations extracted by each of the combinations. Since SIWN and LSP are commonly used by previous taxonomic relation identification systems, we consider the combination of SIWN + LSP as the baseline of the experiment. The results in Table 3 show that the three methods are all well complementary to each other. In addition, the proposed SCS method can contribute up to about 27% - 29% of all the identified taxonomic relations, which were not discovered by the other two baseline methods.

	No. of extracted relations	
	Terrorism	AI domain
SCS	484	1308
SIWN	301	984
LSP	527	1537
SIWN + LSP	711	2203
SCS + SIWN + LSP	976	3122

Table 3: The number of taxonomic relations extracted by different methods.

	Percentage of correct relations	
	Terrorism	AI domain
SCS	91%	88%
SIWN	96%	91%
LSP	93%	93%
SCS + SIWN + LSP	92%	90%

Table 4: Estimated precision of taxonomic relation identification methods in 100 extracted relations.

	Animals domain			Plants domain			Vehicles domain		
	Our	Kozareva	Navigli	Our	Kozareva	Navigli	Our	Kozareva	Navigli
#Correct relations	2427	1643	N.A.	1243	905	N.A.	281	246	N.A.
Term coverage	96%	N.A.	94%	98%	N.A.	97%	97%	N.A.	96%
Precision	95%	98%	97%	95%	97%	97%	93%	99%	91%
Recall	56%	38%	44%	53%	39%	38%	69%	60%	49%
F-measure	71%	55%	61%	68%	56%	55%	79%	75%	64%

Table 5: Comparison of (Navigli et al., 2011), (Kozareva and Hovy, 2010) and our system against WordNet in three domains: Animals, Plants and Vehicles.

We further evaluated the precision of each individual taxonomic relation identification method. For AI and Terrorism domains, we again run the system with each of the three methods and with all together, and then randomly select 100 extracted taxonomic relations each time. These selected taxonomic relations are then examined by two domain experts to check the correctness. The evaluation results are given in Table 4. Note that only the first two modules of term suggestion/filtering and taxonomic relation identification are employed for this experiment as well. The SIWN and LSP methods achieve high precision because they are based on the gold-standard taxonomy hierarchy WordNet and on the well-defined patterns, respectively. In contrast, the SCS method ambitiously looks for terms pairs that share similar syntactic contexts across sentences, though the contextual evidence is restricted to certain syntactic structures, and thus has a slightly lower precision compared to the other two methods.

In short, the SCS method is complementary to the baseline methods, significantly improving the coverage of the combined methods, when its precision is comparable to those of the baseline methods. We performed next experiments to show that the SCS method overall has synergistic impact to improve the F-measure of the combined methods.

3.2 Evaluation against WordNet

In this experiment, we constructed taxonomies for three domains Animals, Plants and Vehicles, and then checked whether the identified relations can be found in the WordNet, and which relations in WordNet are not found by our method. Note that in this comparison, to be fair, we changed our algorithm to avoid using WordNet in identifying taxonomic relations. Specifically, in the SIWN algorithm, all operations of "$\approx_{WN}$" are replaced with normal string-matching comparison, and all "$\gg_{WN}$" relations are falsified. The evaluation uses the following measures:

$$Precision = \frac{\#relations\ found\ in\ WordNet\ and\ by\ the\ method}{\#relations\ found\ by\ the\ method}$$

$$Recall = \frac{\#relations\ found\ in\ WordNet\ and\ by\ the\ method}{\#relations\ found\ in\ WordNet}$$

We also compared our results with those obtained by the approaches of Navigli et al. (2011) and Kozareva and Hovy (2010), where they also compared their resultant taxonomies against WordNet. In this comparison, all the three approaches (i.e. ours, the two previous methods) use the same corpora and term lists. The comparison results are given in Table 5. "$N.A.$" value means that this parameter is not applicable to the corresponding method. The results show that our approach achieves better performance than the other two approaches, in terms of both the number of correctly extracted taxonomic relations and the term coverage. Our system has a slightly lower precision than that of (Navigli et al., 2011) and (Kozareva and Hovy, 2010) due to the SCS method, but it significantly contributes to improve the recall and eventually the F-measure over the other two systems.

To judge the effectiveness of our proposed taxonomy induction algorithm described in Section 2.3, we compared it with the graph-based algorithm of Velardi et al. (2012). Recall that in this algorithm, they treat all taxonomic relations equally, and the pruning task is reduced to finding the best trade-off between path length and the connectivity of traversed nodes. For each of five domains (i.e. Terrorism, AI, Animals, Plants and Vehicles), we alternately run the two taxonomy induction algorithms over the same taxonomic relation set produced by our taxonomic relation identification process. For Terrorism and AI domains, we randomly pick up 100 edges in each resultant taxon-

omy and ask two domain experts to judge for the correctness. For Animals, Plants and Vehicles domains, we check the correctness of the edges in resultant taxonomies by comparing them against the corresponding sub-hierarchies in WordNet. The evaluation is given in Table 6. The results show that the proposed taxonomy induction algorithm can achieve better performance than the algorithm of Velardi et al. (2012). This may be due to the fact that our algorithm considers the scores of the identified taxonomic relations from the relation identification module, and thus is more precise in eliminating incorrect relations during the pruning process.

	Percentage of correct edges	
	Our algorithm	Velardi's algorithm
Terrorism	94%	90%
AI	93%	88%
Animals	95%	93%
Plants	95%	92%
Vehicles	93%	92%

Table 6: Comparison of our taxonomy induction algorithms and that of Velardi et al. (2012).

In addition, when comparing Tables 4 and 6, we can find that the precision of taxonomic relations after the pruning process is higher than that before the pruning process, which proves that the proposed taxonomy induction algorithm effectively trims the incorrect relations of Terrorism and AI taxonomies, leveraging the percentage of correct relations 2% - 3% up.

For the SCS method, besides the triple *Subject-Verb-Object*, we also explore other syntactic structures like *Noun-Preposition-Noun* and *Noun-Adjective-Noun*. For example, from the sentence *"I visited Microsoft in Washington"*, the triple *(Microsoft, in, Washington)* is extracted using *Noun-Preposition-Noun* structure. Similarly, from the sentence *"Washington is a beautiful city"*, the triple *(Washington, beautiful, city)* is extracted using *Noun-Adjective-Noun* structure. We then use the triples for the contextual subsumption method described in Section 2.2.3, and test the method against the Animals, Plants and Vehicles domains. The results are then compared against WordNet sub hierarchies. The experiment results in Table 7 show that the triples of *Subject-Verb-Object* give the best performance compared to the other syntactic structures. These can be explained as the number of triples of two types *Noun-Preposition-Noun* and *Noun-Adjective-Noun* are smaller than that of *Subject-Verb-Object*, and the number of *Verb* is much greater than number of *Preposition* or *Adjective*.

	S-V-O	*N-P-N*	*N-A-N*
Animals domain			
Precision	95%	68%	72%
Recall	56%	52%	47%
F-measure	71%	59%	57%
Plants domain			
Precision	95%	63%	66%
Recall	53%	41%	43%
F-measure	68%	50%	52%
Vehicles domain			
Precision	93%	59%	60%
Recall	69%	45%	48%
F-measure	79%	51%	53%

Table 7: Comparison of three syntactic structures: *S-V-O* (*Subject-Verb-Object*), *N-P-N* (*Noun-Preposition-Noun*) and *N-A-N* (*Noun-Adjective-Noun*).

All experiment results are available at *http://nlp.sce.ntu.edu.sg/wiki/projects/taxogen*.

4 Conclusion

In this paper, we proposed a novel method of identifying taxonomic relations using contextual evidence from syntactic structure and Web data. This method is proved well complementary with previous method of linguistic pattern matching. We also present a novel graph-based algorithm to induce an optimal taxonomy from a given taxonomic relation set. The experiment results show that our system can generally achieve better performance than the state-of-the-art methods. In the future, we will apply the proposed taxonomy construction method to other domains such as biomedicine and integrate it into other frameworks such as ontology authoring.

Analysing recall loss in named entity slot filling

Abstract

State-of-the-art fact extraction is heavily constrained by recall, as demonstrated by recent performance in TAC Slot Filling. We isolate this recall loss for NE slots by systematically analysing each stage of the slot filling pipeline as a filter over correct answers. Recall is critical as candidates never generated can never be recovered, whereas precision can always be increased in downstream processing.

We provide precise, empirical confirmation of previously hypothesised sources of recall loss in slot filling. While NE type constraints substantially reduce the search space with only a minor recall penalty, we find that 10% to 39% of slot fills will be entirely ignored by most systems. One in six correct answers are lost if coreference is not used, but this can be mostly retained by simple name matching rules.

1 Introduction

The TAC Knowledge Base Population (KBP) Slot Filling (SF) consists of extracting named attributes from text. Given a query, e.g. John Kerry, a system searches a corpus for documents which contain the entity. It then fills a list of *slots*, named attributes such as (`per:spouse`, Teresa Heinz).

The top TAC SF 2013 (TAC13) system scored 37.3% F-score (Roth et al., 2013), and the median F-score was 16.9% (Surdeanu, 2013). Recall for SF systems is especially low, with many systems using precise extractors with low recall. Precision ranges from 9% to 40% *greater than recall* for the top 5 systems in TAC13, and unsurprisingly, Roth et al. (2013) has the highest recall at 33%. Closing the recall gap without substantially increasing the search space is critical to improving SF results.

Ji and Grishman (2011) and Min and Grishman (2012) identify many of the challenges of SF, and suggest that inference, coreference and named entity recognition (NER) are key sources of error. Min and Grishman categorise the slot fills found by human annotators but not found in the aggregated output of all systems. However, this approach only allows them to hypothesise the likely source of recall loss. For instance, it is impossible to distinguish candidate generation errors from answer merging errors. Roth et al. (2014) categorise these errors at a high level, without specific analysis of candidate generation pipeline components such as coreference.

In this paper, we take this analysis further by performing a systematic recall analysis that allows us to pinpoint the cause of every recall error (candidates lost that can never be recovered) and estimate upper bounds on recall in existing approaches. We implement a collection of naïve SF systems utilizing a set of increasingly restrictive filters over documents and named entities (NEs). TAC has three slot types: NE, string and value slots. We consider only those slots filled by NEs as there are widely-used, high accuracy tools available for NER, and focusing on NEs only allows us to precisely gauge performance of filters. String slots do not have reliable classifiers, and value slots require more normalisation than directly returning a token span. Otherwise, this evaluation is not specifically dependent on the nature of NEs, and we expect similar results for other slot types.

We focus on systems which first generate candidates and then process them, the approach of the majority of TAC systems. Our filters apply hard constraints over NEs commonly used in the literature, accounting for a typical SF candidate generation pipeline—matching the query term, the form of candidate fills and the distance between the query and the candidate—but not performing any further scoring or thresholding. We compare sev-

eral forms of coreference as filters, motivated by the need for efficient coreference resolution when processing large corpora. Complementing these unsupervised experiments, we implement a maximum recall bootstrap to identify which fills are reachable from training data.

We find ∼10% of recall is ignored by most systems due to NER bounds errors, and despite state-of-the-art coreference, 8% is lost when queries and fills occur in different sentences. Using NE type constraints is very effective, reducing recall by only 2% for a search space reduction of 81%. Without any coreference, 16% of typed fills are lost, but 12% of this recall can be recovered using fast naïve name matching rules, reducing the search space to 59% that of full coreference. 15% of recall is lost if a SF approach, such as a bootstrapping, requires that dependency paths be non-unique in a corpus. We show that most remaining candidates are reachable via bootstrapping from a small number of seeds. Our results provide systematic confirmation that effective coreference and NER are critical to high recall slot filling.

2 Why focus on recall?

In this work, we determine the recall loss caused by candidate generation constraints in SF systems. SF pipelines are typically implemented using a coarse-to-fine approach, where all possible candidates are generated and then filtered by hard constraints and more sophisticated downstream processes. Following this, we maximally generate candidates and assume a high-precision but relatively costly downstream process selects the final extractions. While ultimately any system makes precision-recall trade-offs, the recall of a system's coarse candidate generation process sets a hard upper bound on performance, as candidates that are not generated at all can never be recovered by downstream processes. SF systems could generate every noun phrase in a corpus as potential candidates, but they apply hard candidate generation constraints for efficiency and precision.

We implement these hard constraints as a series of filters, and return every candidate which passes a filter without further ranking or thresholding. These filters are comprised of generic components, such as NER, which are representative of SF pipelines. We are only interested in precision in so much as it corresponds to the size of the search space (the candidates generated), assuming a small, fixed number of answers. The search space determines the workload of later stages responsible for extraction, merging and ranking. Precision can be improved by this post-processing of the candidate set, but recall cannot.

3 Background

Slot filling (SF) is a query-oriented relation extraction (RE) task in the Knowledge Base Population (KBP) track of the Text Analysis Conferences (TAC) (McNamee and Dang, 2009). A SF system is queried with a name and a predefined relation schema, or *slots*, and must seek instances of any relations involving the query entity, and the corresponding slot fills, from a corpus.

Systems typically consist of several pipelined stages (Ji et al., 2011), providing many potential locations for error. The basic pipeline, in Figure 1, consists of four stages (Ji and Grishman, 2011): document retrieval, candidate generation, answer extraction, and answer merging and ranking. The output of the second stage is a set of candidates which are then usually ranked using RE techniques,[1] to precisely pinpoint answers. TAC penalises redundant responses, requiring a final answer merging and ranking stage. The first two stages are the focus of this work, as they inadvertently filter correct answers that cannot be recovered, and they determine the size of the search space for later stages.

Min and Grishman (2012) conducted an analysis of the 140 TAC 2010 SF fills that were found by human annotators but not any system, and manually look for evidence in the reference document and categorise the hypothetical sources of error. They find inference, coreference and NER to be the top sources of error, and that the most studied component (sentence-level RE) is not the dominant problem, contributing only 10% of recall loss. We precisely characterise the contribution of these sources of error.

We follow the SF literature in adopting RE techniques for filtering candidates. RE focuses on identifying relations between entities (or attributes of entities) as mentioned in text. Both relation schema and training data are often provided, and extraction is done using learnt classifiers (Mintz et al., 2009; Surdeanu et al., 2012; Riedel et al.,

[1] We note that question answering techniques have been used directly by SF systems (Byrne and Dunnion, 2011) but RE techniques are the primary method for answer extraction.

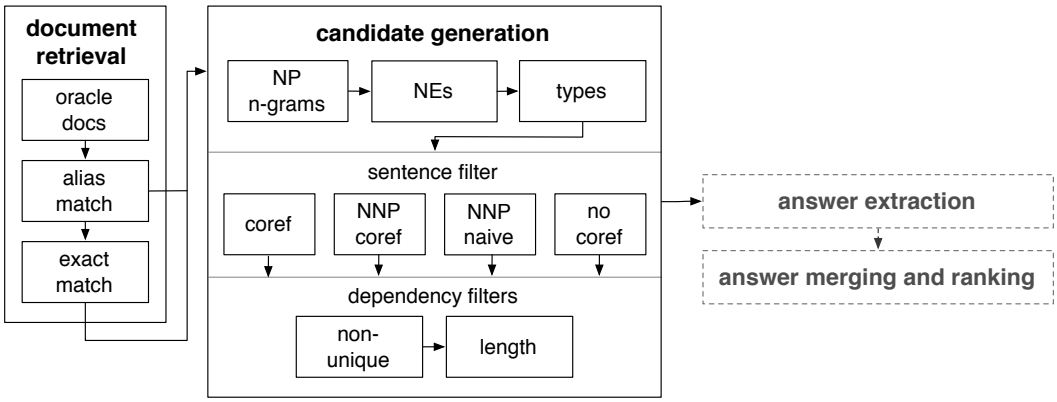

Figure 1: Candidate filters within the standard SF pipeline. Arrows indicate a sequence of filters.

2013; Zhang et al., 2013) or semi-supervised techniques (Agichtein and Gravano, 2000; Wang et al., 2011; Carlson et al., 2010).

Relation phrases or patterns may be identified without labels (Fader et al., 2011; Mausam et al., 2012) or clustered (Yao et al., 2012) into types. Generating candidate entity pairs and using the syntactic or surface path between them to decide whether a relation exists are common threads in RE that also form part of the SF pipeline. In some RE tasks, entities mentioned may already be identified in a document and provided to a RE system; in general, automatic NER is required. Some tasks are defined more generally to include common noun phrases (Fader et al., 2011; Carlson et al., 2010). SF specifically includes slots that can be filled by arbitrary strings such as `per:cause of death`, which make up a large number of slot fills but may require the use of different techniques for extraction, separate from names. NER may be further enhanced by resolving names to a KB (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012; Wang et al., 2011), reducing noise in learning and extraction processes, but we do not take this step in this work.

Typically, a RE system will only consider entities mentioned together in a sentence. When seeking all instances of a given relation between known entities, coreference resolution is necessary to substantially expand the set of candidate pairs (Gabbard et al., 2011). Coreference resolution may not be necessary where each relation is redundantly mentioned in a large corpus, as in SF; in this vein, "Open" approaches prefer precision and avoid automatic coreference resolution (Banko et al., 2007). Moreover, previous analysis attributed substantial SF error to these tools (Ji and Grishman, 2011). Our work evaluates NER, locality heuristics and coreference within a SF context.

Classification features for RE typically encode: attributes of the entities; the surface form, dependency path, or phrase structure subtree between them; and surrounding context (Zhou et al., 2005; Mintz et al., 2009; Zhang et al., 2013). We evaluate the length of dependency path between entities as a variable affecting SF candidate recall, and apply naïve entity pair bootstrapping (Brin, 1998; Agichtein and Gravano, 2000) to assess the generalisation over dependency paths from examples.

4 Experimental setup

We begin with a set of queries (a query being a NE entity grounded in a mention in a document) and, for each query q, the documents D_q known to contain any slot fill for q, as determined by oracle information retrieval (IR) from human annotation and judged system output. Filling every slot in q with every n-gram in D_q constitutes a system with nearly perfect recall. We apply a series of increasingly restrictive filters over this set. As in Figure 1, SF systems in practice must retrieve relevant documents and generate candidates. We propose filters that allow for analysis of recall lost during these stages. We ignore the remaining stages and evaluate the set of candidates directly.

Filters define what documents or NEs are allowed to pass through, based on constraints imposed by query matching, entity form, and sentence and syntactic context. We combine these filters in series in a number of configurations. The use or absence of coreference varies across our configurations, as the need to identify the query mention and terms that refer to the query mention is critical. Finally, we experiment with a boot-

strapping training process, to reflect constraints implicitly applied by a training approach.

The SF typical system pipeline presented in Section 3 applies to most, but not all SF approaches. The following filters directly apply only to systems that use NER as the method of candidate generation, and where candidate generation is distinct from answer extraction. Fourteen of the eighteen teams participating in TAC13 submitted system reports (Surdeanu, 2013). Eleven of these systems identify NEs with NER and pass these to an answer extraction process. The remaining three systems either do not document whether they rely on or do not rely on NER for candidate generation for `name` slots. We include a high recall baseline based on noun phrases (NPs) to cover these systems.

4.1 Filters

The first step in the SF pipeline is to find a relevant document and the query entity mentioned within that document. We use oracle IR to find documents D_q (ORACLE DOCS in Figure 1) but need to find a reference to q in these documents for other filters and downstream stages (ALIAS MATCH in Figure 1). An exact match to the query name is trivial, but some documents may not contain the query verbatim. This primarily occurs in cases where an alias is used, e.g. where the query Fyffes PLC is only mentioned as Fyffes in a document.

SF systems typically implement a query expansion step prior to searching for relevant documents, generating and extracting aliases based on the corpus and external sources (Ji et al., 2011). For documents that do not mention the query verbatim, we manually annotate the longest token span which refers to the query. All of our filters are applied to this base setup. To measure the effect of our manual aliases on recall, we implement a naïve EXACT MATCH filter, which allows a document only if a NE matches the query verbatim.

Entity form filters are based on the form of the entities extracted from documents. We initially consider all substrings of all NPs for a high-recall, yet tractable, baseline. The NP N-GRAMS filter allows every n-gram of every NP. NES allows NEs only; and for TYPES, fill NEs must be of a NER type defined by the slot, e.g. for `per:city of birth` only LOC NEs are allowed.

Sentence filters require the query mention and fill to be in the same sentence, or to have mentions in the same sentence. Sentence filters are COREF: the query and the fill must be mentioned in the same sentence; COREF NNP: as for COREF, but the query and the fill must have coreferent proper noun mentions in the same sentence; NAÏVE NNP: as for COREF NNP, but instead of using a full coreference system and identifying proper noun mentions, we use a naïve proper noun coreference process; and NOCOREF: the verbatim query and the fill must be named in the same sentence.

As dependency paths are often a key feature for extracting relations, we apply further syntactic filters based on dependency paths between NEs and mentions in sentences. Where we use dependencies, we use the Stanford collapsed and propagated representation (de Marneffe and Manning, 2008), e.g. in Alice is an employee of Bob and Charlie the collapsed and propagated dependency path between Alice and Charlie is $\rightarrow$`nsubj`$\rightarrow$employee$\leftarrow$`prep_of`$\leftarrow$.

Syntactic filters roughly capture the complexity of the syntactic configuration between query and filler: LENGTH $\leq$ N requires that the query and fill are separated by a dependency path of at most N arcs, e.g. the above dependency path is two arcs; VERB requires a verb to be present in the dependency path between the query and fill mentions or names; and NON-UNIQUE requires the dependency path between the query and fill to occur more than once in a corpus, modelling a hard constraint on bootstrapping and other learning processes that require a shared dependency context between training and test examples.

4.2 Bootstrapping reachability

In addition to the upper bound set by these explicit hard constraints, we want to reflect constraints that are implicitly applied by an extraction process—are there fills that are never learnable given a set of features and a set of training data? We extend our evaluation to include a training process in a semi-supervised setting. We treat this as a bootstrapping task (Agichtein and Gravano, 2000): given training pairs of NEs in text (each pair effectively a query entity and a candidate slot fill, or vice-versa), extract the context of each pair, and find other pairs in the corpus that share that context. A pair is reachable, and hence learnable, if it can be found by iterating this process. We continue to evaluate maximum recall and do not apply thresholding or ranking that would typically be utilised in a bootstrapping process. We simply output all

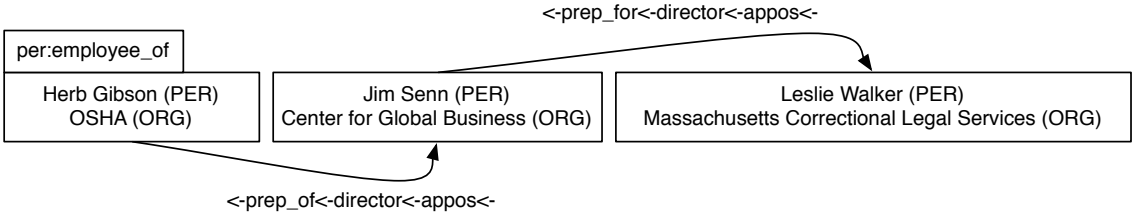

Figure 2: Bootstrapping. The rightmost vertex is labelled with `per:employee of` after two iterations.

possible candidates in order to measure recall loss: as with hard constraints applied by filters, if recall is lost it can never be recovered.

Given a set of training data, we identify if we can reach a test instance by bootstrapping, no matter how remotely it is connected to training instances. We use lemmatised dependency paths as the context for this process as they are relatively precise and discriminative, compared to other features used for SF. In order to simplify processing, we construct a graph of all pairs and paths in the corpus first, and then bootstrap from training instances over this graph. Bootstrapping more general features (e.g. bag-of-words) results in the graph becoming too large to process on our computing resources.

The graph is constructed as follows. Each vertex represents a typed pair of NEs that occur in the same sentence in the TAC KBP Source Data (LDC, 2010), collapsing vertices that have equal names and types into a single vertex. An edge exists between pairs that are connected at least once by the same dependency path. The constructed graph is equivalent to the EXACT MATCH + NOCOREF + NON-UNIQUE filter. Constructing a graph for COREF (which requires many more edges than NOCOREF) was impractical.

Initially, pairs in training data are labelled with their corresponding slots (see Figure 2). In each bootstrap iteration, the labels of each vertex are added to its neighbouring vertices. There is no filtering or competition between labels on a vertex, they are all added. We analyse performance after each iteration, evaluating by mapping the labelled graph back to the equivalent SF queries. This enables us to determine what fills are recoverable from the bootstrapping process.

5 Evaluation

We evaluate our filters on the TAC KBP English Slot Filling 2011 corpus, queries and task specification. As we aim to determine recall upper bounds and recall loss, we use only the documents D from the TAC KBP Source Data (LDC, 2010) that are known to contain at least one correct slot fill in the TAC KBP 2011 English Slot Filling Assessment Results (LDC, 2011).

We restrict the assessment results and the evaluation process to all slot types that are filled by `name` content types as opposed to `value` or `string`. We also do not evaluate the `per:alternate names` or `org:alternate names` slots, as extraction of fills for these slots typically falls outside the RE task: while X also known as Y or similar may appear in text, X and Y are typically mentioned independently across documents.

There are 100 TAC11 queries, 50 PER and 50 ORG. There are 535 fills in our reduced evaluation, 1,171 correct responses over these fills: 56% of the original evaluation slots. The distribution of fills per slot is listed in Table 1. The number of fills per query ranges from 0 (one query has no `name` fills) to 71, with a median of 17. D is comprised of 1,351 documents. The number of documents per query ranges from 0 to 63, with a median of 15.5. We use TAC 2009 and 2010 results and annotations as training data for bootstrapping, with 4,647 relevant training examples.

We evaluate ignoring case and without requiring a specific source document: `nocase` and `anydoc` in SF evaluation. Note that each slot fill is an equivalence class of responses: e.g. for `org:founded by` the correct fills Clifford S. Asness and Clifford Asness are equivalent. Consistent with SF evaluation, we identify at what constraint an entire equivalence class no longer has any member proposed as a fill.

We process documents with Stanford CoreNLP: tokenisation, POS tagging (Toutanova et al., 2003), NER (Finkel et al., 2005), parsing (Klein and Manning, 2003), and coreference resolution (Lee et al., 2011), and these annotations form the relevant components of our filters. Where we use dependency paths, we lemmatise tokens on the

slot	#	slot	#	slot	#
org:top members,employees	118	per:cities of residence	17	per:other family	6
per:employee of	71	per:children	17	per:city of birth	6
per:member of	47	org:stateorprovince of headquarters	17	per:parents	3
org:subsidiaries	32	per:schools attended	16	per:country of birth	3
org:parents	24	per:stateorprovinces of residence	11	org:political,religious affiliation	2
per:origin	23	org:member of	11	per:stateorprovince of birth	1

org:city of headquarters	19	org:founded by	7		
org:shareholders	18	per:siblings	6		

Table 1: Number of fills for slots in the evaluation.

path to increase generality and recall in further analysis. For example, for Alice employs Bob we extract the path ←nsubj←employ→dobj→.

The COREF NNP filter uses CoreNLP coreference, limited to mentions which are headed by NNPs. For NAÏVE NNP we use a naïve rule-based coreference process (Pink et al., 2013), motivated by efficiency reasons, as the full CoreNLP requires parsing and a more complex model. The rules do not require deep processing and can run quickly over large volumes of text. All NEs from a document are matched by processing in decreasing length order. Two names are marked coreferent where, ignoring titles and case: they match exactly; they have a matching final word; they have a matching initial word; or one is an acronym of the other. If multiple conditions are matched, the earliest (the most strict match) is used.

The NON-UNIQUE filter requires that a dependency path occurs more than once between NEs in the full TAC KBP Source Data (LDC, 2010), comprised of 1.8M documents and 318M NE pairs. There are 38.6M distinct lemmatised dependency paths, 5M of which occur more than once.

6 Results

We now analyse where the filters lose recall. Results for non-syntactic filters are listed in Table 2. Figure 3 illustrates our main pipeline which contains filters that would typically be implemented.

NP n-grams We choose all n-grams of NPs (from the CoreNLP constituency parser) to be our highest recall filter, and so our highest baseline has 3% recall loss. We identify the reasons for loss at this filter. There are four errors due to the fill not existing verbatim in text, e.g. Pinellas and Pasco counties does not contain Pinellas County verbatim. Four errors occur where an NP is not correctly identified, which occurs in two different cases: where there is genuine error or where the sentence being parsed is actually a list or other semi-structured data as opposed to an actual sentence. four errors are where a correct answer has not been annotated as correct, we refer to this as ANNOTATION error below, and one case where an incorrect response has been annotated as correct.

While 97% recall is an excellent starting point, 53M candidates is a huge, likely intractable search space for any downstream process. Hence NER is commonly used as the starting point for SF.

NEs Most errors here are due to NER errors, and these errors result in nearly a 10% recall loss. 25 errors are caused where no token in the fill has been tagged as part of a NE (NO NER); and 13 where some tokens were missed (NER BOUNDS). There are two additional cases of ANNOTATION due to determiners not being included in an NE, where they perhaps should have also been annotated. Hence, in agreement with previous analyses, NER error has a large impact on SF.

On this data set we have 10% recall loss that most SF or RE approaches would never be able to extract. However, it is still fairly unconstrained and a high recall bound in comparison to the following filters. Recall errors could be substantially reduced if SF approaches were to take into consideration all NEs in documents as a set of candidates, and take a more document-based approach to RE as opposed to sentence-based. While there has been some work in extracting relations across sentences without coreference (Swampillai and Stevenson, 2011), RE across sentence boundaries is effectively limited to coreference chains between sentences. Currently whole document extraction is not a research focus for SF, and the implementation of whole document techniques throughout SF pipelines would likely be beneficial.

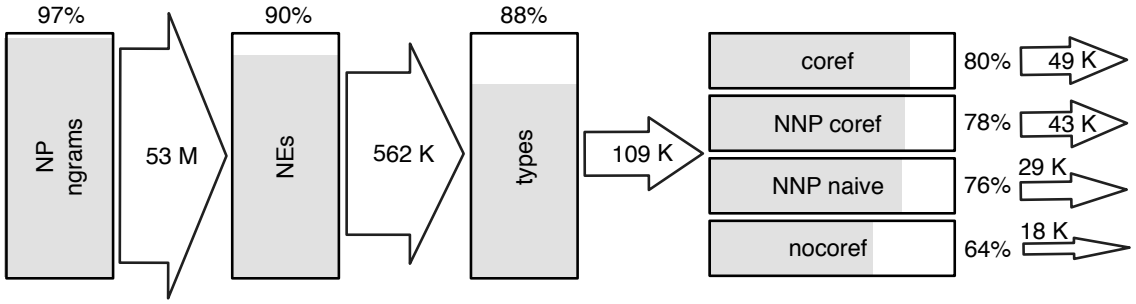

Figure 3: Results for NP N-GRAMS + NES + TYPES, followed by sentence filters with a range of coreference configurations. Grey fill and % indicates recall after each filter, and the number in the arrow is the size of the result set passed to the next filter or to the downstream process.

(2) + NNP COREF + NON-UNIQUE	60	16712
(2) + NNP NAÏVE + NON-UNIQUE	56	13064
(2) + NOCOREF + NON-UNIQUE	43	7236

Table 2: Results on D given sets of filters configurations. The ellipses indicate the previous line.

Exact match Requiring that the query name is exactly matched (EXACT MATCH) loses a further 2% recall. Effectively this is the recall error created by the IR component of SF. Five error cases occur when an alias is required, e.g. Quds Force for IRGC-QF; Chris Bentley for Christopher Bentley. Eight errors occur where the query term is a reference to an entity but not its name, all pertaining to the query GMAC's Residential Capital LLC.

Types All errors created by the TYPES filter are due to incorrect NER types on mentions proposed by CoreNLP. We do not aggregate the NE type over the coreference chain. Applying this filter cuts down the search space substantially, with minimal loss to recall. Adding TYPES results in a recall loss of 2%, but cuts down the search space by 80%.

Coref This filter is the starting point for many recent SF approaches: we consider entities that are either named or mentioned in the same sentence. Table 3 shows that coreference is the largest category of recall error created by the COREF filter. NN COREF, NNP COREF and PRP COREF indicate failure to resolve common noun, proper noun and pronoun coreference.

The remainder of the errors are cases where mentions of the fills do not occur in the same sentence. ROLE INF indicates that an individual's role is mentioned, e.g. Gene Roberts, the executive editor, where The Inquirer is mentioned in a previous sentence. LOC INF where additional location knowledge is required: a French company is headquartered in France. The search space has been substantially reduced, by a further 55% to 0.1% of the original space. However, the recall upper bound has dropped to 80% of all fills.

Coref NNP and naive NNP While coreference is important for high recall, more difficult coreference cases (common noun and pronoun coreference) may generate a large number of spurious cases. Using COREF NNP as the sentence filter loses 2% recall, to an upper bound of 78%, for a 12% reduction in the search space. However, using a full coreference system generates may more candidates than using simple NNP coreference. NAÏVE NNP has an upper bound of 76%. This is only 4% lower recall than COREF, but for a 41% reduction in search space. In addition, CoreNLP coreference is much more expensive than our naïve approach as it requires parsing.

No coref Errors for NOCOREF are listed in Table 3. INF indicates that inference or more sophisticated analysis is required to find the fill, such as correctly identifying the relation between entities

Experiment	NN COREF	NNP COREF	PRP COREF	ROLE INF	LOC INF	INF	NO NER	ANNOTATION
COREF	9	6	13	4	3	0	8	1
NOCOREF	16	52	20	4	3	2	14	3

Table 3: Error types for COREF and NOCOREF.

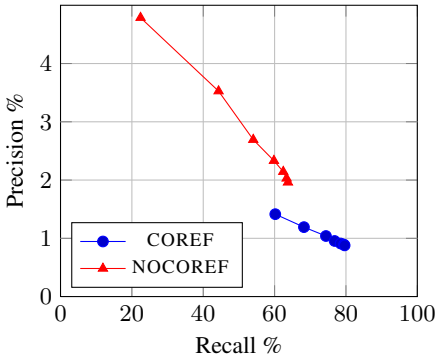

Figure 4: Effect of COREF.

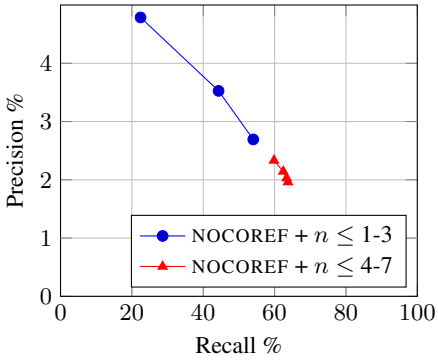

Figure 5: Effect of short dependency paths, taking the NOCOREF points from Figure 4.

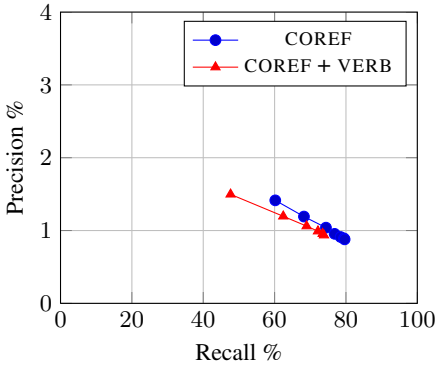

Figure 6: Effect of the VERB filter.

referred to in an interview. NOCOREF results in a recall upper bound of 64%. While this gives us a small search space, we are now losing a substantial proportion of the correct fills.

Precision-recall curves for the dependency path filters are given in Figures 4, 5 and 6. We choose to report precision for simplicity, and note that the downstream search space is the inverse of precision multiplied by the number of correct fills. Dots from low recall to high recall indicate maximum dependency path length from $n = 1$ to $n = 7$. Dependency paths of length 7 give maximum recall in our experiments. Results for the addition of the NON-UNIQUE constraint are given in Table 2.

Use of coreference While critical for recall, use of coreference generates a large number of candidates and presents a key trade-off for SF, as indicated by Figure 4. At maximum dependency path length, coreference gives 16% greater recall at a cost of 1.1% precision, roughly half the precision of no coreference.

Higher precision indicates that fewer candidates are generated. Fewer candidates allows for SF approaches to be scaled to larger amounts of data, and enables techniques that take advantage of redundancy or clustering to be used. Hence the higher precision no coreference approach may allow for more precise learning methods to be used, which may provide better results overall than an approach using coreference.

Short dependency paths In all of our filter configurations, a short dependency path length is sufficient for extracting the majority of slot fills for that particular configuration. Improving precision of fills found on short dependency paths may be a more effective and scalable approach to improving F-score rather than focusing on long paths.

In Figure 5 we consider NOCOREF. Limiting the dependency path length to three loses 11% recall, but gains 0.7% precision. While this loss of recall is high, the reduction in unique dependency paths is substantial. For maximum path length three there are 10,732 paths (1,551 unique); for all paths there are 17,394 paths (2,863 unique).

Verb Figure 6 shows the VERB filters has less impact or recall or precision than some other dependency filters. For COREF with all paths, adding the VERB filter loses 6% recall for a 0.1% gain in precision. Some slots not included in this analysis, such as `per:title`, tend to be described

by shorter paths that often do not include verbs. These slots are also frequent in the TAC11 dataset.

Non-unique The frequency of a dependency path may be a critical feature for learning, as paths that occur only once will not been seen by a bootstrapping process or may not be considered by other machine learning approaches. Applying the NON-UNIQUE filter (Table 2) has a large effect on recall: COREF loses 15% recall for a 41% reduction in the size of the search space; NOCOREF loses 15% recall for a 44% reduction in search space. To recover this recall, the strictness of this filter could be relaxed by further generalising dependency paths or using a different similarity metric to direct match of paths. However, this is the upper bound for approaches which consider only exact dependency paths as a feature.

Bootstrapping A small amount of training data quickly finds slot fills via bootstrapping. One iteration has a recall of 24%, with 7,665 candidates generated. Two to four iterations have recall of 37%–39% (maximum recall), with 31,702–37,797 candidates. The recall upper bound for these configurations is 43%—more training data will allow for better precision, but will only minimally improve recall in this setup. We note that limiting bootstrap to one or two iterations is ideal for the best trade-off between recall and search space. However, closer analysis of discriminative paths is required for a full SF system.

Note that even when bootstrapping through every dependency path in the corpus, there is an upper bound on recall of 39%. Even if we used the test data as additional training data the recall would still be limited to 43%. This demonstrates that systems need distributional features, dependency tree kernels or other similarity comparison as opposed to exact feature matching if dependency paths are to be a useful feature for SF.

7 Discussion

We present an analysis of SF recall bounds given hard constraints applied by standard system components. Pipeline error is common across all NLP tasks. Our analysis suggests that high-precision naïve tools, e.g. naïve coreference, can lead to state-of-the-art performance.

However, the SF task is not strictly an exhaustive evaluation for each query, as the evaluation data is comprised of the time-limited human annotation plus aggregated system output only. There may be fills that are missed in the evaluation results but are correct and returned by our high recall filters—affecting our reported precisions.

We manually evaluate a small sample of the queries, the first five person and the first five organization queries, to identify missed fills in the COREF output (2,903 of 49,170 total fills, or 5.9%). For these fills, there were 29 fills in the assessment data. Of these fills, 21 are returned by COREF, however there are two correct fills found by COREF that are not in the assessment data. One of these two errors would be identified with correct coreference, and the other requires complex long range inference. These additional correct fills that are identified will not have a large impact on the absolute precision, as there are two of 2,903 more fills. However, the relative difference in true positives, 21 to 23, results in some uncertainty in results when comparing them relatively.

8 Conclusion

Recent TAC KBP Slot Filling results have shown that state-of-the-art systems are substantially limited by low recall. In this work, we perform a maximum recall analysis of slot filling, providing a comprehensive analysis of recall error created in the document retrieval and candidate generation stages. We focus on recall error in candidate generation as a performance limitation, as candidates that are lost in the pipeline cannot be recovered by downstream processes.

We find ∼10% of recall is ignored by most slot filling systems due to NER error, and while state-of-the-art coreference provides a substantial recall gain over no coreference, 8% of recall is still lost when queries and fills occur in different sentences. Using NE type constraints is very effective, reducing recall by only 2% for a search space reduction of 81%. Without coreference, a further 16% of fills are lost, but 12% of this recall can be regained using efficient naïve name matching rules, while still reducing the search space by 41%, making such an approach possibly preferable over full coreference. We confirm that coreference and accurate NER are critical to high recall slot filling.

We find that using maximum recall bootstrapping, 39% of test slots fills are reachable from the TAC09 and TAC10 training data, limited by an upper bound on non-unique paths of 43%.

In the future, we intend to assess how specific

slots are affected by recall and search space trade-off, and perform evaluation over all slot types: names, values and strings. In addition, we intend to expand the bootstrapping experiments with variations over the training data.

This work highlights NER, coreference and typing as the areas that have the most impact on slot filling recall, enabling researchers to focus on problems that will most improve performance.

Abstract

Several state-of-the-art event extraction systems employ models based on Support Vector Machines (SVMs) in a pipeline architecture, which fails to exploit the joint dependencies that typically exist among events and arguments. While there have been attempts to overcome this limitation using Markov Logic Networks (MLNs), it remains challenging to perform joint inference in MLNs when the model encodes many high-dimensional sophisticated features such as those essential for event extraction. In this paper, we propose a new model for event extraction that combines the power of MLNs and SVMs, dwarfing their limitations. The key idea is to reliably learn and process high-dimensional features using SVMs; encode the output of SVMs as low-dimensional, soft formulas in MLNs; and use the superior joint inferencing power of MLNs to enforce joint consistency constraints over the soft formulas. We evaluate our approach for the task of extracting biomedical events on the BioNLP 2013, 2011 and 2009 Genia shared task datasets. Our approach yields the best F1 score to date on the BioNLP'13 (53.61) and BioNLP'11 (58.07) datasets and the second-best F1 score to date on the BioNLP'09 dataset (58.16).

1 Introduction

Event extraction is the task of extracting and labeling all instances in a text document that correspond to a pre-defined event type. This task is quite challenging for a multitude of reasons: events are often nested, recursive and have several arguments; there is no clear distinction between arguments and events; etc. For instance, consider the BioNLP Genia event extraction shared task (Nédellec et al., 2013). In this task, participants are asked to extract instances of a pre-defined set of biomedical events from text. An event is identified by a keyword called the *trigger* and can have an arbitrary number of arguments that correspond to pre-defined argument types. The task is complicated by the fact that an event may serve as an argument of another event (nested events). An example of the task is shown in Figure 1. As we can see, event $E13$ takes as arguments two events, $E14$ and $E12$, which in turn has $E11$ as one of its arguments.

A standard method that has been frequently employed to perform this shared task uses a *pipeline* architecture with three steps: (1) detect if a token is a trigger and assign a trigger type label to it; (2) for every detected trigger, determine all its arguments and assign types to each detected argument; and (3) combine the extracted triggers and arguments to obtain events. Though adopted by the top-performing systems such as the highest scoring system on the BioNLP'13 Genia shared task (Kim et al., 2013), this approach is problematic for at least two reasons. First, as is typical in pipeline architectures, errors may propagate from one stage to the next. Second, since each event/argument is identified and assigned a type independently of the others, it fails to capture the relationship between a trigger and its neighboring triggers, an argument and its neighboring arguments, etc.

More recently, researchers have investigated joint inference techniques for event extraction using Markov Logic Networks (MLNs) (e.g., Poon and Domingos (2007), Poon and Vanderwende (2010), Riedel and McCallum (2011a)), a statistical relational model that enables us to model the dependencies between different instances of a data sample. However, it is extremely challenging to make joint inference using MLNs work well in practice (Poon and Domingos, 2007). One reason is that it is generally difficult to model sophisticated linguistic features using MLNs. The diffi-

. . . demonstrated that HOIL-1L interacting protein (HOIP), a ubiquitin ligase that can catalyze the assembly of linear polyubiquitin chains, is recruited to DC40 in a TRAF2-dependent manner following engagement of CD40 . . .

(a) Sentence fragment

ID	Event Type	Trigger	Arguments
$E11$	*Binding*	recruited	*Theme*={HOIL-1L interacting protein,CD40}
$E12$	*Regulation*	dependent	*Theme*=$E11$, *Cause*=TRAF2
$E13$	*+ve Regulation*	following	*Theme*=$E12$, *Cause*=$E14$
$E14$	*Binding*	engagement	*Theme*=CD40

(b) Events

Figure 1: Example of event extraction in the BioNLP Genia task. The table in (b) shows all the events extracted from sentence (a). Note that successful extraction of $E13$ depends on $E12$ and $E14$.

culty stems from the fact that some of these features are extremely high dimensional (e.g., Chen and Ng (2012), Huang and Riloff (2012b), Li et al. (2012), Li et al. (2013b), Li et al. (2013c)), and to reliably learn weights of formulas that encode such features, one would require an enormous number of data samples. Moreover, even the complexity of approximate inference on such models is quite high, often prohibitively so. For example, a trigram can be encoded as an MLN formula, $\texttt{Word}(w_1, p-1) \wedge \texttt{Word}(w_2, p) \wedge \texttt{Word}(w_3, p+1) \Rightarrow \texttt{Type}(p, T)$. For any given position (p), this formula has W^3 groundings, where W is the number of possible words, making it too large for learning/inference. Therefore, current MLN-based systems tend to include a highly simplified model ignoring powerful linguistic features. This is problematic because such features are essential for event extraction.

Our contributions in this paper are two-fold. First, we propose a novel model for biomedical event extraction based on MLNs that addresses the aforementioned limitations by leveraging the power of Support Vector Machines (SVMs) (Vapnik, 1995; Joachims, 1999) to handle high-dimensional features. Specifically, we (1) learn SVM models using rich linguistic features for trigger and argument detection and type labeling; (2) design an MLN composed of *soft formulas* (each of which encodes a soft constraint whose associated weight indicates how important it is to satisfy the constraint) and *hard formulas* (constraints that always need to be satisfied, thus having a weight of ∞) to capture the relational dependencies between triggers and arguments; and (3) encode the SVM output as *prior knowledge* in the MLN in the form of soft formulas, whose weights are computed using the confidence values generated by the SVMs. This formulation naturally allows SVMs and MLNs to complement each other's strengths and weaknesses: learning in a large and sparse feature space is much easier with SVMs than with MLNs, whereas modeling relational dependencies is much easier with MLNs than with SVMs.

Our second contribution concerns making inference with this MLN feasible. Recall that inference involves detecting and assigning the type label to all the triggers and arguments. We show that existing Maximum-a-posteriori (MAP) inference methods, even the most advanced approximate ones (e.g., Selman et al. (1996), Marinescu and Dechter (2009), Sontag and Globerson (2011)), are infeasible on our proposed MLN because of their high memory cost. Consequently, we identify decompositions of the MLN into disconnected components and solve each independently, thereby drastically reducing the memory requirements.

We evaluate our approach on the BioNLP 2009, 2011 and 2013 Genia shared task datasets. On the BioNLP'13 dataset, our model significantly outperforms state-of-the-art pipeline approaches and achieves the best F1 score to date. On the BioNLP'11 and BioNLP'09 datasets, our scores are slightly better and slightly worse respectively than the best reported results. However, they are significantly better than state-of-the-art MLN-based systems.

2 Background

2.1 Related Work

As a core task in information extraction, event extraction has received significant attention in the natural language processing (NLP) community. The development and evaluation of large-scale learning-based event extraction systems was propelled in part by the availability of annotated corpora produced as part of the Message Understanding Conferences (MUCs), the Automatic Content Extraction (ACE) evaluations, and the BioNLP shared

tasks on event extraction. Previous work on event extraction can be broadly divided into two categories, one focusing on the development of features (henceforth *feature-based* approaches) and the other focusing on the development of models (henceforth *model-based* approaches).

Feature-based approaches. Early work on feature-based approaches has primarily focused on designing local sentence-level features such as token and syntactic features (Grishman et al., 2005; Ahn, 2006). Later, it was realized that local features were insufficient to reliably and accurately perform event extraction in complex domains and therefore several researchers proposed using *high-level features*. For instance, Ji and Grishman (2008) used global information from related documents; Gupta and Ji (2009) extracted implicit time information; Patwardhan and Riloff (2009) used broader sentential context; Liao and Grishman (2010; 2011) leveraged document-level cross-event information and topic-based features; and Huang and Riloff (2012b) explored discourse properties.

Model-based approaches. The model-based approaches developed to date have focused on modeling global properties and seldom use rich, high-dimensional features. To capture global event structure properties, McClosky et al. (2011a) proposed a dependency parsing model. To extract event arguments, Li et al. (2013b) proposed an Integer Linear Programming (ILP) model to encode the relationship between event mentions. To overcome the error propagation problem associated with the pipeline architecture, several joint models have been proposed, including those that are based on MLNs (e.g., Poon and Domingos (2007), Riedel et al. (2009), Poon and Vanderwende (2010)), structured perceptrons (e.g., Li et al. (2013c)), and dual decomposition with minimal domain adaptation (e.g., Riedel and McCallum (2011a; 2011b)).

In light of the high annotation cost required by supervised learning-based event extraction systems, several semi-supervised, unsupervised, and rule-based systems have been proposed. For instance, Huang and Riloff (2012a) proposed a bootstrapping method to extract event arguments using only a small amount of annotated data; Lu and Roth (2012) developed a novel unsupervised sequence labeling model; Bui et al. (2013) implemented a rule-based approach to extract biomedical events; and Ritter et al. (2012) used unsupervised learning to extract events from Twitter data.

Our work extends prior work by developing a rich framework that leverages sophisticated feature-based approaches as well as joint inference using MLNs. This combination gives us the best of both worlds because on one hand, it is challenging to model sophisticated linguistic features using MLNs while on the other hand, feature-based approaches employing sophisticated high-dimensional features suffer from error propagation as the model is generally not rich enough for joint inference.

2.2 The Genia Event Extraction Task

The BioNLP Shared Task (BioNLP-ST) series (Kim et al. (2009), Kim et al. (2011a) and Nédellec et al. (2013)) is designed to tackle the problem of extracting structured information from the biomedical literature. The Genia Event Extraction task is arguably the most important of all the tasks proposed in BioNLP-ST and is also the only task organized in all three events in the series.

The 2009 edition of the Genia task (Kim et al., 2009) was conducted on the Genia event corpus (Kim et al., 2008), which only contains abstracts of the articles that represent domain knowledge around NFκB proteins. The 2011 edition (Kim et al., 2011b) augmented the dataset to include full text articles, resulting in two collections, the abstract collection and the full text collection. The 2013 edition (Kim et al., 2013) further augmented the dataset with recent full text articles but removed the abstract collection entirely.

The targeted event types have also changed slightly over the years. Both the 2009 and 2011 editions are concerned with nine fine-grained event sub-types that can be categorized into three main types, namely simple, binding and regulation events. These three main event types can be distinguished by the kinds of arguments they take. A simple event can take exactly one protein as its $Theme$ argument. A binding event can take one or more proteins as its $Theme$ arguments, and is therefore slightly more difficult to extract than a simple event. A regulation event takes exactly one protein or event as its $Theme$ argument and optionally one protein or event as its $Cause$ argument. If a regulation event takes another event as its $Theme$ or $Cause$ argument, it will lead to a nested event. Regulation events are considered the most difficult-to-extract among the three event types owing in part to the presence of an optional $Cause$ argument and their recursive structure. The 2013 edition intro-

duced a new event type, protein-mod, and its three sub-types. Theoretically, a protein-mod event takes exactly one protein as its $Theme$ argument and optionally one protein or event as its $Cause$ argument. In practice, however, it rarely occurs: there are only six protein-mod events having $Cause$ arguments in the training data for the 2013 edition. Consequently, our model makes the simplifying assumption that a protein-mod event can only take one $Theme$ argument, meaning that we are effectively processing protein-mod events in the same way as simple events.

2.3 Markov Logic Networks

Statistical relational learning (SRL) (Getoor and Taskar, 2007) is an emerging field that seeks to unify logic and probability, and since most NLP techniques are grounded either in logic or probability or both, NLP serves as an ideal application domain for SRL. In this paper, we will employ a popular SRL approach called Markov logic networks (MLNs) (Domingos and Lowd, 2009). At a high level, an MLN is a set of weighted first-order logic formulas (f_i, w_i), where w_i is the weight associated with formula f_i. Given a set of constants that model objects in the domain, it defines a Markov network or a log-linear model (Koller and Friedman, 2009) in which we have one node per ground first-order atom and a propositional feature corresponding to each grounding of each first-order formula. The weight of the feature is the weight of the corresponding first-order formula.

Formally, the probability of a world ω, which represents an assignment of values to all ground atoms in the Markov network, is given by:

$$\Pr(\omega) = \frac{1}{Z} \exp\left(\sum_i w_i N(f_i, \omega)\right)$$

where $N(f_i, \omega)$ is the number of groundings of f_i that evaluate to True in ω and Z is a normalization constant called the partition function.

The key inference tasks over MLNs are computing the partition function (Z) and the most-probable explanation given evidence (the MAP task). Most queries, including those required by event extraction, can be reduced to these inference tasks. Formally, the partition function and the MAP tasks are given by:

$$Z = \sum_\omega \exp\left(\sum_i w_i N(f_i, \omega)\right) \quad (1)$$

$$\arg\max_\omega P(\omega) = \arg\max_\omega \sum_i w_i N(f_i, \omega) \quad (2)$$

3 Pipeline Model

We implement a pipeline event extraction system using SVMs. This pipeline model serves two important functions: (1) providing a baseline for evaluation and (2) producing prior knowledge for the joint model.

Our pipeline model consists of two steps: trigger labeling and argument labeling. In the trigger labeling step, we determine whether a candidate trigger is a true trigger and label each true trigger with its trigger type. Then, in the argument labeling step, we identify the arguments for each true trigger discovered in the trigger labeling step and assign a role to each argument.

We recast each of the two steps as a classification task and employ $\mathbf{SVM}^{multiclass}$ (Tsochantaridis et al., 2004) to train the two classifiers. We describe each step in detail below.

3.1 Trigger Labeling

A preliminary study of the BioNLP'13 training data suggests that 98.7% of the true triggers' head words[1] are either verbs, nouns or adjectives. Therefore, we consider only those words whose part-of-speech tags belong to the above three categories as candidate triggers. To train the trigger classifier, we create one training instance for each candidate trigger in the training data. If the candidate trigger is not a trigger, the class label of the corresponding instance is $None$; otherwise, the label is the type of the trigger. Thus, the number of class labels equals the number of trigger types plus one. Each training instance is represented by the features described in Table 1(a). These features closely mirror those used in state-of-the-art trigger labeling systems such as Miwa et al. (2010b) and Björne and Salakoski (2013).

After training, we apply the resulting trigger classifier to classify the test instances, which are created in the same way as the training instances. If a test instance is predicted as $None$ by the classifier, the corresponding candidate trigger is labeled as a non-trigger; otherwise, the corresponding candidate trigger is posited as a true trigger whose type is the class value assigned by the classifier.

[1] Head words are found using Collins' (1999) rules.

(a) Features for trigger labeling

Token features	The basic token features (see Table 1(c)) computed from (1) the candidate trigger word and (2) the surrounding tokens in a window of two; character bigrams and trigrams of the candidate trigger word; word n-grams (n=1,2,3) of the candidate trigger word and its context words in a window of three; whether the candidate trigger word contains a digit; whether the candidate trigger word contains an upper case letter; whether the candidate trigger word contains a symbol.
Dependency features	The basic dependency path features (see Table 1(c)) computed using the shortest paths from the candidate trigger to (1) the nearest protein word, (2) the nearest protein word to its left, and (3) the nearest protein word to its right.
Other features	The distances from the candidate trigger word to (1) the nearest protein word, (2) the nearest protein word to its left, and (3) the nearest protein word to its right; the number of protein words in the sentence.

(b) Features for argument labeling

Token features	Word n-grams (n=1,2,3) of (1) the candidate trigger word and its context in a window of three and (2) the candidate argument word and its context in a window of three; the basic token features (see Table 1(c)) computed from (1) the candidate trigger word and (2) the candidate argument word; the trigger type of the candidate trigger word.
Dependency features	The basic dependency features (see Table 1(c)) computed using the shortest path from the candidate trigger word to the candidate argument word.
Other features	The distance between the candidate trigger word and the candidate argument word; the number of proteins between the candidate trigger word and the candidate argument word; the concatenation of the candidate trigger word and the candidate argument word; the concatenation of the candidate trigger type and the candidate argument word.

(c) Basic token and dependency features

Basic token features	Six features are computed given a token t, including: (a) the lexical string of t, (b) the lemma of t, (c) the stem of t obtained using the Porter stemmer (Porter, 1980), (d) the part-of-speech tag of t, (e) whether t appears as a true trigger in the training data, and (f) whether t is a protein name.
Basic dependency features	Six features are computed given a dependency path p, including: (a) the vertex walk in p, (b) the edge walk in p, (c) the n-grams (n=2,3,4) of the (stemmed) words associated with the vertices in p, (d) the n-grams (n=2,3,4) of the part-of-speech tags of the words associated with the vertices in p, (e) the n-grams (n=2,3,4) of the dependency types associated with the edges in p, and (f) the length of p.

Table 1: Features for trigger labeling and argument labeling.

3.2 Argument Labeling

The argument classifier is trained as follows. Each training instance corresponds to a candidate trigger and one of its candidate arguments.[2] A candidate argument for a candidate trigger ct is either a protein or a candidate trigger that appears in the same sentence as ct. If ct is not a true trigger, the label of the associated instance is set to $None$. On the other hand, if ct is a true trigger, we check whether the candidate argument in the associated instance is indeed one of ct's arguments. If so, the class label of the instance is the argument's role; otherwise, the class label is $None$. The features used for representing each training instance, which are modeled after those used in Miwa et al. (2010b) and Björne and Salakoski (2013), are shown in Table 1(b).

After training, we can apply the resulting classifier to classify the test instances, which are created in the same way as the training instances. If a test instance is assigned the class $None$ by the classifier, the corresponding candidate argument is classified as not an argument of the trigger. Otherwise, the candidate argument is a true argument of the trigger whose role is the class value assigned by the classifier.

[2]Following the definition of the GENIA event extraction task, the protein names are provided as part of the input.

4 Joint Model

In this section, we describe our Markov logic model that encodes the relational dependencies in the shared task and uses the output of the pipeline model as prior knowledge (soft evidence). We begin by describing the structure of our Markov logic model, and then describe the parameter learning and inference algorithms for it.

4.1 MLN Structure

Figure 2 shows our proposed MLN for BioNLP event extraction, which we refer to as `BioMLN`. The MLN contains six predicates.

The *query predicates* in Figure 2(a) are those whose assignments are not given during inference and thus need to be predicted. Predicate `TriggerType`(sid,tid,$ttype$!) is true when the token located in sentence sid at position tid has type $ttype$. Δ_{ttype}, which denotes the set of constants (or objects) that the logical variable $ttype$

TriggerType(sid,tid,$ttype$!) ArgumentRole(sid,aid,tid,$arole$!) (a) Query	Simple(sid,tid) Regulation(sid,tid) (b) Hidden	Word(sid,tid,$word$) DepType(sid,aid,tid,$dtype$) (c) Evidence

1. $\exists t$ TriggerType(i,j,t).
2. $\exists a$ ArgumentRole(i,k,j,a).
3. $\neg$TriggerType(i,j,$None$) $\Rightarrow \exists k$ ArgumentRole(i,k,j,$Theme$).
4. Simple(i,j) $\Rightarrow \neg \exists k$ ArgumentRole(i,k,j,$Cause$).
5. TriggerType(i,j,$None$) $\Leftrightarrow$ ArgumentRole(i,k,j,$None$).
6. $\neg$ArgumentRole(i,k,j,$None$) $\wedge \neg$TriggerType(i,k,$None$) $\Rightarrow$ Regulation(i,j).
7. Simple(i,j) $\Leftrightarrow$ TriggerType(i,j,$Simple1$) $\vee \ldots \vee$ TriggerType(i,j,$Binding$).
8. Regulation(i,j) $\Leftrightarrow$ TriggerType(i,j,Reg) $\vee$ TriggerType(i,j,$PosReg$) $\vee$ TriggerType(i,j,$NegReg$).
9. Word(i,j,+w) $\wedge$ TriggerType(i,j,+t) $\wedge$ DepType(i,k,j,+d) $\wedge$ ArgumentRole(i,k,j,+a)

(d) Joint Formulas

Figure 2: The BioMLN structure.

can be instantiated to, includes all possible trigger types in the dataset plus $None$ (which indicates that the token is not a trigger). The "!" symbol models commonsense knowledge that only one of the types in the domain Δ_{ttype} of $ttype$ is true for every unique combination of sid and tid. Similarly, predicate ArgumentRole(sid,aid,tid,$arole$!) asserts that a token in sentence sid at position aid plays *exactly one* argument role, denoted by $arole$, with respect to the token at position tid. Δ_{arole} includes the two argument types, namely, $Theme$ and $Cause$ plus the additional $None$ that indicates that the token is not an argument.

The hidden predicates in Figure 2(b) are "clusters" of trigger types. Predicate Simple(sid,tid) is true when the token in sentence sid at position tid corresponds to one of the *Simple* event trigger types (BioNLP'13 has 9 simple events, BioNLP'09/'11 have 5) or a binding event trigger type. Similarly, Regulation(sid,tid) asserts that the token in sentence sid at position tid corresponds to any of the three regulation event trigger types.

The *evidence* predicates in Figure 2(c) are those that are always assumed to be known during inference. We define two evidence predicates based on dependency structures. Word(sid,tid,$word$) is true when the word in sentence sid at position tid is equal to $word$. DepType(sid,aid,tid,$dtype$) asserts that $dtype$ is the dependency type in the dependency parse tree that connects the token at position tid to the token at position aid in sentence sid. If the word at tid and the word at aid are directly connected in the dependency tree, then $dtype$ is the label of dependency edge with direction; otherwise $dtype$ is $None$.

The MLN formulas, expressing commonsense, prior knowledge in the domain (Poon and Vanderwende, 2010; Riedel and McCallum, 2011a), are shown in Fig. 2(d). All formulas, except Formula (9), are hard formulas, meaning that they have infinite weights. Note that during weight learning, we only learn the weights of soft formulas.

Formulas (1) and (2) along with the "!" constraint in the predicate definition ensure that the token types are mutually exclusive and exhaustive. Formula (3) asserts that every trigger should have an argument of type $Theme$, since a $Theme$ argument is mandatory for any event. Formula (4) models the constraint that a $Simple$ or $Binding$ trigger has no arguments of type $Cause$ since only regulation events have a $Cause$. Formula (5) asserts that non-triggers have no arguments and vice-versa. Formula (6) models the constraint that if a token is both an argument of t and a trigger by itself, then t must belong to one of the three regulation trigger types. This formula captures the recursive relationship between triggers. Formulas (7) and (8) connect the hidden predicates with the query predicates. Formula (9) is a soft formula encoding

the relationship between triggers and arguments in a dependency parse tree. It joins a word and the dependency type label that connects the word token to the argument token in the dependency parse tree with the trigger types and argument types of the two tokens. The "+" symbol indicates that each grounding of Formula (9) may have a different weight.

4.2 Weight Learning

We can learn BioMLN from data either discriminatively or generatively. Since discriminative learning is much faster than generative learning, we use the former. In discriminative training, we maximize the conditional log-likelihood (CLL) of the query and the hidden variables given an assignment to the evidence variables. In principle, we can use the standard gradient descent algorithm for maximizing the CLL. In each iteration of gradient descent, we update the weights using the following equation (cf. Singla and Domingos (2005) and Domingos and Lowd (2009)):

$$w_j^{t+1} = w_j^t - \alpha(\mathbb{E}_{\mathbf{w}}(n_j) - n_j) \qquad (3)$$

where w_j^t represents the weight of the j^{th} formula in the t^{th} iteration, n_j is the number of groundings in which the j^{th} formula is satisfied in the training data, $\mathbb{E}_{\mathbf{w}}(n_j)$ is the expected number of groundings in which the j^{th} formula is satisfied given the current weight vector $\mathbf{w}$, and α is the learning rate.

As such, the update rule given in Equation (3) is likely to yield poor accuracy because the number of training examples of some types (e.g., $None$) far outnumber other types. To rectify this ill-conditioning problem (Singla and Domingos, 2005; Lowd and Domingos, 2007), we divide the gradient with the number of true groundings in the data, namely, we compute the gradient using $\frac{(\mathbb{E}_{\mathbf{w}}(n_j)-n_j)}{n_j}$.

Another key issue with using Equation (3) is that computing $\mathbb{E}_{\mathbf{w}}(n_j)$ requires performing inference over the MLN. This step is intractable, #P-complete in the worst case. To circumvent this problem and for fast, scalable training, we instead propose to use the voted perceptron algorithm (Collins, 2002; Singla and Domingos, 2005). This algorithm approximates $\mathbb{E}_{\mathbf{w}}(n_j)$ by counting the number of satisfied groundings of each formula in the MAP assignment. Computing the MAP assignment is much easier (although still NP-hard in the worst case) than computing $\mathbb{E}_{\mathbf{w}}(n_j)$, and as a result the voted perceptron algorithm is more scalable than the standard gradient descent algorithm. In addition, it converges much faster.

4.3 Testing

In the testing phase, we combine BioMLN with the output of the pipeline model (see Section 3) to obtain a new MLN, which we refer to as BioMLN$^+$. For every candidate trigger, the SVM trigger classifier outputs a vector of signed confidence values (which is proportional to the distance from the separating hyperplane) of dimension Δ_{ttype} with one entry for each trigger type. Similarly, for every candidate argument, the SVM argument classifier outputs a vector of signed confidence values of dimension Δ_{arole} with one entry for each argument role. In BioMLN$^+$, we model the SVM output as soft evidence, using two soft unit clauses, TriggerType(i,+j,+t) and ArgumentRole(i,+k,+j,+a). We use the confidence values to determine the weights of these clauses. Intuitively, higher (smaller) the confidence, higher (smaller) the weight.

Specifically, the weights of the soft unit clauses are set as follows. If the SVM trigger classifier determines that the trigger in sentence i at position j belongs to type t with confidence $C_{i,j}$, then we attach a weight of $\frac{C_{i,j}}{\alpha n_i}$ to the clause TriggerType(i,j,t). Here, n_i denotes the number of trigger candidates in sentence i. Similarly, if the SVM argument classifier determines that the token at position k in sentence i belongs to the argument role a with respect to the token at position j, with confidence $C'_{i,k,j}$, then we attach a weight of $\frac{C'_{i,k,j}}{\beta \sum_{j=1}^{n_i} m_{ij}}$ to the clause ArgumentRole(i, k, j,a). Here, m_{ij} denotes the number of argument candidates for the j^{th} trigger candidate in sentence i. α and β act as *scale parameters* for the confidence values ensuring that the weights don't get too large (or too small).

4.4 Inference

As we need to perform MAP inference, both at training time and at test time, in this subsection we will describe how to do it efficiently by exploiting unique properties of our proposed BioMLN.

Naively, we can perform MAP inference by grounding BioMLN to a Markov network and then reducing the Markov network by removing from it all (grounded propositional) formulas that are inconsistent with the evidence. On the re-

duced Markov network, we can then compute the MAP solution using standard MAP solvers such as MaxWalkSAT (a state-of-the-art local search based MAP solver) (Selman et al., 1996) and Gurobi[3] (a state-of-the-art, parallelized ILP solver).

The problem with the above approach is that grounding the MLN is infeasible in practice; even the reduced Markov network is just too large. For example, assuming a total of $|\Delta_{sid}|$ sentences and a maximum of N tokens in a sentence, Formula (3) alone has $O(|\Delta_{sid}|N^3)$ groundings. Concretely, at training time, assuming 1000 sentences with 10 tokens per sentence, Formula (3) itself yields one million groundings. Clearly, this approach is not scalable. It turns out, however, that the (ground) Markov network can be decomposed into several disconnected components, each of which can be solved independently. This greatly reduces the memory requirement of the inference step. Specifically, for every grounding of sid, we get a set of nodes in the Markov network that are disconnected from the rest of the Markov network and therefore independent of the rest of the network. Formally,

Proposition 1. *For any world ω of the* `BioMLN`*,*

$$P_{\mathcal{M}}(\omega) = P_{\mathcal{M}_i}(\omega_i)P_{\mathcal{M}\setminus\mathcal{M}_i}(\omega \setminus \omega_i) \quad (4)$$

where ω_i is the world ω projected on the groundings of sentence i and $\mathcal{M}_i$ is `BioMLN` *grounded only using sentence i.*

Using Equation (4), it is easy to see that the MLN $\mathcal{M}$ can be decomposed into $|\Delta_{sid}|$ disjoint MLNs, $\{\mathcal{M}_k\}_{k=1}^{|\Delta_{sid}|}$. The MAP assignment to $\mathcal{M}$ can be computed using, $\bigcup_{i=1}^{|\Delta_{sid}|}\left(\arg\max_{\omega_i} P_{\mathcal{M}_i}(\omega_i)\right)$. This result ensures that to approximate the expected counts $\mathbb{E}_{\mathbf{w}}(n_j)$, it is sufficient to keep exactly *one sentence's groundings in memory*. Specifically, $\mathbb{E}_{\mathbf{w}}(n_j)$ can be written as $\sum_{k=1}^{|\Delta_{sid}|}\mathbb{E}_{\mathbf{w}}(n_j^k)$, where $\mathbb{E}_{\mathbf{w}}(n_j^k)$ indicates the expected number of satisfied groundings of the j^{th} formula in the k^{th} sentence. Since the MAP computation is decomposable, we can estimate $\mathbb{E}_{\mathbf{w}}(n_j^k)$ using MAP inference on just the k^{th} sentence.

5 Evaluation

5.1 Experimental Setup

We evaluate our system on the BioNLP'13 (Kim et al., 2013), '11 (Kim et al., 2011a) and '09 (Kim et al., 2009) Genia datasets for the main event extraction shared task. Note that this task is the most important one for Genia and therefore has the most active participation. Statistics on the datasets are shown in Table 2. All our evaluations use the online tool provided by the shared task organizers. We report scores obtained using the *approximate span, recursive* evaluation.

Dataset	#Papers	#Abstracts	#TT	#Events
BioNLP'13	(10,10,14)	(0,0,0)	13	(2817,3199,3348)
BioNLP'11	(5,5,4)	(800,150,260)	9	(10310,4690,5301)
BioNLP'09	(0,0,0)	(800,150,260)	9	(8597,1809,3182)

Table 2: Statistics on the BioNLP datasets, which consist of annotated papers/abstracts from PubMed. (x, y, z): x in training, y in development and z in test. #TT indicates the total number of trigger types. The total number of argument types is 2.

To generate features, we employ the supporting resources provided by the organizers. Specifically, sentence split and tokenization are done using the GENIA tools, while part-of-speech information is provided by the BLLIP parser that uses the self-trained biomedical model (McClosky, 2010). Also, we create dependency features from the parse trees provided by two dependency parsers, the Enju parser (Miyao and Tsujii, 2008) and the aforementioned BLLIP parser that uses the self-trained biomedical model, which results in two sets of dependency features.

For MAP inference, we use Gurobi, a parallelized ILP solver. After inference, a post-processing step is required to generate biomedical events from the extracted triggers and arguments. Specifically, for binding events, we employ a learning-based method similar to Björne and Salakoski (2011), while for the other events, we employ a rule-based approach similar to Björne et al. (2009). Both the SVM baseline system and the combined MLN+SVM system employ the same post-processing strategy.

During weight learning, in order to combat the problem of different initializations yielding radically different parameter estimates, we start at several different initialization points and average the weights obtained after 100 iterations of gradient descent. However, we noticed that if we simply choose random initialization points, the variance of the weights was quite high and some initialization points were much worse than others. To counter this, we use the following method to systematically

[3] http://www.gurobi.com/

System	Rec.	Prec.	F1
Our System	48.95	59.24	**53.61**
EVEX (Hakala et al., 2013)	45.44	58.03	50.97
TEES-2.1 (Björne and Salakoski, 2013)	46.17	56.32	50.74
BIOSEM (Bui et al., 2013)	42.47	62.83	50.68

Table 3: Recall (Rec.), Precision (Prec.) and F1 score on the BioNLP'13 test data.

initialize the weights. Let n_i be the number of satisfied groundings of formula f_i in the training data and m_i be the total number of possible groundings of f_i. We use a threshold γ to determine whether we wish to make the initial weight positive or negative. If $\frac{n_i}{m_i} \leq \gamma$, then we choose the initial weight uniformly at random from the range $[-0.1, 0]$. Otherwise, we chose it from the range $[0, 0.1]$. These steps ensure that the weights generated from different initialization points have smaller variance. Also, in the testing phase, we set the scale parameters for the soft evidence as $\alpha = \beta = \max_{c \in \mathbf{C}} |c|$, where $\mathbf{C}$ is the set of SVM confidence values.

5.2 Results on the BioNLP'13 Dataset

Among the three datasets, the BioNLP'13 dataset is most "realistic" one because it is the only one that contains full papers and no abstracts. As a result, it is also the most challenging dataset among the three. Table 3 shows the results of our system along with the results of other top systems published in the official evaluation of BioNLP'13. Our system achieves the best F1-score (an improvement of 2.64 points over the top-performing system) and has a much higher recall (mainly because our system detects more regulation events which outnumber other event types in the dataset) and a slightly higher precision than the winning system. Of the top five teams, NCBI is the only other joint inference system, which adopts joint pattern matching to predict triggers and arguments at the same time. These results illustrate the challenge in using joint inference effectively. NCBI performed much worse than the SVM-based pipeline systems, EVEX and TEES2.1. It was also worse than BIOSEM, a rule-based system that uses considerable domain expertise. Nevertheless, it was better than DLUTNLP, another SVM-based system.

Figure 3 compares our baseline pipeline model with our combined model. We can clearly see that the combined model has a significantly better F1 score than the pipeline model on most event types.

System	Rec.	Prec.	F1
Our System	53.42	63.61	**58.07**
Miwa12 (Miwa et al., 2012)	53.35	63.48	57.98
Riedel11 (Riedel et al., 2011)	–	–	56
UTurku (Björne and Salakoski, 2011)	49.56	57.65	53.30
MSR-NLP (Quirk et al., 2011)	48.64	54.71	51.50

Table 4: Results on the BioNLP'11 test data.

The regulation events are considered the most complex events to detect because they have a recursive structure. At the same time, this structure yields a large number of joint dependencies. The advantage of using a rich model such as MLNs can be clearly seen in this case; the combined model yields a 10 point and 6 point increase in F1-score on the test data and development data respectively compared to the pipeline model.

5.3 Results on the BioNLP'11 Dataset

Table 4 shows the results on the BioNLP'11 dataset. We can see that our system is marginally better than Miwa12, which is a pipeline-based system. It is also more than two points better than Riedel11, a state-of-the-art structured prediction-based joint inference system. Reidel11 incorporates the Stanford predictions (McClosky et al., 2011b) as features in the model. On the two hardest, most complex tasks, detecting regulation events (which have recursive structures and more joint dependencies than other event types) and detecting binding events (which may have multiple arguments), our system performs better than both Miwa12 and Riedel11.[4] Specifically, our system's F1 score for regulation events is 46.84, while those of Miwa12 and Riedel11 are 45.46 and 44.94 respectively. Our system's F1 score for the binding event is 58.79, while those of Miwa12 and Riedel11 are 56.64 and 48.49 respectively. These results clearly demonstrate the effectiveness of enforcing joint dependencies along with high-dimensional features.

5.4 Results on the BioNLP'09 Dataset

Table 5 shows the results on the BioNLP'09 dataset. Our system has a marginally lower score (by 0.11 points) than Miwa12, which is the best performing system on this dataset. Specifically, our system achieves a higher recall but a lower precision than Miwa12. However, note that Miwa12 used co-reference features while we are able to achieve

[4]Detailed results are not shown for any of these three datasets due to space limitations.

Table 5: Results on the BioNLP'09 test data. "–" indicates that the corresponding values are not known.

similar accuracy without the use of co-reference data. The F1 score of Miwa10, which does not use co-reference features, is nearly 2 points lower than that of our system. Our system also has a higher F1 score than Reidel11, which is the best joint inference-based system for this task.

On the regulation events, our system (47.55) outperforms both Miwa12 (45.99) and Riedel11 (46.9), while on the binding event, our system (59.88) is marginally worse than Miwa12 (59.91) and significantly better than Riedel11 (52.6). As mentioned earlier, these are the hardest events to extract. Also, existing MLN-based joint inference systems such as RiedelMLN and PoonMLN do not achieve state-of-the-art results because they do not leverage complex, high-dimensional features.

6 Summary and Future Work

Markov logic networks (MLNs) are a powerful representation that can compactly encode rich relational structures and ambiguities (uncertainty). As a result, they are an ideal representation for complex NLP tasks that require joint inference, such as event extraction. Unfortunately, the superior representational power greatly complicates inference and learning over MLN models. Even the most advanced methods for inference and learning in MLNs (Gogate and Domingos, 2011) are unable to handle complex, high-dimensional features, and therefore existing MLN systems primarily use low-dimensional features. This limitation severely affects the accuracy of MLN-based NLP systems, and as a result, in some cases their performance is inferior to pipeline methods that do not employ joint inference.

In this paper, we presented a general approach for exploiting the power of high-dimensional linguistic features in MLNs. Our approach involves reliably processing and learning high-dimensional features using SVMs and encoding their output as low-dimensional features in MLNs. We showed that we could achieve scalable learning and inference in our proposed MLN model by exploiting decomposition. Our results on the BioNLP shared tasks from '13, '11, and '09 clearly show that our proposed combination is extremely effective, achieving the best or second best score on all three datasets.

In future work, we plan to (1) improve our joint model by incorporating co-reference information and developing model ensembles; (2) transfer the results of this investigation to other complex NLP tasks that can potentially benefit from joint inference; and (3) develop scalable inference and learning algorithms (Ahmadi et al., 2013).

Syllable weight encodes mostly the same information for English word segmentation as dictionary stress

John K Pate **Mark Johnson**

{john.pate,mark.johnson}@mq.edu.au

Abstract

Stress is a useful cue for English word segmentation. A wide range of computational models have found that stress cues enable a 2-10% improvement in segmentation accuracy, depending on the kind of model, by using input that has been annotated with stress using a pronouncing dictionary. However, stress is neither invariably produced nor unambiguously identifiable in real speech. Heavy syllables, i.e. those with long vowels or syllable codas, attract stress in English. We devise Adaptor Grammar word segmentation models that exploit either stress, or syllable weight, or both, and evaluate the utility of syllable weight as a cue to word boundaries. Our results suggest that syllable weight encodes largely the same information for word segmentation in English that annotated dictionary stress does.

1 Introduction

One of the first skills a child must develop in the course of language acquisition is the ability to segment speech into words. Stress has long been recognized as a useful cue for English word segmentation, following the observation that words in English are predominantly stress-initial (Cutler and Carter, 1987), together with the result that 9-month-old English-learning infants prefer stress-initial stimuli (Jusczyk et al., 1993). A range of statistical (Doyle and Levy, 2013; Christiansen et al., 1998; Börschinger and Johnson, 2014) and rule-based (Yang, 2004; Lignos and Yang, 2010) models have used stress information to improve word segmentation. However, that work uses stress-marked input prepared by marking vowels that are listed as stressed in a pronouncing dictionary. This pre-processing step glosses over the fact that stress identification itself involves a non-trival learning problem, since stress has many possible phonetic reflexes and no known invariants (Campbell and Beckman, 1997; Fry, 1955; Fry, 1958). One known strong correlate of stress in English is syllable weight: heavy syllables, which end in a consonant or have a long vowel, attract stress in English. We present experiments with Bayesian Adaptor Grammars (Johnson et al., 2007) that suggest syllable weight encodes largely the same information for word segmentation that dictionary stress information does.

Specifically, we modify the Adaptor Grammar word segmentation model of Börschinger and Johnson (2014) to compare the utility of syllable weight and stress cues for finding word boundaries, both individually and in combination. We describe how a shortcoming of Adaptor Grammars prevents us from comparing stress and weight cues in combination with the full range of phonotactic cues for word segmentation, and design two experiments to work around this limitation. The first experiment uses grammars that provide parallel analyses for syllable weight and stress, and learns initial/non-initial phonotactic distinctions. In this first experiment, syllable weight cues are actually more useful than stress cues at larger input sizes. The second experiment focuses on incorporating phonotactic cues for typical word-final consonant clusters (such as inflectional morphemes), at the expense of parallel structures. In this second experiment, weight cues merely match stress cues at larger input sizes, and the learning curve for the combined weight-and-stress grammar follows almost perfectly with the stress-only grammar. This second experiment suggests that the advantage of weight over stress in the first experiment was purely due to poor modeling of word-final consonant clusters by the stress-only grammar, not weight *per se*. All together, these results indicate that syllable weight

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 844–853,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

is highly redundant with dictionary-based stress for the purposes of English word segmentation; in fact, in our experiments, there is no detectable difference between relying on syllable weight and relying on dictionary stress.

2 Background

Stress is the perception that some syllables are more prominent than others, and reflects a complex, language-specific interaction between acoustic cues (such as loudness and duration), and phonological patterns (such as syllable shapes). The details on how stress is assigned, produced, and perceived vary greatly across languages. Three aspects of the English stress system are relevant for this paper. First, although English stress can shift in different contexts (Liberman and Prince, 1977), such as from the first syllable of 'fourteen' in isolation to the second syllable when followed by a stressed syllable, it is largely stable across different tokens of a given word. Second, most words in English end up being stress-initial on a type and token basis. Third, heavy syllables (those with a long vowel or a consonant coda) attract stress in English.

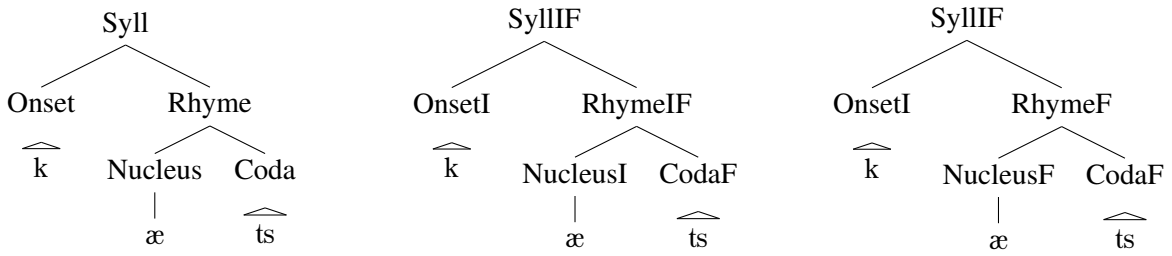
There is experimental evidence that English-learning infants prefer stress-initial words from around the age of seven months (Jusczyk et al., 1993; Juszcyk et al., 1999; Jusczyk et al., 1993; Thiessen and Saffran, 2003). A variety of computational models have subsequently been developed that take stress-annotated input and use this regularity to improve segmentation accuracy. The earliest Simple Recurrent Network (SRN) modeling experiments of Christiansen et al. (1998) and Christiansen and Curtin (1999) found that stress improved word segmentation from about 39% to 43% token f-score (see Evaluation). Rytting et al. (2010) applied the SRN model to probability distributions over phones obtained from a speech recognition system, and found that the entropy of the probability distribution over phones, as a proxy to local hyperarticulation and hence a stress cue, improved token f-score from about 16% to 23%. In a deterministic approach using pre-syllabified input, Yang (2004), with follow-ups in Lignos and Yang (2010) and Lignos (2011; 2012), showed that a 'Unique Stress Constraint' (USC), or assuming each word has at most one stressed syllable, leads to an improvement of about 2.5% boundary f-score.

Among explicitly probabilistic models, Doyle and Levy (2013) incorporated stress into Goldwater et al.'s (2009) Bigram model. They did this by modifying the base distribution over lexical forms to generate not simply phone strings but a sequence of syllables that may or may not be stressed. The resulting model can learn that some sequences of syllables (in particular, sequences that start with a stressed syllable) are more likely than others. However, observed stress improved token f-score by only 1%. Börschinger and Johnson (2014) used Adaptor Grammars (Johnson et al., 2007), a generalization of Goldwater et al.'s (2009) Bigram model that will be described shortly, and found a clearer 4-10% advantage in token f-score, depending on the amount of training data.

Together, the experimental and computational results suggest that infants in fact pay attention to stress, and that stress carries useful information for segmenting words in running speech. However, stress identification is itself a non-trivial task, as stress has many highly variable, context-sensitive, and optional phonetic reflexes. However, one strong phonological cue in English is syllable weight: heavy syllables attract stress. Heavy syllables, in turn, are syllables with a coda and/or a long vowel, which, in English, are tense vowels. Turk et al. (1995) replicated the Jusczyk et al. (1993) finding that English-learning infants prefer stress-initial stimuli (using non-words), and then examined how stress interacted with syllable weight. They found that syllable weight was not a necessary condition to trigger the preference: infants preferred stress-initial stimuli even if the initial syllable was light. However, they also found that infants most strongly preferred stimuli whose first syllable was both stressed and heavy: infants preferred stress-initial and heavy-initial stimuli to stress-initial and light-initial stimuli. This result suggests that infants are sensitive to syllable weight in determining typical stress and rythmic patterns in their language.

2.1 Models

We will adopt the Adaptor Grammar framework used by Börschinger and Johnson (2014) to explore the utility of syllable weight as a cue to word segmentation by way of its covariance with stress. Adaptor Grammars are Probabilistic Context Free Grammars (PCFGs) with a spe-



(a) Basic syllable. (b) Mono-syllable with initial Rhyme. (c) Mono-syllable with final Rhyme.

Figure 1: Different ways to incorporate phonotactics. It is not possible to capture word-final codas and word initial rhymes in monosyllabic words with factors the size of a PCFG rule.

cial set of *adapted* non-terminal nodes. We underline adapted non-terminals (X) to distinguish them from non-adapted non-terminals (Y). While a vanilla PCFG can only directly model regularities that are expressed by a single re-write rule, an Adaptor Grammar model caches entire subtrees that are rooted at adapted non-terminals. Adaptor Grammars can thus learn the internal structure of words, such as syllables, syllable onsets, and syllable rhymes, while still learning entire words as well.

In Adaptor Grammars, parameters are associated with PCFG rules. While this has been a useful factorization in previous work, it makes it difficult to integrate syllable weight and syllable stress in a linguistically natural way. A syllable is typically analyzed as having an optional onset followed by a rhyme, with the rhyme rewriting to a nucleus (the vowel) followed by an optional coda, as in Figure 1a. We expect stress and syllable weight to be useful primarily because initial syllables tend to be different from non-initial syllables. However, distinguishing final from non-final codas should be useful as well, due to the frequency of suffixes in English, and the importance of edge phenomena in phonology more generally (Brent and Cartwright, 1996). These principles come into conflict when modeling monosyllabic words. If we say that a monosyllable is an Initial and Final SyllIF, and has an initial Onset and an initial Rhyme, as in Figure 1b, then we can learn the initial/non-initial generalization about stressed or heavy rhymes at the expense of the generalization about final and non-final codas. If we say that a monosyllable is an initial onset with a final rhyme, the reverse occurs: we can learn the final/non-final coda generalization at the expense of the initial/non-initial regularities. If we split the symbols further, we'd generalize even less: we'd essentially have to learn the initial/non-initial patterns separately for monosyllables and polysyllables.

The most direct solution would introduce factors that are 'smaller' than a single PCFG rule. Essentially, we would compute the score of a PCFG rule in terms of multiple features of its right-hand side, rather than a single 'one-hot' feature identifying the expansion. We left this direction for future work and instead carried out two experiments using Adaptor Grammars that were designed to work around this limitation.

Our first experiment focuses on modeling the initial/non-initial distinction, leaving the final/non-final coda distinction unmodeled. The models in this experiment assume parallel structures for syllable weight and stress, and focus on providing the *most direct* comparison between syllable weight and stress with a strictly initial/non-initial distinction. This first experiment shows that observing dictionary stress is better early in learning, but that modeling syllable weight is better later in learning. However, it is possible that syllable weight was more useful because modeling syllable weight involves modeling the characteristics of codas; the advantage may not have been due to weight *per se* but due to having learned something about the effects of suffixes on final codas.

Our second experiment focuses on modeling some aspects of final codas at the expense of maintaining a rigid parallelism in the structures for syllable weight and stress. The models in this experiment split only those symbols that are necessary to bring stress or weight patterns into the expressive power of the model, and focus on comparing *richer* models of syllable weight and stress that account for inital/internal/final distinctions. This second experiment shows that observing dictionary stress is better early in learning, and that modeling syllable weight merely catches up to

$$\text{Sentence} \rightarrow \underline{\text{Collocations3}}^{+} \quad (1)$$
$$\underline{\text{Collocations3}} \rightarrow \underline{\text{Collocations2}}^{+} \quad (2)$$
$$\underline{\text{Collocations2}} \rightarrow \underline{\text{Collocation}}^{+} \quad (3)$$
$$\underline{\text{Collocation}} \rightarrow \underline{\text{Word}}^{+} \quad (4)$$

Figure 2: Three levels of collocation; symbols followed by $^{+}$ may occur one or more times.

stress without surpassing it. Moreover, a combined stress-and-weight model does no better than a stress model, suggesting that the weight grammar's contribution is fully redundant, for the purposes of word segmentation, with the stress observations.

Together, these experiments suggest that syllable weight eventually encodes everything about word segmentation that dictionary stress does, and that any advantage that syllable weight has over observing dictionary stress is entirely redundant with knowledge of word-final codas.

3 Experiments

3.1 Adaptor Grammars

We follow Börschinger and Johnson (2014) in using a 3-level collocation Adaptor Grammar, as introduced by Johnson and Goldwater (2009) and presented in Figure 2, as the backbone for all models, including the baseline. A 3-level collocation grammar assumes that words are grouped into collocations of words that tend to appear with each other, and that the collocations themselves are grouped into larger collocations, up to three levels of collocations. This collocational structure allows the model to capture strong word-to-word dependencies without having to group frequently-occuring word sequences into a single, incorrect, undersegmented 'word' as the unigram model tends to do (Johnson and Goldwater, 2009)

Word rewrites in different ways in Experiment I and Experiment II, which will be explained in the relevant experiment section.

3.2 Experimental Set-up

We applied the same experimental set-up used by Börschinger and Johnson (2014), to their dataset, as described below. To understand how different modeling assumptions interact with corpus size, we train on prefixes of each corpus with increasing input size: 100, 200, 500, 1,000, 2,000, 5,000, and 10,000 utterances. Inference closely followed Börschinger and Johnson (2014) and Johnson and Goldwater (2009). We set our hyperparameters to encourage onset maximization. The hyperparameter for syllable nodes to rewrite to an onset followed by a rhyme was 10, and the hyperparameter for syllable nodes to rewrite to a rhyme only was 1. Similarly, the hyperparameter for rhyme nodes to include a coda was 1, and the hyperparameter for rhyme nodes to exclude the coda was 10. All other hyperparameters specified vague priors. We ran eight chains of each model for 1,000 iterations, collecting 20 samples with a lag of 10 iterations between samples and a burn-in of 800 iterations. We used the same batch-initialization and table-label resampling to encourage the model to mix.

After gathering the samples, we used them to perform a single minimum Bayes risk decoding of a separate, held-out test set. This test set was constructed by taking the last 1,000 utterances of each corpus. We use a common test-set instead of just evaluating on the training data to ensure that performance figures are comparable across input sizes; when we see learning curves slope upward, we can be confident that the increase is due to learning rather than easier evaluation sets.

We measured our models' performance with the usual token f-score metric (Brent, 1999), the harmonic mean of how many proposed word tokens are correct (token precision) and how many of the actual word tokens are recovered (token recall). For example, a model may propose "the in side" when the true segmentation is "the inside." This segmentation would have a token precision of $\frac{1}{3}$, since one of three predicted words matches the true word token (even though the other predicted words are valid word types), and a token recall of $\frac{1}{2}$, since it correctly recovered one of two words, yield a token f-score of 0.4.

3.3 Dataset

We evaluated on a dataset drawn from the Alex portion of the Providence corpus (Demuth et al., 2006). This dataset contains $17,948$ utterances with $72,859$ word tokens directed to one child from the age of 16 months to 41 months. We used a version of this dataset that contained annotations of primary stress that Börschinger and Johnson (2014) added to this input using an extended

Figure 3: Experiment I Grammars

version of CMUDict (cmu, 2008).[1] The mean number of syllables per word token was 1.2, and only three word tokens had more than five syllables. Of the $40,323$ word tokens with a stressed syllable, $27,258$ were monosyllabic. Of the $13,065$ polysyllabic word tokens with a stressed syllable, $9,931$ were stress-initial. Turning to the $32,536$ word tokens with no stress (i.e., the function words), all but 23 were monosyllabic (the 23 were primarily contractions, such as "couldn't").

3.4 Experiment I: Parallel Structures

The goal of this first experiment is to provide the most direct comparison possible between grammars that attend to stress cues and grammars that attend to syllable weight cues. As these are both hypothesized to be useful by way of an initial/non-initial distinction, we defined a word to be an initial syllable SyllI followed by zero to three syllables, and syllables to consist of an optional onset and a rhyme:

$$\underline{\text{Word}} \rightarrow \text{SyllI} \quad (\text{Syll})^{\{0,3\}} \tag{5}$$

$$\text{SyllI} \rightarrow (\underline{\text{OnsetI}}) \quad \text{RhymeI} \tag{6}$$

$$\text{Syll} \rightarrow (\underline{\text{Onset}}) \quad \text{Rhyme} \tag{7}$$

In the baseline grammar, presented in Figure 3c, rhymes rewrite to a vowel followed by an optional consonant coda. Rhymes then rewrite to be heavy or light in the weight grammar, as in Figure 3a, to be stressed or unstressed in the stress grammar, as in Figure 3b. In the combination grammar, rhymes rewrite to be heavy or light and stressed or unstressed, as in Figure 3d. LongVowel and ShortVowel both re-write to all vowels. An additional grammar that restricted them to rewrite to long and short vowels, respectively, led to virtually identical performance, suggesting that vowel quantity can be learned for the purposes of word segmentation from distributional cues. We will also present evidence that the model did manage to learn most of the contrast.

Figure 4 presents learning curves for the grammars in this parallel structured comparison. We see that observing stress without modeling weight

[1] This dataset and these Adaptor Grammar models are available at: `http://web.science.mq.edu.au/~jpate/stress/`

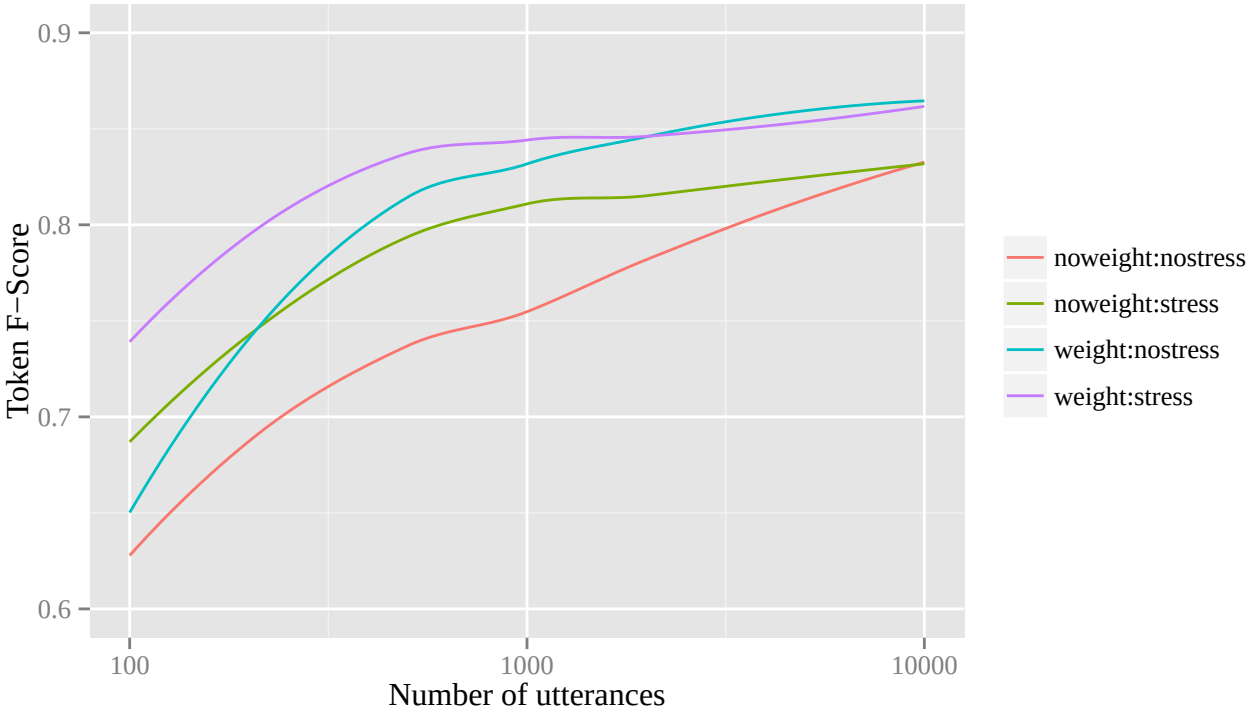

Figure 4: Learning curves on the Alex corpus for Experiment I grammars with parallel distinctions between Stressed/Unstressed and Heavy/Light syllable rhymes.

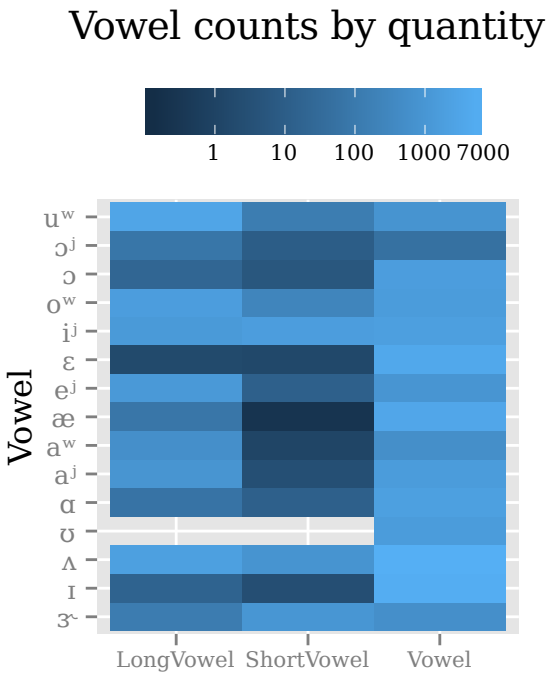

Figure 5: Heatmap of learned vowels in the Experiment I weight-only grammar. Each cell corresponds to the count of a particular vowel being analyzed as one of the three vowel types. Diphthongs are rarely ShortVowel.

outperforms both the baseline and the weight-only grammar early in learning. The weight-only grammar rapidly improves in performance at larger training data sizes, increasing its advantage over the baseline, while the advantage of the stress-only grammar slows and appears to disappear at the largest training data size. At 10,000 utterances, the improvement of the weight-only grammar over the stress-only grammar is significant according to an independent samples t-test ($t = 7.2, p < 0.001$, 14 degrees of freedom). This pattern suggests that annotated dictionary stress is easy to take advantage of at low data sizes, but that, with sufficient data, syllable weight can provide even more information about word boundaries. The best overall performance early in learning is obtained by the combined grammar, suggesting that syllable weight and dictionary stress provide information about word segmentation that is not redundant.

An examination of the final segmentation suggests that the weight grammar has learned that initial syllables tend to be heavy. Specifically, across eight runs, 98.1% of RhymeI symbols rewrote to HeavyRhyme, whereas only 54.5% of Rhyme symbols (i.e. non-initial rhymes) rewrote to HeavyRhyme.

Model	Mean TF	Std. Dev.
noweight:nostress	0.830	0.005
noweight:stress	0.831	0.008
weight:nostress	0.861	0.008
weight:stress	0.861	0.008

Table 1: Segmentation Token F-score for Experiment I at 10,000 utterances across eight runs.

We also examined the final segmentation to see well the model learned the distinction between long vowels and short vowels. Figure 5 presents a heatmap, with colors on a log-scale, showing how many times each vowel label rewrote to each possible vowel in the (translated to IPA). Although the quantity generalisations are not perfect, we do see a general trend where ShortVowel rarely rewrites to diphthongs.

3.5 Experiment II: Word-final Codas

Experiment I suggested that, under a basic initial/non-initial distinction, syllable weight eventually encodes more information about word boundaries than does dictionary stress. This is a surprising result, since we initially investigated syllable weight as a noisy proxy for dictionary stress. One possible source of the 'extra' advantage that the syllable weight grammar exhibited has to do with the importance of word-final codas, which can encode word-final morphemes in English (Brent and Cartwright, 1996). Even though the grammars did not explicitly model them, the weight grammar could implicitly capture a bias for or against having a coda in non-initial position, while the stress grammar could not. This is because most word tokens are one or two syllables, and only one of the two rhyme types of the weight grammar included a coda. Thus, the HeavyRhyme symbol could simultaneously capture the most important aspects of both stress and coda constraints.

To see if the extra advantage of the syllable weight grammar can be attributed to the influence of word-final codas, we formulated a set of grammars that model word-final codas and also can learn stress and/or syllable weight patterns. These grammars are more similar in structure to the ones that Börschinger and Johnson (2014) used. For the baseline and weight grammar, we again defined words to consist of up to four syllables with an initial SyllI syllable, but this time distinguished final syllables SyllF in polysyllabic words. The non-stress grammars use the following rules for producing syllables:

$$\underline{\text{Word}} \rightarrow \text{SyllIF} \tag{8}$$

$$\underline{\text{Word}} \rightarrow \text{SyllI} \quad (\text{Syll})^{\{0,2\}} \quad \text{SyllF} \tag{9}$$

$$\text{SyllIF} \rightarrow (\text{OnsetI}) \quad \text{RhymeI} \tag{10}$$

$$\text{SyllI} \rightarrow (\text{OnsetI}) \quad \text{RhymeI} \tag{11}$$

$$\text{Syll} \rightarrow (\text{Onset}) \quad \text{Rhyme} \tag{12}$$

$$\text{SyllF} \rightarrow (\text{Onset}) \quad \text{RhymeF} \tag{13}$$

For the stress grammar, we followed Börschinger and Johnson (2014) in distinguishing stressed and unstressed syllables, rather than simply stressed rhymes as in Experiment I, to allow the model to learn likely stress patterns at the word level. A word can consist of up to four syllables, and any syllable and any number of syllables may be stressed, as in Figure 6a.

The baseline grammar is similar to the previous one, except it distinguishes word-final codas, as in Figure 6b. The weight grammar, presented in Figure 6c, rewrites rhymes to a nucleus followed by an optional coda and distinguishes nuclei in open syllables according to their position in the word. The stress grammar, presented in Figure 6d, is the all-stress-patterns model (without the unique stress constraint) Börschinger and Johnson (2014). This grammar introduces additional distinctions at the syllable level to learn likely stress patterns, and distinguishes final from non-final codas. The combined model is identical to the stress model, except Vowel non-terminals in closed and word-internal syllables are replaced with Nucleus non-terminals, and Vowel non-terminals in word-inital (-final) open syllables are replaced with NucleusI (NucleusF) non-terminals.

To summarize, the stress models distinguish stressed and unstressed syllables in initial, final, and internal position. The weight models distinguish the vowels of initial open syllables, the vowels of final open syllables, and other vowels, allowing them to take advantage of an important cue from syllable weight for word segmentation: if an initial vowel is open, it should usually be long.

Figure 7 shows segmentation performance on the Alex corpus with these more complete models. While the performance of the weight grammars is virtually unchanged compared to Figure 4, the two grammars that do not model syllable weight improve dramatically. This result supports our proposal that much of the advantage of the weight

$$\underline{\text{Word}} \rightarrow \{\text{SyllUIF}|\text{SyllSIF}\}$$
$$\underline{\text{Word}} \rightarrow \{\text{SyllUI}|\text{SyllSI}\} \quad \{\text{SyllU}|\text{SyllS}\}^{\{0,2\}} \quad \{\text{SyllUF}|\text{SyllSF}\}$$

(a) The all-patterns stress model

$$\text{Rhyme} \rightarrow \text{Vowel} \quad (\underline{\text{Coda}})$$
$$\text{RhymeF} \rightarrow \text{Vowel} \quad (\underline{\text{CodaF}})$$

(b) Baseline grammar

$$\text{RhymeI} \rightarrow \underline{\text{NucleusI}}$$
$$\text{RhymeI} \rightarrow \underline{\text{Nucleus}} \quad \underline{\text{Coda}}$$
$$\text{Rhyme} \rightarrow \underline{\text{Nucleus}} \quad (\underline{\text{Coda}})$$
$$\text{RhymeF} \rightarrow \underline{\text{NucleusF}}$$
$$\text{RhymeF} \rightarrow \underline{\text{Nucleus}} \quad \underline{\text{CodaF}}$$

(c) Weight-sensitive grammar

$$\text{SyllSIF} \rightarrow \underline{\text{OnsetI}} \quad \text{RhymeSF}$$
$$\text{SyllUIF} \rightarrow \underline{\text{OnsetI}} \quad \text{RhymeUF}$$
$$\text{SyllSI} \rightarrow \underline{\text{Onset}} \quad \text{RhymeS}$$
$$\text{SyllUI} \rightarrow \underline{\text{Onset}} \quad \text{RhymeU}$$
$$\text{SyllSF} \rightarrow \underline{\text{Onset}} \quad \text{RhymeSF}$$
$$\text{SyllUF} \rightarrow \underline{\text{Onset}} \quad \text{RhymeUF}$$
$$\text{RhymeSI} \rightarrow \text{Vowel} \quad \text{Stress} \quad (\underline{\text{Coda}})$$
$$\text{RhymeUI} \rightarrow \text{Vowel} \quad (\underline{\text{Coda}})$$
$$\text{RhymeS} \rightarrow \text{Vowel} \quad \text{Stress} \quad (\underline{\text{Coda}})$$
$$\text{RhymeU} \rightarrow \text{Vowel} \quad (\underline{\text{Coda}})$$
$$\text{RhymeSF} \rightarrow \text{Vowel} \quad \text{Stress} \quad (\underline{\text{CodaF}})$$
$$\text{RhymeUF} \rightarrow \text{Vowel} \quad (\underline{\text{CodaF}})$$

(d) Stress-sensitive grammar

Figure 6: Experiment II Grammars.

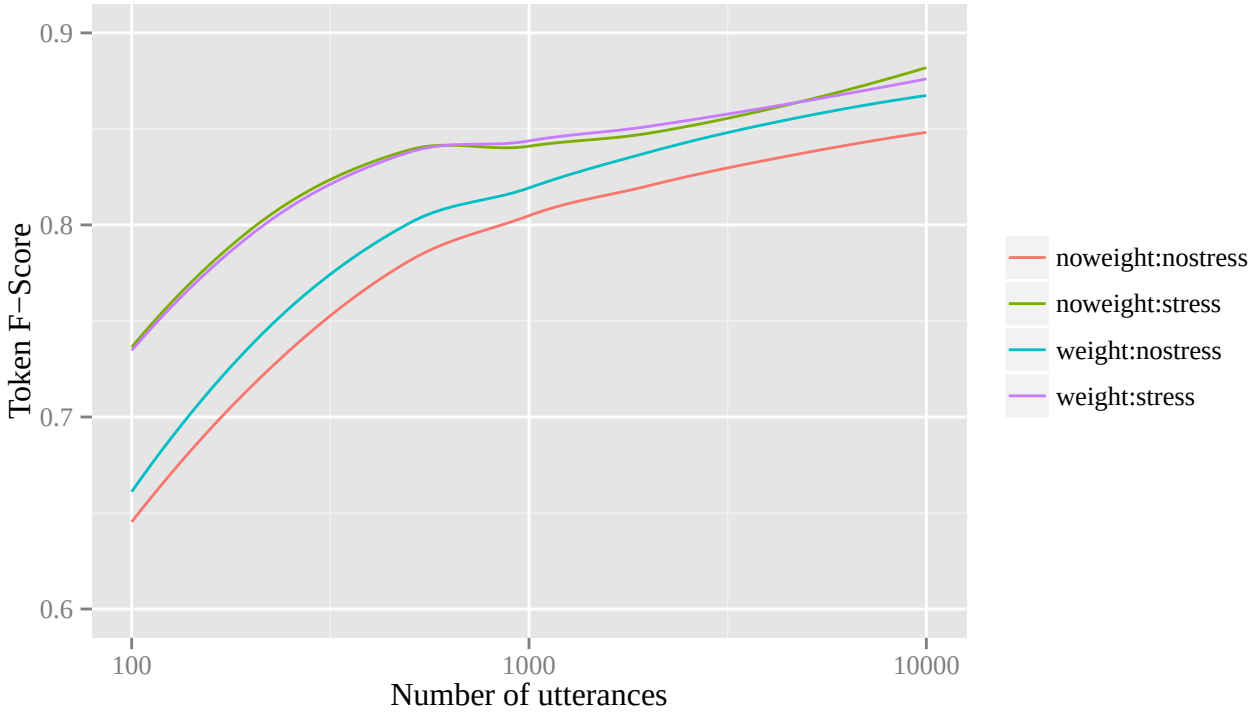

Figure 7: Learning curves on the Alex corpus for Experiment II grammars with word-final phonotactics that exploit Stress and Weight.

Model	Mean TF	Std. Dev.
noweight:nostress	0.846	0.007
noweight:stress	0.880	0.005
weight:nostress	0.865	0.011
weight:stress	0.875	0.005

Table 2: Segmentation Token F-score for Experiment II at 10,000 utterances across eight runs.

grammars over stress in Experiment I was due to modeling of word-final coda phonotactics.

Table 2 presents token f-score at 10,000 training utterances averaged across eight runs, along with the standard deviation in f-score. We see that the noweight:nostress grammar is several standard deviations than the grammars that model syllable weight and/or stress, while the syllable weight and/or stress grammars exhibit a high degree of overlap.

4 Conclusion

We have presented computational modeling experiments that suggest that syllable weight (eventually) encodes nearly everything about word segmentation that dictionary stress does. Indeed, our experiments did not find a persistent advantage to observing stress over modeling syllable weight. While it is possible that a different modeling approach might find such a persistent advantage, this advantage could not provide more than 13% absolute F-score. This result suggests that children may be able to learn and exploit important rhythm cues to word boundaries purely on the basis of segmental input. However, this result also suggests that annotating input with dictionary stress has missed important aspects of the role of stress in word segmentation. As mentioned, Turk et al. (1995) found that infants preferred initial light syllables to be stressed. Such a preference obviously cannot be learned by attending to syllable weight alone, so infants who have learned weight distinctions must also be sensitive to non-segmental acoustic correlates to stress. There was no long-term advantage to observing stress in addition to attending to syllable weight in our models, however, suggesting that annotated dictionary stress does not capture the relevant non-segmental phonetic detail. More modeling is necessary to assess the non-segmental phonetic features that distinguish stressed light syllables from unstressed light syllables.

This investigation also highlighted a weakness of current Adaptor Grammar models: the 'smallest' factors are the size of one PCFG rule. Allowing further factorizations, perhaps using feature functions of a rule's right-hand side, would allow models to capture finer-grained distinctions without fully splitting the symbols that are involved.

Abstract

In this paper, we propose a joint model for unsupervised Chinese word segmentation (CWS). Inspired by the "products of experts" idea, our joint model firstly combines two generative models, which are word-based hierarchical Dirichlet process model and character-based hidden Markov model, by simply multiplying their probabilities together. Gibbs sampling is used for model inference. In order to further combine the strength of goodness-based model, we then integrated nVBE into our joint model by using it to initializing the Gibbs sampler. We conduct our experiments on PKU and MSRA datasets provided by the second SIGHAN bakeoff. Test results on these two datasets show that the joint model achieves much better results than all of its component models. Statistical significance tests also show that it is significantly better than state-of-the-art systems, achieving the highest F-scores. Finally, analysis indicates that compared with nVBE and HDP, the joint model has a stronger ability to solve both combinational and overlapping ambiguities in Chinese word segmentation.

1 Introduction

Unlike English and many other western languages, there are no explicit word boundaries in Chinese sentences. Therefore, word segmentation is a crucial first step for many Chinese language processing tasks such as syntactic parsing, information retrieval and machine translation. A great deal of supervised methods have been proposed for Chinese word segmentation. While successful, they require manually labeled resources and often suffer from issues like poor domain adaptability. Thus, unsupervised word segmentation methods are still attractive to researchers due to its independence on domain and manually labeled corpora.

Previous unsupervised approaches to word segmentation can be roughly classified into two types. The first type uses carefully designed goodness measure to identify word candidates. Popular goodness measures include description length gain (DLG) (Kit and Wilks, 1999), accessor variety (AV) (Feng et al., 2004), boundary entropy (BE) (Jin and Tanaka-Ishii, 2006) and normalized variation of branching entropy (nVBE) (Magistry and Sagot, 2012) etc. Goodness measure based model is not segmentation model in a very strict meaning and is actually strong in generating word list without supervision. It inherently lacks capability to deal with ambiguous string, which is one of main sources of segmentation errors and has been extensively explored in supervised Chinese word segmentation.

The second type focuses on designing sophisticated statistical model, usually nonparametric Bayesian models, to find the segmentation with highest posterior probability, given the observed character sequences. Typical statistical models includes Hierarchical Dirichlet process (HDP) model (Goldwater et al., 2009), Nested Pitman-Yor process (NPY) model (Mochihashi et al., 2009) etc, which are actually nonparametric language models and therefor can be categorized as word-based model. Word-based model makes decision on wordhood of a candidate character sequence mainly based on information outside the sequence, namely, the wordhood of character sequences being adjacent to the concerned sequence.

Inspired by the success of character-based model in supervised word segmentation, we propose a Bayesian HMM model for unsupervised Chinese word segmentation. With the Bayesian HMM model, we formulate the unsupervised segmentation tasks as procedure of tagging positional

tags to characters. Different from word-based model, character-based model like HMM-based model as we propose make decisions on wordhood of a candidate character sequence based on information inside the sequence, namely, ability of characters to form words. Although the Bayesian HMM model alone does not produce competitive results, it contributes substantially to the joint model as proposed in this paper.

Our joint model takes advantage from three different models: namely, a character-based model (HMM-based), a word-based model (HDP-based) and a goodness measure based model (nVBE model). The combination of HDP-based model and HMM-based model enables to utilize information of both word-level and character-level. We also show that using nVBE model as initialization model could further improve the performance to outperform the state-of-the-art systems and leads to improvement in both wordhood judgment and disambiguation ability.

Word segmentation systems are usually evaluated with metrics like precision, recall and F-Score, regardless of supervised or unsupervised. Following normal practice, we evaluate our model and compare it with state-of-the-art systems using F-Score. However, we argue that the ability to solve segmentation ambiguities is also important when evaluating different types of unsupervised word segmentation systems.

This paper is organized as follows. In Section 2, we will introduce several related systems for unsupervised word segmentation. Then our joint model is presented in Section 3. Section 4 shows our experiment results on the benchmark datasets and Section 5 concludes the paper.

2 Related Work

Unsupervised Chinese word segmentation has been explored in a number of previous works and by various methods. Most of these methods can be divided into two categories: goodness measure based methods and nonparametric Bayesian methods.

There have been a plenty of work that is based on a specific goodness measure. Zhao and Kit (2008) compared several popular unsupervised models within a unified framework. They tried various types of goodness measures, such as Description Length Gain (DLG) proposed by Kit and Wilks (1999), Accessor Variety (AV) proposed by Feng et al. (2004) and Boundary Entropy (Jin and Tanaka-Ishii, 2006). A notable goodness-based method is ESA: "Evaluation, Selection, Adjustment", which is proposed by Wang et al. (2011) for unsupervised Mandarin Chinese word segmentation. ESA is an iterative model based on a new goodness algorithm that adopts a local maximum strategy and avoids threshold setting. One disadvantage of ESA is that it needs to iterate the process several times on the corpus to get good performance. Another disadvantage is the requirement for a manually segmented training corpus to find best value for parameters (they called it *proper exponent*). Another notable work is nVBE: Magistry and Sagot (2012) proposed a model based on the Variation of Branching Entropy. By adding normalization and viterbi decoding, they improve performance over Jin and Tanaka-Ishii (2006) and remove most of the parameters and thresholds from the model.

Nonparametric Bayesian models also achieved state-of-the-art performance in unsupervised word segmentation. Goldwater et al. (2009) introduced a unigram and a bigram model for unsupervised word segmentation, which are based on Dirichlet process and hierarchical Dirichlet process (Teh et al., 2006) respectively. The main drawback is that it needs almost 20,000 iterations before the Gibbs sampler converges. Mochihashi et al. (2009) extended this method by introducing a nested character model and an efficient blocked Gibbs sampler. Their method is based on what they called nested Pitman-Yor language model.

One disadvantage of goodness measure based methods is that they do not have any disambiguation ability in theory in spite of their competitive performances. This is because once the goodness measure is given, the decoding algorithm will segment any ambiguous strings into the same word sequences, no matter what their context is. In contrast, nonparametric Bayesian language models aim to segment character string into a "reasonable" sentence according to the posterior probability. Thus, theoretically, this method should have better ability to solve ambiguities over goodness measure based methods.

3 Joint Model

In this section, we will discuss our joint model in detail.

3.1 Combining HDP and HMM

In supervised Chinese word segmentation literature, word-based approaches and character-based approaches often have complementary advantages (Wang et al., 2010).Since the two types of model try to solve the problem from different perspectives and by utilizing different levels of information (word level and character level). In unsupervised Chinese word segmentation literature, the HDP-base model can be viewed as a typical word-based method. And we can also build a character-based unsupervised model by using a hidden Markov model. We believe that the HDP-based model and the HMM-based model are also complementary with each other, and a combination of them will take advantage of both and thus capture different levels of information.

Now the problem we are facing is how to combine these two models. To keep the joint model simple and involve as little extra parameters as possible, we combine the two baseline models by just multiplying their probabilities together and then renormalizing it. Let $C = c_1 c_2 \cdots c_{|C|}$ be a string of characters and $W = w_1 w_2 \cdots w_{|W|}$ is the corresponding segmented words sequence. Then the conditional probability of the segmentation W given the character string C in our joint model is defined as:

$$P_J(W|C) = \frac{1}{Z(C)} P_D(W|C) P_M(W|C) \quad (1)$$

where $P_D(W|C)$ is the probability from the HDP model as given in Equation 6 and $P_M(W|C)$ is the probability given by the Bayesian HMM model as given in Equation 2. $Z(C)$ is a normalization term to make sure that $P_J(W|C)$ is a probability distribution. The combining method is inspired by Hinton (1999), which proved that it is possible to combine many individual expert models by multiplying the probabilities and then renormalizing it. They called it "product of experts". We can see that combining models in this way does not involve any extra parameters and Gibbs sampling can be easily used for model inference.

3.2 Bayesian HMM

The dominant method for supervised Chinese word segmentation is character-based model which was first proposed by Xue (2003). This method treats word segmentation as a tagging problem, each tag indicates the position of a character within a word. The most commonly used tag set is {**S**ingle, **B**egin, **M**iddle, **E**nd}. Specifically, **S** means the character forms a single word, **B/E** means the character is the begining/ending character of the word, and **M** means the character is in the middle of the word. Existing models are trained on manually annotated data in a supervised way based on discriminative models such as Conditional Random Fields (Peng et al., 2004; Tseng et al., 2005). Supervised character-based methods make full use of character level information and thus have been very successful in the last decade. However, no unsupervised model has utilized character level information in the way as supervised method does.

We can also build a character-based model for Chinese word segmentation using hidden Markov model(HMM) as formulated in the following equation:

$$P_M(W|C) = \prod_{i=1}^{|C|} P_t(t_i|t_{i-1}) P_e(c_i|t_i) \quad (2)$$

where C and W have the same meaning as before. $P_t(t_i|t_{i-1})$ is the transition probability of tag t_i given its former tag t_{i-1} and $P_e(c_i|t_i)$ is the emission probability of character c_i given its tag t_i. This model can be easily trained with Maximum Likelihood Estimation (MLE) on annotated data or with Expectation Maximization (EM) on raw texts. But using any of this methods will make it difficult to combine it with the HDP-based model. Instead, we propose a Bayesian HMM for unsupervised word segmentation. The Bayesian HMM model is defined as follows:

$$\begin{aligned} t_i|t_{i-1} = t, p^t &\sim Mult(p^t) \\ c_i|t_i = t, e^t &\sim Mult(e^t) \\ p^t|\theta &\sim Dirichlet(\theta) \\ e^t|\sigma &\sim Dirichlet(\sigma) \end{aligned}$$

where p^t and e^t are transition and emission distributions, θ and σ are the symmetric parameters of Dirichlet distributions. Now suppose we have observed tagged text h, then the conditional probability $P_M(w_i|w_{i-1} = l, h)$ can be obtained:

$$\begin{aligned} &P_M(w_i|w_{i-1} = l, h) \\ &\quad = \prod_{j=1}^{|w_i|} P_t(t_j|t_{j-1}, h) P_e(c_j|t_j, h) \quad (3) \end{aligned}$$

where $< w_{i-1}, w_i >$ is a word bigram, l is the index of word w_{i-1}, c_j is the jth character in word

w_i and t_j is the corresponding tag.$P_t(t_j|t_{j-1}, h)$ and $P_e(c_j|t_j, h)$ are the posterior probabilities, they are given as:

$$P_t(t_j|t_{j-1}, h) = \frac{n_{<t_{j-1},t_j>} + \theta}{n_{<t_{j-1},*>} + T\theta} \quad (4)$$

$$P_e(c_j|t_j, h) = \frac{n_{<t_j,c_j>} + \sigma}{n_{<t_j,*>} + V\sigma} \quad (5)$$

where $n_{<t_{j-1},t_j>}$ is the tag bigram count of $< t_{j-1}, t_j >$ in h, $n_{<t_j,c_j>}$ denotes the number of occurrences of tag t_j and character c_j, and $*$ means a sum operation. T and V are the size of character tag set (we follow the commonly used {**SBME**} tag set and thus $T = 4$ in this case) and character vocabulary.

3.3 HDP Model

Goldwater et al. (2009) proposed a nonparametric Bayesian model for unsupervised word segmentation which is based on HDP (Teh et al., 2006). In this model, the conditional probability of the segmentation W given the character string C is defined as:

$$P_D(W|C) = \prod_{i=0}^{|W|} P_D(w_i|w_{i-1}) \quad (6)$$

where w_i is the ith word in W. This is actually a nonparametric bigram language model. This bigram model assumes that each different word has a different distribution over words following it, but all these different distributions are linked through a HDP model:

$$\begin{aligned} w_i|w_{i-1} = l &\sim G_l \\ G_l &\sim DP(\alpha_1, G_0) \\ G_0 &\sim DP(\alpha, H) \end{aligned}$$

where DP denotes a Dirichlet process.

Suppose we have observed segmentation result h, then we can get the posterior probability $P_D(w_i|w_{i-1} = l, h)$ by integrating out G_l:

$$\begin{aligned} &P_D(w_i|w_{i-1} = l, h) \\ &\quad = \frac{n_{<w_{i-1},w_i>} + \alpha_1 P_D(w_i|h)}{n_{<w_{i-1},*>} + \alpha_1} \end{aligned} \quad (7)$$

where $n_{<w_{i-1},w_i>}$ denotes the total number of occurrences of the bigram $< w_{i-1}, w_i >$ in the observation h. And $P_D(w_i|h)$ can be got by integrating out G_0:

$$P_D(w_i|h) = \frac{t_{w_i} + \alpha H(w_i)}{t + \alpha} \quad (8)$$

where t_{w_i} denotes the number of tables associated with w_i in the Chinese Restaurant Franchise metaphor (Teh et al., 2006), t is the total number of tables and $H(w_i)$ is the base measure of G_0. In fact, $H(w_i)$ is the prior distribution over words, so prior knowledge can be injected in this distribution to enhance the performance.

In Goldwater et al. (2009)'s work, the base measure $H(w_i)$ are defined as a character unigram model:

$$H(w_i) = (1 - p_s)^{|w_i|-1} p_s \prod_j P(c_{ij})$$

where, p_s is the probability of generating a word boundary. $P(c_{ij})$ is the probability of the jth character c_{ij} in word w_i, this probability can be estimated from the training data using maximum likelihood estimation.

3.4 Initializing with nVBE

Among various goodness measure based models, we choose nVBE (Magistry and Sagot, 2012) to initialize our Gibbs sampler with its segmentation results. nVBE achieved a relatively high perfomance over other goodness measure based methods. And it's very simple as well as efficient.

Theoretically, the Gibbs sampler may be initialized at random or using any other methods. Initialization does not make a difference since the Gibbs sampler will eventually converge to the posterior distribution if it iterates as much as possible. This is an essential attribute of Gibbs sampling. However, we believe that initializing the Gibbs sampler with the result of nVBE will benefit us in two ways. On one hand, in consideration of its combination of nonparametric Bayesian method and goodness-based method, it will improve the overall performance as well as solve more segmentation ambiguities with the help of HDP-based model. On the other hand, it makes the convergence of Gibbs sampling faster. In practice, random initialization often leads to extremely slow convergence.

3.5 Inference with Gibbs Sampling

In our proposed joint model, Gibbs sampling (Casella and George, 1992) can be easily used to identify the highest probability segmentation from among all possibilities. Following Goldwater et al. (2009), we can repeatedly sample from potential word boundaries. Each boundary

variable can only take on two possible values, corresponding to a word boundary or not word boundary.

For instance, suppose we have obtained a segmentation result $\beta|c_{i-2}c_{i-1}c_ic_{i+1}c_{i+2}|\gamma$, where β and γ are the words sequences to the left and right and $c_{i-2}c_{i-1}c_ic_{i+1}c_{i+2}$ are characters between them. Now we are sampling at location i to decide whether there is a word boundary between c_i and c_{i+1}. Denote h_1 as the hypothesis that it forms a word boundary (the corresponding result is $\beta w_1 w_2 \gamma$ where $w_1 = c_{i-2}c_{i-1}c_i$ and $w_2 = c_{i+1}c_{i+2}$), and h_2 as the opposite hypothesis (then the corresponding result is $\beta w \gamma$ where $w = c_{i-2}c_{i-1}c_ic_{i+1}c_{i+2}$). The posterior probability for these two hypotheses would be:

$$P(h_1|h^-) \propto P_D(h_1|h^-)P_M(h_1|h^-) \quad (9)$$
$$P(h_2|h^-) \propto P_D(h_2|h^-)P_M(h_2|h^-) \quad (10)$$

where $P_D(h|h^-)$ and $P_M(h|h^-)$ are the posterior probabilities in HDP-based model and in HMM-based model, and h^- denotes the current segmentation results for all observed data except $c_{i-2}c_{i-1}c_ic_{i+1}c_{i+2}$. Note that the normalization term $Z(C)$ can be ignored during inference. The posterior probabilities for these two hypotheses in the HDP-based model is given as:

$$\begin{aligned} P_D(h_1|h^-) &= P_D(w_1|w_l, h^-) \\ &\times P_D(w_2|w_1, h^-)P_D(w_r|w_2, h^-) \quad (11) \\ P_D(h_2|h^-) &= P_D(w|w_l, h^-) \\ &\times P_D(w_r|w, h^-) \quad (12) \end{aligned}$$

where $w_l(w_r)$ is the first word to the left (right) of w. And the posterior probabilities for the Bayesian HMM model is given as:

$$\begin{aligned} &P_M(h_1|h^-) \\ &\propto \prod_{j=i-2}^{i+2} P_t(t_j|t_{j-1}, h^-)P_e(c_j|t_j, h^-) \quad (13) \\ &P_M(h_2|h^-) \\ &\propto \prod_{j=i-2}^{i+2} P_t(t_j|t_{j-1}, h^-)P_e(c_j|t_j, h^-) \quad (14) \end{aligned}$$

where $P_t(t_j|t_{j-1}, h^-)$ and $P_e(c_j|t_j, h^-)$ are given in Equation 4 and 5. The difference is that under hypothesis h_1, $c_{i-2}c_{i-1}c_ic_{i+1}c_{i+2}$ are tagged as "BMEBE" and under hypothesis h_2 as "BMMME".

Once the Gibbs sampler is converged, a natural way to is to treat the result of last iteration as the final segmentation result, since each set of assignments to the boundary variables uniquely determines a segmentation.

4 Experiments

In this section, we test our joint model on PKU and MSRA datesets provided by the Second Segmentation Bake-off (SIGHAN 2005) (Emerson, 2005). Most previous works reported their results on these two datasets, this will make it convenient to directly compare our joint model with theirs.

4.1 Setting

The second SIGHAN Bakeoff provides several large-scale labeled data for evaluating the performance of Chinese word segmentation systems. Two of the four datasets are used in our experiments. Both of the dataset contains only simplified Chinese. Table 1 shows the statistics of the two selected corpus. For development set, we randomly select a small subset (about 10%) of the training data. Specifically, 2000 sentences are selected for PKU corpus and 8000 sentences for MSRA corpus. The rest training data plus the test set is then combined for segmentation but only test data is used for evaluation. The development set is used to tune parameters of the HDP-based model and HMM-based model separately. Since our joint model does not involve any additional parameters, we reuse the parameters of the HDP-based model and HMM-based model in the joint model. Specifically, we set $\alpha_1 = 1000.0, \alpha = 10.0, p_s = 0.5$ for the HDP-based model and set $\theta = 1.0, \sigma = 0.01$ for the HMM-based model.

For evaluation, we use standard F-Score on words for all following experiments. F-Score is the harmonic mean of the word precision and recall. Precision is given as:

$$P = \frac{\#correct\ words\ in\ result}{\#total\ words\ in\ result}$$

and recall is given as:

$$R = \frac{\#correct\ words\ in\ result}{\#total\ words\ in\ gold\ corpus}$$

then F-Score is calculated as:

$$F = \frac{2 \times R \times F}{R + F}$$

Corpus	TrainingSize (words)	TestSize (words)
PKU	1.1M	104K
MSRA	2.37M	107K

Table 1: Statistics of training and testing data

Huang and Zhao (2007) provided an empirical method to estimate the consistency between the four different segmentation standards involved in the Bakeoff-3. A lowest consistency rate 84.8% is found among the four standards. Zhao and Kit (2008) considered this figure as the upper bound for any unsupervised Chinese word segmentation systems. We also use it as the **topline** in our comparison.

4.2 Prior Knowledge Used

When it comes to the evaluation and comparison for unsupervised word segmentation systems, an important issue is what kind of pre-processing steps and prior knowledge are needed. To be fully unsupervised, any prior knowledge such as punctuation information, encoding scheme and word length could not be used in principle. Nevertheless, information like punctuation can be easily injected to most existing systems and significantly enhance the performance. The problem we are faced with is that we don't know for sure what kind of prior information are used in other systems. One may use a small punctuation set to segment a long sentence into shorter ones, while another may write simple regular expressions to identify dates and numbers. Lot of work we compare to don't even mention this subject.

Fortunately, we notice that Wang et al. (2011) provided four kinds of preprocessings (they call *settings*). In their settings 1 and 2, punctuation and other encoding information are not used. In setting 3, punctuation is used to segment character sequences into sentences, and both punctuation and other encoding information are used in setting 4. Then the results reported in Magistry and Sagot (2012) relied on setting 3 and setting 4. In order to make the comparison as fair as possible, we use setting 3 in our experiment, i.e., only a punctuation set for simplified Chinese is used in all our experiments. We will compare our experiment results to previous work on the same setting if they are provided .

4.3 Experiment Results

Table 2 summarizes the F-Scores obtained by different models on PKU and MSRA corpus, as well as several state-of-the-art systems. Detailed information about the presented models are listed as follows:

- **nVBE:** the model based on Variation of Branching Entropy in Magistry and Sagot (2012). We re-implement their model on setting 3[1].
- **HDP:** the HDP-based model proposed by Goldwater et al. (2009), initialized randomly.
- **HDP+HMM:** the model combining HDP-based model and HMM-based model as proposed in Section 3, initialized randomly.
- **HDP+nVBE:** the HDP-based model, initialized with the results of nVBE model.
- **Joint:** the "HDP+HMM" model initialized with nVBE model.
- **ESA:** the model proposed in Wang et al. (2011), as mentioned above, the conducted experiments on four different settings, we report their results on setting 3.
- **NPY(2):** the 2-gram language model presented by Mochihashi et al. (2009).
- **NPY(3):** the 3-gram language model presented by Mochihashi et al. (2009).

For all of our Gibbs samplers, we run 5 times to get the averaged F-Scores. We also give the variance of the F-Scores in Table 2. For each run, we find that random initialization takes around 1,000 iterations to converge, while initialing with nVBE only takes as few as 10 iterations. This makes

[1]The results we got with our implementation is slightly lower than what was reported in Magistry and Sagot (2012). According to Pei et al. (2013), they had contacted the authors and confirmed that the higher results was due to a bug in code. So we report the results with our bug free implementation as Pei et al. (2013) did. Our reported results are identical to those of Pei et al. (2013)

System	PKU			MSRA		
	R	**P**	**F**	**R**	**P**	**F**
nVBE	78.3	77.5	77.9	79.1	77.3	78.2
HDP	69.0	68.4	68.7(0.012)	70.4	69.4	69.9(0.020)
HDP+HMM	77.5	73.2	75.3(0.005)	79.9	73.0	76.3(0.013)
HDP+nVBE	80.7	77.9	79.3(0.012)	81.8	77.3	79.5(0.005)
Joint	**83.1**	**79.2**	**81.1**(0.002)	**84.2**	**79.3**	**81.7**(0.005)
ESA	N/A	N/A	77.4	N/A	N/A	78.4
NPY(2)	N/A	N/A	N/A	N/A	N/A	80.2
NPY(3)	N/A	N/A	N/A	N/A	N/A	80.7
Topline	N/A	N/A	84.8	N/A	N/A	84.8

Table 2: Experiment results and comparison to state-of-the-art systems. The figures in parentheses denote the variance the of F-Scores.

our joint model very efficient and possible to work in practical applications as well. At last, a single sample (the last one) is used for evaluation.

From Table 2, we can see that the joint model (Joint) outperforms all the presented systems in F-Score on all testing corpora. Specifically, comparing "HDP+HMM" with "HDP", the former model increases the overall F-Score from 68.7% to 75.3% (+6.6%) in PKU corpora and from 69.9% to 76.3% (+6.4%) in MSRA corpora, which proves that the character information in the HMM-based model can actually enhance the performance of the HDP-based model. Comparing "HDP+nVBE" with "HDP", the former model also increases the overall F-Score by 10.6%/9.6% in PKU/MSRA corpora, which demonstrates that initializing the HDP-based model with nVBE will improve the performance by a large margin. Finally, the joint model "Joint" take advantage from both from the character-based HMM model and the nVBE model, it achieves a F-Score of 81.1% on PKU and 81.7% on MSRA. This result outperforms all its component baselines such as "HDP", "HDP+HMM" and "HDP+nVBE".

Our joint model also shows competitive advantages over several state-of-the-art systems. Compared with nVBE,the F-Score increases by 3.2% on PKU corpora and by 3.5% on MSRA corpora. Compared with ESA, the F-Score increases by 3.7%/3.3% in PKU/MSRA corpora. Lastly, compared to the nonparametric Bayesian models (NPY(n)), our joint model still increases the F-Score by 1.5% (NPY(2)) and 1.0% (NPY(3)) on MSRA corpora. Moreover, compared with the empirical topline figure 84.8%, our joint model achieves a pretty close F-Score. The differences are 3.7% on PKU corpora and 3.1% on MSRA corpora.

An phenomenon we should pay attention to is the poor performance of the HMM-based model. With our implementation of the Bayesian HMM, we achieves a 34.3% F-Score on PKU corpora and a 34.9% F-Score on MSRA corpora, just slightly better than random segmentation. The result show that the hidden Markov Model alone is not suitable for character-based Chinese word segmentation problem. However, it still substantially contributes to the joint model.

We find that the variance of the results are rather small, this shows the stability of our Gibbs samplers. From the segmentation results generated by the joint model, we also found that quite a large amount of errors it made are related to dates, numbers (both Chinese and English) and English words. This problem can be easily addressed during preprocessing by considering encoding information as previous work, and we believe this will bring us much better performance.

4.4 Disambiguation Ability

Previous unsupervised work usually evaluated their models using F-score, regardless of goodness measure based model or nonparametric Bayesian model. However, segmentation ambiguity is a very important factor influencing accuracy of Chinese word segmentation systems (Huang and Zhao, 2007). We believe that the disambiguation ability of the models should also be considered when evaluating different types of unsupervised segmentation systems, since different type of models shows different disambiguation ability. We will compare the disambiguation ability of dif-

ferent systems in this section.

In general, there are mainly two kinds of ambiguity in Chinese word segmentation problem:

- **Combinational Ambiguity**: Given character strings "A" and "B", if "A", "B", "AB" are all in the vocabulary, and "AB" or "A-B" (here "-" denotes a space) occurred in the real text,then "AB" can be called a combinational ambiguous string.
- **Overlapping Ambiguity**: Given character strings "A", "J" and "B", if "A", "B", "AJ" and "JB" are all in the vocabulary, and "A-JB" or "AJ-B" occurred in the real text, then "AJB" can be called an overlapping ambiguous string.

We count the total number of mistakes different systems made at ambiguous strings (the vocabulary is obtained from the gold standard answer of testing set). As we have mentioned in Section 2, goodness measure based methods such as nVBE do not have any disambiguation ability in theory. Our observation is identical to this argument. We find that nVBE always segments ambiguous strings into the same result. Take a combinational string "只有" as an example, "只 (just)", "有 (have)" and "只有 (only)" are all in the vocabulary. In the PKU test set, this string occurs 14 times as "只-有 (just have)" and 18 times as "只有 (only)", 32 times in total. nVBE segments all the 32 strings into "只有 (only)" (i.e. 18 of them are correct), while the joint model segments it 22 times as "只有 (only)" and 10 times as "只-有 (just have)" according to its context, and 24 of them are correct.

Table 3 and 4 show the statistics of combinational ambiguity and overlapping ambiguity respectively. The numbers in parentheses denote the total number of ambiguous strings. From these tables, we can see that HDP+nVBE makes less mistakes than nVBE in most circumstances, except that it solves less combinational ambiguities on MSRA corpora. But our proposed joint model solves the most combinational and overlapping ambiguities, on both PKU and MSRA corpora. Specifically, compared to nVBE, the joint model correctly solves 171/871 more combinational ambiguities on PKU/MSRA corpora, which is a $0.6\%/13.8\%$ relative error reduction. It also solves 28/45 more overlapping ambiguities on PKU/MSRA corpora, which is a $11.5\%/23.4\%$ relative error reduction. This indicates that the joint model has a stronger ability of disambiguation over the compared systems.

System	PKU(35371)	MSRA(38506)
nVBE	8087	7236
HDP+nVBE	7970	7500
Joint	**7916**	**6305**

Table 3: Statistics of combinational ambiguity. This table shows the total number of mistakes made by different systems at combinational ambiguous strings. The numbers in parentheses denote the total number of combinational ambiguous strings.

System	PKU(603)	MSRA(467)
nVBE	244	192
HDP+nVBE	239	164
Joint	**216**	**157**

Table 4: Statistics of overlapping ambiguity. This table shows the total number of mistakes made by different systems at overlapping ambiguous strings. The numbers in parentheses denote the total number of overlapping ambiguous strings.

4.5 Statistical Significance Test

The main results presented in Table 2 has shown that our proposed joint model outperforms the two baselines as well as state-of-the-art systems. But it is also important to know if the improvement is statistically significant over these systems. So we conduct statistical significance tests of F-scores among these various models. Following Wang et al. (2010), we use the bootstrapping method (Zhang et al., 2004).

Here is how it works: suppose we have a testing set T_0 to test several word segmentation systems, there are N testing examples (sentences or line of characters) in T_0. We create a new testing set T_1 with N examples by sampling with replacement from T_0, then repeat these process $M-1$ times. And we will have a total $M+1$ testing sets. In our test procedures, M is set to 2000.

Since we just implement our joint model and its component models, we can not generate paired samples for other models (i.e. ESA and NPY(n)). Instead, we follow Wang et al. (2010)'s method and first calculate the 95% confidence interval for

our proposed model. Then other systems can be compared with the joint model in this way: if the F-score of system **B** doesn't fall into the 95% confidence interval of system **A**, they are considered as statistically significantly different from each other.

For all significant tests, we measure the 95% confidence interval for the difference between two models. First, the test results show that "HDP+nVBE" and "HDP+HMM" are both significantly better than "HDP". Second, the "Joint" model significantly outperforms all its component models, including "HDP", "nVBE", "HDP+nVBE" and "HDP+HMM". Finally, the comparison also shows that the joint model significantly outperforms state-of-the-art systems like ESA and NPY(n).

5 Conclusion

In this paper, we proposed a joint model for unsupervised Chinese word segmentation. Our joint model is a combination of the HDP-based model, which is a word-based model, and HMM-based model, which is a character-based model. The way we combined these two component baselines makes it natural and simple to inference with Gibbs sampling. Then the joint model take advantage of a goodness-based method (nVBE) by using it to initialize the sampler. Experiment results conducted on PKU and MSRA datasets provided by the second SIGHAN Bakeoff show that the proposed joint model not only outperforms the baseline systems but also achieves better performance (F-Score) over several state-of-the-art systems. Significance tests showed that the improvement is statistically significant. Analysis also indicates that the joint model has a stronger ability to solve ambiguities in Chinese word segmentation. In summary, the joint model we proposed combines the strengths of character-based model, nonparametric Bayesian language model and goodness-based model.

Abstract

Supervised methods have been the dominant approach for Chinese word segmentation. The performance can drop significantly when the test domain is different from the training domain. In this paper, we study the problem of obtaining partial annotation from freely available data to help Chinese word segmentation on different domains. Different sources of free annotations are transformed into a unified form of partial annotation and a variant CRF model is used to leverage both fully and partially annotated data consistently. Experimental results show that the Chinese word segmentation model benefits from free partially annotated data. On the SIGHAN Bakeoff 2010 data, we achieve results that are competitive to the best reported in the literature.

1 Introduction

Statistical Chinese word segmentation gains high accuracies on newswire (Xue and Shen, 2003; Zhang and Clark, 2007; Jiang et al., 2009; Zhao et al., 2010; Sun and Xu, 2011). However, manually annotated training data mostly come from the news domain, and the performance can drop severely when the test data shift from newswire to blogs, computer forums and Internet literature (Liu and Zhang, 2012).

Several methods have been proposed for solving the domain adaptation problem for segmentation, which include the traditional token- and type-supervised methods (Song et al., 2012; Zhang et al., 2014). While token-supervised methods rely on manually annotated target-domain sentences, type-supervised methods leverage manually assembled domain-specific lexicons to improve target-domain segmentation accuracies. Both methods are competitive given the same amount of annotation effects (Garrette and Baldridge, 2012; Zhang et al., 2014). However, obtaining manually annotated data can be expensive.

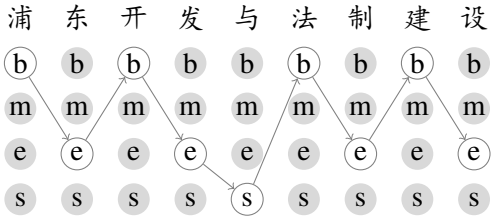

Figure 1: The segmentation problem, illustrated using the sentence "浦东 (Pudong) 开发 (development) 与 (and) 法制 (legal) 建设 (construction)". Possible segmentation labels are drawn under each character, where *b, m, e, s* stand for the beginning, middle, end of a multi-character word, and a single character word, respectively. The path shows the correct segmentation by choosing one label for each character.

On the other hand, there are *free* data which contain limited but useful segmentation information over the Internet, including large-scale unlabeled data, domain-specific lexicons and semi-annotated web pages such as Wikipedia. In the last case, word-boundary information is contained in hyperlinks and other markup annotations. Such free data offer a useful alternative for improving the segmentation performance, especially on domains that are not identical to newswire, and for which little annotation is available.

In this paper, we investigate techniques for adopting freely available data to help improve the performance on Chinese word segmentation. We propose a simple but robust method for constructing partial segmentation from different sources of free data, including unlabeled data and the Wikipedia. There has been work on making use of both unlabeled data (Sun and Xu, 2011; Wang et al., 2011) and Wikipedia (Jiang et al., 2013)

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 864–874,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

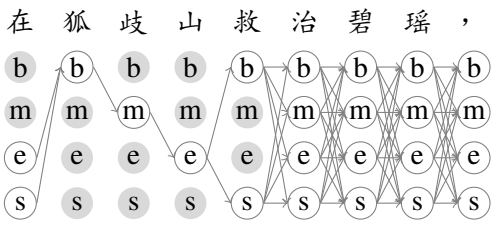
to improve segmentation. However, no empirical results have been reported on a unified approach to deal with different types of free data. We use a conditional random fields (Lafferty et al., 2001; Tsuboi et al., 2008) variant that can leverage the partial annotations obtained from different sources of free annotation. Training is achieved by a modification to the learning objective, incorporating partial annotation likelihood, so that a single model can be trained consistently with a mixture of full and partial annotation.

Experimental results show that our method of using partially annotated data can consistently improves cross-domain segmentation performance. We obtain results which are competitive to the best reported in the literature. Our segmentor is freely released at `https://github.com/ExpResults/partial-crfsuite`.

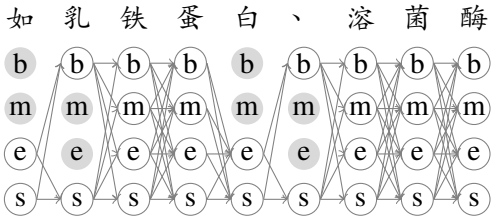
2 Obtaining Partially Annotated Data

We model the Chinese word segmentation task as a character sequence tagging problem, which is to give each character in a sentence a word-boundary tag (Xue and Shen, 2003). We adopt four tags, *b, m, e* and *s*, which represent the *b*eginning, *m*iddle, *e*nd of a multi-character word, and a *s*ingle character word, respectively. A manually segmented sentence can be represented as a tag sequence, as shown in Figure 1.

We investigate two major sources of freely-available annotations: lexicons and natural annotation, both with the help of unannotated data. To make use of the first source of information, we incorporate words from a lexicon into unannotated sentences by matching of character sequences, resulting in partially annotated sentences, as shown in Figure 2a. In this example, the word "狐岐山 (the Huqi Mountain)" in the unannotated sentence matches an item in the lexicon. As a result, we obtain a partially-annotated sentence, in which the segmentation ambiguity of the characters "狐 (fox)", "岐 (brandy road)" and "山 (mountain)" are resolved ("狐" being the beginning, "岐" being the middle and "山" being the end of the same word). At the same time, the segmentation ambiguity of the surrounding characters "在 (at)" and "救 (save)" are reduced ("在" being either a single-character word or the end of a multi-character word, and "救" being either a single-character word or the beginning of a multi-character word).



(a) "在 (at) 狐岐山 (Huqi Mountain) 救 治 (save) 碧 瑶 (Biyao)", where "狐岐山" matches a lexicon word.



(b) "如 (e.g.) 乳铁蛋白 (lysozyme) 、 溶菌酶 (lactoferrin)", where "乳铁蛋白" is a hyperlink.

Figure 2: Examples of partially annotated data. The paths show possible correct segmentations.

Natural annotation, which refers to word boundaries that can be inferred from URLs, fonts or colors on web pages, also result in partially-annotated sentences. Taking a web page shown in Figure 2b for example. It can be inferred from the URL tags on "乳铁蛋白" that "乳" should be either the beginning of a multi-character word or a single-character word, and "白" should be either the end a multi-character word or single-character word. Similarly, possible tags of the surrounding character "如" and "、" can also be inferred.

We turn both lexicons and natural annotation into the same form of *partial annotation* with same unresolved ambiguities, as shown in Figure 2, and use them together with available *full annotation* (Figure 1) as the training data for the segmentor. In this section, we describe in detail how to obtain partially annotated sentences from each resource, respectively.

2.1 Lexicons

In this scenario, we assume that there are unlabeled sentences along with a lexicon for the target domain. We obtain partially segmented sentences by extracting word boundaries from the unlabeled sentences with the help of the lexicon. Previous matching methods (Wu and Tseng, 1993; Wong and Chan, 1996) for Chinese word segmentation largely rely on the lexicons, and are generally considered being weak in ambiguity resolution (Gao

(b) Similar subsequence "字段(field)" is segmented differently under different domains in Wikipedia.

Table 1: Examples natural annotation from Wikipedia. Underline marks annotated words.

et al., 2005). But for obtaining the partial labeled data with lexicon, the matching method can still be a solution. Since we do not aim to recognize every word from sentence, we can select a lexicon with smaller coverage but less ambiguity to achieve relatively precise matching result.

In this paper, we apply two matching schemes to the same raw sentences to obtain partially annotated sentences. The first is a simple forward-maximum matching (FMM) scheme, which is very close to the forward maximum matching algorithm of Wu and Tseng (1993) for Chinese word segmentation. This scheme scans the input sentence from left to right. At each position, it attempts to find the longest subsequence of Chinese characters that matches a lexicon entry. If such an entry is found, the subsequence is tagged with the corresponding tags, and its surrounding characters are also constrained to a smaller set of tags. If no subsequence is found in the lexicon, the character is left with all the possible tags. Taking the sentence in Figure 2a for example. When the algorithm scans the second character, "狐", and finds the entry "狐岐山" in the lexicon, the subsequence of characters is recognized as a word, and tagged with *b, m* and *e*, respectively. At the same time, the previous character "在" can be inferred as only end of a multi-character word (*e*) or a single-character word (*s*). The second matching scheme is backward maximum matching, which can be treated as the application of FMM on the reverse of unlabeled sentences using a lexicon of reversed words.

To mitigate the errors resulting from one single matching scheme, we combine the two matching results by agreement. The basic idea is that if a subsequence of sentence is recognized as word by multiple matching results, it can be considered as a more precise annotation. Our algorithm reads partial segmentation by different methods and selects the subsequences that are identified as word by all methods as annotated words.

2.2 Natural Annotation

We use the Chinese Wikipedia for natural annotation. Partially annotated sentences are readily formed in Wikipedia by markup syntax, such as URLs. However, some subtle issues exist if the sentences are used directly. One problem is incompatibility of segmentation standards between the annotated training data and Wikipedia. Jiang et al. (2009) discuss this incompatibility problem between two corpora — the CTB and the People's Daily; the problem is even more severe on Wikipedia because it can be edited by any user. Table 1a shows a case of incompatible annotation between the People's Daily data and natural annotation in Wikipedia, where the three characters "旅游业" are segmented differently. Both can be treated as correct, although they have different segmentation granularities.

Another problem is the intrinsic ambiguity of segmentation. The same character sequence can be segmented into different words under different contexts. If the training and test data contain different contexts, the learned model can give incorrect results on the test data. This is particularly true across different domains. Table 1b gives such an example, where the character sequence "字段" is segmented differently in two of our test domains, but both cases exist in Wikipedia.

In summary, Wikipedia introduces both useful information for domain adaptation and harmful noise with negative effects on the model. To

achieve better performance of domain adaptation using Wikipedia, one intuitive approach is to select more domain-related data and less irrelevant data to minimize the risks that result from incompatible annotation and domain difference.

To this end, we assume that there are some raw sentences on the target domain, which can be used to evaluate the relevance between Wikipedia and target domain test data. We assume that URL-tagged entries reflect the segmentation standards of Wikipedia sentence, and use them to match Wikipedia sentences with the raw target domain data. If the character sequence of any URL-tagged entry in a Wikipedia sentence matches the target domain data, the Wikipedia sentence is selected for training. Another advantage of such data selection is that the training time consumption can be reduced by reducing the size of training data.

3 CRF for Word Segmentation

We follow the work of Zhao et al. (2010) and Sun and Xu (2011), and adopt the Conditional Random Fields (CRF) model (Lafferty et al., 2001) for the sequence labeling problem of word segmentation. Given an input characters sequence, the task is to assign one segmentation label from $\{b, m, e, s\}$ on each character. Let $\mathbf{x} = (x_1, x_2, ..., x_T)$ be the sequence of characters in sentence whose length is T, and $\mathbf{y} = (y_1, y_2, ..., y_T)$ be the corresponding label sequence, where $y_i \in Y$. The linear-chain conditional random field for Chinese word segmentation can be formalized as

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z} \exp \sum_{t=1}^{T} \sum_{k} \lambda_k f_k(y_t, y_{t-1}, \mathbf{x}) \quad (1)$$

where λ_k are the model parameters, f_k are the feature functions and Z is the probability normalizer.

$$Z = \sum_{\mathbf{y}} \exp \sum_{t=1}^{T} \sum_{k} \lambda_k f_k(y_t, y_{t-1}, \mathbf{x}) \quad (2)$$

We follow Sun and Xu (2011) and use the feature templates shown in Table 2 to model the segmented task. For ith character in the sentence, the n-gram features represent the surrounding characters of this character; $Type$ categorizes the character it into $digit$, $punctuation$, $english$ and $other$; $Identical$ indicates whether the input character is the same with its surrounding characters. This feature captures repetition patterns such as "试试 (try)" or "走走 (stroll)".

Type	Template
unigram	C_s $(i-3 < s < i+3)$
bigram	C_sC_{s+1} $(i-3 < s < i+2)$
	C_sC_{s+2} $(i-3 < s < i+1)$
type	$Type(C_i)$
	$Type(C_s)Type(C_{s+1})$ $(i-1 < s < i+2)$
identical	$Identical(C_s, C_{s+1})$ $(i-3 < s < i+1)$
	$Identical(C_s, C_{s+2})$ $(i-3 < s < i)$

Table 2: Feature templates for the ith character.

For fully-annotated training data, the learning problem of conditional random fields is to maximize the log likelihood over all the training data (Lafferty et al., 2001)

$$\mathcal{L} = \sum_{n=1}^{N} \log p(\mathbf{y}^{(n)}|\mathbf{x}^{(n)})$$

Here N is the number of training sentences. Both the likelihood $p(\mathbf{y}^{(n)}|\mathbf{x}^{(n)})$ and its gradient can be calculated by performing the forward-backward algorithm (Baum and Petrie, 1966) on the sequence, and several optimization algorithm can be adopted to learn parameters from data, including L-BFGS (Liu and Nocedal, 1989) and SGD (Bottou, 1991).

4 Training a CRF with partially annotated data

For word segmentation with partially annotated data, some characters in a sentence can have a definite segmentation label, while some can have multiple labels with ambiguities remaining. Taking the partially annotated sentence in Figure 2a for example, the corresponding potential label sequence for "在狐岐山救" is $\{(e, s), (b), (m), (e), (b, s)\}$, where the characters "狐", "岐" and "山" have fixed labels but for "在" and "救", some ambiguities exist. Note that the full annotation in Figure 1 can be regarded as a special case of partial annotation, where the number of potential labels for each character is one.

We follow Tsuboi et al. (2008) and model marginal probabilities over partially annotated data. Define the possible labels that correspond to the partial annotation as $\mathbf{L} = (L_1, L_2, ..., L_T)$, where each L_i is a non-empty subset of Y that corresponds to the set of possible labels for x_i. Let

$\mathbf{Y_L}$ be the set of all possible label sequences where $\forall \mathbf{y} \in \mathbf{Y_L}$, $y_i \in L_i$. The marginal probability of $\mathbf{Y_L}$ can be modeled as

$$p(\mathbf{Y_L}|\mathbf{x}) = \frac{1}{Z} \sum_{\mathbf{y} \in \mathbf{Y_L}} \exp \sum_{t=1}^{T} \sum_{k} \lambda_k f_k(y_t, y_{t-1}, \mathbf{x}) \quad (3)$$

Defining the unnormalized marginal probability as

$$Z_{\mathbf{Y_L}} = \sum_{\mathbf{y} \in \mathbf{Y_L}} \exp \sum_{t=1}^{T} \sum_{k} \lambda_k f_k(y_t, y_{t-1}, \mathbf{x}),$$

and the normalizer Z being the same as Equation 2, the log marginal probability of $\mathbf{Y_L}$ over N partially annotated training examples can be formalized as

$$\mathcal{L}_{\mathbf{Y_L}} = \sum_{n=1}^{N} \log p(\mathbf{Y_L}|\mathbf{x}) = \sum_{n=1}^{N} (\log Z_{\mathbf{Y_L}} - \log Z)$$

The gradient of the likelihood can be written as

$$\frac{\partial \mathcal{L}_{\mathbf{Y_L}}}{\partial \lambda_k} = \sum_{n=1}^{N} \sum_{t=1}^{T} \sum_{\substack{y_{\mathbf{Y_L}} \in L_t, \\ y'_{\mathbf{Y_L}} \in L_{t-1}}} f_k(y_{\mathbf{Y_L}}, y'_{\mathbf{Y_L}}, \mathbf{x}) p_{\mathbf{Y_L}}(y_{\mathbf{Y_L}}, y'_{\mathbf{Y_L}}|\mathbf{x}) - \sum_{n=1}^{N} \sum_{t=1}^{T} \sum_{y,y'} f_k(y, y', \mathbf{x}) p(y, y'|\mathbf{x})$$

Both $Z_{\mathbf{Y_L}}$ and its gradient are similar in form to Z. By introducing a modification to the forward-backward algorithm, $Z_{\mathbf{Y_L}}$ and $\mathcal{L}_{\mathbf{Y_L}}$ can be calculated. Define the *forward variable* for partially annotated data $\alpha_{\mathbf{Y_L},t}(j) = p_{\mathbf{Y_L}}(x_{\langle 1,\ldots,t \rangle}, y_t = j)$. A modification on the forward algorithm can be formalized as

$$\alpha_{\mathbf{Y_L},t}(j) = \begin{cases} 0 & j \notin L_t \\ \sum_{i \in L_{t-1}} \Psi_t(j, i, x_t) \alpha_{\mathbf{Y_L},t-1}(i) & j \in L_t \end{cases}$$

where $\Psi_t(j, i, x)$ is a potential function that equals $\sum_k \lambda_k f_k(y_t = j, y_{t-1} = i, x_t)$. Similarly, for the *backward variable* $\beta_{\mathbf{Y_L},t}$,

$$\beta_{\mathbf{Y_L},t}(i) = \begin{cases} 0 & i \notin L_t \\ \sum_{j \in L_{t+1}} \Psi_t(j, i, x_{t+1}) \beta_{\mathbf{Y_L},t+1}(j) & i \in L_t \end{cases}$$

$Z_{\mathbf{Y_L}}$ can be calculated by $\alpha_{\mathbf{Y_L}}(T)$, and $p_{\mathbf{Y_L}}(y, y'|x)$ can be calculated by $\alpha_{\mathbf{Y_L},t-1}(y') \Psi_t(y, y', x_t) \beta_{\mathbf{Y_L},t}(y)$.

Note that if each element in $\mathbf{Y_L}$ is constrained to one single label, the CRF model in Equation 3 degrades into Equation 1. So we can train a unified model with both fully and partially annotated data. We implement this CRF model based on a open source toolkit CRFSuite.[1] In our experiments, we use the L-BFGS (Liu and Nocedal, 1989) algorithm to learn parameters from both fully and partially annotated data.

5 Experiments

We perform our experiments on the domain adaptation test data from SIGHAN Bakeoff 2010 (Zhao et al., 2010), adapting annotated training sentences from People's Daily (PD) (Yu et al., 2001) to different test domains. The fully annotated data is selected from the People's Daily newspaper in January of 1998, and the four test domains from the SIGHAN Bakeoff 2010 include finance, medicine, literature and computer. Sample segmented data in the computer domain from this bakeoff is used as development set. Statistics of the data are shown in first half of Table 3. We use wikidump20140419[2] for the Wikipedia data. All the traditional Chinese pages in Wikipedia are converted to simplified Chinese. After filtering functional pages like *redirection* and removing duplication, 5.45 million sentences are reserved.

For comparison with related work on using a lexicon to improve segmentation, another set of test data is chosen for this setting. We use the Chinese Treebank (CTB) as the source domain data, and Zhuxian (a free Internet novel, also named as "Jade dynasty", referred to as ZX henceforth) as the target domain data.[3] The ZX data are written in a different style from newswire, and contains many out-of-vocabulary words. This setting has been used by Liu and Zhang (2012) and Zhang et al. (2014) for domain adaptation of segmentation and POS-tagging. We use the standard training, development and test split. Statistics of the test data annotated by Zhang et al. (2014) are shown in the second half of Table 3.

The data preparation method in Section 2 and the CRF method in Section 4 are used for all the experiments. Both recall of out-of-vocabulary words (R_{oov}) and F-score are used to evaluate the

segmentation performance. There is a mixture of Chinese characters, English words and numeric expression in the test data from SIGHAN Bakeoff 2010. To test the influence of Wikipedia data on Chinese word segmentation alone, we apply regular expressions to detect English words and numeric expressions, so that they are marked as *not segmented*. After performing this preprocessing step, cleaned test input data are fed to the CRF model to give a relatively strong baseline.

5.1 Free Lexicons

5.1.1 Obtaining lexicons

For domain adaption from CTB to ZX, we use a lexicon released by Zhang et al. (2014). The lexicon is crawled from a online encyclopedia[4], and contains the names of 159 characters and artifacts in the Zhuxian novel. We follow Zhang et al. (2014) and name it **NR** for convenience of further discussion. The NR lexicon can be treated as a strongly domain-related, high quality but relatively small lexicon. It's a typical example of freely available lexicon over the Internet.

For domain adaptation from PD to medicine and computer, we collect a list of page titles under the corresponding categories in Wikipedia. For medicine, entries under *essential medicines*, *biological system* and *diseases* are collected. For computer, entries under *computer network*, *Microsoft Windows* and *software widgets* are selected. These lexicons are typical freely available lexicons that we can access to.

5.1.2 Obtaining Unlabeled Sentences

For ZX, partially annotated sentences are obtained using the *NR* lexicon and unlabeled ZX sentences by applying the matching scheme described in Section 2. The CTB5 training data and the partially annotated data are mixed as the final training data. Different amounts of unlabeled data are applied to the development test set, and results are shown in Figure 3. From this figure we can see that incorporating 16K sentences gives the highest accuracy, and adding more partial labeled data does not change the accuracy significantly. So for the ZX experiments, we choose the 16K sentences as the unlabeled data.

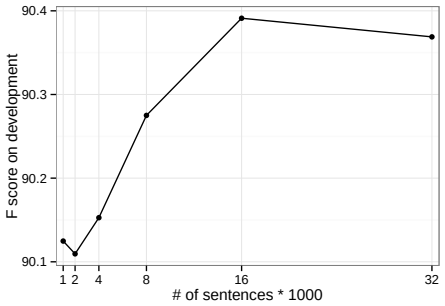

Figure 3: F-score on the development data when using different numbers of unlabeled data.

For the medicine and computer experiments, we selected domain-specific sentences by matching with the domain-specific lexicons. About 46K out of the 5.45 million wiki sentences contain subsequences in the medicine lexicon and 22K in the case of the computer domain. We randomly select 16K sentences as the unlabeled data for each domain, respectively.

5.1.3 Final results

We incorporate the partially annotated data obtained with the help of lexicon for each of the test domain. For adaptation from CTB to ZX, we trained our baseline model on the CTB5 training data with the feature templates in Table 2. For adaptation from PD to medicine and computer, we

trained our baseline model on the PD training data with the same feature template setting.

Previous research makes use of a lexicon by adding lexicon features directly into a model (Sun and Xu, 2011; Zhang et al., 2014), rather than transforming them into partially annotated sentences. To make a comparison, we follow Sun and Xu (2011) and add three lexicon features to represent whether c_i is located at the beginning, middle or the end of a word in the lexicon, respectively. For each test domain, the lexicon for the lexicon feature model consists of the most frequent words in the source domain training data (about 6.7K for CTB5 and 8K for PD, respectively) and the domain-specific lexicon we obtained in Section 5.1.1.

The results are shown in Table 4, where the first row shows the performance of the baseline models and the second row shows the performance of the model incorporating lexicon feature. The third row shows our method using partial annotation. On the ZX test set, our method outperforms the baseline by more than 3 absolute percentage. The model with partially annotated data performs better than the one with additional lexicon features. Similar conclusion is obtained when adapting from PD to medicine and computer. By incorporating the partially annotated data, the segmentation of lexicon words, along with the context, is learned.

We also compare our method with the work of Zhang et al. (2014), who reported results only on the ZX test data. We use the same lexicon settings. Our method gives better result than Zhang et al. (2014), showing that the combination of a lexicon and unannotated sentence into partially annotated data can lead to better performance than using a dictionary alone in type-supervision. Given that we only explore the use of free resource, combining a lexicon with *unannotated* sentences is a better option than using the lexicon directly. Zhang et al.'s concern, on the other hand, is to compare type- and token-annotation. Our partial annotation can thus be treated as a compromise to obtain some *pseudo* partial token-annotations when *full* token annotations are unavailable. Another thing to note is that the model of Zhang et al. (2014) is a joint model for segmentation and POS-tagging, which is generally considered stronger than a single segmentation model.

Table 5: The performance of data selection on the development set of the computer domain.

5.2 Free Natural Annotation

When extracting word boundaries from Wikipedia sentences, we ignore natural annotations on English words and digits because these words are recognized by the preprocessor. Following Jiang et al. (2013), we also recognize a naturally annotated two-character subsequence as a word.

5.2.1 Effect of data selection

To make better use of more domain-specific data, and to alleviate noise in partial annotation, we apply the selection method proposed in Section 2 to the Wikipedia data. On the computer domain development test data, this selection method results in 9.4K computer-related sentences with partial annotation. A model is trained with both the PD training data and the partially annotated computer domain Wikipedia data. For comparison, we also trained a model with 160K randomly selected Wikipedia sentences. The experimental result is shown in Table 5. The model incorporating selected data achieves better performance compared to the model with randomly sampled data, demonstrating that data selection is helpful to improving

the domain adaption accuracy.

5.2.2 Final Result

The final results on the four test domains are shown in Table 6. From this table, we can see that significant improvements are achieved with the help of the partially annotated Wikipedia data, when compared to the baseline. The models trained with selected partial annotation perform better than those trained with random partial annotation. Our F-scores are competitive to those reported by Jiang et al. (2013). However, since their model is trained on a different source domain, the results are not directly comparable.

5.2.3 Analysis

In this section, we study the effect of Wikipedia on domain adaptation when no data selection is performed, in order to analyze the effect of partially annotated data. We randomly sample 10K, 20K, 40K, 80K and 160K sentences from the 5.45 million Wikipedia sentences, and incorporate them into the training process, respectively. Five models are obtained adding the baseline, and we test their performances on the four test domains. Figure 4 shows the results.

From the figure we can see that for the medicine and computer domains, where the OOV rate is relatively high, the F-score generally increases when more data from Wikipedia are used. The trends of F-score and OOV recall against the volume of Wikipedia data are almost identical. However, for the finance and literature domains, which have low OOV rates, such a relation between data size and accuracy is not witnessed. For the literature domain, even an opposite trends is shown.

We can draw the following conclusions: (1) Natural annotation on Wikipedia data contributes to the recognition of OOV words on domain adaptation; (2) target domains with more OOV words benefit more from Wikipedia data. (3) along with the positive effect on OOV recognition, Wikipedia data can also introduce noise, and hence data selection can be useful.

5.3 Combining Lexicon and Natural Annotation

To make the most use of free annotation, we combine available free lexicon and natural annotation resources by joining the partially annotated sentences derived using each resource, training our CRF model with these partially annotated sentences and the fully annotated PD sentences. The tests are performed on medicine and computer domains. Table 7 shows the results, where further improvements are made on both domains when the two types of resources are combined.

6 Related Work

There has been a line of research on making use of unlabeled data for word segmentation. Zhao and Kit (2008) improve segmentation performance by mutual information between characters, collected from large unlabeled data; Li and Sun (2009) use punctuation information in a large raw corpus to learn a segmentation model, and achieve better recognition of OOV words; Sun and Xu (2011) explore several statistical features derived from unlabeled data to help improve character-based word segmentation. These investigations mainly focus on in-domain accuracies. Liu and Zhang (2012)

study domain adaptation using an unsupervised self-training method. In contrast to their work, we make use of not only unlabeled data, but also leverage any free annotation to achieve better results for domain adaptation.

There has also been work on making use of a dictionary and natural annotation for segmentation. Zhang et al. (2014) study type-supervised domain adaptation for Chinese segmentation. They categorize domain difference into two types: different vocabulary and different POS distributions. While the first type of difference can be effectively resolved by using lexicon for each domain, the second type of difference needs to be resolved by using annotated sentences. They found that given the same manual annotation time, a combination of the lexicon and sentence is the most effective. Jiang et al. (2013) use 160K Wikipedia sentences to improves segmentation accuracies on several domains. Both Zhang et al. (2014) and Jiang et al. (2013) work on discriminative models using the structure perceptron (Collins, 2002), although they study two different sources of information. In contrast to their work, we unify both types of information under the CRF framework.

CRF has been used for Chinese word segmentation (Tseng, 2005; Shi and Wang, 2007; Zhao and Kit, 2008; Wang et al., 2011). However, most previous work train a CRF by using full annotation only. In contrast, we study CRF based segmentation by using both full and partial annotation.

Several other variants of CRF model has been proposed in the machine learning literature, such as the generalized expectation method (Mann and McCallum, 2008), which introduce knowledge by incorporating a manually annotated feature distribution into the regularizer, and the JESS-CM (Suzuki and Isozaki, 2008), which use a EM-like method to iteratively optimize the parameter on both the annotated data and unlabeled data. In contrast, we directly incorporate the likelihood of partial annotation into the objective function. The work that is the most similar to ours is Tsuboi et al. (2008), who modify the CRF learning objective for partial data. They focus on Japanese lexical analysis using manually collected partial data, while we investigate the effect of partial annotation from freely available sources for Chinese segmentation.

7 Conclusion

In this paper, we investigated the problem of domain adaptation for word segmentation, by transferring various sources of free annotations into a consistent form of partially annotated data and applying a variant of CRF that can be trained using fully- and partially-annotated data simultaneously. We performed a large set of experiments to study the effectness of free data, finding that they are useful for improving segmentation accuracy. Experiments also show that proper data selection can further benefit the model's performance.

Abstract

Most studies on statistical Korean word spacing do not utilize the information provided by the input sentence and assume that it was completely concatenated. This makes the word spacer ignore the correct spaced parts of the input sentence and erroneously alter them. To overcome such limit, this paper proposes a structural SVM-based Korean word spacing method that can utilize the space information of the input sentence. The experiment on sentences with 10% spacing errors showed that our method achieved 96.81% F-score, while the basic structural SVM method only achieved 92.53% F-score. The more the input sentence was correctly spaced, the more accurately our method performed.

1 Introduction

Automatic word spacing is a task to decide boundaries between words, which is frequently used for correcting spacing errors of text messages, Tweets, or Internet comments before using them in information retrieval applications (Lee and Kim, 2012). It is also often used in post-processing optical character recognition (OCR) or voice recognition (Lee et al., 2007). Except for some Asian languages such as Chinese, Japanese and Thai, most languages have explicit word spacing that improves the readability of the text and helps readers better understand the meaning of it. Korean especially has a tricky word spacing system and users often make mistakes, which makes automatic word spacing an interesting and essential task.

In order to easily acquire the training data, most studies on statistical Korean word spacing assume that well-spaced raw text (e.g. newspaper articles) is perfectly spaced and use it for training (Lee and Kim, 2012; Lee and Kim, 2013; Lee et al., 2007; Shim, 2011). This approach, however, cannot observe incorrect spacing since the assumption makes the training data devoid of negative example. Consequently, word spacers cannot use the spacing information given by the user, and erroneously alter the correctly spaced parts of the sentence. To utilize the user-given spacing information, a corpus of input sentences and their correctly spaced version is necessary. Constructing such corpus, however, requires much time and resource.

In this paper, to resolve such issue, we propose a structural SVM-based Korean word spacing model that can utilize the word spacing information given by the user. We name the proposed model "Balanced Word Spacing Model (BWSM)". Our approach trains a basic structural SVM-based Korean word spacing model as in (Lee and Kim, 2013), and tries to obtain the sentence which achieves the maximum score for the basic model while minimally altering the input sentence.

In the following section, we discuss related studies. In Section 3, the proposed method and its relation to Karush-Kuhn-Tucker (KKT) condition are explained. The experiment and discussion is presented in Section 4. Finally, in Section 5, the conclusion and future work for this study is given.

2 Related Work

There are two common approaches to Korean word spacing: rule-based approach and statistical approach. In rule-based approach, it is not easy to construct rules and maintain them. Furthermore, it requires morphological analysis to apply rule-based approach, which slows down the process. Recent studies, therefore, mostly focus on the statistical approach.

Most statistical approaches use well-spaced raw corpus as training data (e.g. newspaper articles) assuming that they are perfectly spaced. This is to avoid the expensive job of constructing new training data. Lee et al. (2007) treated the word spacing task as a sequence labeling problem on the input sentence which is a sequence of syllables. They proposed a method based on Hidden Markov Model (HMM). Shim (2011) also considered the word spacing task as a sequence labeling problem and proposed a method using Conditional Random Field (CRF) (Lafferty et al., 2001), which is a well-known powerful model for sequence labeling tasks. Lee and Kim

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 875–879,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

(2013) tried to solve the sequence labeling problem using structural SVM (Tsochantaridis et al., 2004; Joachims et al., 2009; Lee and Jang 2010; Shalev-Shwartz et al., 2011).

The studies above (Lee and Kim, 2013; Lee et al., 2007; Shim, 2011), however, do not take advantage of the spacing information provided by the user, and often erroneously alter the correctly spaced part of the sentence. Lee et al. (2007) tries to resolve this issue by combining an HMM model with an additional confidence model constructed from another corpus. Given an input sentence, they first apply the basic HMM model to obtain a candidate sentence. For every different word spacing between the input sentence and the candidate sentence, they calculate and compare the confidence using the confidence model, and whichever gets the higher confidence is used. The spacing accuracy was improved from 97.52% to 97.64%[1].

This study is similar to (Lee et al., 2007) in that it utilizes the spacing information given by the user. But unlike (Lee et al., 2007), BWSM uses structural SVM as the basic model and do not require an additional confidence model. Furthermore, while Lee et al. (2007) compares the spacing confidence for each syllable to obtain the final outcome, BWSM considers the whole sentence when altering its spacing, enabling it to achieve higher improvement on performance (from 92.53% F-score to 96.81% F-score).

3 Balanced Word Spacing Model

Like previous studies, the proposed model treats the Korean word spacing task as a sequence labeling problem. The label consists of *B* and *I*, which are assigned to each syllable of the sentence. Assuming that $\mathbf{x} = \langle x_1, x_2, \ldots, x_T \rangle$ is a sequence of total *T* syllables of the input sentence and $\mathbf{y} = \langle y_1, y_2, \ldots, y_T \rangle$ is a sequence of labels for each syllable, an example could be given as follows[2]:

Input: ah/beo/ji/ga bang/eh deul/eo/ga/sin/da (Father entered the room)
x = <ah, beo, ji, ga, bang, eh, deul, eo, ga, sin, da>
y = <B, I, I, I, B, I, B, I, I, I, I>

Figure 1: An example of word spacing.

In order to utilize the spacing information provided by the user, we propose a new model, the Balanced Word Spacing Model that adheres to the following principles:

1. The model must obtain the most likely sequence of labels($\mathbf{y}^*$), while minimally altering the user-given sequence of labels ($\mathbf{y}_{input}$).
2. We assume that it costs α per syllable to change the spacing of the original sentence, in order to keep the original spacing information as much as possible.

Mathematically formulating the above principles would give us the following equation:

$$\mathbf{y}^* = \text{argmax}\{score(\mathbf{x}, \mathbf{y}) - \alpha \cdot L(\mathbf{y}_{input}, \mathbf{y})\} \quad (1)$$

In Equation 1, $score(\mathbf{x}, \mathbf{y})$ calculates how compatible the sequence of label **y** is with the input sentence **x**. It is calculated by a basic word spacing model as in (Lee and Kim, 2013). $L(\mathbf{y}_{input}, \mathbf{y})$ counts the number of different labels between the user-given sequence of labels $\mathbf{y}_{input}$ and an arbitrary sequence of labels **y**. $\mathbf{y}^*$ of Equation 1 can be obtained by setting the gradient of $score(\mathbf{x}, \mathbf{y}) - \alpha \cdot L(\mathbf{y}_{input}, \mathbf{y})$ to 0, which is equivalent to the following equation:

$$\nabla score(\mathbf{x}, \mathbf{y}^*) = \alpha \cdot \nabla L(\mathbf{y}_{input}, \mathbf{y}^*) \quad (2)$$

In order to view the proposed model in a different perspective, we consider BWSM in terms of Karush-Kuhn-Tucker (KKT) condition. KKT condition is a technique for solving optimization problems with inequality constraints. It is a generalized version of Lagrange multipliers, which is a technique for solving optimization problems with equality constraints. Converting the aforementioned principles to a constrained optimization problem gives:

$$\text{Maximize: } score(\mathbf{x}, \mathbf{y})$$
$$\text{subject to } L(\mathbf{y}_{input}, \mathbf{y}) \leq b \quad (3)$$

Equation 3 tries to obtain **y** that maximizes $score(\mathbf{x}, \mathbf{y})$, namely the score of the basic model, while maintaining $L(\mathbf{y}_{input}, \mathbf{y})$ below *b*, which is equivalent to altering the word spacing of the input sentence less than or equal to *b* times. To solve this constrained optimization problem, we apply KKT condition and define a new Lagrangian function as follows:

$$\Lambda(\mathbf{x}, \mathbf{y}, \alpha) = score(\mathbf{x}, \mathbf{y}) - \alpha\{L(\mathbf{y}_{input}, \mathbf{y}) - b\} \quad (4)$$

[1] Accuracy was calculated based on syllables.
[2] Slashes are used for distinguishing between syllables.

Setting the gradient of the Equation 4 to zero, namely $\nabla\Lambda(\mathbf{x}, \mathbf{y}, \alpha) = 0$, we get the following necessary conditions:

$$\begin{aligned}&\text{Stationarity: } \nabla score(\mathbf{x}, \mathbf{y}^*) = \alpha^*\{\nabla L(\mathbf{y}_{input}, \mathbf{y}^*)\}\\&\text{Primal feasibility: } L(\mathbf{y}_{input}, \mathbf{y}^*) \leq b\\&\text{Dual feasibility: } \alpha^* \geq 0\\&\text{Complementary slackness: } \alpha^*\{L(\mathbf{y}_{input}, \mathbf{y}^*) - b\} = 0 \quad (5)\end{aligned}$$

Comparing Equation 1 with Equation 4 reveals that they are the same except the constant b. And $\mathbf{y}^*$ which satisfies the conditions of Equation 5, and hence the solution to Equation 4, is also the same as $\mathbf{y}^*$ which satisfies Equation 2, and hence the solution to Equation 1.

For the basic word spacing model, we use margin rescaled version of structural SVM as Lee and Kim (2013). The objective function of structural SVM is as follows:

$$\begin{aligned}&\min_{w,\xi} \frac{1}{2} \| \mathbf{w} \|^2 + \frac{C}{n}\sum_i^n \xi_i, \ \ s.t. \ \forall i, \ \xi_i \geq 0\\&\forall i, \forall \mathbf{y} \in Y \backslash \mathbf{y}_i : \mathbf{w}^{\mathrm{T}} \delta\Psi(\mathbf{x}_i, \mathbf{y}) \geq L(\mathbf{y}_i, \mathbf{y}) - \xi_i\\&\text{where } \delta\Psi(\mathbf{x}_i, \mathbf{y}) = \Psi(\mathbf{x}_i, \mathbf{y}_i) - \Psi(\mathbf{x}_i, \mathbf{y}) \quad (6)\end{aligned}$$

In Equation 6, $(\mathbf{x}_i, \mathbf{y}_i)$ represents the i-th sequence of syllables and its correct spacing labels. $L(\mathbf{y}_i, \mathbf{y})$ is a loss function that counts the number of different labels between the correct labels $\mathbf{y}_i$ and the predicted sequence of labels $\mathbf{y}$. $\Psi(\mathbf{x}, \mathbf{y})$ is a typical feature vector function. The features used for the basic word spacing model are the same features used in (Lee and Kim, 2013). Since structural SVM was used for the basic word spacing model, the score function of Equation 1 becomes $score(\mathbf{x}, \mathbf{y}) = \mathbf{w}^{\mathrm{T}}\Psi(\mathbf{x}, \mathbf{y})$.

We propose two approaches for implementing Equation 1.

1. N-best re-ranking: N-best sequences of spacing labels are obtained using the basic structural SVM model. For each of the sequence, $\alpha^* L(\mathbf{y}_{input}, \mathbf{y}^*)$ is calculated and subtracted from $score(\mathbf{x}, \mathbf{y})$. The result of the subtraction is used to re-rank the sequences, and the one with the highest rank is chosen.
2. Modified Viterbi search: Viterbi search algorithm, which is used in the basic word spacing model to solve $\mathbf{y}^* = \text{argmax}\{\mathbf{w}^{\mathrm{T}}\Psi(\mathbf{x}, \mathbf{y})\}$, is modified to solve $\mathbf{y}^* = \text{argmax}\{\mathbf{w}^{\mathrm{T}}\Psi(\mathbf{x}, \mathbf{y}) - \alpha \cdot L(\mathbf{y}_{input}, \mathbf{y})\}$. Both $\Psi(\mathbf{x}, \mathbf{y})$ and $L(\mathbf{y}_{input}, \mathbf{y})$ can be calculated syllable by syllable, which makes it easy to modify Viterbi search algorithm.

The first approach seems straightforward and easy, but it would take a long time to obtain N-best sequences of labels. Furthermore, the correct label sequence might not be in those N-best sequences, hence degrading the overall performance. The second approach is fast since it does not calculate N-best sequences, and unlike the first approach, will always consider the correct label sequence as a candidate.

4 Experiment

In order to compare the performance of BWSM with HMM-based Korean word spacing and structural SVM-based Korean word spacing, we use Sejong raw corpus (Kang and Kim, 2004) as train data and ETRI POS tagging corpus as test data[3]. Pegasos-struct algorithm from (Lee and Kim, 2013) was used to train the basic structural SVM-based model. The optimal value for the tradeoff variable C of structural SVM was found after conducting several experiments[4].

The rate of word spacing error varies depending on the corpus. Newspaper articles rarely have word spacing errors but text messages or Tweets frequently contain word spacing errors. To reflect such variety, we randomly insert spacing errors into the test set to produce various test sets with spacing error rate 0%, 10%, 20%, 35%, 50%, 60%, and 70%[5].

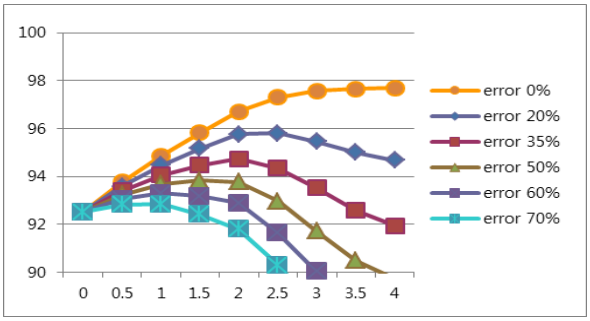

Figure 2: Word-based F-score of N-best re-ranking approach.

Figure 2 shows the relation between α(x-axis) and word-based F-score[6](y-axis) of N-best re-

[3] The number of words for the training set and test set are 26 million and 290,000 respectively.
[4] We experimented with 10, 100, 1000, 10000, 100000 and 1000000, the optimal value being 100000.
[5] We altered the input to the system and retained the original gold standard's space unit.
[6] Word-based F-score = 2*$\text{Prec}_{\text{word}}$*$\text{Recall}_{\text{word}}$ / ($\text{Prec}_{\text{word}}$ + $\text{Recall}_{\text{word}}$),
$\text{Prec}_{\text{word}}$ = (# of correctly spaced words) / (the total number of words produced by the system),

ranking approach using test sets with different spacing error rate. When $\alpha = 0$, BWSM becomes a normal structural SVM-based model. As α increases, F-score also increases for a while but decreases afterward. And F-score increases more when using test sets with low error rate. It is worth noticing that when using the test set with 0% error rate, as α increases, F-score converges to 98%. The reason it does not reach 100% is that the correct label sequence is sometimes not included in the N-best sequences.

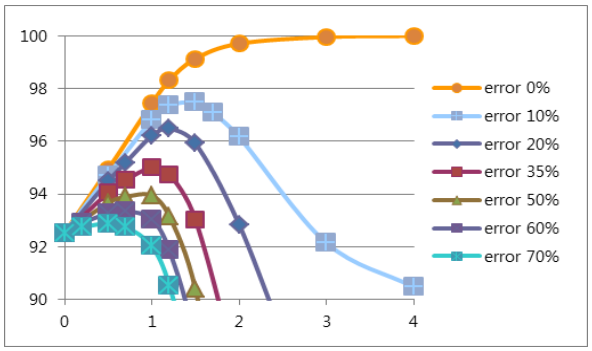

Figure 3: Word-based F-score of modified Viterbi search.

Figure 3 shows the relation between α(x-axis) and word-based F-score(y-axis) of modified Viterbi search approach using test sets with different spacing error rate. The graphs are similar to Figure 2, but F-score reaches higher values compared to N-best re-ranking approach. Notice that, when using the test set with 0% error rate, F-score becomes 100% as α surpasses 3. This is because, unlike N-best re-ranking approach, modified Viterbi search approach considers all possible sequences as candidates.

From Figure 2 and 3, it can be seen that BWSM, which takes into consideration the spacing information provided by the user, can improve performance significantly. It is also apparent that modified Viterbi search approach outperforms N-best re-ranking approach. The optimal value for α varies as test sets with different error rate are used. It is natural that, for test sets with low error rate, the optimal value of α increases, thus forcing the model to more utilize the user-given spacing information. It is difficult to automatically obtain the optimal α for an arbitrary input sentence. Therefore we set α to 1, which, according to Figure 3, is more or less the optimal value for most of the test sets.

$\text{Recall}_{\text{word}}$ = (# of correctly spaced words) / (the total number of words in the test data)

Model	Syllable based precision	Word based precision
HMM (Lee et al., 2007)	98.44	90.31
S-SVM (Lee and Kim, 2013)	99.01	92.53
Modified Viterbi (error rate 10%)	**99.64**	**96.81**
Modified Viterbi (error rate 20%)	**99.55**	**96.21**
Modified Viterbi (error rate 35%)	**99.35**	**95.01**

Table 1: Precision of BWSM and previous studies

With α set to 1, and using modified Viterbi search algorithm, the performance of BWSM is shown in Table 1 with other previous studies (Lee and Kim, 2013; Lee et al., 2007). Table 1 shows that BWSM gives superior performance than other studies that do not utilize user-given spacing information.

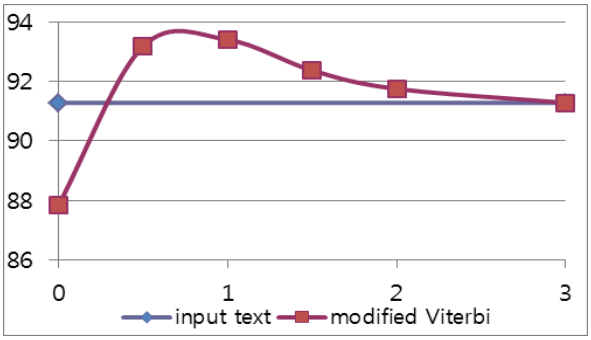

Figure 4: Word-based F-score of modified Viterbi search on Tweets.

We also collected Tweets from Twitter and tested modified Viterbi algorithm on them. Figure 4 shows the relation between α (x-axis) and word-based F-score (y-axis). The raw Tweets showed word-based F-score of approximate 91%, and the basic structural SVM model ($\alpha = 0$) showed somewhat inferior 88%. Modified Viterbi algorithm showed the similar behavior as Figure 3, showing 93.2~93.4% word-based F-score when α was set to 0.5~1. Figure 4 shows that BWSM is effective not only on text with randomly inserted spacing errors, but also on actual data, Tweets.

5 Conclusion

In this paper, we proposed BWSM, a new structural SVM-based Korean word spacing model that utilizes user-given spacing information. BWSM can obtain the most likely sequence of spacing labels while minimally altering the word spacing of the input sentence. Experiments on test sets with various error rate showed that BWSM significantly improved word-based F-

score, from 95.47% to 98.39% in case of the test set with 10% error rate.

For future work, there are two interesting directions. First is to improve BWSM so that it can automatically obtain the optimal value of α for an arbitrary sentence. This will require a training set consisting of text with actual human spacing errors and its corrected version. Second is to apply BWSM to other interesting problems such as named entity recognition (NER). Newspaper articles often use certain symbols such as quotation marks or brackets around the titles of movies, songs and books. Such symbols can be viewed as user-given input, which BWSM will try to respect as much as possible while trying to find the most likely named entities.

Abstract

We explore the impact of morphological segmentation on keyword spotting (KWS). Despite potential benefits, state-of-the-art KWS systems do not use morphological information. In this paper, we augment a state-of-the-art KWS system with sub-word units derived from supervised and unsupervised morphological segmentations, and compare with phonetic and syllabic segmentations. Our experiments demonstrate that morphemes improve overall performance of KWS systems. Syllabic units, however, rival the performance of morphological units when used in KWS. By combining morphological, phonetic and syllabic segmentations, we demonstrate substantial performance gains.

1 Introduction

Morphological analysis plays an increasingly important role in many language processing applications. Recent research has demonstrated that adding information about word structure increases the quality of translation systems and alleviates sparsity in language modeling (Chahuneau et al., 2013b; Habash, 2008; Kirchhoff et al., 2006; Stallard et al., 2012).

In this paper, we study the impact of morphological analysis on the keyword spotting (KWS) task. The aim of KWS is to find instances of a given keyword in a corpus of speech data. The task is particularly challenging for morphologically rich languages as many target keywords are unseen in the training data. For instance, in the Turkish dataset (Babel, 2013) we use, from the 2013 IARPA Babel evaluations, 36.06% of the test words are unseen in the training data. However, 81.44% of these unseen words have a morphological variant in the training data. Similar patterns are observed in other languages used in the Babel evaluations. This observation strongly supports the use of morphological analysis to handle out-of-vocabulary (OOV) words in KWS systems.

Despite this potential promise, state-of-the-art KWS systems do not commonly use morphological information. This surprising fact can be due to multiple reasons, ranging from the accuracy of existing morphological analyzers to the challenge of integrating morphological information into existing KWS architectures. While using morphemes is likely to increase coverage, it makes recognition harder due to the inherent ambiguity in the recognition of smaller units. Moreover, it is not clear a priori that morphemes, which are based on the semantics of written language, are appropriate segmentation units for a speech-based application.

We investigate the above hypotheses in the context of a state-of-the-art KWS architecture (Karakos et al., 2013). We augment word lattices with smaller units obtained via segmentation of words, and use these modified lattices for keyword spotting. We consider multiple segmentation algorithms, ranging from near-perfect supervised segmentations to random segmentations, along with unsupervised segmentations and purely phonetic and syllabic segmentations. Our experiments show how sub-word units can be used effectively to improve the performance of KWS systems. Further, we study the extent of impact of the subwords, and the manner in which they can be used in KWS systems.

2 Related Work

Prior research on applications of morphological analyzers has focused on machine translation, language modeling and speech recognition (Habash, 2008; Chahuneau et al., 2013a; Kirchhoff et al., 2006). Morphological analysis enables us to link together multiple inflections of the same root, thereby alleviating word sparsity common in mor-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 880–885,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

phologically rich languages. This results in improved language model perplexity, better word alignments and higher BLEU scores.

Recent work has demonstrated that even morphological analyzers that use little or no supervision can help improve performance in language modeling and machine translation (Chahuneau et al., 2013b; Stallard et al., 2012). It has also been shown that segmentation lattices improve the quality of machine translation systems (Dyer, 2009).

In this work, we leverage morphological segmentation to reduce OOV rates in KWS. We investigate segmentations produced by a range of models, including acoustic sub-word units. We incorporate these subword units into a lattice framework within the KWS system. We also demonstrate the value of using alternative segmentations instead of or in combination with morphemes. In addition to improving the performance of KWS systems, this finding may also benefit other applications that currently use morphological segmentation for OOV reduction.

3 Segmentation Methods

Supervised Morphological Segmentation Due to the unavailability of gold morphological segmentations for our corpus (Babel, 2013), we use a resource-rich supervised system as a proxy. As training data for this system, we use the MorphoChallenge 2010 corpus[1] which consists of 1760 gold segmentations for Turkish.

We consider two supervised frameworks, both made up of two stages. In the first stage, common to both systems, we use a FST-based morphological parser (Çöltekin, 2010) that generates a set of candidate segmentations, leveraging a large database of Turkish roots and affixes. This stage tends to overgenerate, segmenting each word in eight different ways on average. In the next stage, we filter the resulting segmentations using one of two supervised filters (described below) trained on the MorphoChallenge corpus.

In the first approach, we use a binary log-linear classifier to accept/reject each segmentation hypothesis. For each word, this classifier may accept multiple segmentations, or rule out all the alternatives. In the second approach, to control the number of segmentations per word, we train a log-linear ranker that orders the segmentations for a word in decreasing order of likelihood. In our training corpus, each word has on average 2.5 gold segmentations. Hence, we choose the top two segmentations per word from the output of the ranker to use in our KWS system. In both filters, we use several features like morpheme unigrams, bigrams, lengths, number of morphemes, and phone sequences corresponding to the morphemes.

Feature	Example
morpheme unigrams	tak, acak
morpheme bigram	⟨tak, acak⟩
phonetic seq. unigrams	t.a.k., 1v.dZ.a.k.
phonetic seq. bigram	⟨t.a.k., 1v.dZ.a.k.⟩
number of morphemes	2
morpheme lengths	3, 4

Table 1: Example of features used in the supervised filters for the segmentation *tak-acak*. Each phone is followed by a dot for clarity.

In our supervised systems, we can encode features that go beyond individual boundaries, like the total number of morphemes in the segmentation. This global view distinguishes our classifier/ranker from traditional approaches that model segmentation as a sequence tagging task (Ruokolainen et al., 2013; Kudo et al., 2004; Kruengkrai et al., 2006). Another departure of our approach is the use of phonetic information, in the form of phonetic sequences corresponding to the morpheme unigrams and bigrams. The hypothesis is that syllabic boundaries are correlated with morpheme boundaries to some extent. The phonetic sequences for words are obtained using a publicly available Text-to-Phone (T2P) system (Lenzo, 1998).

Unsupervised Morphological Segmentation We employ a widely-used unsupervised system Morfessor (Creutz and Lagus, 2005) which achieves state-of-the-art unsupervised performance in the MorphoChallenge evaluation. Morfessor uses probabilistic generative models with sparse priors which are motivated by the Minimum Description Length (MDL) principle. The system derives segmentations from raw data, without reliance on extra linguistic sources. It outputs a single segmentation per word.

Random Segmentation As a baseline, we include sub-word units from random segmentations, where we mark a segmentation boundary at each character position in a word with a fixed probability p. For comparison purposes, we consider two

[1] http://research.ics.aalto.fi/events/morphochallenge2010/

Sub-word units	Example
Morphemes	tak - acak
Random	t - aka - c - a - k
Phones	t - a - k - 1v - dZ - a - k
Syllables	ta - k1v - dZak

Table 2: Segmentations of the word *takacak* into different types of sub-word units.

types of random segmentations that match the supervised morphological segmentations in terms of the number of uniques morphemes and the average morpheme length, respectively. These segmentations are obtained by adjusting the segmentation probability p appropriately.

Phones and Syllables In addition to letter-based segmentation, we also consider other subword units that stem from word acoustics. In particular, we consider segmentation using phones and syllables, which are available for the Babel data we work with.

Table 2 shows examples of different segmentations for the Turkish word *takacak*.

4 Keyword Spotting

The keyword spotting system used in this work follows, to a large extent, the pipeline of (Bulyko et al., 2012). Using standard speech recognition machinery, the system produces a detailed lattice of word hypotheses. The resulting lattice is used to extract keyword hits with nominal posterior probability scores.

We modify this basic architecture in two ways. First, we use subwords instead of whole-words in the decoding lexicon. Second, we represent keywords using all possible paths in a lattice of subwords. For each sequence of matching arcs in the lattice, the posteriors of these arcs are multiplied together to form the score of detection (hit). A post-processing step adds up (or takes the max of) the scores of all hits of each keyword which have significant overlap in time. Finally, the hit lists are processed by the score normalization and combination method described in (Karakos et al., 2013).

We use whole-word extraction for words in vocabulary, but rely on subword models for OOV words. Since we combine the hits separately for IV and OOV keywords, using subwords can only improve the performance of the overall system.

Language	Dev Set	Eval Set
Turkish	403	226
Assamese	158	563
Bengali	176	629
Haitian	107	319
Lao	110	194
Tamil	238	700
Zulu	323	1251

Table 3: Number of OOV keywords in the different Dev and Eval sets.

5 Experimental Setup

Data The segmentation algorithms described in Section 3 are tested using the setup of the KWS system described in Section 4. Our experiments are conducted using the IARPA Babel Program language collections for Turkish, Assamese, Bengali, Haitian, Lao, Tamil and Zulu (Babel, 2013)[2]. The dataset contains audio corpora and a set of keywords. The training corpus for KWS consists of 10 hours of speech, while the development and test sets have durations of 10 and 5 hours, respectively. We evaluate KWS performance over the OOV keywords in the data, which are unseen in the training set, but appear in the development/test set. Table 3 contains statistics on the number of OOV keywords in the data for each language.

In our experiments, we consider the pre-indexed condition, where the keywords are known only after the decoding of the speech has taken place.

Evaluation Measures We consider two different evaluation metrics. To evaluate the accuracy of the different segmentations, we compare them against gold segmentations from the MorphoChallenge data for Turkish. This set consists of 1760 words, which are manually segmented. We use a measure of word accuracy (**WordAcc**), which captures the accuracy of all segmentation decisions within the word. If one of the segmentation boundaries is wrong in a proposed segmentation, then that segmentation does not contribute towards the WordAcc score. We use 10-fold cross-validation for the supervised segmentations, while we use the entire set for unsupervised and acoustic cases.

We evaluate the performance of our KWS system using a widely used metric in KWS, the Ac-

[2]We perform the experiments with supervised segmentation only on Turkish, due to the lack of gold morphological data for the other languages.

tual Term Weighted Value (ATWV) measure, as described in (Fiscus et al., 2007). This measure uses a combination of penalties for misses and false positives to score the system. The maximum score achievable is 1.0, if there are no misses and false positives, while the score can be lower than 0.0 if there are a lot of misses or false positives.

6 Results

Table 4 summarizes the performance of all considered segmentation systems in the KWS task on Turkish. The quality of the segmentations compared to the gold standard is also shown. Table 5 shows the OOV ATWV performance on the six other languages, used in the second year of the IARPA Babel project. We summarize below our conclusions based on these results.

Using sub-word units improves overall KWS performance If we use a word-based KWS system, the ATWV score will be 0.0 since the OOV keywords are not present in the lexicon. Enriching our KWS system with sub-word segments yields performance gains for all the segmentation methods, including random segmentations. However, the observed gain exhibits significant variance across the segmentation methods. For instance, the gap between the performance of the KWS system using the best supervised classifier-based segmenter (*CP*) and that using the unsupervised segmenter (*U*) is 0.059, which corresponds to a 43.7% in relative gain. Table 4 also shows that while methods with shorter sub-units (*U*, *P*) yield lower OOV rate, they do not necessarily fare better in the KWS evaluation.

Syllabic units rival the performance of morphological units A surprising discovery from our experiments is the good performance of the syllabic segmentation-based KWS system (*S*). It outperforms all the alternative segmentations on the test set, and ranks second on the development set behind the *CP* system. These units are particularly attractive as they can easily be computed from acoustic input and do not require any prior linguistic knowledge. We hypothesize that the granularity of this segmentation is crucial to its success. For instance, a finer-grained phone-based segmentation (*P*) performs substantially worse than other segmentation algorithms as the derived sub-units are shorter and hence, harder to recognize.

Improving morphological accuracy beyond a certain level does not translate into improved KWS performance We observe that the segmentation accuracy and KWS performance are not positively correlated. Clearly, bad segmentations translate into poor ATWV scores, as in the case of random and unsupervised segmentations. However, gains on segmentation accuracy do not always result in better KWS performance. For instance, the ranker systems (*RP, RNP*) have better accuracies on MC2010, while the classifier systems (*CP, CNP*) perform better on the KWS task. This discrepancy in performance suggests that further gains can be obtained by optimizing segmentations directly with respect to KWS metrics.

Adding phonetic information improves morphological segmentation For all the morphological systems, adding phonetic information results in consistent performance gains. For instance, it increases segmentation accuracy by 4% when added to the classifier (*CNP* and *CP* in table 4). The phonetic information used in our experiments is computed automatically using a T2P system (Lenzo, 1998), and can be easily obtained for a range of languages. This finding sheds new light on the relation between phonetic and morphological systems, and can be beneficial for morphological analyzers developed for other applications.

Combining morphological, phonetic and syllabic segmentations gives better results than either in isolation As table 4 shows, the best KWS results are achieved when syllabic and morphemic systems are combined. The best combination system (*CP+P+S*) outperforms the best individual system (*S*) by 5.5%. This result suggests that morphemic, phonemic and syllabic segmentations encode complementary information which benefits KWS systems in handling OOV keywords.

Morphological segmentation helps KWS across different languages Table 5 demonstrates that we can obtain gains in KWS performance across different languages using unsupervised segmentation. The improvement is significant in 3 of the 6 languages - as high as 3.2% for Assamese and Bengali, and 2.7% for Tamil (absolute percentages). As such, the results of Table 2 cannot be directly compared to those of Table 1 since the system architecture is slightly different[3]. How-

[3]The keyword spotting pipeline is based on the one used by the Babelon team in the 2014 NIST evaluation (Tsakalidis, 2014). The pipeline was much more involved than the one described for Turkish; multiple search methods (with/without fuzzy search) and data structures (lattices, confusion networks and generalized versions of these) were all used in combination (Karakos and Schwartz, 2014). The recognition

Method	Unique units	Avg. unit length	Reduction in OOV (abs)	WordAcc	Dev ATWV	Test ATWV

Table 5: ATWV scores for languages used in the second year of the IARPA Babel project, using two KWS systems: Phone + Syllable (P+S) and Phone + Syllable + Unsupervised Morphemes (P+S+U). Bold numbers show significant performance gains obtained by adding morphemes to the system.

ever, they are indicative of the large gains (1.5%, on average, over the six languages) that can be obtained through unsupervised morphology, on top of a very good combined phonetic/syllabic system.

7 Conclusion

We explore the extent of impact of morphological segmentation on keyword spotting (KWS). To investigate this issue, we augmented a KWS system with sub-word units derived by multiple segmentation algorithms. Our experiments demonstrate that morphemes improve the overall performance of KWS systems. Syllabic units, however, rival the performance of morphemes in the KWS task. Furthermore, we demonstrate that substantial performance gains in KWS performance are obtained by combining morphological, phonetic and syllabic segmentations. Finally, we also show that adding phonetic information improves the quality of morphological segmentation.

was done with audio features supplied by BUT (Karafiát et al., 2014), which were improved versions of those used for Turkish.

Abstract

In this paper we address the problem of multilingual part-of-speech tagging for resource-poor languages. We use parallel data to transfer part-of-speech information from resource-rich to resource-poor languages. Additionally, we use a small amount of annotated data to learn to "correct" errors from projected approach such as tagset mismatch between languages, achieving state-of-the-art performance (91.3%) across 8 languages. Our approach is based on modest data requirements, and uses minimum divergence classification. For situations where no universal tagset mapping is available, we propose an alternate method, resulting in state-of-the-art 85.6% accuracy on the resource-poor language Malagasy.

1 Introduction

Part-of-speech (POS) tagging is a crucial task for natural language processing (NLP) tasks, providing basic information about syntax. Supervised POS tagging has achieved great success, reaching as high as 95% accuracy for many languages (Petrov et al., 2012). However, supervised techniques need manually annotated data, and this is either lacking or limited in most resource-poor languages. Fully unsupervised POS tagging is not yet useful in practice due to low accuracy (Christodoulopoulos et al., 2010). In this paper, we propose a semi-supervised method to narrow the gap between supervised and unsupervised approaches. We demonstrate that even a small amount of supervised data leads to substantial improvement.

Our method is motivated by the availability of parallel data. Thanks to the development of multilingual documents from government projects, book translations, multilingual websites, and so forth, parallel data between resource-rich and resource-poor languages is relatively easy to acquire. This parallel data provides the bridge that permits us to transfer POS information from a resource-rich to a resource-poor language.

Systems that make use of cross-lingual tag projection typically face several issues, including mismatches between the tagsets used for the languages, artifacts from noisy alignments and cross-lingual syntactic divergence. Our approach compensates for these issues by training on a small amount of annotated data on the target side, demonstrating that only 1k tokens of annotated data is sufficient to improve performance.

We first tag the resource-rich language using a supervised POS tagger. We then project POS tags from the resource-rich language to the resource-poor language using parallel word alignments. The projected labels are noisy, and so we use various heuristics to select only "good" training examples. We train the model in two stages. First, we build a maximum entropy classifier T on the (noisy) projected data. Next, we train a supervised classifier P on a small amount of annotated data (1,000 tokens) in the target language, using a minimum divergence technique to incorporate the first model, T. Compared with the state of the art (Täckström et al., 2013), we make more-realistic assumptions (e.g. relying on a tiny amount of annotated data rather than a huge crowd-sourced dictionary) and use less parallel data, yet achieve a better overall result. We achieved 91.3% average accuracy over 8 languages, exceeding Täckström et al. (2013)'s result of 88.8%.

The test data we employ makes use of mappings from language-specific POS tag inventories to a universal tagset (Petrov et al., 2012). However, such a mapping might not be available for resource-poor languages. Therefore, we also pro-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 886–897,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

pose a variant of our method which removes the need for identical tagsets between the projection model T and the correction model P, based on a two-output maximum entropy model over tag pairs. Evaluating on the resource-poor language Malagasy, we achieved 85.6% accuracy, exceeding the state-of-the-art of 81.2% (Garrette et al., 2013).

2 Background and Related Work

There is a wealth of prior work on multilingual POS tagging. The simplest approach takes advantage of the typological similarities that exist between languages pairs such as Czech and Russian, or Serbian and Croatian. They build the tagger — or estimate part of the tagger — on one language and apply it to the other language (Reddy and Sharoff, 2011, Hana et al., 2004).

Yarowsky and Ngai (2001) pioneered the use of parallel data for projecting tag information from a resource-rich language to a resource-poor language. Duong et al. (2013b) used a similar method on using sentence alignment scores to rank the goodness of sentences. They trained a seed model from a small part of the data, then applied this model to the rest of the data using self-training with revision.

Das and Petrov (2011) also used parallel data but additionally exploited graph-based label propagation to expand the coverage of labelled tokens. Each node in the graph represents a trigram in the target language. Each edge connects two nodes which have similar context. Originally, only some nodes received a label from direct label projection, and then labels were propagated to the rest of the graph. They only extracted the dictionary from the graph because the labels of nodes are noisy. They used the dictionary as the constraints for a feature-based HMM tagger (Berg-Kirkpatrick et al., 2010). Both Duong et al. (2013b) and Das and Petrov (2011) achieved 83.4% accuracy on the test set of 8 European languages.

Goldberg et al. (2008) pointed out that, with the presence of a dictionary, even an incomplete one, a modest POS tagger can be built using simple methods such as expectation maximization. This is because most of the time, words have a very limited number of possible tags, thus a dictionary that specifies the allowable tags for a word helps to restrict the search space. With a gold-standard dictionary, Das and Petrov (2011) achieved an accuracy of approximately 94% on the same 8 languages. The effectiveness of a gold-standard dictionary is undeniable, however it is costly to build one, especially for resource-poor languages. Li et al. (2012) used the dictionary from Wiktionary,[1] a crowd-sourced dictionary. They scored 84.8% accuracy on the same 8 languages. Currently, Wiktionary covers over 170 languages, but the coverage varies substantially between languages and, unsurprisingly, it is poor for resource-poor languages. Therefore, relying on Wiktionary is not effective for building POS taggers for resource-poor languages.

Täckström et al. (2013) combined both token information (from direct projected data) and type constraints (from Wiktionary's dictionary) to form the state-of-the-art multilingual tagger. They built a tag lattice and used these token and type constraints to prune it. The remaining paths are the training data for a CRF tagger. They achieved 88.8% accuracy on the same 8 languages.

Table 1 summarises the performance of the above models across all 8 languages. Note that these methods vary in their reliance on external resources. Duong et al. (2013b) use the least, i.e. only the Europarl Corpus (Koehn, 2005). Das and Petrov (2011) additionally use the United Nation Parallel Corpus. Li et al. (2012) didn't use any parallel text but used Wiktionary instead. Täckström et al. (2013) exploited more parallel data than Das and Petrov (2011) and also used a dictionary from Li et al. (2012).

Another approach for resource-poor languages is based on the availability of a small amount of annotated data. Garrette et al. (2013) built a POS tagger for Kinyarwanda and Malagasy. They didn't use parallel data but instead exploited four hours of manual annotation to build ∼4,000 tokens or ∼3,000 word-types of annotated data. These tokens or word-types were used to build a tag dictionary. They employed label propagation for expanding the coverage of this dictionary in a similar vein to Das and Petrov (2011), but they also used an external dictionary. They built training examples using the combined dictionary and then trained the tagger on this data. They achieved 81.9% and 81.2% accuracy for Kinyarwanda and Malagasy respectively. Note that their usage of an external dictionary compromises their claim of using only 4 hours of annotation.

Table 1: Previously published token-level POS tagging accuracy for various models across 8 languages — Danish (da), Dutch (nl), German (de), Greek (el), Italian (it), Portuguese (pt), Spanish (es), Swedish (sv) — evaluated on CoNLL data (Buchholz and Marsi, 2006).

The method we propose in this paper is similar in only using a small amount of annotation. However, we directly use the annotated data to train the model rather than using a dictionary. We argue that with a proper "guide", we can take advantage of very limited annotated data.

2.1 Annotated data

Our annotated data mainly comes from CoNLL shared tasks on dependency parsing (Buchholz and Marsi, 2006). The language specific tagsets are mapped into the universal tagset. We will use this annotated data mainly for evaluation. Table 2 shows the size of annotated data for each language. The 8 languages we are considering in this experiment are not actually resource-poor languages. However, running on these 8 languages makes our system comparable with previously proposed methods. Nevertheless, we try to use as few resources as possible, in order to simulate the situation for resource-poor languages. Later in Section 6 we adapt the approach for Malagasy, a truly resource-poor language.

2.2 Universal tagset

We employ the universal tagset from (Petrov et al., 2012) for our experiment. It consists of 12 common tags: *NOUN, VERB, ADJ* (adjective), *ADV* (adverb), *PRON* (pronoun), *DET* (determiner and article), *ADP* (preposition and postposition), *CONJ* (conjunctions), *NUM* (numerical), *PRT* (particle), *PUNC* (punctuation) and *X* (all other categories including foreign words and abbreviations). Petrov et al. (2012) provide the mapping from each language-specific tagset to the universal tagset.

The idea of using the universal tagset is of great use in multilingual applications, enabling comparison across languages. However, the mapping is not always straightforward. Table 2 shows the size of the annotated data for each language, the number of tags presented in the data, and the list of tags that are not matched. We can see that only 8 tags are presented in the annotated data for Danish, i.e, 4 tags (*DET, PRT, PUNC,* and *NUM*) are missing.[2] Thus, a classifier using all 12 tags will be heavily penalized in the evaluation.

Li et al. (2012) considered this problem and tried to manually modify the Danish mappings. Moreover, *PRT* is not really a universal tag since it only appears in 3 out of the 8 languages. Plank et al. (2014) pointed out that *PRT* often gets confused with *ADP* even in English. We will later show that the mapping problem causes substantial degradation in the performance of a POS tagger exploiting parallel data. The method we present here is more target-language oriented: our model is trained on the target language, in this way, only relevant information from the source language is retained. Thus, we automatically correct the mapping, and other incompatibilities arising from incorrect alignments and syntactic divergence between the source and target languages.

Lang	Size(k)	# Tags	Not Matched
da	94	8	DET, PRT, PUNC, NUM
nl	203	11	PRT
de	712	12	
el	70	12	
it	76	11	PRT
pt	207	11	PRT
es	89	11	PRT
sv	191	11	DET
AVG	205		

Table 2: The size of annotated data from CoNLL (Buchholz and Marsi, 2006), and the number of tags included and missing for 8 languages.

[2]Many of these are mistakes in the mapping, however, they are indicative of the kinds of issues expected in low-resource languages.

3 Directly Projected Model (DPM)

In this section we describe a maximum entropy tagger that only uses information from directly projected data.

3.1 Parallel data

We first collect Europarl data having English as the source language, an average of 1.85 million parallel sentences for each of the 8 language pairs. In terms of parallel data, we use far less data compared with other recent work. Das and Petrov (2011) used Europarl and the ODS United Nation dataset, while Täckström et al. (2013) additionally used parallel data crawled from the web. The amount of parallel data is crucial for alignment quality. Since DPM uses alignments to transfer tags from source to target language, the performance of DPM (and other models that exploit projection) largely depends on the quantity of parallel data. The "No LP" model of Das and Petrov (2011), which only uses directly projected labels (without label propagation), scored 81.3% for 8 languages. However, using the same model but with more parallel data, Täckström et al. (2013) scored 84.9% on the same test set.

3.2 Label projection

We use the standard alignment tool Giza++ (Och and Ney, 2003) to word align the parallel data. We employ the Stanford POS tagger (Toutanova et al., 2003) to tag the English side of the parallel data and then project the label to the target side. It has been confirmed in many studies (Täckström et al., 2013, Das and Petrov, 2011, Toutanova and Johnson, 2008) that directly projected labels are noisy. Thus we need a method to reduce the noise. We employ the strategy of Yarowsky and Ngai (2001) of ranking sentences using a their alignment scores from IBM model 3.

Firstly, we want to know how noisy the projected data is. Thus, we use the test data to build a simple supervised POS tagger using the TnT tagger (Brants, 2000) which employs a second-order Hidden Markov Model (HMM). We tag the projected data and compare the label from direct projection and from the TnT tagger. The labels from the TnT Tagger are considered as pseudo-gold labels. Column "Without Mapping" from Table 3 shows the average accuracy for the first n-sentences ($n = 60k, 100k, 200k, 500k$) for 8 languages according to the ranking. Column "Coverage" shows the percentages of projected label (the other tokens are Null aligned). We can see that when we select more data, both coverage and accuracy fall. In other words, using the sentence alignment score, we can rank sentences with high coverage and accuracy first. However, even after ranking, the accuracy of projected labels is less than 80% demonstrating how noisy the projected labels are.

Table 3 (column "With Mapping") additionally shows the accuracy using simple tagset mapping, i.e. mapping each tag to the tag it is assigned most frequently in the test data. For example *DET, PRT, PUNC, NUM*, missing from Danish gold data, will be matched to *PRON, X, X, ADJ* respectively. This simple matching yields a $\sim$ 4% (absolute) improvement in average accuracy. This illustrates the importance of handling tagset mapping carefully.

3.3 The model

In this section, we introduce a maximum entropy tagger exploiting the projected data. We select the first 200k sentences from Table 3 for this experiment. This number represents a trade-off between size and accuracy. More sentences provide more information but at the cost of noisier data. Duong et al. (2013b) also used sentence alignment scores to rank sentences. Their model stabilizes after using 200k sentences. We conclude that 200k sentences is enough and capture most information from the parallel data.

Features	Descriptions
W@-1	Previous word
W@+1	Next word
W@0	Current word
CAP	First character is capitalized
NUMBER	Is number
PUNCT	Is punctuation
SUFFIX@k	Suffix up to length 3 ($k <= 3$)
WC	Word class

Table 4: Feature template for a maximum entropy tagger

We ignore tokens that don't have labels, which arise from null alignments and constitute approximately 14% of the data. The remaining data ($\sim$1.4 million tokens) are used to train a maximum entropy (MaxEnt) model. MaxEnt is one of the simplest forms of probabilistic classifier, and is appropriate in this setting due to the incomplete

Data Size (k)	Coverage (%)	Without Mapping	With Mapping
60	91.5	79.9	84.2
100	89.1	79.4	83.6
200	86.1	79.1	82.9
500	82.4	78.0	81.5

Table 3: The coverage, and POS tagging accuracy with and without tagset mapping of directly projected labels, averaged over 8 languages for different data sizes

Table 5: The accuracy of Directed Project Model (DPM) with different feature sets, removing one feature set at a time

sequence data. While sequence models such as HMMs or CRFs can provide more accurate models of label sequences, they impose a more stringent training requirement.[3] We also experimented with a first-order linear chain CRF trained on contiguous sub-sequences but observed $\sim 4\%$ (absolute) drop in performance.

The maximum entropy classifier estimates the probability of tag t given a word w as

$$P(t|w) = \frac{1}{Z(w)} \exp \sum_{j=1}^{D} \lambda_j f_j(w,t)\,,$$

where $Z(w) = \sum_t \exp \sum_{j=1}^{D} \lambda_j f_j(w,t)$ is the normalization factor to ensure the probabilities $P(t|w)$ sum to one. Here f_j is a feature function and λ_j is the weight for this feature, learned as part of training. We use Maximum A Posteriori (MAP) estimation to maximize the log likelihood of the training data, $\mathcal{D} = \{w_i, t_i\}_{i=1}^{N}$, subject to a zero-mean Gaussian regularisation term,

$$\begin{aligned}\mathcal{L} &= \log P(\Lambda) \prod_{i=1}^{N} P(t^{(i)}|w^{(i)}) \\ &= -\sum_{j=1}^{D} \frac{\lambda_j^2}{2\delta^2} + \sum_{i=1}^{N} \sum_{j=1}^{D} \lambda_j f_j(w_i, t_i) - \log Z(w_i)\end{aligned}$$

where the regularisation term limits over-fitting, an important concern when using large feature sets. For our experiments we set $\delta^2 = 1$. We use L-BFGS which performs gradient ascent to maximize $\mathcal{L}$. Table 4 shows the features we considered for building the DPM. We use $mkcls$, an unsupervised method for word class induction which is widely used in machine translation (Och, 1999). We run $mkcls$ to obtain 100 word classes, using only the target language side of the parallel data.

Table 5 shows the accuracy of the DPM evaluated on 8 languages ("All features model"). DPM performs poorly on Danish, probably because of the tagset mapping issue discussed above. The DPM result of 80.2% accuracy is encouraging, particularly because the model had no explicit supervision.

To see what features are meaningful for our model, we remove features in turn and report the result. The result in Table 5 disagrees with Täckström et al. (2013) on the word class features. They reported a gain of approximately 3% (absolute) using the word class. However, it seems to us that these features are not especially meaningful (at least in the present setting). Possible reasons for the discrepancy are that they train the word class model on a massive quantity of external monolingual data, or their algorithms for word clustering are better (Uszkoreit and Brants, 2008). We can see that the most informative features are Capitalization, Number and Punctuation. This makes sense because in languages such as German, capitalization is a strong indicator of *NOUN*. Number and punctuation features ensure that we classify *NUM* and *PUNCT* tags correctly.

[3] Täckström et al. (2013) train a CRF on incomplete data, using a tag dictionary heuristic to define a 'gold standard' lattice over label sequences.

4 Correction Model

In this section we incorporate the directly projected model into a second *correction* model trained on a small supervised sample of 1,000 annotated tokens. Our DPM model is not very accurate; as we have discussed it makes many errors, due to invalid or inconsistent tag mappings, noisy alignments, and cross-linguistic syntactic divergence. However, our aim is to see how effectively we can exploit the strengths of the DPM model while correcting for its inadequacies using direct supervision. We select only 1,000 annotated tokens to reflect a low resource scenario. A small supervised training sample is a more realistic form of supervision than a tag dictionary (noisy or otherwise). Although used in most prior work, a tag dictionary for a new language requires significant manual effort to construct. Garrette and Baldridge (2013) showed that a 1,000 token dataset could be collected very cheaply, requiring less than 2 hours of non-expert time.

Our correction model makes use of a *minimum divergence* (MD) model (Berger et al., 1996), a variant of the maximum entropy model which biases the target distribution to be similar to a static reference distribution. The method has been used in several language applications including machine translation (Foster, 2000) and parsing (Plank and van Noord, 2008, Johnson and Riezler, 2000). These previous approaches have used various sources of reference distribution, e.g., incorporating information from a simpler model (Johnson and Riezler, 2000) or combining in- and out-of-domain models (Plank and van Noord, 2008). Plank and van Noord (2008) concluded that this method for adding prior knowledge only works with high quality reference distributions, otherwise performance suffers.

In contrast to these previous approaches, we consider the specific setting where both the learned model and the reference model $s_o = P(t|w)$ are both maximum entropy models. In this case we show that the MD setup can be simplified to a regularization term, namely a Gaussian prior with a non-zero mean. We model the classification probability, $P'(t|w)$ as the product between a base model and a maximum entropy classifier,

$$P'(t|w) \propto P(t|w) \exp \sum_{j=1}^{D} \gamma_j f_j(w,t)$$

where here we use the DPM model as base model $P(t|w)$. Under this setup, where P' uses the same features as P, and both are log-linear models, this simplifies to

$$\begin{aligned} P'(t|w) &\propto \exp\left(\sum_{j=1}^{D} \lambda_j f_j(w,t) + \sum_{j=1}^{D} \gamma_j f_j(w,t)\right) \\ &\propto \exp \sum_{j=1}^{D} (\lambda_j + \gamma_j) f_j(w,t) \end{aligned} \quad (1)$$

where the constant of proportionality is $Z'(w) = \sum_t \exp \sum_{j=1}^{D} (\lambda_j + \gamma_j) f_j(w,t)$. It is clear that Equation (1) also defines a maximum entropy classifier, with parameters $\alpha_j = \lambda_j + \gamma_j$, and consequently this might seem to be a pointless exercise. The utility of this approach arises from the prior: MAP training with a zero mean Gaussian prior over γ is equivalent to a Gaussian prior over the aggregate weights, $\alpha_j \sim \mathcal{N}(\lambda_j, \sigma^2)$. This prior enforces parameter sharing between the two models by penalising parameter divergence from the underlying DPM model λ. The resulting training objective is

$$\mathcal{L}^{\text{corr}} = \log P(\mathbf{t}|\mathbf{w}, \alpha) - \frac{1}{2\sigma^2} \sum_{j=1}^{D} (\alpha_j - \lambda_j)^2$$

which can be easily optimised using standard gradient-based methods, e.g., L-BFGS. The contribution of the regulariser is scaled by the constant $\frac{1}{2\sigma^2}$.

4.1 Regulariser sensitivity

Careful tuning of the regularisation term σ^2 is critical for the correction model, both to limit overfitting on the very small training sample of 1,000 tokens, and to control the extent of the influence of the DPM model over the correction model. A larger value of σ^2 lessens the reliance on the DPM and allows for more flexible modelling of the training set, while a small value of σ^2 forces the parameters to be close to the DPM estimates at the expense of data fit. We expect the best value to be somewhere between these extremes, and use line-search to find the optimal value for σ^2. For this purpose, we hold out 100 tokens from the 1,000 instance training set, for use as our development set for hyper-parameter selection.

From Figure 1, we can see that the model performs poorly on small values of σ^2. This is understandable because the small σ^2 makes the model

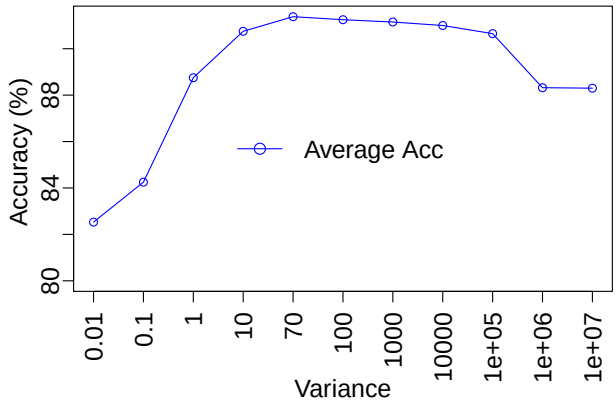

Figure 1: Sensitivity of regularisation parameter σ^2 against the average accuracy measured on 8 languages on the development set

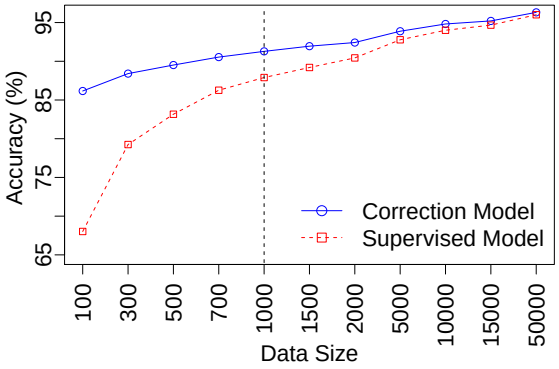

Figure 2: Learning curve for correction model and supervised model: the x-axis is the size of data (number of tokens); the y-axis is the average accuracy measured on 8 languages; the dashed line shows the data condition reported in Table 6

too similar to DPM, which is not very accurate (80.2%). At the other extreme, if σ^2 is large, the DPM model is ignored, and the correction model is equivalent with the supervised model ($\sim$ 88% accuracy). We select the value of $\sigma^2 = 70$, which maximizes the accuracy on the development set.

4.2 The model

Using the value of $\sigma^2 = 70$, we retrain the model on the whole 1,000-token training set and evaluate the model on the rest of the annotated data. Table 6 shows the performance of DPM, Supervised model, Correction model and the state-of-the-art model (Täckström et al., 2013). The supervised model trains a maximum entropy tagger using the same features as in Table 4 on this 1000 tokens. The only difference between the supervised model and the correction model is that in the correction model we additionally incorporate DPM as the prior.

The supervised model performs surprisingly well confirming that our features are meaningful in distinguishing between tags. This model achieves high accuracy on Danish compared with other languages probably because Danish is easier to learn since it contains only 8 tags. Despite the fact that the DPM is not very accurate, the correction model consistently outperforms the supervised model on all considered languages, approximately 4.3% (absolute) better on average. This shows that our method of incorporating DPM to the model is efficient and robust.

The correction model performs much better than the state-of-the-art for 7 languages but slightly worse for 1 language. On average we achieve 91.3% accuracy compared with 88.8% for the state-of-the-art, an error rate reduction of 22.3%. This is despite using fewer resources and only modest supervision.

5 Analysis

Tagset mismatch In the correction model, we implicitly resolve the mismatched tagset issue. DPM might contain tags that don't appear in the target language or generally are errors in the mapping. However, when incorporating DPM into the correction model, only the feature weight of tags that appear in the target language are retained. In general, because we don't explicitly do any mapping between languages, we might have trouble if the tagset size of the target language is bigger than the source language tagset. However, this is not the case for our experiment because we choose English as the source-side and English has the full 12 tags.

Learning curve We investigate the impact of the number of available annotated tokens on the correction model. Figure 2 shows the learning curve of the correction model and the supervised model. We can clearly see the differences between 2 models when the size of training data is small. For example, at 100 tokens, the difference is very large, approximately 18% (absolute), it is also 6% (absolute) better than DPM. This difference diminishes as we add more data. This make sense because when we add more data, the supervised model become stronger, while the effective-

Model	da	nl	de	el	it	pt	es	sv	Avg

Table 6: The comparison of our Directly Projected Model, Supervised Model, Correction Model and the state-of-the-art system (Täckström et al., 2013). The best performance for each language is shown in bold. The models that are built with a dictionary are provided for reference.

ness of the DPM prior on the correction model is wearing off. An interesting observation is that the correction model is always better, even when we add massive amounts of annotated data. At 50,000 tokens, when the supervised model reaches 96% accuracy, the correction model is still 0.3% (absolute) better, reaching 96.3%. It means that even at that high level of confidence, some information can still be added from DPM to the correction model. This improvement probably comes from the observation that the ambiguity in one language is explained through the alignment. It also suggests that this method could improve the performance of a supervised POS tagger even for resource-rich languages.

Our methods are also relevant for annotation projects for resource-poor languages. Assuming that it is very costly to annotate even 100 tokens, applying our methods can save annotation effort but maintain high performance. For example, we just need 100 tokens to match the accuracy of a supervised method trained on 700 tokens, or we just need 500 tokens to match the performance with nearly 2,000 tokens of supervised learning.

Our method is simple, but particularly suitable for resource-poor languages. We need a small amount of annotated data for a high performance POS tagger. For example, we need only around 300 annotated tokens to reach the same accuracy as the state-of-the-art unsupervised POS tagger (88.8%).

Tag dictionary Although, it is not our objective to rely on the dictionary, we are interested in whether the gains from the correction model still persist when the DPM performance is improved. We attempt to improve DPM, following the method of Li et al. (2012) by building a tag dictionary using Wiktionary. This dictionary is then used as a feature which fires for word-tag pairings present in the dictionary. We expect that when we add this additional supervision, the DPM model should perform better. Table 6 shows the performance of DPM and the correction model when incorporating the dictionary. The DPM model only increases 0.6% absolute but the correction model increases 1.3%. Additionally, it shows that our model can improve further by incorporating external information where available.

CRF Our approach of using simple classifiers begs the question of whether better results could be obtained using sequence models, such as conditional random fields (CRFs). As mentioned previously, a CRF is not well suited for incomplete data. However, as our second 'correction' model is trained on complete sequences, we now consider using a CRF in this stage. The training algorithm is as follows: first we estimate the DPM feature weights on the incomplete data as before, and next we incorporate the feature weights into a CRF trained on the 1,000 annotated tokens. This is complicated by the different feature sets between the MaxEnt classifier and the CRF, however the classifier uses a strict subset of the CRF features. Thus, we use the minimum divergence prior for the token level features, and a standard zero-mean prior for the sequence features. That is, the objective function of the CRF correction model becomes:

$$\mathcal{L}_{\text{crf}}^{\text{corr}} = \log P(\mathbf{t}|\mathbf{w}, \alpha) - \frac{1}{2\delta_1^2}\sum_{j\in F_1}(\alpha_j - \lambda_j)^2 - \frac{1}{2\delta_2^2}\sum_{j\in F_2}\alpha_j^2 \quad (2)$$

where F_1 is the set of features referring to only one label as in the DPM maxent model and F_2 is the set of features over label pairs. The union of $F = F_1 \cup F_2$ is the set of all features for the CRF. We perform grid search using held out

data as before for δ_1^2 and δ_2^2. The CRF correction model scores 88.1% compared with 86.5% of the supervised CRF model trained on the 1,000 tokens. Clearly, this is beneficial, however, the CRF correction model still performs worse than the MaxEnt correction model (91.3%). We are not sure why but one reason might be overfitting of the CRF, due to its large feature set and tiny training sample. Moreover, this CRF approach is orthogonal to Täckström et al. (2013): we could use their CRF model as the DPM model and train the CRF correction model using the same minimum divergence method, presumably resulting in even higher performance.

6 Two-output model

Garrette and Baldridge (2013) also use only a small amount of annotated data, evaluating on two resource-poor languages Kinyarwanda (KIN) and Malagasy (MLG). As a simple baseline, we trained a maxent supervised classifier on this data, achieving competitive results of 76.4% and 80.0% accuracy compared with their published results of 81.9% and 81.2% for KIN and MLG, respectively. Note that the Garrette and Baldridge (2013) method is much more complicated than this baseline, and additionally uses an external dictionary.

We want to further improve the accuracy of MLG using parallel data. Applying the technique from Section 4 will not work directly, due to the tagset mismatch (the Malagasy tagset contains 24 tags) which results in highly different feature sets. Moreover, we don't have the language expertise to manually map the tagset. Thus, in this section, we propose a method capable of handling tagset mismatch. For data, we use a parallel English-Malagasy corpus of $\sim$100k sentences,[4] and the POS annotated dataset developed by Garrette and Baldridge (2013), which comprises 4230 tokens for training and 5300 tokens for testing.

6.1 The model

Traditionally, MaxEnt classifiers are trained using a single label.[5] The method we propose is trained with pairs of output labels: one for the Malagasy tag (t_M) and one for the universal tag (t_U), which are both predicted conditioned on a Malagasy word (w_M) in context. Our two-output model is defined as

$$P(t_M, t_U|w_M) = \frac{1}{Z(w_M)} \exp\Bigg(\sum_{j=1}^{D} \lambda_j f_j^M(w, t_M) + \sum_{j=1}^{E} \gamma_j f_j^U(w, t_U) + \sum_{j=1}^{F} \alpha_j f_j^B(w, t_M, t_U)\Bigg) \quad (3)$$

where f^M, f^U, f^B are the feature functions considering t_M only, t_U only, and over both outputs t_M and t_U respectively, and $Z(w_M)$ is the partition function. We can think of Eq. (3) as the combination of 3 models: the Malagasy maxent supervised model, the DPM model, and the tagset mapping model. The central idea behind this model is to learn to predict not just the MLG tags, as in a standard supervised model, but also to learn the mapping between MLG and the noisy projected universal tags. Framing this as a two output model allows for information to flow both ways, such that confident taggings in either space can inform the other, and accordingly the mapping weights α are optimised to maximally exploit this effect.

One important question is how to obtain labelled data for training the two-output model, as our small supervised sample of MLG text is only annotated for MLG labels t_M. We resolve this by first learning the DPM model on the projected labels, after which we automatically label our correction training set with predicted tags from the DPM model. That is, we augment the annotated training data from (t_M, w_M) to become (t_M, t_U, w_M). This is then used to train the two-output maxent classifier, optimising a MAP objective using standard gradient descent. Note that it would be possible to apply the same minimum divergence technique for the two-output maxent model. In this case the correction model would include a regularization term over the λ to bias towards the DPM parameters, while γ and α would use a zero-mean regularizer. However, we leave this for future work.

Table 7 summarises the performance of the state-of-the-art (Garrette et al., 2013), the supervised model and the two-output maxent model evaluated on the Malagasy test set. The two-output maxent model performs much better than the supervised model, achieving $\sim$5.3% (absolute) im-

[4] http://www.ark.cs.cmu.edu/global-voices/

[5] Or else a sequence of labels, in the case of a conditional random field (Lafferty et al., 2001). However, even in this case, each token is usually assigned a single label. An exception is the factorial CRF (Sutton et al., 2007), which models several co-dependent sequences. Our approach is equivalent to a factorial CRF without edges between tags for adjacent tokens in the input.

Model	Accuracy (%)
Garrette et al. (2013)	81.2
MaxEnt Supervised	80.0
2-output MaxEnt (Universal tagset)	85.3
2-output MaxEnt (Penn tagset)	85.6

Table 7: The performance of different models for Malagasy.

provement. An interesting property of this approach is that we can use different tagsets for the DPM. We also tried the original Penn treebank tagset which is much larger than the universal tagset (48 vs. 12 tags). We observed a small improvement reaching 85.6%, suggesting that some pertinent information is lost in the universal tagset. All in all, this is a substantial improvement over the state-of-the-art result of 81.2% (Garrette et al., 2013) and an error reduction of 23.4%.

7 Conclusion

In this paper, we thoroughly review the work on multilingual POS tagging of the past decade. We propose a simple method for building a POS tagger for resource-poor languages by taking advantage of parallel data and a small amount of annotated data. Our method also efficiently resolves the tagset mismatch issue identified for some language pairs. We carefully choose and tune the model. Comparing with the state-of-the-art, we are using the more realistic assumption that a small amount of labelled data can be made available rather than requiring a crowd-sourced dictionary. We use less parallel data which as we pointed out in section 3.1, could have been a huge disadvantage for us. Moreover, we did not exploit any external monolingual data. Importantly, our method is simpler but performs better than previously proposed methods. With only 1,000 annotated tokens, less than 1% of the test data, we can achieve an average accuracy of 91.3% compared with 88.8% of the state-of-the-art (error reduction rate $\sim$22%). Across the 8 languages we are substantially better at 7 and slightly worse at one. Our method is reliable and could even be used to improve the performance of a supervised POS tagger.

Currently, we are building the tagger and evaluating through several layers of mapping. Each layer might introduce some noise which accumulates and leads to a biased model. Moreover, the tagset mappings are not available for many resource-poor languages. We therefore also proposed a method to automatically match between tagsets based on a two-output maximum entropy model. On the resource-poor language Malagasy, we achieved the accuracy of 85.6% compared with the state-of-the-art of 81.2% (Garrette et al., 2013). Unlike their method, we didn't use an external dictionary but instead use a small amount of parallel data.

In future work, we would like to improve the performance of DPM by collecting more parallel data. Duong et al. (2013a) pointed out that using a different source language can greatly alter the performance of the target language POS tagger. We would like to experiment with different source languages other than English. We assume that we have 1,000 tokens for each language. Thus, for the 8 languages we considered we will have 8,000 annotated tokens. Currently, we treat each language independently, however, it might also be interesting to find some way to incorporate information from multiple languages simultaneously to build the tagger for a single target language.

Abstract

Active learning (AL) consists of asking human annotators to annotate automatically selected data that are assumed to bring the most benefit in the creation of a classifier. AL allows to learn accurate systems with much less annotated data than what is required by pure supervised learning algorithms, hence limiting the tedious effort of annotating a large collection of data.

We experimentally investigate the behavior of several AL strategies for sequence labeling tasks (in a *partially-labeled* scenario) tailored on Partially-Labeled Conditional Random Fields, on four sequence labeling tasks: phrase chunking, part-of-speech tagging, named-entity recognition, and bio-entity recognition.

1 Introduction

Today, the state-of-the-art methods in most natural language processing tasks are supervised machine learning approaches. Their main problem lies in their need of large human-annotated training corpus, which requires a tedious and expensive work from domain experts. The process of *active learning* (AL) employs one or more human annotators by asking them to label new samples which are supposed to be the most informative in the creation of a new classifier. A classifier is incrementally retrained with all the data labeled by the annotator. AL has been demonstrated to work well and to produce accurate classifiers while saving much human annotation effort. One critical issue is to define a measure of the informativeness which should reflect how much new information a new example would give in the learning of a new classifier once annotated.

A lot of work has been done on the AL field in the past years (see (Settles, 2012) for an exhaustive overview). In particular, AL proved its usefulness in sequence labeling tasks (Settles and Craven, 2008). Yet, researchers have always adopted as annotation unit an entire sequence (i.e., the annotator is asked to annotate the whole sequence) while it looks like it could be much more relevant to ask for labeling only small parts of it (e.g., the ones with highest ambiguity). A few works have investigated this idea. For instance, Wanvarie et al. (2011) proposed to use Partially-Labeled Conditional Random Fields (PL-CRFs) (Tsuboi et al., 2008), a semi-supervised variation of Conditional Random Fields (CRFs) (Lafferty et al., 2001) able to deal with partially-labeled sequences, thus enabling to adopt as annotation unit single tokens and still learning from full sequences. AL with partially labeled sequences has proven to be effective in substantially reducing the amount of annotated data with respect to common AL approaches (see (Wanvarie et al., 2011)).

In this work we focus on AL strategies for partially labeled sequences adopting the single token as annotation unit and PL-CRFs as learning algorithm given its nature in dealing with partially labeled sequences. We propose several AL strategies based on measures of *uncertainty* adapted for the AL with partially labeled sequences scenario and tailored on PL-CRFs. We further propose two strategies that exploit the finer granularity given by the partially-labeled scenario. We also show that the choice of single-token annotation can bring to unpredictable results on sequence labeling tasks in which the structure of the sequences is not regular, e.g., named-entity recognition. We propose a first solution to the problem of unpredictability. The aim of this work is thoroughly compare the effectiveness and the behavior of all the proposed AL strategies on four standard sequence labeling tasks, phrase chunking, part-of-speech tagging, named-entity recognition and bio-entity recognition.

The remainder of this paper is as follows. In Section 2 we summarize the related work in AL, in Section 3 we describe PL-CRFs, the semi-supervised algorithm we adopt in this work. Section 4 describes in details the AL framework and the AL strategies we propose. Section 5 provides a description of the experimental setting, the datasets, and discusses the empirical results. Section 6 summarizes our findings.

2 Related Work

Our work belongs to the pool-based AL framework. It considers the case in which a large amount (pool) of unlabeled examples is available, from which samples to be labeled must be chosen. This framework fits all the sequence labeling problems we consider here. For a more exhaustive survey on other AL frameworks see

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 898–906,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

(Settles, 2012).

Most of the AL works on sequence labeling adopted the entire sequence as annotation unit (Settles and Craven, 2008) which was demonstrated by Wanvarie et al. (2011) to be less effective than using the single token as annotation unit. The main AL works in this latter line of work are (Shen et al., 2004), (Tomanek and Hahn, 2009) and (Wanvarie et al., 2011). Shen et al. (2004) adopted SVMs as learning algorithm and proposed two strategies that combine three criteria, informativeness, representativeness and diversity. SVMs allowed them to use as annotation unit a subset of the tokens in a sequence, without annotating, in any way, the rest of the tokens in the sequence. In (Tomanek and Hahn, 2009), the most uncertain tokens of the sequence are singularly annotated, but the rest of the labels in the sequence are then chosen by the classifier in a semi-supervised fashion. Wanvarie et al. (2011) is the closest work to ours, they adopt a minimum confidence selection strategy with re-estimation using the PL-CRFs. Differently from our work, Wanvarie et al. (2011) show that adopting the AL with partially labeled sequences using re-estimation, the annotation cost can be dramatically reduced (by annotating from 8% to 10% of the tokens of the entire training set), obtaining the same level of performance of the classifier trained on the entire, fully-labeled, training set. We started our work from this conclusion and we focused on AL with partially labeled sequences using re-estimation by comparing several AL strategies in order to find the strategy that allows to create the best classifier with the minimum annotation effort.

3 Partially-Labeled Conditional Random Fields

Nowadays, CRFs are the *de-facto* standard for the solution of sequence labeling tasks (Sarawagi, 2008). In traditional CRFs (Lafferty et al., 2001) the conditional probability of a sequence of labels $\mathbf{y}$ given a sequence of observed feature vectors $\mathbf{x}$ is given by:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{t=1}^{T} \Psi_t(\mathbf{y}, \mathbf{x}) \tag{1}$$

where a standard choice for sequence labeling tasks are the so called Linear-chain CRFs:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{t=1}^{T} \Psi_t(y_t, y_{t-1}, \mathbf{x}_t) \tag{2}$$

with:

$$\Psi_t(y_t, y_{t-1}, \mathbf{x}_t) = \Psi_u(y_t, x_t)\Psi_b(y_t, y_{t-1}) \tag{3}$$

where $\Psi_u(y_t, x_t)$ models the co-occurrence between features x_t, and label y_t at time t, and $\Psi_b(y_t, y_{t-1})$ models the co-occurrence between two adjacent labels y_t and y_{t-1}.

PL-CRFs introduced by Tsuboi et al. (2008) allow to learn a CRF model using partially-labeled sequences, marginalizing on those tokens that do not have an assigned label. In PL-CRFs, $\mathbf{L}$ denotes a partially labeled information about a sequence. It consists of a sequence of sets L_t in which $L_t = \mathcal{Y}$ (where $\mathcal{Y}$ is the set of all the possible labels) if there is no label information for token at time t. L_t is a singleton containing y_t if the label of the token at time t is known, and $\mathbf{Y_L}$ is the set of label sequences that fits the partial label information $\mathbf{L}$. Then the probability of a partial labeling may be computed as:

$$p(\mathbf{Y_L}|\mathbf{x}) = \sum_{\mathbf{y} \in \mathbf{Y_L}} p(\mathbf{y}|\mathbf{x}) \tag{4}$$

In order to perform inference and parameter learning on PL-CRFs, some modifications on traditional CRFs inference algorithms are required.

3.1 Forward-Backward Algorithm

Differently from traditional CRFs, the forward and backward scores (respectively α and β), are calculated as follows:

$$\alpha_{t,\mathbf{L}}(j) = \begin{cases} 0 & \text{if } j \notin L_t \\ \Psi_1(j, y_0, x_1) & \text{else if } t = 1 \\ & \text{and } j \in L_t \\ SA(j) & \text{otherwise} \end{cases} \tag{5}$$

$$\beta_{t,\mathbf{L}}(i) = \begin{cases} 0 & \text{if } j \notin L_t \\ 1 & \text{else if } t = T \\ & \text{and } j \in L_t \\ SB(j) & \text{otherwise} \end{cases} \tag{6}$$

where

$$SA(j) = \sum_{i \in L_{t-1}} \alpha_{t-1,\mathbf{L}}(i)\Psi_t(j, i, x_t) \tag{7}$$

$$SB(j) = \sum_{j \in L_{t+1}} \beta_{t+1,\mathbf{L}}(j)\Psi_{t+1}(j, i, x_{t+1}) \tag{8}$$

and y_0 is a special label that encodes the beginning of a sequence.

3.2 Marginal Probability

The marginal probability $p(y_t = j|\mathbf{x}, \mathbf{L})$ is calculated as:

$$p(y_t = j|\mathbf{x}, \mathbf{L}) = \frac{\alpha_{t,\mathbf{L}}(j) \cdot \beta_{t,\mathbf{L}}(j)}{Z_{\mathbf{L}}(\mathbf{x})} \tag{9}$$

with:

$$\forall t, Z_{\mathbf{L}}(\mathbf{x}) = \sum_{j \in L_t} \alpha_{t,\mathbf{L}}(j) \cdot \beta_{t,\mathbf{L}}(j) \tag{10}$$

In case there is no label information, the formulas for forward and backward scores (Equations (5) and (6)) and for the marginal probabilities (Equation (9)) yield the standard results of CRFs.

3.3 Viterbi Algorithm

The most probable sequence assignment may be derived with a Viterbi algorithm by recursively computing the following quantities:

$$\delta_{t,\mathbf{L}}(j) = \begin{cases} 0 & \text{if } j \notin L_t \\ \Psi_1(j, y_0, x_1) & \text{else if } t = 1 \\ & \text{and } j \in L_t \\ M(j) & \text{otherwise} \end{cases} \quad (11)$$

where

$$M(j) = \max_{i \in L_{t-1}} \delta_{t-1,\mathbf{L}}(i) \Psi_t(j, i, x_t) \quad (12)$$

The most probable assignment is then calculated as: $\mathbf{y}^* = argmax_{\mathbf{y}} p(\mathbf{y}|\mathbf{x}, \mathbf{L})$

3.4 Log-Likelihood

PL-CRFs's parameters θ are learnt through maximum log-likelihood estimation, that is to maximize the log-likelihood function $LL(\theta)$:

$$\begin{aligned} LL(\theta) &= \sum_{i=1}^{N} \log p(\mathbf{Y}_{\mathbf{L}^{(i)}}|\mathbf{x}^{(i)}) \\ &= \sum_{i=1}^{N} \log Z_{\mathbf{Y}_{L^{(i)}}}(\mathbf{x}^{(i)}) - \log Z_{\mathbf{Y}}(\mathbf{x}^{(i)}) \end{aligned} \quad (13)$$

The parameters θ that maximize Equation (13) are computed via the LBFGS optimization method (Byrd et al., 1994).

4 Active Learning Strategies

Pool-based AL (see (Lewis and Catlett, 1994)) is probably the most common scenario in AL, where one has a large amount (pool) of unlabeled examples $\mathcal{U}_1$ and a small amount of labeled examples $\mathcal{T}_1$. In this scenario, the process of AL consists in a series of n iterations where a classifier Φ_i is trained with labeled examples $\mathcal{T}_i$, and then is used to classify the unlabeled examples $\mathcal{U}_i$. At this point an AL strategy $\mathcal{S}$ will select a number of examples B that once labeled will hopefully improve the performance of the next classifier Φ_{i+1}.

Algorithm 1 shows the pool-based AL framework for partially annotated sequences as introduced in (Wanvarie et al., 2011). Differently from AL for fully labeled sequences (Esuli et al., 2010), thanks to the finer granularity of the partially labeled model, we use the token as basic annotation unit, instead of the entire sequence.

The point of using the partial labeling is in saving the request for human annotations on tokens whose labels are already known (inferred) by the classifier and concentrate on those tokens that the classifier finds hard to label. Using the semi-supervised approach of the PL-CRFs we can take advantage of single-labeled tokens instead of an entire labeled sequence.

The entire pool-based AL process with partially labeled sequences is summarized in Algorithm 1. The

Algorithm 1 Pool-based active learning framework

Require: $\mathcal{T}_1$, the initial training set
$\mathcal{U}_1$, the initial unlabeled set

n, the number of iterations
B, the dimension of the update batch

1: **for** $i \leftarrow 1$ to n **do**
2: $\quad \Phi_i \leftarrow \text{train}(\mathcal{T}_i)$
3: $\quad \mathcal{L}_i \leftarrow \Phi_i(\mathcal{U}_i)$
4: $\quad$ **for** $b \leftarrow 1$ to B **do**
5: $\quad\quad \mathbf{x}_*^{(b)} \leftarrow \arg\min_{\mathbf{x}_t \in \mathbf{x}, \mathbf{x} \in \mathcal{L}_i} \mathcal{S}(t, \mathbf{x})$
6: $\quad\quad \mathcal{L}_i \leftarrow \mathcal{L}_i - \mathbf{x}^{(b)} \cup \Phi_i(\mathbf{x}^{(b)}, y_*)$
7: $\quad\quad \mathcal{U}_i \leftarrow \mathcal{U}_i - \mathbf{x}_*^{(b)} \cup (\mathbf{x}_*^{(b)}, y_*)$
8: $\quad\quad \mathcal{T}_i \leftarrow \mathcal{T}_i - \mathbf{x}_*^{(b)} \cup (\mathbf{x}_*^{(b)}, y_*)$
9: $\quad \mathcal{U}_{i+1} \leftarrow \mathcal{U}_i$
10: $\quad \mathcal{T}_{i+1} \leftarrow \mathcal{T}_i$

function $\mathcal{S}(t, \mathbf{x})$ is what, hereafter, we call an AL *strategy*. $\mathcal{S}(t, \mathbf{x})$ takes as input an automatically annotated sequence $\mathbf{x}$ and an element t of this sequence, from the set of sequences $\mathcal{L}_i$ annotated by the PL-CRF classifier Φ_i, and returns a measure of informativeness as a function of the classifier decision.

For each iteration through the update batch B, the most informative element $\mathbf{x}_*^{(b)}$, according to the AL strategy, is chosen. The subscript $*$, in this case, represents the most informative token, while the superscript (b) represents the sequence in which the token appears. After the choice of the most informative token the sets $\mathcal{L}_i$, $\mathcal{U}_i$ and $\mathcal{T}_i$ are updated. $\mathcal{L}_i$ is updated by removing the annotated sequence $\mathbf{x}^{(b)}$ and all the information given by the classifier, and by adding the same sequence with the new manually labeled token (y_*) and all the re-estimated annotation given by the classifier $\Phi_i(\mathbf{x}^{(b)}, y_*)$. In the unlabeled set $\mathcal{U}_i$ and the training set $\mathcal{T}_i$ the most informative token $\mathbf{x}_*^{(b)}$ is updated with its manually labeled version $(\mathbf{x}_*^{(b)}, y_*)$[1]. After B token annotations, the unlabeled set and the training set for the next iteration, respectively $\mathcal{U}_{i+1}$ and $\mathcal{T}_{i+1}$, are updated.

The inference methods of Section 3 allow not only to train a CRF model with partially labeled sequences, but give the possibility of classifying partially labeled sequences, using the known labels as support for the prediction of the other ones. Thus, in this AL scenario, each time a token is chosen it is immediately labeled, and this new information, as we can see from line 6 of Algorithm 1, is promptly used to re-estimate the informativeness of the other tokens in the sequence in which the chosen token appears.

One may argue that, for a human annotator, anno-

[1] In order to have a light notation we omit the fact that when the most informative token is the first annotated token of a sentence, the whole sentence, with just one annotated token, is added to the training set $\mathcal{T}_i$

tating only one or few tokens, instead of the entire sequence, is a difficult task. This would be correct in the scenario in which the text is presented to the human annotator without any visual clue about the annotations. However, in (Culotta and McCallum, 2005) it is shown that presenting to the human annotator the highlighted sequence to be annotated along with the associated sequence of labels obtained by the classifier requires much less effort from the annotator than performing the annotation without any visual and contextual clue.

4.1 Greedy Strategies

In this section we present three AL strategies that select the most informative tokens, regardless of the assignment performed by the Viterbi algorithm. The rationale behind these strategies is that, even though we are looking for the most probable sequence assignment, we also want to annotate the most informative tokens singularly.

The **Minimum Token Probability (MTP)** strategy employs as measure of informativeness the probability of the most probable assignment at time t. This strategy greedily samples the tokens whose highest probability among the labels is lowest.

$$\mathcal{S}^{MTP}(t, \mathbf{x}) = \max_{j \in \mathcal{Y}} p(y_t = j | \mathbf{x}, \mathbf{L}) \tag{14}$$

The **Maximum Token Entropy (MTE)** strategy relies on the entropy measure to evaluate the ambiguity about the label of a token. The rationale of it is that, if more than one label have the same assigned marginal probability, the entropy will be high, that is,

$$\mathcal{S}^{MTE}(t, \mathbf{x}) = \sum_{j \in \mathcal{Y}} p(y_t = j | \mathbf{x}, \mathbf{L}) \cdot \log p(y_t = j | \mathbf{x}, \mathbf{L}) \tag{15}$$

In order to directly plug the $\mathcal{S}^{MTE}$ strategy into the AL framework of Algorithm 1, we removed the minus sign at the beginning of the entropy formula. This allow us to use the $\min$ operator with a maximum entropy approach.

The **Minimum Token Margin (MTM)** strategy is a variant of the margin sampling strategy introduced in (Scheffer et al., 2001). It calculates the informativeness by considering the two most probable assignments and by subtracting the highest probability by the lowest. With $\max'$ that calculates the second maximum value, MTM is defined as:

$$\mathcal{S}^{MTM}(t, \mathbf{x}) = \max_{j \in \mathcal{Y}} p(y_t = j | \mathbf{x}, \mathbf{L}) - \max_{j \in \mathcal{Y}}{}' p(y_t = j | \mathbf{x}, \mathbf{L}) \tag{16}$$

4.2 Viterbi Strategies

The following AL strategies take into consideration the most probable sequence assignments obtained from the Viterbi algorithm computed on already known labels in the sequence.

The rationale is that, with these strategies, the measure of uncertainty is chosen according to the information obtained from the outcome of the Viterbi algorithm (i.e., the most probable sequence assignment).

The **Minimum Viterbi Probability (MVP)** is the base strategy adopted in (Wanvarie et al., 2011). It takes as measure of informativeness the probability of the label chosen by the Viterbi algorithm.

$$\mathcal{S}^{MVP}(t, \mathbf{x}) = p(y_t^* | \mathbf{x}, \mathbf{L}) \tag{17}$$

where y_t^* is the label assignment chosen by the Viterbi algorithm. In general, the token assignments that maximize the probability of the sequence assignment y_t^* are different from the token assignments that maximize the probability of the individual token assignments $argmax_{j \in \mathcal{Y}} p(y_t = j)$.

The **Maximum Viterbi Pseudo-Entropy (MVPE)** strategy calculates for each token the "pseudo" entropy of the most probable sequences at the variation of the label at position t. The prefix pseudo is used because even though it is calculated as an entropy, the summation is over all the possible labels that can be associated to a token, and not all the possible sequence assignments.

$$\mathcal{S}^{MVPE}(t, \mathbf{x}) = \sum_{j \in \mathcal{Y}} p(\mathbf{y}^*_{y_t=j} | \mathbf{x}, \mathbf{L}) \cdot \log p(\mathbf{y}^*_{y_t=j} | \mathbf{x}, \mathbf{L}) \tag{18}$$

where $\mathbf{y}^*_{y_t=j}$ represents the most probable assignment with the label at time t constrained to the value j. As in the MTE strategy the minus sign is removed in order to plug the functions directly into the AL framework of Algorithm 1.

The **Minimum Viterbi Margin (MVM)** strategy calculates the difference of the sequence probabilities of the two most probable sequence assignments at the variation of the label at time t. When the difference at time t is low, the Viterbi algorithm, in that time, chooses between two almost equally probable, sequence assignments. Formally:

$$\mathcal{S}^{MVM}(t, \mathbf{x}) = p(\mathbf{y}^*_{y_t^*} | \mathbf{x}, \mathbf{L}) - p(\mathbf{y}'^*_{y_t'^*} | \mathbf{x}, \mathbf{L}) \tag{19}$$

where $\mathbf{y}'^*$ is the second most probable assignment.

PL-CRFs allow us to inspect one token at time in order to decide if it is worth to annotate. This fact give us the possibility of exploit two quantities in order to estimate the informativeness of a token, the sequence probability, usually adopted in the traditional AL for sequence labeling, and the marginal probabilities of the single tokens as in Section 4.1. The **Minimum Expectation (ME)** strategy combines the marginal probabilities, $p(y_t = j | \mathbf{x}, \mathbf{L})$ and $p(\mathbf{y}^*_{y_t=j} | \mathbf{x}, \mathbf{L})$.

$$\mathcal{S}^{ME}(t, \mathbf{x}) = \sum_{j \in \mathcal{Y}} p(y_t = j | \mathbf{x}, \mathbf{L}) \cdot p(\mathbf{y}^*_{y_t=j} | \mathbf{x}, \mathbf{L}) \tag{20}$$

Here the maximum sequence probability is seen as a function, and what we calculate is the expected value of this very function. The rationale of this strategy is picking those tokens in which both, the sequence probability returned by the Viterbi algorithm, and the marginal probability of the considered labels are low.

Given that the ME strategy gives a high weight to the sequence probability, one might expect that tokens that belongs to longer sequences are selected more frequently, given that, the sequence probability of longer sequences is usually lower than shorter ones. One way to normalize this difference is subtracting the current maximum sequence probability, that is, the maximum sequence probability calculated without any new label estimation, to the expected value obtained from the estimation of the label assignment of the token. This is the **Minimum Expectation Difference (MED)** strategy.

$$\mathcal{S}^{MED}(t, \mathbf{x}) = \mathcal{S}^{ME}(t, \mathbf{x}) - p(\mathbf{y}^*|\mathbf{x}, \mathbf{L}) \qquad (21)$$

The rationale of this strategy is that when the expected value is far from the maximum value, that is the value returned by the Viterbi algorithm, it means that we have uncertainty on the token taken into consideration.

The **Random (RAND)** strategy samples random tokens without any external information. It is used as *baseline* to compare the real effectiveness of the proposed strategy.

At the best of our knowledge the strategies presented in this section (with the exception of the MVP strategy) have never been applied in the context of AL with partially labeled sequences scenario.

5 Experiments

5.1 Datasets

We have experimented and evaluated the AL strategies of Section 4 on four sequence labeling tasks, part-of-speech tagging, phrase chunking, named-entity recognition and bio-entity recognition. We used the CoNLL2000 dataset (Tjong Kim Sang and Buchholz, 2000) for the phrase chunking task, the CoNLL2003 dataset (Tjong Kim Sang and De Meulder, 2003), for the named-entity recognition task, the NLPBA2004 dataset (Kim et al., 2004), for the biomedical entity recognition task and the CoNLL2000POS dataset[2] for the part-of-speech labeling task. All the datasets are publicly available and are standard benchmarks in sequence labeling tasks. Table 1 shows some statistics of the datasets in terms of dimensions, number of labels, distribution of the labels, etc. The data heterogeneity of the different datasets allowed us to test the AL strategies on different "experimental settings", thus to have a more robust empirical evaluation.

[2]This is the CoNLL2000 dataset annotated with part-of-speech labels instead of chunking labels.

5.2 Experimental Setting

We tested the AL strategies described in Section 4 on test sets composed by 2012 sequences and 47377 tokens for the CoNLL2000 and CoNLL2000POS datasets, by 3452 sequences and 46394 tokens for the CoNLL2003 dataset and by 3856 sequences and 101039 tokens for the NLPBA2004 dataset. We chose an initial training set $\mathcal{T}_1$ of $\sim$5 sequences on CoNLL2000 and CoNLL2000POS datasets, $\sim$7 sequences on CoNLL2003 dataset and $\sim$4 sequences on NLPBA2004 dataset, for a total of $\sim$100 labeled tokens for each dataset. The dimension of the batch update B has been chosen as a trade-off between an ideal case in which the system is retrained after every single annotation (i.e., $B = 1$) and a practical case with higher B to limit the algorithmic complexity (since the PL-CRF classifier must be retrained every iteration). We used in our experiments $B = 50$. We fixed the number of AL iterations n at 40 because what matters here is how the strategies behave in the beginning of AL process when the annotation effort remains low. For each strategy and for each dataset, we report averaged results of three runs with a different randomly sampled initial training set $\mathcal{T}_1$.

For each dataset we adopted a standard set of features. For the CoNLL2000 dataset we adopted the same standard features used in (Wanvarie et al., 2011) for the same dataset, for the CoNLL2003 and the NLPBA2004 dataset we adopted the features used in (Wanvarie et al., 2011) for the CoNLL2003 dataset, while for the CoNLL2000POS dataset we used the features presented in (Ratnaparkhi, 1996). As evaluation measure we adopted the token variant of the F_1 measure, introduced by Esuli and Sebastiani (2010). This variant, instead of the entire annotation (chunk/entity), calculates TPs, FPs, and FNs, singularly for each token that compose the annotation, bringing to a finer evaluation.

5.3 Results

From the learning curves of Figure 1 and Figure 2 it is clear that most of the strategies have the same trend throughout the different datasets. This results is somewhat different from the results obtained in (Settles and Craven, 2008) in which there is not a clear winner among the strategies they proposed in a fully-labeled scenario. The strategies that perform particularly bad (worse than the RAND strategy in CoNLL2000POS and in CoNLL2003 dataset) in all the datasets are the MTE and MTP. This is expected, because the choice of the measure of informativeness related to the token without taking in consideration the Viterbi path is suboptimal in this task. Surprisingly, the MTM strategy even though based on the same principle of MTE and MTP, is very effective in most of the datasets. The most effective strategies, that is, the ones that are the faster at helping the classifier to reach a better accuracy are the MTM, MVM, and MVP, in particular the margin-based strategies perform very good in all the

Table 1: Training Data Statistics. #S is the number of total sequences in the dataset, #T is the number of tokens in the dataset, #L is the number of positive labels (labels different from the negative label O), AAL is the average length, in tokens, of annotations (sequence of tokens that refer to the same instance of a label), APT is the average number of token in a sequence annotated with a positive label, ASL is the average length of a sequence, AA is the average number of annotations in a sequence, %AC is the percentage of sequences with more than one positive annotation, %DAC is the percentage of sequences that have two or more annotations with different labels.

Dataset	#S	#T	#L	AAL	APT	ASL	AA	%AC	%DAC
CoNLL2000	8936	211727	11	1.6	20.6	24	12.0	98%	98%
CoNLL2000POS	8936	211727	35	1.0	20.8	24	20.8	100%	99%
CoNLL2003	17290	254979	4	1.4	2.5	15	2.2	45%	32%
NLPBA2004	18546	492551	5	2.5	5.9	27	3.1	72%	47%

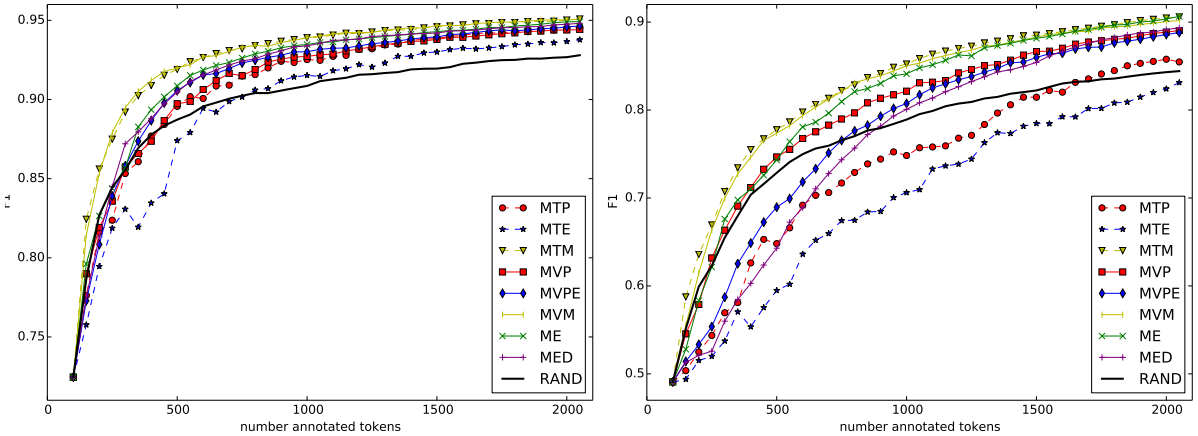

Figure 1: F_1 results on CoNLL2000 dataset (left) and CoNLL2000POS dataset (right). For both datasets the maximum number of annotated tokens used (2100) represents ∼1% of the entire training set.

datasets. The MVPE strategy performs particularly bad in the CoNLL2003 dataset but it performs better than the RAND strategy in the other datasets. The performance of the ME strategy is always above the average, in particular it is the best performing strategy in the NLPBA2004 dataset. However, in the CoNLL2003 dataset its performance is similar to the RAND's performance. Looking at the data, as expected, ME tends to choose tokens belonging to the longest sequences, regardless if the sequence is already partially annotated, that is, it tends to choose tokens from the same sequences. This behavior is not particularly relevant on the CoNLL2003 dataset given that the average number of positive tokens per sentence is not high (2.5, see Table 1). For the other datasets, the average number of positive tokens per sentence is high, and so the ME strategy is particularly effective. The MED strategy has the most heterogeneous behavior among the datasets. It shows average performances in the CoNLL2000 dataset and NLPBA2004 dataset, but is slower than the RAND strategy in the CoNLL2003 and CoNLL2000POS datasets.

In Figure 2 (left) we can notice that there are some strategies that are consistently worse than the RAND strategy. The difference between the strategies below the RAND strategy and the RAND strategy itself might be due to the fact that those strategies ask to label tokens that are "outliers" (if we imagine tokens as points of the features space) that rarely appear in the training and test set, and on which the classifier is very uncertain. Given that we are in a semi-supervised setting, with very few training examples, these "outliers" can introduce a lot of noise in the created models and so yielding poor results. This phenomenon does not happen in the RAND strategy given that it samples uniformly from the unlabeled set and given that the "outliers" (special cases) are not many, the probability of randomly selecting an "outlier" is low.

5.3.1 Performance Drop

The AL strategies applied on the CoNLL2003 dataset (Figure 2 (left)) suffer of some "random" drop of performance. We believe that the first reason that yield such a behavior is that named entities often appear once in a sentence, and have heterogeneous structures with respect to some homogenous structures as the chunk and POS. The second reason is that, it may happen that the strategies are not accurate enough to localize precisely the best token to label or that getting the label of an isolated token does not help the classifier much

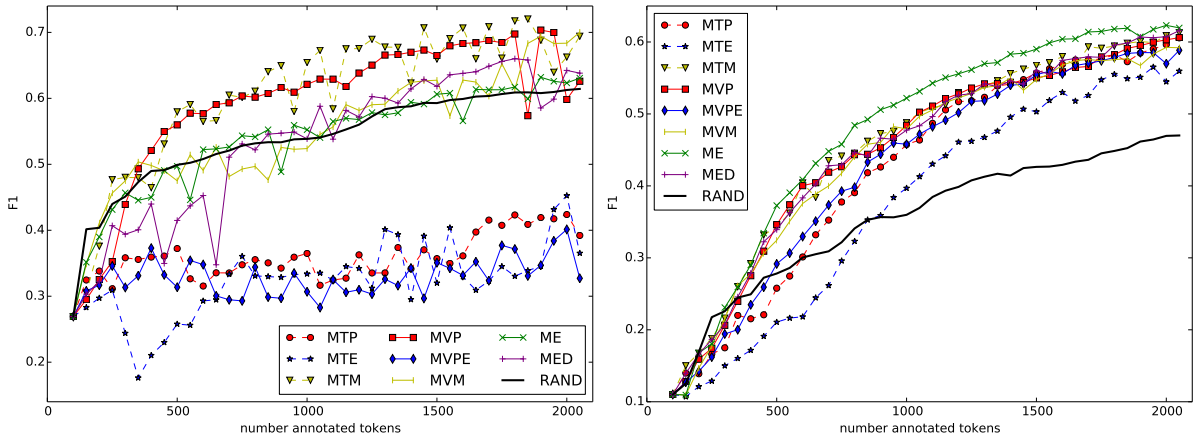

Figure 2: F_1 results on CoNLL2003 dataset (left) and NLPBA2004 dataset (right). 2100 annotated tokens represent the $\sim$0.8% and $\sim$0.4% respectively of the CoNLL2003 training set and the NLPBA2004 training set.

for the remaining of the (unlabeled) tokens in the sequence.

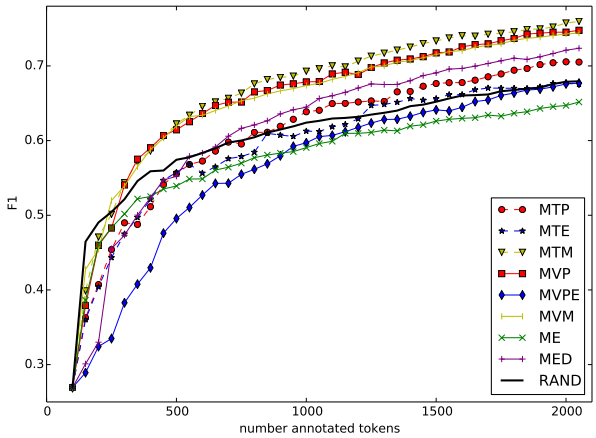

Figure 3: F_1 results on CoNLL2003 dataset, three tokens annotation. 6100 annotated tokens represent the $\sim$2.4% of the CoNLL2003 training set.

A similar phenomenon, called *missed class effect* (Tomanek et al., 2009), happens in AL when the strategies inspect regions of the example space around the decision boundaries, bringing to a slow AL process. In (Tomanek et al., 2009) the missed class effect problem is solved by helping the AL strategies to inspect regions far from the decision boundaries, that is, by choosing an entire sequence instead of a single token. This solution is not suitable in this context given that we will loose all the advantages we have in the partially-labeled scenario, thus, we decided to annotate for each chosen token the previous token and the next token. The learning curves of the AL strategies adopting this method (Figure 3) show a monotonically increasing performance in function of the number of annotated tokens.

By annotating three tokens at time, the tokens that were considered "outliers" in the scenario with a single token annotation are now supported by other tokens of the sequence. This fact helps to decrease the noise introduced in the semi-supervised model yielding better results.

5.3.2 Statistical Analysis

Figure 4 reports a few statistics that highlight the behavior of the methods on one of the datasets. One may see for instance that the MVM and ME strategies are very different from the other methods in that they select tokens that belong to significantly longer sentences on average. Also it may be seen that MVM in particular selects tokens that are far from already annotated tokens in the sentence. This strategy probably yields a particular behavior with respect to exploration and exploitation that seems to suit the two tasks well. The other strategies do exhibit different behaviors that intuitively should not work well. For instance the MED and the MVPE strategies select tokens from new fully unlabeled sentences (not shown statistics), preferably short, so that the distance from selected tokens to already labeled tokens in the sentence (when any) is low. These curves look like relevant indicators of the behavior of the methods, and it would probably be worth monitoring these all along the AL process to make sure the learning exhibit a suitable behavior. This will be a future study that is out of the scope of this work.

6 Conclusion

In this paper we have presented several AL strategies tailored for the PL-CRFs in a pool-based scenario. We have tested the proposed strategies on four different datasets for four different sequence labeling tasks. Differently from other similar work in the field of AL, in this study we have shown that margin-based strategies constantly achieve good performance on four tasks with very different data characteristics. Furthermore, we have found that on datasets with certain characteristics a particular phenomenon that makes the entire

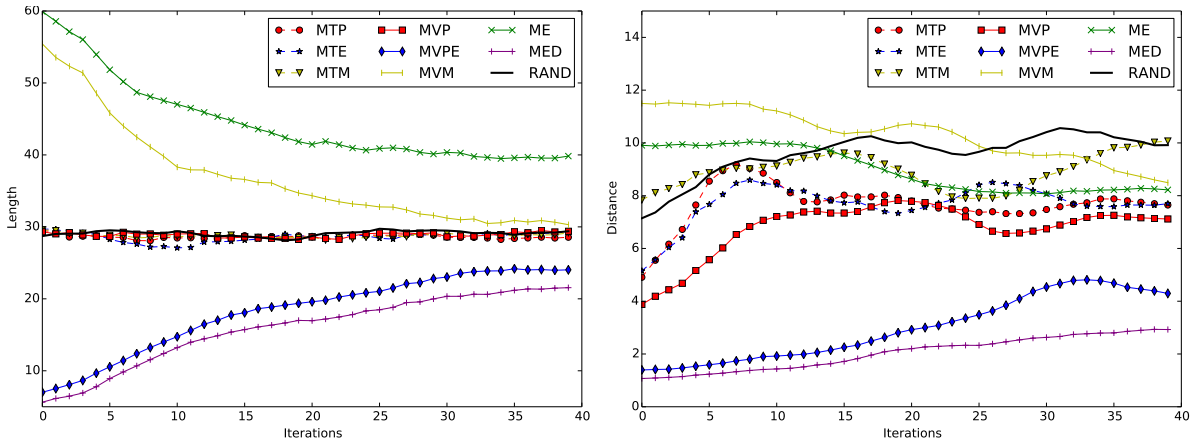

Figure 4: Behavior of the methods on CoNLL2000 dataset as a function of the number of the iterations (x-axis, from 1 to 40). Average length of the sentence the tokens that are selected by the AL strategy belong to (left) and average distance from a token that is selected to the closest already labeled token in the sentence, if any (right).

AL process highly unpredictable shows up. This phenomenon consists in random drops of accuracy of the classifiers learnt during the AL process. We have proposed a first solution for this problem that does not have a relevant impact on the human annotation effort.

Language Modeling with Functional Head Constraint for Code Switching Speech Recognition

Abstract

In this paper, we propose novel structured language modeling methods for code mixing speech recognition by incorporating a well-known syntactic constraint for switching code, namely the Functional Head Constraint (FHC). Code mixing data is not abundantly available for training language models. Our proposed methods successfully alleviate this core problem for code mixing speech recognition by using bilingual data to train a structured language model with syntactic constraint. Linguists and bilingual speakers found that code switch do not happen between the functional head and its complements. We propose to learn the code mixing language model from bilingual data with this constraint in a weighted finite state transducer (WFST) framework. The constrained code switch language model is obtained by first expanding the search network with a translation model, and then using parsing to restrict paths to those permissible under the constraint. We implement and compare two approaches - lattice parsing enables a sequential coupling whereas partial parsing enables a tight coupling between parsing and filtering. We tested our system on a lecture speech dataset with 16% embedded second language, and on a lunch conversation dataset with 20% embedded language. Our language models with lattice parsing and partial parsing reduce word error rates from a baseline mixed language model by 3.8% and 3.9% in terms of word error rate relatively on the average on the first and second tasks respectively. It outperforms the interpolated language model by 3.7% and 5.6% in terms of word error rate relatively, and outperforms the adapted language model by 2.6% and 4.6% relatively. Our proposed approach avoids making early decisions on code-switch boundaries and is therefore more robust. We address the code switch data scarcity challenge by using bilingual data with syntactic structure.

1 Introduction

In multilingual communities, it is common for people to mix two or more languages in their speech. A single sentence spoken by bilingual speakers often contains the main, matrix language and an embedded second language. This type of linguistic phenomenon is called "code switching" by linguists. It is increasingly important for automatic speech recognition (ASR) systems to recognize code switching speech as they exist in scenarios such as meeting and interview speech, lecture speech, and conversational speech. Code switching is common among bilingual speakers of Spanish-English, Hindi-English, Chinese-English, and Arabic-English, among others. In China, lectures, meetings and conversations with technical contents are frequently peppered with English terms even though the general population is not considered bilingual in Chinese and English. Unlike the thousands and tens of thousands of hours of monolingual data available to train, for example, voice search engines, transcribed code switch data necessary for training language models is hard to come by. Code switch language modeling is therefore an even harder problem than acoustic modeling.

One approach for code switch speech recognition is to explicitly recognizing the code switch points by language identification first using phonetic or acoustic information, before applying speech recognizers for the matrix and embedded languages (Chan et. al, 2004; Shia et. al,

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 907–916,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

2004; Lyu and Lyu, 2008). This approach is extremely error-prone as language identification at each frame of the speech is necessary and any error will be propagated in the second speech recognition stage leading to fatal and irrecoverable errors.

Meanwhile, there are two general approaches to solve the problem of lack of training data for language modeling. In a first approach, two language models are trained from both the matrix and embedded language separately and then interpolated together (Vu et. al, 2012; Chan et. al, 2006). However, an interpolated language model effectively allows code switch at all word boundaries without much of a constraint. Another approach is to adapt the matrix language language model with a small amount of code switch data (Tsai et. al, 2010; Yeh et. al, 2010; Bhuvanagiri and Kopparapu, 2010; Cao et. al, 2010). The effectiveness of adaptation is also limited as positions of code switching points are not generalizable from the limited data. Significant progress in speech recognition has been made by using deep neural networks for acoustic modeling and language model. However, improvement thus gained on code switch speech recognition remains very small. Again, we propose that syntactic constraints of the code switching phenomenon can help improve performance and model accuracy. Previous work of using part-of-speech tags (Zhang et. al, 2008; Vu et al 2012) and our previous work using syntactic constraints (Li and Fung, 2012, 2013) have made progress in this area. Part-of-speech is relatively weak in predicting code switching points. It is generally accepted by linguists that code switching follows the so-called Functional Head Constraint, where words on the nodes of a syntactic sub tree must follow the language of that of the headword. If the headword is in the matrix language then none of its complements can switch to the embedded language.

In this work, we propose two ways to incorporate the Functional Head Constraint into speech recognition and compare them. We suggest two approaches of introducing syntactic constraints into the speech recognition system. One is to apply the knowledge sources in a sequential order. The acoustic model and a monolingual language model are used first to produce an intermediate lattice, then a second pass choose the best result using the syntactic constraints. Another approach uses tight coupling. We propose using structured language model (Chelba and Jelinek, 2000) to build the syntactic structure incrementally.

Following our previous work, we suggest incorporating the acoustic model, the monolingual language model and a translation model into a WFST framework. Using a translation model allows us to learn what happens when a language switches to another with context information. We will motivate and describe this WFST framework for code switching speech recognition in the next section. The Functional Head Constraint is described in Section 3. The proposed code switch language models and speech recognition coupling is described in Section 4. Experimental setup and results are presented in Section 5. Finally we conclude in Section 6.

2 Code Switch Language Modeling in a WFST Framework

As code switch text data is scarce, we do not have enough data to train the language model for code switch speech recognition. We propose instead to incorporate language model trained in the matrix language with a translation model to obtain a code switch language model. We propose to integrate a bilingual acoustic model (Li et. al, 2011) and the code switch language model in a weighted finite state transducer framework as follows.

Suppose X denotes the observed code switch speech vector, w_1^J denotes a word sequence in the matrix language, the hypothesis transcript v_1^I is as follows:

$$\begin{aligned}
\hat{v}_1^I &= \arg\max_{v_1^I} P(v_1^I|X) \\
&= \arg\max_{v_1^I} P(X|v_1^I)P(v_1^I) \\
&= \arg\max_{v_1^I} P(X|v_1^I) \sum_{w_1^J} P(v_1^I|w_1^J)P(w_1^J) \\
&\cong \arg\max_{v_1^I} P(X|v_1^I)P(v_1^I|w_1^J)P(w_1^J) \quad (1)
\end{aligned}$$

where $P(X|v_1^I)$ is the acoustic model and $P(v_1^I)$ is the language model in the mixed language.

Our code switch language model is obtained from a translation model $P(v_1^I|w_1^J)$ from the matrix language to the mixed language, and the language model in the matrix language $P(w_1^J)$.

Instead of word-to-word translation, the transduction of the context dependent lexicon transfer is constrained by previous words. Assume the transduction depends on the previous n words:

$$
\begin{aligned}
P(v_1^I|w_1^J) &= \prod_{i=1}^{I} P(v_i|v_1^{i-1}, w_1^i) \\
&\cong \prod_{i=1}^{I} P(v_{i-n+1}^{i-1}|w_{i-n+1}^{i}) \\
&= \prod_{i=1}^{I} \frac{P(v_i, w_i|v_{i-n+1}^{i-1}, w_{i-n+1}^{i-1})}{P(w_i|v_{i-n+1}^{i-1}, w_{i-n+1}^{i-1})} \\
&= \prod_{i=1}^{I} \frac{P(v_i, w_i|v_{i-n+1}^{i-1}, w_{i-n+1}^{i-1})}{P(w_i|\sum_{v_i} v_{i-n+1}^{i-1}, w_{i-n+1}^{i-1})}
\end{aligned} \tag{2}
$$

There are C-level and H-level search networks in the WFST framework. The C-level search network is composed of the universal phone model P, the context model C, the lexicon L, and the grammar G

$$N = P \circ C \circ L \circ G \tag{3}$$

The H-level search network is composed of the state model H, the phoneme model P, the context model C, the lexicon L, and the grammar G

$$N = H \circ P \circ C \circ L \circ G \tag{4}$$

The C-level requires less memory then the H-level search network. We propose to use a weighted finite state transducer framework incorporating the bilingual acoustic model P, the context model C, the lexicon L, and the code switching language models G_{CS} into a C-level search network for mixed language speech recognition. The output of the recognition result is in the mixed language after projection $\pi(G_{CS})$.

$$N = P \circ C \circ L \circ \pi(G_{CS}) \tag{5}$$

The WFST implementation to obtain the code switch language model G_{CS} is as follows:

$$G_{cs} = \mathcal{T} \circ G \tag{6}$$

where T is the translation model

$$P(\tilde{v}_1^L|w_1^J) = \prod_{l=1}^{L} P_l(\tilde{v}_l|w_l) \tag{7}$$

$P_l(\tilde{v}_l|w_l)$ is the probability of w_l translated into $\tilde{v}_l$.

In order to make use of the text data in the matrix language to recognize speech in the mixed language, the translation model $P(v_1^I|w_1^J)$ transduce the language model in the matrix language to the mixed language.

$$
\begin{aligned}
P(v_1^I|w_1^J) = \sum_{\tilde{v}_1^L, c_1^L, r_1^K, \tilde{w}_1^K} & P(\tilde{w}_1^K|w_1^J) \\
& \cdot P(r_1^K|\tilde{w}_1^K, w_1^J) \\
& \cdot P(c_1^L, r_1^K, \tilde{w}_1^K, w_1^J) \\
& \cdot P(\tilde{v}_1^K|c_1^L, r_1^K, \tilde{w}_1^K, w_1^J) \\
& \cdot P(v_1^I|\tilde{v}_1^K, r_1^K, \tilde{w}_1^K, w_1^J)
\end{aligned} \tag{8}
$$

where $P(\tilde{w}_1^K|w_1^J)$ is the word-to-phrase segmentation model, $P(r_1^K|\tilde{w}_1^K, w_1^J)$ is the phrasal reordering model, $P(c_1^L, r_1^K, \tilde{w}_1^K, w_1^J)$ is the chunk segmentation model, $P(\tilde{v}_1^K|c_1^L, r_1^K, \tilde{w}_1^K, w_1^J)$ is the chunk-to-chunk transduction model, $P(v_1^I|\tilde{v}_1^K, r_1^K, \tilde{w}_1^K, w_1^J)$ is the chunk-to-word reconstruction model.

The word-to-phrase segmentation model extracts a table of phrases $\{\tilde{v}_1, \tilde{v}_2, ..., \tilde{v}_K\}$ for the transcript in the embedded language and $\{\tilde{w}_1, \tilde{w}_2, ..., \tilde{w}_K\}$ for the transcript in the matrix language based on word-to-word alignments trained in both directions with GIZA++ (Och and Ney, 2003). The chunk segmentation model performs the segmentation of a phrase sequence $\tilde{w}_1^K$ into L phrases $\{c_1, c_2, ..., c_L\}$ using a segmentation weighted finite-state transducer. Assumes that a chunk c_l is code-switched to the embedded language independently by each chunk, the chunk-to-chunk transduction model is the probability of a chunk to be code switched to the embedded language trained on parallel data. The reconstruction model generates word sequence from chunk sequences and operates in the opposite direction to the segmentation model.

3 Functional Head Constraint

Many linguistics (Abney 1986; Belazi et. al, 1994; Bhatt 1994) have discovered the so-called Functional Head Constraint in code switching. They have found that code switches between a functional head (a complementizer, a determiner, an inflection, etc.) and its complement (sentence, noun-phrase, verb-phrase) do not happen in natural speech. In addition, the Functional Head Constraint is language independent.

In this work, we propose to investigate and incorporate the Functional Head Constraint into code switching language modeling in a WFST framework. Figure 1 shows one of the Functional Head Constraint examples. Functional heads are

the roots of the sub trees and complements are part of the sub trees. Actual words are the leaf nodes. According to the Functional Head Constraint, the leave nodes of a sub tree must be in either the matrix language or embedded language, following the language of the functional head. For instance, the third word "東西/something" is the head of the constituents "非常/very 重要的/important 東西/something". These three constituent words cannot be switched. Thus, it is not permissible to code switch in the constituent. More precisely, the language of the constituent is constrained to be the same as the language of the headword. In the following sections, we describe the integration of the Functional Head Constraint and the language model.

We have found this constraint to be empirically sound as we look into our collected code mixing speech and language data. The only violation of the constraint comes from rare cases of borrowed words such as brand names with no translation in the local, matrix language. Borrowed words are used even by monolingual speakers so they are in general part of the matrix language lexicon and require little, if any, special treatment in speech recognition.

In the following sections, we describe the integration of Functional Head Constraint and the language model.

4 Code Switching Language Modeling with Functional Head Constraint

We propose two approaches of language modeling with Functional Head Constraint: 1) lattice-parsing and sequential-coupling (Chapplerler et. al, 1999); 2) partial-parsing and tight-coupling (Chapplerler et. al, 1999). The two approaches will be described in the followed sections.

4.1 Sequential-coupling by Lattice-based Parsing

In this first approach, the acoustic models, the code switch language model and the syntactic constraint are incorporated in a sequential order to progressively constrain the search. The acoustic models and the matrix language model are used first to produce an intermediate output. The intermediate output is a lattice in which word sequences are compactly presented. Lattice-based parsing is used to expand the word lattice generated from the first decoding step according to the Functional Head Constraint.

We have reasons to use word lattice instead of N-best hypothesis. The number of hypothesis of word lattice is larger than N-best hypothesis. Moreover, different kinds of errors correspond to the language model would be observed if N-best list is extracted after the first decoding step. The second pass run over the N-best list will prevent the language model with Functional Head Constraint from correcting the errors. In order to obtain a computational feasible number of hypotheses without bias to the language model in the first decoding step, word lattice is used as the intermediate output of the first decoding step.

A Probabilistic Context-Free Grammar (PCFG) parser is trained on Penn Treebank data. The PCFG parser is generalized to take the lattice generated by the recognizer as the input. Figure 2 illustrates a word lattice which is a compact representation of the hypothesis transcriptions of a an input sentence. All the nodes of the word-lattice are ordered by increasing depth.

A CYK table is obtained by associating the arcs with their start and end states in the lattice instead of their sentence position and initialized all the cells in the table corresponding to the arcs (Chapplerler et. al, 1999). Each cell $C_{k,j}$ of the table is filled by a n-tuple of the non-terminal A, the length k and the starting position of the word sequence $w_j...w_{j+k}$ if there exists a PCFG rule $A \rightarrow w_j...w_{j+k}$, where A is a non-terminal which parse sequences of words $w_j...w_{j+k}$. In order to allow all hypothesis transcriptions of word lattice to be taken into account, multiple word sequences of the same length and starting point are initialized in the same cell. Figure 2 mapped the word lattice of the example to the table, where the starting node label of the arc is the column index and the length of the arc is the row index.

The sequential-coupling by lattice-parsing consists of the standard cell-filling and the self-filling steps. First, the cells $C_{k,j}$ and $C_{i-k,j+k}$ are combined to produce a new interpretation for cell $C_{i,j}$. In order to handle the unary context-free production $A \rightarrow B$ and update the cells after the standard cell-filling, a n-tuple of A, i and j is added for each n-tuple of the non-terminal B, the length i and the start j in the cell $C_{i,j}$. The parse trees extracted are associated with the input lattice from the table starting from the non-terminal label of the top cell. After the parse tree is obtained, we re-

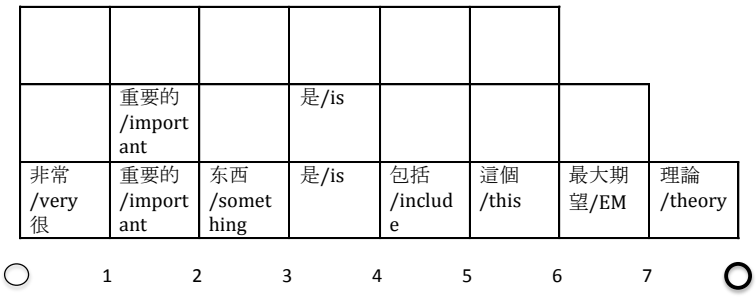

Figure 3: The mapping of the example word lattice to the table.

cursively enumerate all its subtrees. Each subtree is able to code-switch to the embedded language with a translation probability $P_l(\tilde{v}_l|w_l)$.

The lattice parsing operation consists of the an encoding of a given word sequence along with a parse tree (W,T) and a sequence of elementary model actions. In order to obtain a correct probability assignment $P(W,T)$ one simply assign proper conditional probabilities to each transition in the weighted finite states.

The probability of a parse T of a word sequence $WP(W,T)$ can be calculated as the product of the probabilities of the subtrees.

$$P(W,T) = \prod_{k=1}^{n+1} [P(wk|W_{k-1}T_{k-1}) \quad (9)$$

Where $W_k = w_0...w_k$ is the first k words in the sentence, and (W_k, T_k) is the word-and-parse k-prefix. The probability of the n-tuple of the non-terminal A, the length i and the starting position j is the probability of the subtree corresponding to A parsing throughout the sequence $w_j...w_{j+i-1}$. The probability of the partial parsing is the product of probabilities of the subtree parses it is made of. The probability of an n-tuple is the maximum over the probabilities of probable parsing path.

The N most probable parses are obtained during the lattice-parsing.

The probability of a sentence is computed by adding on the probability of each new context-free rule in the sentences.

4.2 Tight-coupling by Incremental Parsing

To integrate the acoustic models, language model and the syntactic constraint in time synchronous decoding, an incremental operation is used in this approach. The final word-level probability assigned by our model is calculated using the acoustic models, the matrix language model, the structured language model and the translation model. The structured language model uses probabilistic parameterization of a shift-reduce parse (Chelba and Jelinek, 2000). The tight-coupled language model consists of three transducers, the word predictor, the tagger and the constructor. As shown in Figure 3, $W_k = w0...wk$ is the first k words of the sentence, T_k contains only those binary subtrees whose leaves are completely included in W_k, excluding w_0 =<s>. Single words along with their POS tag can be regarded as root-only trees. The exposed head h_k is a pair of the headword of the constituent W_k and the non-terminal label. The exposed head of single words are pairs of the words and their POS tags.

Given the word-and-parse (k-1)-prefix $W_{k-1}T_{k-1}$, the new word w_k is predicted by the word-predictor $P(w_k|W_{k-1}T_{k-1})$. Taking the word-and-parse $k-1$-prefix and the next word as input, the tagger $P(t_k|w_k, W_{k-1}T_{k-1})$ gives the POS tag t_k of the word w_k. Constructor $P(p_i^k|W_kT_k)$ assigns a non-terminal label to the constituent W_{k+1}. The headword of the newly built constituent is inherited from either the headword of the constituent W_k or the next word w_{k+1}.

$$\begin{aligned} &P(w_k|W_{k-1}T_{k-1}) \\ &= P(w_k|[W_{k-1}T_{k-1}]) \\ &= P(w_k|h_0, h_{-1}) \quad (10) \\ &P(t_k|w_k, W_{k-1}T_{k-1}) \\ &= P(t_k|w_k, [W_{k-1}T_{k-1}]) \\ &= P(t_k|w_k, h_0.tag, h_{-1}.tag) \quad (11) \\ &P(p_i^k|W_kT_k) \\ &= P(p_i^k|[W_kT_k]) \\ &= P(p_i^k|h_0, h_1) \quad (12) \end{aligned}$$

The probability of a parse tree T $P(W,T)$ of a word sequence W and a complete parse T can be calculated as:

$$\begin{aligned} P(W,T) = \prod_{k=1}^{n+1} [&P(w_k|W_{k-1}T_{k-1}) \\ &P(t_k|W_{k-1}T_{k-1}, w_k) \\ &P(T_k|W_{k-1}T_{k-1}, w_k, t_k)] \quad (13) \end{aligned}$$

$$\begin{aligned} &P(T_{k-1}^k|W_{k-1}T_{k-1}, w_k, t_k) \\ &= \prod_{i=1}^{N_k} P(p_k|W_{k-1}T_{k-1}, w_k, t_k, p_1^k...p_{i-1}^k) \end{aligned} \quad (14)$$

Where w_k is the word predicted by the word-predictor, t_k is the POS tag of the word w_k predicted by the tagger, $W_{k-1}T_{k-1}$ is the word-parse (k - 1)-prefix, T_{k-1}^k is the incremental parse structure that generates $T_k = T_{k-1}||T_{k-1}^k$ when attached to T_{k-1}; it is the parse structure built on top of T_{k-1} and the newly predicted word wk; the $||$ notation stands for concatenation; N_{k-1} is the number of operations the constructor executes at

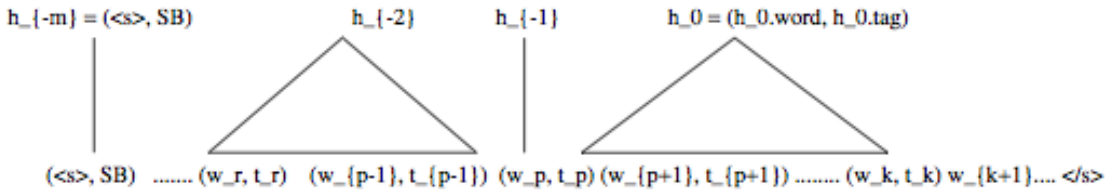

Figure 4: A word-and-parse example.

position k of the input string before passing control to the word-predictor (the N_k th operation at position k is the null transition); N_k is a function of T ; p_i^k denotes the i th constructor action carried out at position k in the word string.

The probability models of word-predictor, tagger and constructor are initialized from the Upenn Treebank with headword percolation and binarization. The headwords are percolated using a context-free approach based on rules of predicting the position of the headword of the constituent. The approach consists of three steps. First a parse tree is decomposed to phrase constituents. Then the headword position is identified and filled in with the actual word percolated up from the leaves of the tree recursively.

Instead of the UPenn Treebank-style, we use a more convenient binary branching tree. The parse trees are binarized using a rule-based approach.

The probability models of the word-predictor, tagger and constructor are trained in a maximization likelihood manner. The possible POS tag assignments, binary branching parse, non-terminal labels and the head-word annotation for a given sentence are hidden. We re-estimate them using EM algorithm.

Instead of generating only the complete parse, all parses for all the subsequences of the sentence are produced. The headwords of the subtrees are code switched to the embedded language with a translation probability $P_l(\tilde{v}_l|w_l)$ as well as the leaves.

4.3 Decoding by Translation

Using either lattice parsing or partial parsing, a two-pass decoding is needed to recognize code switch speech. A computationally feasible first pass generates an intermediate result so that the language model with Functional Head constraint can be used in the second pass. The first decoding pass composes of the transducer of the universal phoneme model P, the transducer C from context-dependent phones to context-independent phones, the lexicon transducer L which maps context-independent phone sequences to word strings and the transducer of the language model G. A T3 decoder is used in the first pass.

$$ASR_1 = P \circ C \circ L \circ G \tag{15}$$

Instead of N-best list, word lattice is used as the intermediate output of the first decoding step.

The language model G_{CS} of the transducer in the second pass is improved from G by composing with the translation model $P_l(\tilde{v}_l|w_l)$. Finally, the recognition transducer is optimized by determination and minimization operations.

$$ASR_2 = P \circ C \circ min(det(L \circ min(det(\pi(G_{CS}))))) \tag{16}$$

5 Experiments

5.1 Experimental Setup

The bilingual acoustic model used for our mixed language ASR is trained from 160 hours of speech from GALE Phase 1 Chinese broadcast conversation, 40 hours of speech from GALE Phase 1 English broadcast conversation, and 3 hours of in-house nonnative English data. The acoustic features used in our experiments consist of 39 components (13MFCC, 13MFCC, 13 MFCC using cepstral mean normalization), which are analyzed at a 10msec frame rate with a 25msec window size. The acoustic models used throughout our paper are state-clustered crossword tri-phone HMMs with 16 Gaussian mixture output densities per state. We use the phone set consists of 21 Mandarin standard initials, 37 Mandarin finals, 6 zero initials and 6 extended English phones. The pronunciation dictionary is obtained by modifying Mandarin and English dictionaries using the phone set. The acoustic models are reconstructed

Table 1: *Code switching point detection evaluation (Precision/Recall/F-measure)*

	Lecture speech	Lunch conversation
MixedLM	0.61/0.64/0.64	0.54/0.63/0.58
InterpolatedLM	0.62/0.66/0.64	0.55/0.63/0.58

Sequential coupling	0.66/0.71/0.68	0.55/0.70/0.61
Tight coupling	**0.68/0.71/0.70**	**0.56/0.70/0.62**

by decision tree tying. We also collected two speech databases with Chinese to English code switching - namely, 20 hours of lecture speech corpus (Data 1) and 3 hours of lunch conversation corpus (Data 2). 18 hours of Data 1 is used for acoustic model adaptation and 1 hour of data are used as the test set (Test 1). 2 hours of Data 2 containing 2389 utterances is used to adapt the acoustic model and 280 utterances are used as the test set (Test 2). To train the parser, we use Chinese Treebank Version 5.0 which consists of 500 thousand words and use the standard data split (Petrov and Klein, 2007).

For the language models, transcriptions of 18 hours of Data 1 are trained as a baseline mixed language model for the lecture speech domain. 250,000 sentences from Chinese speech conference papers, power point slides and web data are used for training a baseline Chinese matrix language model for the lecture speech domain (LM 1). Transcriptions of 2 hours of Data 2 are used as the baseline mixed language model in the lunch conversation domain. 250,000 sentences of the GALE Phase 1 Chinese conversational speech transcriptions are used to train a Chinese matrix language model (LM 2). 250,000 of GALE Phase 1 English conversational speech transcription are used to train the English embedded language model (LM 3). To train the bilingual translation model, the Chinese Gale Phase 1 conversational speech transcriptions are used to generate a bilingual corpus using machine translation. For comparison, an interpolated language model for the lunch conversation domain is trained from interpolating LM 2 with LM 3. Also for comparison, an adapted language model for lecture speech is trained from LM 1 and transcriptions of 18 hours of Data 1. An adapted language mode l for conversation is trained from LM 2 and 2 hours of Data 2. The size of the vocabulary for recognition is 20k words. The perplexity of the baseline language model trained on the code switching speech transcription is 236 on the lecture speech and 279 on the conversation speech test sets.

5.2 Experimental Results

Table 1 reports precision, recall and F-measure of code switching point in the recognition results of the baseline and our proposed language models. Our proposed code switching language models with functional head constraint improve both precision and recall of the code switching point detection on the code switching lecture speech and lunch conversation 4.48%. Our method by tight-coupling increases the F-measure by 9.38% relatively on the lecture speech and by 6.90% relatively on the lunch conversation compared to the baseline adapted language model.

The Table 2 shows the word error rates (WERs) of experiments on the code switching lecture speech and Table 3 shows the WERs on the code switching lunch conversations. Our proposed code switching language model with Functional Head Constraints by sequential-coupling reduces the WERs in the baseline mixed language model by 3.72% relative on Test 1, and 5.85% on Test 2. Our method by tight-coupling also reduces WER by 2.51% relative compared to the baseline language model on Test 1, and by 4.57% on Test 2. We use the speech recognition scoring toolkit (SCTK) developed by the National Institute of Standards and Technology to compute the significance levels, which is based on two-proportion z-test comparing the difference between the recognition results of our proposed approach and the baseline. All the WER reductions are statistically significant. For our reference, we also compare the performance of using Functional Head Constraint to that of using inversion constraint in (Li and Fung, 2012, 2013) and found that the present model reduces WER by 0.85% on Test 2 but gives no improvement on Test 1. We hypothesize that since

Table 2: *Our proposed system outperforms the baselines in terms of WER on the lecture speech*

	Matrix	Embedded	Overall
MixedLM	34.41%	39.16%	35.17%
InterpolatedLM	34.11%	40.28%	35.10%
AdaptedLM	35.11%	38.41%	34.73%
Sequential coupling	33.17%	36.84%	33.76%
Tight coupling	**33.14%**	**36.65%**	**33.70%**

Table 3: *Our proposed system outperforms the baselines in terms of WER on the lunch conversation*

	Matrix	Embedded	Overall
MixedLM	46.4%	48.55%	46.83%
InterpolatedLM	46.04%	49.04%	46.64%
AdaptedLM	46.64%	48.39%	46.20%
Sequential coupling	43.24%	46.27%	43.89%
Tight coupling	**42.97%**	**46.03%**	**43.58%**

Test 1 has mostly Chinese words, the proposed method is not as advantageous compared to our previous work. Another future direction is for us to improve the lattice parser as we believe it will lead to further improvement on the final result of our proposed method.

6 Conclusion

In this paper, we propose using lattice parsing and partial parsing to incorporate a well-known syntactic constraint for code mixing speech, namely the Functional Head Constraint, into a continuous speech recognition system. Under the Functional Head Constraint, code switch cannot occur between the functional head and its complements. Since code mixing speech data is scarce, we propose to instead learn the code mixing language model from bilingual data with this constraint. The constrained code switching language model is obtained by first expanding the search network with a translation model, and then using parsing to restrict paths to those permissible under the constraint. Lattice parsing enables a sequential coupling of parsing then constraint filtering whereas partial parsing enables a tight coupling between parsing and filtering. A WFST-based decoder then combines a bilingual acoustic model and the proposed code-switch language model in an integrated approach. Lattice-based parsing and partial parsing are used to provide the syntactic structure of the matrix language. Matrix words at the leave nodes of the syntax tree are permitted to switch to the embedded language if the switch does not violate the Functional Head Constraint. This reduces the permissible search paths from those expanded by the bilingual language model. We tested our system on a lecture speech dataset with 16% embedded second language, and on a lunch conversation dataset with 20% embedded second language. Our language models with lattice parsing and partial parsing reduce word error rates from a baseline mixed language model by 3.72% to 3.89% relative in the first task, and by 5.85% to 5.97% in the second task. They are reduced from an interpolated language model by 3.69% to 3.74%, and by 5.46% to 5.77% in the first and second task respectively. WER reductions from an adapted language model are 2.51% to 2.63%, and by 4.47% to 4.74% in the two tasks. The F-measure for code switch point detection is improved from 0.64 by the interpolated model to 0.68, and from 0.67 by the adapted model to 0.70 by our method. Our proposed approach avoids making early decisions on code-switch boundaries and is therefore more robust. Our approach also avoids the bottleneck of code switch data scarcity by using bilingual data with syntactic structure. Moreover, our method reduces word error rates for both the matrix and the embedded language.

Abstract

The introduction of dynamic oracles has considerably improved the accuracy of greedy transition-based dependency parsers, without sacrificing parsing efficiency. However, this enhancement is limited to projective parsing, and dynamic oracles have not yet been implemented for parsers supporting non-projectivity. In this paper we introduce the first such oracle, for a non-projective parser based on Attardi's parser. We show that training with this oracle improves parsing accuracy over a conventional (static) oracle on a wide range of datasets.

1 Introduction

Greedy transition-based parsers for dependency grammars have been pioneered by Yamada and Matsumoto (2003) and Nivre (2003). These methods incrementally process the input sentence from left to right, predicting the next parsing action, called transition, on the basis of a compact representation of the derivation history.

Greedy transition-based parsers can be very efficient, allowing web-scale parsing with high throughput. However, the accuracy of these methods still falls behind that of transition-based parsers using beam-search, where the accuracy improvement is obtained at the cost of a decrease in parsing efficiency; see for instance Zhang and Nivre (2011), Huang and Sagae (2010), Choi and McCallum (2013). As an alternative to beam-search, recent research on transition-based parsing has therefore explored possible ways of improving accuracy at no extra cost in parsing efficiency.

The training of transition-based parsers relies on a component called the parsing oracle, which maps parser configurations to optimal transitions with respect to a gold tree. A discriminative model is then trained to simulate the oracle's behavior, and is later used for decoding. Traditionally, so-called static oracles have been exploited in training, where a static oracle is defined only for configurations that have been reached by computations with no mistake, and it returns a single canonical transition among those that are optimal.

Very recently, Goldberg and Nivre (2012), Goldberg and Nivre (2013) and Goldberg et al. (2014) showed that the accuracy of transition-based parsers can be substantially improved using dynamic oracles. A dynamic oracle returns the set of all transitions that are optimal for a given configuration, with respect to the gold tree, and is well-defined and correct for every configuration that is reachable by the parser.

Naïve implementations of dynamic oracles run in exponential time, since they need to simulate all possible computations of the parser for the input configuration. Polynomial-time implementations of dynamic oracles have been proposed by the above mentioned authors for several projective dependency parsers. To our knowledge, no polynomial-time algorithm has been published for transition-based parsers based on non-projective dependency grammars.

In this paper we consider a restriction of a transition-based, non-projective parser originally presented by Attardi (2006). This restriction was further investigated by Kuhlmann and Nivre (2010) and Cohen et al. (2011). We provide an implementation for a dynamic oracle for this parser running in polynomial time.

We experimentally compare the parser trained with the dynamic oracle to a baseline obtained by training with a static oracle. Significant accuracy improvements are achieved on many languages when using our dynamic oracle. To our knowledge, these are the first experimental results on non-projective parsing based on a dynamic oracle.

2 Preliminary Definitions

Transition-based dependency parsing was originally introduced by Yamada and Matsumoto (2003) and Nivre (2003). In this section we briefly summarize the notation we use for this framework and introduce the notion of dynamic oracle.

2.1 Transition-Based Dependency Parsing

We represent an input sentence as a string $w = w_0 \cdots w_n$, $n \geq 1$, where each w_i with $i \neq 0$ is a lexical symbol and w_0 is a special symbol called root. Set $V_w = \{i \mid 0 \leq i \leq n\}$ denotes the symbol occurrences in w. For $i, j \in V_w$ with $i \neq j$, we write $i \rightarrow j$ to denote a grammatical **dependency** of some unspecified type between w_i and w_j, where w_i is the head and w_j is the dependent.

A **dependency tree** t for w is a directed tree with node set V_w and with root node 0. An arc of t is a pair (i, j), encoding a dependency $i \rightarrow j$; we will often use the latter notation to denote arcs.

A transition-based dependency parser typically uses a stack data structure to process the input string from left to right, in a way very similar to the classical push-down automaton for context-free languages (Hopcroft et al., 2006). Each stack element is a node from V_w, representing the root of a dependency tree spanning some portion of the input w, and no internal state is used. At each step the parser applies some transition that updates the stack and/or consumes one symbol from the input. Transitions may also construct new dependencies, which are added to the current configuration of the parser.

We represent the **stack** as an ordered sequence $\sigma = [h_d, \ldots, h_1]$, $d \geq 0$, of nodes $h_i \in V_w$, with the topmost element placed at the right. When $d = 0$, we have the empty stack $\sigma = []$. We use the vertical bar to denote the append operator for σ, and write $\sigma = \sigma'|h_1$ to indicate that h_1 is the topmost element of σ.

The portion of the input string still to be processed by the parser is called the **buffer**. We represent the buffer as an ordered sequence $\beta = [i, \ldots, n]$ of nodes from V_w, with i the first element of the buffer. We denote the empty buffer as $\beta = []$. Again, we use the vertical bar to denote the append operator, and write $\beta = i|\beta'$ to indicate that i is the first symbol occurrence of β; consequently, we have $\beta' = [i + 1, \ldots, n]$.

In a transition-based parser, the parsing process is defined through the technical notions of configuration and transition. A **configuration** of the parser relative to w is a triple $c = (\sigma, \beta, A)$, where σ and β are a stack and a buffer, respectively, and A is the set of arcs that have been built so far. A **transition** is a partial function mapping the set of parser configurations into itself. Each transition-based parser is defined by means of some finite inventory of transitions. We will later introduce the specific inventory of transitions for the parser that we investigate in this paper. We use the symbol $\vdash$ to denote the binary relation formed by the union of all transitions of a parser.

With the notions of configuration and transition in place, we can define a **computation** of the parser on w as a sequence $c_0, c_1, \ldots, c_m$, $m \geq 0$, of configurations relative to w, under the condition that $c_{i-1} \vdash c_i$ for each i with $1 \leq i \leq m$. We use the reflexive and transitive closure of $\vdash$, written $\vdash^*$, to represent computations.

2.2 Configuration Loss and Dynamic Oracles

A transition-based dependency parser is a nondeterministic device, meaning that a given configuration can be mapped into several configurations by the available transitions. However, in several implementations the parser is associated with a discriminative model that, on the basis of some features of the current configuration, always chooses a single transition. In other words, the model is used to run the parser as a pseudo-deterministic device. The training of the discriminative model relies on a component called the parsing **oracle**, which maps parser configurations to "optimal" transitions with respect to some reference dependency tree, which we call the **gold** tree.

Traditionally, so-called **static** oracles have been used which return a single, canonical transition and they do so only for configurations that can reach the gold tree, that is, configurations representing parsing histories with no mistake. In recent work, Goldberg and Nivre (2012), Goldberg and Nivre (2013) and Goldberg et al. (2014) have introduced **dynamic** oracles, which return the set of all transitions that are optimal with respect to a gold tree, and are well-defined and correct for every configuration that is reachable by the parser. These authors have shown that the accuracy of transition-based dependency parsers can be substantially improved if dynamic oracles are used in place of static ones. In what follows, we provide a mathematical definition of dynamic oracles, following Goldberg et al. (2014).

$$(\sigma, k|\beta, A) \vdash_{\mathsf{sh}} (\sigma|k, \beta, A)$$
$$(\sigma|i|j, \beta, A) \vdash_{\mathsf{la}} (\sigma|j, \beta, A \cup \{j \rightarrow i\})$$
$$(\sigma|i|j, \beta, A) \vdash_{\mathsf{ra}} (\sigma|i, \beta, A \cup \{i \rightarrow j\})$$
$$(\sigma|i|j|k, \beta, A) \vdash_{\mathsf{la}_2} (\sigma|j|k, \beta, A \cup \{k \rightarrow i\})$$
$$(\sigma|i|j|k, \beta, A) \vdash_{\mathsf{ra}_2} (\sigma|i|j, \beta, A \cup \{i \rightarrow k\})$$

Figure 1: Transitions of the non-projective parser.

Let t_1 and t_2 be dependency trees for w, with arc sets A_1 and A_2, respectively. The **loss** of t_1 with respect to t_2 is defined as

$$\mathcal{L}(t_1, t_2) = |A_1 \setminus A_2| \ . \tag{1}$$

Note that $\mathcal{L}(t_1, t_2) = \mathcal{L}(t_2, t_1)$, since $|A_1| = |A_2|$. Furthermore $\mathcal{L}(t_1, t_2) = 0$ if and only if t_1 and t_2 are the same tree.

Let c be a configuration of a transition-based parser relative to w. Let also $\mathcal{D}(c)$ be the set of all dependency trees that can be obtained in a computation of the form $c \vdash^* c_f$, where c_f is a final configuration, that is, a configuration that has constructed a dependency tree for w. We extend the loss function in (1) to configurations by letting

$$\mathcal{L}(c, t_2) = \min_{t_1 \in \mathcal{D}(c)} \mathcal{L}(t_1, t_2) \ . \tag{2}$$

Let t_G be the gold tree for w. Quantity $\mathcal{L}(c, t_G)$ can be used to define a dynamic oracle as follows. For any transition $\vdash_\tau$ in the finite inventory of our parser, we use the functional notation $\tau(c) = c'$ in place of $c \vdash_\tau c'$. We then let

$$\mathsf{oracle}(c, t_G) = \{\tau \mid \mathcal{L}(\tau(c), t_G) - \mathcal{L}(c, t_G) = 0\} \ . \tag{3}$$

In words, (3) provides the set of transitions that do not increase the loss of c; we call these transitions optimal for c.

A naïve way of implementing (3) would be to explicitly compute the set $\mathcal{D}(c)$ in (2), which has exponential size. More interestingly, the implementation of dynamic oracles proposed by the above cited authors all run in polynomial time. These oracles are all defined for projective parsing. In this paper, we present a polynomial-time oracle for a non-projective parser.

3 Non-Projective Dependency Parsing

In this section we introduce a parser for non-projective dependency grammars that is derived from the transition-based parser originally presented by Attardi (2006), and was further investigated by Kuhlmann and Nivre (2010) and Cohen et al. (2011). Our definitions follow the framework introduced in Section 2.1.

We start with some additional notation. Let t be a dependency tree for w and let k be a node of t. Consider the complete subtree t' of t rooted at k, that is, the subtree of t induced by k and all of the descendants of k in t. The **span** of t' is the subsequence of tokens in w represented by the nodes of t'. Node k has **gap-degree** 0 if the span of t' forms a (contiguous) substring of w. A dependency tree is called **projective** if all of its nodes have gap-degree 0; a dependency tree which is not projective is called **non-projective**.

Given w as input, the parser starts with the initial configuration $([], [0, \ldots, n], \emptyset)$, consisting of an empty stack, a buffer with all the nodes representing the symbol occurrences in w, and an empty set of constructed dependencies (arcs). The parser stops when it reaches a final configuration of the form $([0], [], A)$, consisting of a stack with only the root node and of an empty buffer; in any such configuration, set A always implicitly defines a valid dependency tree (rooted in node 0).

The core of the parser consists of an inventory of five transitions, defined in Figure 1. Each transition is specified using the free variables σ, β, A, i, j and k. As an example, the schema $(\sigma|i|j, \beta, A) \vdash_{\mathsf{la}} (\sigma|j, \beta, A \cup \{j \rightarrow i\})$ means that if a configuration c matches the antecedent, then a new configuration is obtained by instantiating the variables in the consequent accordingly.

The transition $\vdash_{\mathsf{sh}}$, called shift, reads a new token from the input sentence by removing it from the buffer and pushing it into the stack. Each of the other transitions, collectively called reduce transitions, has the effect of building a dependency between two nodes in the stack, and then removing the dependent node from the stack. The removal of the dependent ensures that the output dependency tree is built in a bottom-up order, collecting all of the dependents of each node i before linking i to its head.

The transition $\vdash_{\mathsf{la}}$, called left-arc, creates a leftward arc where the topmost stack node is the head and the second topmost node is the dependent, and removes the latter from the stack. The transition $\vdash_{\mathsf{ra}}$, called right-arc, is defined symmetrically, so that the topmost stack node is at-

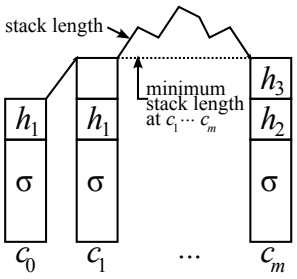

Figure 2: General form of the computations associated with an item $[h_1, h_2, h_3]$.

tached as a dependent of the second topmost node. The combination of the shift, left-arc and right-arc transitions provides complete coverage of projective dependency trees, but no support for non-projectivity, and corresponds to the so-called arc-standard parser introduced by Nivre (2004).

Support for non-projective dependencies is achieved by adding the transitions $\vdash_{\mathsf{la}_2}$ and $\vdash_{\mathsf{ra}_2}$, which are variants of the left-arc and right-arc transitions, respectively. These new transitions create dependencies involving the first and the *third* topmost nodes in the stack. The creation of dependencies between non-adjacent stack nodes might produce crossing arcs and is the key to the construction of non-projective trees.

Recall that transitions are partial functions, meaning that they might be undefined for some configurations. Specifically, the shift transition is only defined for configurations with a non-empty buffer. Similarly, the left-arc and right-arc transitions can only be applied if the length of the stack is at least 2, while the transitions $\vdash_{\mathsf{la}_2}$ and $\vdash_{\mathsf{ra}_2}$ require at least 3 nodes in the stack.

Transitions $\vdash_{\mathsf{la}_2}$ and $\vdash_{\mathsf{ra}_2}$ were originally introduced by Attardi (2006) together with other, more complex transitions. The parser we define here is therefore more restrictive than Attardi (2006), meaning that it does not cover all the non-projective trees that can be processed by the original parser. However, the restricted parser has recently attracted some research interest, as it covers the vast majority of non-projective constructions appearing in standard treebanks (Attardi, 2006; Kuhlmann and Nivre, 2010), while keeping simplicity and interesting properties like being compatible with polynomial-time dynamic programming (Cohen et al., 2011).

4 Representation of Computations

Our oracle algorithm exploits a dynamic programming technique which, given an input string, combines certain pieces of a computation of the parser from Section 3 to obtain larger pieces. In order to efficiently encode pieces of computations, we borrow a representation proposed by Cohen et al. (2011), which is introduced in this section.

Let $w = a_0 \cdots a_n$ and V_w be specified as in Section 2, and let w' be some substring of w. (The specification of w' is not of our concern in this section.) Let also $h_1, h_2, h_3 \in V_w$. We are interested in computations of the parser processing the substring w' and having the form $c_0, c_1, \ldots, c_m$, $m \geq 1$, that satisfy both of the following conditions, exemplified in Figure 2.

- For some sequence of nodes σ with $|\sigma| \geq 0$, the stack associated with c_0 has the form $\sigma|h_1$ and the stack associated with c_m has the form $\sigma|h_2|h_3$.
- For each intermediate configuration c_i, $1 \leq i \leq m-1$, the stack associated with c_i has the form $\sigma\sigma_i$, where σ_i is a sequence of nodes with $|\sigma_i| \geq 2$.

An important property of the above definition needs to be discussed here, which is at the heart of the polynomial-time algorithm in the next section. If in $c_0, c_1, \ldots, c_m$ we replace σ with a different sequence σ', we obtain a valid computation for w' constructing exactly the same dependencies as the original computation. To see this, let $c_{i-1} \vdash_{\tau_i} c_i$ for each i with $1 \leq i \leq m$. Then $\vdash_{\tau_1}$ must be a shift, otherwise $|\sigma_1| \geq 2$ would be violated. Consider now a transition $\vdash_{\tau_i}$ with $2 \leq i \leq m$ that builds some dependency. From $|\sigma_i| \geq 2$ we derive $|\sigma_{i-1}| \geq 3$. We can easily check from Figure 1 that none of the nodes in σ can be involved in the constructed dependency.

Intuitively, the above property asserts that the sequence of transitions $\vdash_{\tau_1}, \vdash_{\tau_2}, \ldots, \vdash_{\tau_m}$ can be applied to parse substring w' independently of the context σ. This suggests that we can group into an equivalence class all the computations satisfying the conditions above, for different values of σ. We indicate such class by means of the tuple $[h_1, h_2 h_3]$, called **item**. It is easy to see that each item represents an exponential number of computations. In the next section we will show how we can process items with the purpose of obtaining an efficient computation for dynamic oracles.

5 Dynamic Oracle Algorithm

Our algorithm takes as input a gold tree t_G for string w and a parser configuration $c = (\sigma, \beta, A)$ relative to w, specified as in Section 2. We assume that t_G can be parsed by the non-projective parser of Section 3 starting from the initial configuration.

5.1 Basic Idea

The algorithm consists of two separate stages, informally discussed in what follows. In the first stage we identify some tree fragments of t_G that can be constructed by the parser after reaching configuration c, in a way that does not depend on the content of σ. This means that these fragments can be precomputed by looking only into β. Furthermore, since these fragments are subtrees of t_G, their computation has no effect on the overall loss of a computation on w.

For each fragment t with the above properties, we replace all the nodes in β that are also nodes of t with the root node of t itself. The result of the first stage is therefore a new node sequence shorter than β, which we call the reduced buffer β_R.

In the second stage of the algorithm we use a variant of the tabular method developed by Cohen et al. (2011), which was originally designed to simulate all computations of the parser in Section 3 on an input string w. We run the above method on the concatenation of the stack and the reduced buffer, with some additional constraints that restrict the search space in two respects. First, we visit only those computations of the parser that step through configuration c. Second, we reach only those dependency trees that contain all the tree fragments precomputed in the first stage. We can show that such search space always contains at least one dependency tree with the desired loss, which we then retrieve performing a Viterbi search.

5.2 Preprocessing of the Buffer

Let t be a complete subtree of t_G, having root node k in β. Consider the following two conditions, defined on t.

- *Bottom-up completeness*: No arc $i \rightarrow j$ in t is such that i is a node in β, $i \neq k$, and j is a node in σ.
- *Zero gap-degree*: The nodes of t that are in β form a (contiguous) substring of w.

We claim that if t satisfies the above conditions, then we can safely reduce the nodes of t appearing in β, replacing them with node k. We only report here an informal discussion of this claim, and omit a formal proof.

As a first remark, recall that our parser implements a purely bottom-up strategy. This means that after a tree has been constructed, all of its nodes but the root are removed from the parser configuration. Then the Bottom-up completeness condition guarantees that if we remove from β all nodes of t but k, the nodes of t that are in σ can still be processed in a way that does not affect the loss, since their parent must be either k or a node that is neither in β nor in σ. Note that the nodes of t that are neither in β nor in σ are irrelevant to the precomputation of t from β, since these nodes have already been attached and are no longer available to the parser.

As a second remark, the Zero gap-degree condition guarantees that the span of t over the nodes of β is not interleaved by nodes that do not belong to t. This is also an important requirement for the precomputation of t from β, since a tree fragment having a discontinuous span over β might not be constructable independently of σ. More specifically, parsing such fragment implies dealing with the nodes in the discontinuities, and this might require transitions involving nodes from σ.

We can now use the sufficient condition above to compute β_R. We process β from left to right. For each node k, we can easily test the Bottom-up completeness condition and the Zero gap-degree condition for the complete subtree t of t_G rooted at k, and perform the reduction if both conditions are satisfied. Note that in this process a node k resulting from the reduction of t might in turn be removed from β if, at some later point, we reduce a supertree of t.

5.3 Computation of the Loss

We describe here our dynamic programming algorithm for the computation of the loss of an input configuration c. We start with some additional notation. Let $\gamma = \sigma\beta_R$ be the concatenation of σ and β_R, which we treat as a string of nodes. For integers i with $0 \leq i \leq |\gamma| - 1$, we write $\gamma[i]$ to denote the $(i+1)$-th node of γ. Let also $\ell = |\sigma|$. Symbol ℓ is used to mark the boundary between the stack and the reduced buffer in γ, thus $\gamma[i]$ with $i < \ell$ is a node of σ, while $\gamma[i]$ with $i \geq \ell$ is a node of β_R.

Algorithm 1 computes the loss of c by processing the sequence γ in a way quite similar to the

standard nested loop implementation of the CKY parser for context-free grammars (Hopcroft et al., 2006). The algorithm uses a two-dimensional array $\mathcal{T}$ whose indexes range from 0 to $|\gamma| = \ell + |\beta_R|$, and only the cells $\mathcal{T}[i,j]$ with $i < j$ are filled.

We view each $\mathcal{T}[i,j]$ as an association list whose keys are items $[h_1, h_2 h_3]$, defined in the context of the substring $\gamma[i] \cdots \gamma[j-1]$ of γ; see Section 4. The value stored at $\mathcal{T}[i,j]([h_1, h_2 h_3])$ is the minimum loss contribution due to the computations represented by $[h_1, h_2 h_3]$. For technical reasons, we assume that our parser starts with a symbol $\$ \notin V_w$ in the stack, denoting the bottom of the stack.

We initialize the table by populating the cells of the form $\mathcal{T}[i, i+1]$ with information about the trivial computations consisting of a single $\vdash_{\mathsf{sh}}$ transition that shifts the node $\gamma[i]$ into the stack. These computations are known to have zero loss contribution, because a $\vdash_{\mathsf{sh}}$ transition does not create any arcs. In the case where the node $\gamma[i]$ belongs to σ, i.e., $i < \ell$, we assign loss contribution 0 to the entry $\mathcal{T}[i, i+1]([\gamma[i-1], \gamma[i-1]\gamma[i]])$ (line 3 of Algorithm 1), because $\gamma[i]$ is shifted with $\gamma[i-1]$ at the top of the stack. On the other hand, if $\gamma[i]$ is in β, i.e., $i \geq \ell$, we assign loss contribution 0 to several entries in $\mathcal{T}[i, i+1]$ (line 6) because, at the time $\gamma[i]$ is shifted, the content of the stack depends on the transitions executed before that point.

After the above initialization, we consider pairs of contiguous substrings $\gamma[i] \cdots \gamma[k-1]$ and $\gamma[k] \cdots \gamma[j-1]$ of γ. At each inner iteration of the nested loops of lines 7-11 we update cell $\mathcal{T}[i,j]$ based on the content of the cells $\mathcal{T}[i,k]$ and $\mathcal{T}[k,j]$. We do this through the procedure ProcessCell$(\mathcal{T}, i, k, j)$, which considers all pairs of keys $[h_1, h_2 h_3]$ in $\mathcal{T}[i,k]$ and $[h_3, h_4 h_5]$ in $\mathcal{T}[k,j]$. Note that we require the index h_3 to match between both items, meaning that their computations can be concatenated. In this way, for each reduce transition τ in our parser, we compute the loss contribution for a new piece of computation defined by concatenating a computation with minimum loss contribution in the first item and a computation with minimum loss contribution in the second item, followed by the transition τ. The fact that the new piece of computation can be represented by an item is exemplified in Figure 3 for the case $\tau = \vdash_{\mathsf{ra}_2}$.

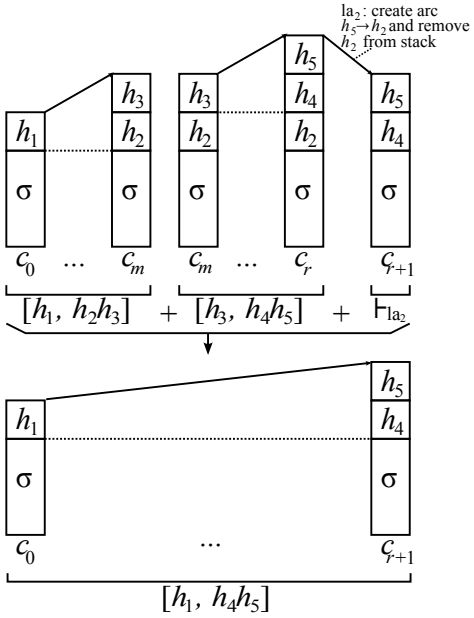

Figure 3: Concatenation of two computations/items and transition $\vdash_{\mathsf{ra}_2}$, resulting in a new computation/item.

The computed loss contribution is used to update the entry in $\mathcal{T}[i,j]$ corresponding to the item associated with the new computation. Observe how the loss contribution provided by the arc created by τ is computed by the δ_G function at lines 17, 20, 23 and 26, which is defined as:

$$\delta_G(i \rightarrow j) \;=\; \begin{cases} 0, & \text{if } i \rightarrow j \text{ is in } t_G; \\ 1, & \text{otherwise.} \end{cases} \quad (4)$$

We remark that the nature of our problem allows us to apply several shortcuts and optimizations that would not be possible in a setting where we actually needed to parse the string γ. First, the range of variable i in the loop in line 8 starts at $\max\{0, \ell - d\}$, rather than at 0, because we do not need to combine pairs of items originating from nodes in σ below the topmost node, as the items resulting from such combinations correspond to computations that do not contain our input configuration c. Second, when we have set values for i such that $i+2 < \ell$, we can omit calling ProcessCell for values of the parameter k ranging from $i+2$ to $\ell-1$, as those calls would use as their input one of the items described above, which are not of interest. Finally, when processing substrings that are entirely in β_R ($i \geq \ell$) we can restrict the transitions that we explore to those that generate arcs that either are in the gold tree t_G, or have a parent node which is not present in γ (see conditions in

28: $\quad\quad\quad\quad \mathcal{T}[i,j]([h_1,h_2h_4]) \leftarrow \min\{loss_{\mathsf{ra}_2}, \mathcal{T}[i,j]([h_1,h_2h_4])\}$ ▷ cell update $\vdash_{\mathsf{ra}_2}$

lines 18, 21, 24, 27), because we know that incorrectly attaching a buffer node as a dependent of another buffer node, when the correct head is available, can never be an optimal decision in terms of loss.

Once we have filled the table $\mathcal{T}$, the loss for the input configuration c can be obtained from the value of the entry $\mathcal{T}[0,|\gamma|]([\$,\$0])$, representing the minimum loss contribution among computations that reach the input configuration c and parse the whole input string. To obtain the total loss, we add to this value the loss contribution accumulated by the dependency trees with root in the stack σ of c. This is represented in Algorithm 1 as $\sum_{i\in[0,\ell-1]} \mathcal{L}_c(\sigma[i], t_G)$, where $\mathcal{L}_c(\sigma[i], t_G)$ is the count of the descendants of $\sigma[i]$ (the $(i+1)$-th element of σ) that had been assigned the wrong head by the parser with respect to t_G.

5.4 Sample Run

Consider the Czech sentence and the gold dependency tree t_G shown in Figure 4(a). Given the configuration $c = (\sigma, \beta, A)$ where $\sigma = [0,1,3,4]$, $\beta = [5,\ldots,13]$ and $A = \{3 \rightarrow 2\}$, we trace the two stages of the algorithm.

Preprocessing of the buffer The complete subtree rooted at node 7 satisfies the Bottom-up completeness and the Zero gap-degree conditions in Section 5.2, so the nodes $5,\ldots,12$ in β can be replaced with the root 7. Note that all the nodes in the span $5,\ldots,12$ have all their (gold) dependents in that span, with the exception of the root 7, with its dependent node 1 still in the stack. No other reduction is possible, and we have $\beta_R = [7,13]$. The corresponding fragment of t_G is represented in Figure 4(b).

Computation of the loss Let $\gamma = \sigma\beta_R$. Algorithm 1 builds the two-dimensional array $\mathcal{T}$ in Figure 4(c). Each cell $\mathcal{T}[i,j]$ contains an association list, whose (key:value) pairs map items to their loss contribution. Figure 4(c) only shows the pairs involved in the minimum-loss computation.

Lines 1-6 of Algorithm 1 initialize the cells in the diagonal, $\mathcal{T}[0,1],\ldots,\mathcal{T}[5,6]$. The boundary between stack and buffer is $\ell = 4$, thus cells $\mathcal{T}[0,1]$, $\mathcal{T}[1,2]$, and $\mathcal{T}[2,3]$ contain only one element, while $\mathcal{T}[3,4]$, $\mathcal{T}[4,5]$ and $\mathcal{T}[5,6]$ contain as many as the previous elements in γ, although not all of them are shown in the figure.

Lines 7-12 fill the superdiagonals until $\mathcal{T}[0,6]$ is reached. The cells $\mathcal{T}[0,2]$, $\mathcal{T}[0,3]$ and $\mathcal{T}[1,3]$

Figure 4: Example of loss computation given the sentence in (a) and considering a configuration c with $\sigma = [0, 1, 3, 4]$ and $\beta = [5, \ldots, 13]$.

are left empty because $\ell = 4$. Once $\mathcal{T}[0, 6]$ is calculated, it contains only the entry with key $[\$, \$, 0]$, with the associated value 1 representing the minimum number of wrong arcs that the parsing algorithm has to build to reach a final configuration from c. Then, Line 13 retrieves the loss of the configuration, computed as the sum of $\mathcal{T}[0, 6]([\$, \$, 0])$ with the term $\mathcal{L}_c$, representing the erroneous arcs made *before* reaching c.

Note that in our example the loss of c is 1, even though $\mathcal{L}_c = 0$, meaning that there are no wrong arcs in A. Indeed, given c, there is no single computation that builds all the remaining arcs in t_G. This is reflected in $\mathcal{T}$, where the path to reach the item with minimum loss has to go through either $\mathcal{T}[3, 5]$ or $\mathcal{T}[2, 4]$, which implies building the erroneous arc $(w_7 \rightarrow w_3)$ or $(w_4 \rightarrow w_3)$, respectively.

6 Computational Analysis

The first stage of our algorithm can be easily implemented in time $\mathcal{O}(|\beta|\,|t_G|)$, where $|t_G|$ is the number of nodes in t_G, which is equal to the length n of the input string.

For the worst-case complexity of the second stage (Algorithm 1), note that the number of cell updates made by calling ProcessCell$(\mathcal{T}, i, k, j)$ with $k < \ell$ is $\mathcal{O}(|\sigma|^3\,|\gamma|^2\,|\beta_R|)$. This is because these updates can only be caused by procedure calls on line 10 (as those on line 12 always set $k \geq \ell$) and therefore the index k always equals $i + 1$, while h_2 must equal h_1 because the item $[h_1, h_2 h_3]$ is one of the initial items created on line 3. The variables i, h_1 and h_3 must index nodes on the stack σ as they are bounded by k, while j ranges over β_R and h_4 and h_5 can refer to nodes either on σ or on β_R.

On the other hand, the number of cell updates triggered by calls to ProcessCell such that $k \geq \ell$ is $\mathcal{O}(|\gamma|^4 |\beta_R|^4)$, as they happen for four indices referring to nodes of β_R (k, j, h_4, h_5) and four indices that can range over σ or β_R (i, h_1, h_2, h_3).

Putting everything together, we conclude that the overall complexity of our algorithm is $\mathcal{O}(|\beta|\,|t_G| + |\sigma|^3\,|\gamma|^2\,|\beta_R| + |\gamma|^4\,|\beta_R|^4)$.

In practice, quantities $|\sigma|$, $|\beta_R|$ and $|\gamma|$ are significantly smaller than n, providing reasonable training times as we will see in Section 7. For instance, when measured on the Czech treebank, the average value of $|\sigma|$ is 7.2, with a maximum of 87. Even more interesting, the average value of $|\beta_R|$ is 2.6, with a maximum of 23. Comparing this to the average and maximum values of $|\beta|$, 11 and 192, respectively, we see that the buffer reduction is crucial in reducing training time.

Note that, when expressed as a function of n, our dynamic oracle has a worst-case time complexity of $\mathcal{O}(n^8)$. This is also the time complexity of the dynamic programming algorithm of Cohen et al. (2011) we started with, simulating all computations of our parser. In contrast, the dynamic oracle of Goldberg et al. (2014) for the projective case achieves a time complexity of $\mathcal{O}(n^3)$ from the dynamic programming parser by Kuhlmann et al. (2011) running in time $\mathcal{O}(n^5)$.

The reason why we do not achieve any asymptotic improvement is that some helpful properties that hold with projective trees are no longer satisfied in the non-projective case. In the projective (arc-standard) case, subtrees that are in the buffer can be completely reduced. As a consequence, each oracle step always combines an inferred entry in the table with either a node from the stack or a node from the reduced buffer, asymptotically reducing the time complexity. However, in the non-projective (Attardi) case, subtrees in the buffer can not always be completely reduced, for the reasons mentioned in the second-to-last paragraph of Section 5.2. As a consequence, the oracle needs to make cell updates in a more general way, which includes linking pairs of elements in the reduced buffer or pairs of inferred entries in the table.

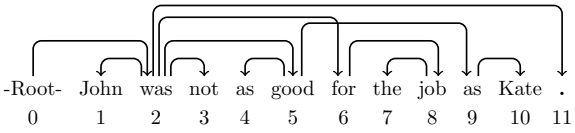

Figure 5: Non-projective dependency tree adapted from the Penn Treebank.

An example of why this is needed is provided by the gold tree in Figure 5. Assume a configuration $c = (\sigma, \beta, A)$ where $\sigma = [0, 1, 2, 3, 4]$, $\beta = [5, \ldots, 11]$, and $A = \emptyset$. It is easy to see that the loss of c is greater than zero, since the gold tree is not reachable from c: parsing the subtree rooted at node 5 requires shifting 6 into the stack, and this makes it impossible to build the arcs $2 \rightarrow 5$ and $2 \rightarrow 6$. However, if we reduced the subtree in the buffer with root 5, we would incorrectly obtain a loss of 0, as the resulting tree is parsable if we start with $\vdash_{\mathsf{sh}}$ followed by $\vdash_{\mathsf{la}}$ and $\vdash_{\mathsf{ra}_2}$. Note that there is no way of knowing whether it is safe to reduce the subtree rooted at 5 without using non-local information. For example, the arc $2 \rightarrow 6$ is crucial here: if 6 depended on 5 or 4 instead, the loss would be zero. These complications are not found in the projective case, allowing for the mentioned asymptotic improvement.

7 Experimental Evaluation

For comparability with previous work on dynamic oracles, we follow the experimental settings reported by Goldberg et al. (2014) for their arc-standard dynamic oracle. In particular, we use the same training algorithm, features, and root node position. However, we train the model for 20 iterations rather than 15, as the increased search space and spurious ambiguity of Attardi's non-projective parser implies that more iterations are required to converge to a stable model. A more detailed description of the experimental settings follows.

Table 1: Unlabelled Attachment Score (UAS) and Labelled Attachment Score (LAS) using a *static* and a *dynamic* oracle. Evaluation on CoNLL 2007 (first block) and CoNLL 2006 (second block) datasets is carried out including punctuation, evaluation on the Penn Treebank excludes it.

7.1 Experimental Setup

Training We train a global linear model using the averaged perceptron algorithm and a labelled version of the parser described in Section 3. We perform on-line training using the oracle defined in Section 5: at each parsing step, the model's weights are updated if the predicted transition results into an increase in configuration loss, but the process continues by following the predicted transition independently of the loss increase.

As our baseline we train the model using the static oracle defined by (Cohen et al., 2012). This oracle follows a canonical computation that creates arcs as soon as possible, and prioritizes the $\vdash_{\mathsf{la}}$ transition over the $\vdash_{\mathsf{la}_2}$ transition in situations

where both create a gold arc. The static oracle is not able to deal with configurations that cannot reach the gold dependency tree, so we constrain the training algorithm to follow the zero-loss transition provided by the oracle.

While this version of Attardi's parser has been shown to cover the vast majority of non-projective sentences in several treebanks (Attardi, 2006; Cohen et al., 2012), there still are some sentences which are not parsable. These sentences are skipped during training, but not during test and evaluation of the model.

Datasets We evaluate the parser performance over CoNLL 2006 and CoNLL 2007 datasets. If a language is present in both datasets, we use the latest version. We also include results over the Penn Treebank (PTB) (Marcus et al., 1993) converted to Stanford basic dependencies (De Marneffe et al., 2006). For the CoNLL datasets we use the provided part-of-speech tags and the standard training/test partition; for the PTB we use automatically assigned tags, we train on sections 2-21 and test on section 23.

7.2 Results and Analysis

In Table 1 we report the unlabelled (UAS) and labelled (LAS) attachment scores for the static and the dynamic oracles. Each figure is an average over the accuracy provided by 5 models trained with the same setup but using a different random seed. The seed is only used to shuffle the sentences in random order during each iteration of training.

Our results are consistent with the results reported by Goldberg and Nivre (2013) and Goldberg et al. (2014). For most of the datasets, we obtain a relevant improvement in both UAS and LAS. For Dutch, Czech and German, we achieve an error reduction of 5.2%, 11.2% and 4.5%, respectively. Exceptions to this general trend are Swedish and Bulgarian, where the accuracy differences are negligible, and the Basque, Catalan and Hungarian datasets, where the performance actually decreases.

If instead of testing on the standard test sets we use 10-fold cross-validation and average the resulting accuracies, we obtain improvements for all languages in Table 1 but Basque and Hungarian. More specifically, measured (UAS, LAS) pairs for Swedish are (86.85, 82.17) with dynamic oracle against (86.6, 81.93) with static oracle; for Bulgarian (88.42, 83.91) against (88.20, 83.55); and for Catalan (88.33, 83.64) against (88.06, 83.13). This suggests that the negligible or unfavourable results in Table 1 for these languages are due to statistical variability given the small size of the test sets.

As for Basque, we measure (75.54, 67.58) against (76.77, 68.20); similarly, for Hungarian we measure (75.66, 67.66) against (77.22, 68.42). Unfortunately, we have no explanation for these performance decreases, in terms of the typology of the non-projective patterns found in these two datasets. Note that Goldberg et al. (2014) also observed a performance decrease on the Basque dataset in the projective case, although not on Hungarian.

The parsing times measured in our experiments for the static and the dynamic oracles are the same, since the oracle algorithm is only used during the training stage. Thus the reported improvements in parsing accuracy come at no extra cost for parsing time. In the training stage, the extra processing needed to compute the loss and to explore paths that do not lead to a gold tree made training about 4 times slower, on average, for the dynamic oracle model. This confirms that our oracle algorithm is fast enough to be of practical interest, in spite of its relatively high worst-case asymptotic complexity.

8 Conclusions

We have presented what, to our knowledge, are the first experimental results for a transition-based non-projective parser trained with a dynamic oracle. We have also shown significant accuracy improvements on many languages over a static oracle baseline.

The general picture that emerges from our approach is that dynamic programming algorithms originally conceived for the simulation of transition-based parsers can effectively be used in the development of polynomial-time algorithms for dynamic oracles.

Abstract

The syntactic ambiguity of a transitive verb (Vt) followed by a noun (N) has long been a problem in Chinese parsing. In this paper, we propose a classifier to resolve the ambiguity of Vt-N structures. The design of the classifier is based on three important guidelines, namely, adopting linguistically motivated features, using all available resources, and easy integration into a parsing model. The linguistically motivated features include semantic relations, context, and morphological structures; and the available resources are treebank, thesaurus, affix database, and large corpora. We also propose two learning approaches that resolve the problem of data sparseness by auto-parsing and extracting relative knowledge from large-scale unlabeled data. Our experiment results show that the Vt-N classifier outperforms the current PCFG parser. Furthermore, it can be easily and effectively integrated into the PCFG parser and general statistical parsing models. Evaluation of the learning approaches indicates that world knowledge facilitates Vt-N disambiguation through data selection and error correction.

1 Introduction

In Chinese, the structure of a transitive verb (Vt) followed by a noun (N) may be a verb phrase (VP), a noun phrase (NP), or there may not be a dependent relation, as shown in (1) below. In general, parsers may prefer VP reading because a transitive verb followed by a noun object is normally a VP structure. However, Chinese verbs can also modify nouns without morphological inflection, e.g., 養殖/*farming* 池/*pond*. Consequently, parsing Vt-N structures is difficult because it is hard to resolve such ambiguities without prior knowledge. The following are some typical examples of various Vt-N structures:

1)
解決/*solve* 問題/*problem* → VP
解決/*solving* 方案/*method* → NP
解決/*solve* 人類/*mankind* (問題/*problem*)→None

To find the most effective disambiguation features, we need more information about the Vt-N → NP construction and the semantic relations between Vt and N. Statistical data from the Sinica Treebank (Chen et al., 2003) indicates that 58% of Vt-N structures are verb phrases, 16% are noun phrases, and 26% do not have any dependent relations. It is obvious that the semantic relations between a Vt-N structure and its context information are very important for differentiating between dependent relations. Although the verb-argument relation of VP structures is well understood, it is not clear what kind of semantic relations result in NP structures. In the next sub-section, we consider three questions: What sets of nouns accept verbs as their modifiers? Is it possible to identify the semantic types of such pairs of verbs and nouns? What are their semantic relations?

1.1 Problem Analysis

Analysis of the instances of NP(Vt-N) structures in the Sinica Treebank reveals the following four types of semantic structures, which are used in the design of our classifier.

Type 1. Telic(Vt) + Host(N): Vt denotes the telic function (purpose) of the head noun N, e.g.,

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 928–937,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

研究/*research* 工具/*tool*; 探測/*explore* 機/*machine*; 賭/*gamble* 館/*house*; 搜尋/*search* 程式/*program*. The telic function must be a salient property of head nouns, such as tools, buildings, artifacts, organizations and people. To identify such cases, we need to know the types of nouns which take telic function as their salient property. Furthermore, many of the nouns are monosyllabic words, such as 員/*people*, 器/*instruments*, 機/*machines*.

Type 2. Host-Event(Vt) + Attribute(N): Head nouns are attribute nouns that denote the attributes of the verb, e.g., 研究/*research* 方法/*method* (*method of research*); 攻擊/*attack* 策略/*strategy* (*attacking strategy*); 書寫/*write* 內容/*context* (*context of writing*); 賭/*gamble* 規/*rule* (*gambling rules*). An attribute noun is a special type of noun. Semantically, attribute nouns denote the attribute types of objects or events, such as *weight*, *color*, *method*, and *rule*. Syntactically, attribute nouns do not play adjectival roles (Liu, 2008). By contrast, object nouns may modify nouns. The number of attributes for events is limited. If we could discover all event-attribute relations, then we can solve this type of construction.

Type 3. Agentive + Host: There is only a limited number of such constructions and the results of the constructions are usually ambiguous, e.g., 炒飯/*fried rice* (NP), 叫聲/*shouting sound*. The first example also has the VP reading.

Type 4. Apposition + Affair: Head nouns are event nouns and modifiers are verbs of apposition events, e.g. 追撞/*collide* 事故/*accident*, 破壞/*destruct* 運動/*movement*, 憤恨/*hate* 行為/*behavior*. There is finite number of event nouns.

Furthermore, when we consider verbal modifiers, we find that verbs can play adjectival roles in Chinese without inflection, but not all verbs play adjectival roles. According to Chang et al. (2000) and our observations, adjectival verbs are verbs that denote event types rather than event instances; that is, they denote a class of events which that are concepts in an upper-level ontology. One important characteristic of adjectival verbs is that they have conjunctive morphological structures, i.e., the words are conjunct with two nearly synonymous verbs, e.g., 研/*study* 究/*search* (*research*), 探/*explore* 測/*detect* (*explore*), and 搜/*search* 尋/*find* (*search*). Therefore, we need a morphological classifier that can detect the conjunctive morphological structure of a verb by checking the semantic parity of two morphemes of the verb.

Based on our analysis, we designed a Vt-N classifier that incorporates the above features to solve the problem. However, there is a data sparseness problem because of the limited size of the current Treebank. In other words, Treebank cannot provide enough training data to train a classifier properly. To resolve the problem, we should mine useful information from all available resources.

The remainder of this paper is organized as follows. Section 2 provides a review of related works. In Section 3, we describe the disambiguation model with our selected features, and introduce a strategy for handling unknown words. We also propose a learning approach for a large-scale unlabeled corpus. In Section 4, we report the results of experiments conducted to evaluate the proposed Vt-N classifier on different feature combinations and learning approaches. Section 5 contains our concluding remarks.

2 Related Work

Most works on V-N structure identification focus on two types of relation classification: modifier-head relations and predicate-object relations (Wu, 2003; Qiu, 2005; Chen, 2008; Chen et al., 2008; Yu et al., 2008). They exclude the independent structure and conjunctive head-head relation, but the cross-bracket relation does exist between two adjacent words in real language. For example, if "遍佈/*all over* 世界/*world* " was included in the short sentence "遍佈/*all over* 世界/*world* 各國/*countries*", it would be an independent structure. A conjunctive head-head relation between a verb and a noun is rare. However, in the sentence "服務 設備 都 甚 周到" (Both service and equipment are very thoughtful.), there is a conjunctive head-head relation between the verb 服務/*service* and the noun 設備/*equipment*. Therefore, we use four types of relations to describe the V-N structures in our experiments. The symbol 'H/X' denotes a predicate-object relation; 'X/H' denotes a modifier-head relation; 'H/H' denotes a conjunctive head-head relation; and 'X/X' denotes an independent relation.

Feature selection is an important task in V-N disambiguation. Hence, a number of studies have suggested features that may help resolve the ambiguity of V-N structures (Zhao and Huang, 1999; Sun and Jurafsky, 2003; Chiu et al., 2004; Qiu, 2005; Chen, 2008). Zhao and Huang used lexicons, semantic knowledge, and word length in-

formation to increase the accuracy of identification. Although they used the Chinese thesaurus CiLin (Mei et al., 1983) to derive lexical semantic knowledge, the word coverage of CiLin is insufficient. Moreover, none of the above papers tackle the problem of unknown words. Sun and Jurafsky exploit the probabilistic rhythm feature (i.e., the number of syllables in a word or the number of words in a phrase) in their shallow parser. Their results show that the feature improves the parsing performance, which coincides with our analysis in Section 1.1. Chiu et al.'s study shows that the morphological structure of verbs influences their syntactic behavior. We follow this finding and utilize the morphological structure of verbs as a feature in the proposed Vt-N classifier. Qiu's approach uses an electronic syntactic dictionary and a semantic dictionary to analyze the relations of V-N phrases. However, the approach suffers from two problems: (1) low word coverage of the semantic dictionary and (2) the semantic type classifier is inadequate. Finally, Chen proposed an automatic VN combination method with features of verbs, nouns, context, and the syllables of words. The experiment results show that the method performs reasonably well without using any other resources.

Based on the above feature selection methods, we extract relevant knowledge from Treebank to design a Vt-N classifier. However we have to resolve the common problem of data sparseness. Learning knowledge by analyzing large-scale unlabeled data is necessary and proved useful in previous works (Wu, 2003; Chen et al., 2008; Yu et al., 2008). Wu developed a machine learning method that acquires verb-object and modifier-head relations automatically. The mutual information scores are then used to prune verb-noun whose scores are below a certain threshold. The author found that accurate identification of the verb-noun relation improved the parsing performance by 4%. Yu et al. learned head-modifier pairs from parsed data and proposed a head-modifier classifier to filter the data. The filtering model uses the following features: a PoS-tag pair of the head and the modifier; the distance between the head and the modifier; and the presence or absence of punctuation marks (e.g., commas, colons, and semi-colons) between the head and the modifier. Although the method improves the parsing performance by 2%, the filtering model obtains limited data; the recall rate is only 46.35%. The authors also fail to solve the problem of Vt-N ambiguity.

Our review of previous works and the observations in Section 1.1 show that lexical words, semantic information, the syllabic length of words, neighboring PoSs and the knowledge learned from large-scale data are important for Vt-N disambiguation. We consider more features for disambiguating Vt-N structures than previous studies. For example, we utilize (1) four relation classification in a real environment, including 'X/H', 'H/X', 'X/X' and 'H/H' relations; (2) unknown word processing of Vt-N words (including semantic type predication and morph-structure predication); (3) unsupervised data selection (a simple and effective way to extend knowledge); and (4) supervised knowledge correction, which makes the extracted knowledge more useful.

3 Design of the Disambiguation Model

The disambiguation model is a Vt-N relation classifier that classifies Vt-N relations into 'H/X' (predicate-object relations), 'X/H' (modifier-head relations), 'H/H' (conjunctive head-head relations), or 'X/X' (independent relations). We use the Maximum Entropy toolkit (Zhang, 2004) to construct the classifier. The advantage of using the Maximum Entropy model is twofold: (1) it has the flexibility to adjust features; and (2) it provides the probability values of the classification, which can be easily integrated into our PCFG parsing model.

In the following sections, we discuss the design of our model for feature selection and extraction, unknown word processing, and world knowledge learning.

3.1 Feature Selection and Extraction

We divide the selected features into five groups: PoS tags of Vt and N, PoS tags of the context, words, semantics, and additional information. Table 1 shows the feature types and symbol notations. We use symbols of t_1 and t_2 to denote the PoS of Vt and N respectively. The context feature is neighboring PoSs of Vt and N: the symbols of t_{-2} and t_{-1} represent its left PoSs, and the symbol t_3 and t_4 represent its right PoSs. The semantic feature is the lexicon's semantic type extracted from E-HowNet sense expressions (Huang et al., 2008). For example, the E-HowNet expression of "車輛/*vehicles*" is {LandVehicle|車:quantity={mass|眾}}, so its semantic type is {LandVehicle|車}. We discuss the model's performance with different feature combinations in Section 4.

Feature	Feature Description
PoS	PoS of Vt and N t_1; t_2
Context	Neighboring PoSs t_{-2}; t_{-1}; t_3; t_4
Word	Lexical word w_1; w_2
Semantic	Semantic type of word st_1; st_2
Additional Information	Morphological structure of verb *Vmorph*
	Syllabic length of noun *Nlen*

Table 1. The features used in the Vt-N classifier

The example in Figure 1 illustrates feature labeling of a Vt-N structure. First, an instance of a Vt-N structure is identified from Treebank. Then, we assign the semantic type of each word without considering the problem of sense ambiguity for the moment. This is because sense ambiguities are partially resolved by PoS tagging, and the general problem of sense disambiguation is beyond the scope of this paper. Furthermore, Zhao and Huang (1999) demonstrated that the retained ambiguity does not have an adverse impact on identification. Therefore, we keep the ambiguous semantic type for future processing.

Table 2 shows the labeled features for "學習/*learn* 中文/*Chinese*" in Figure 1. The column *x* and *y* describe relevant features in "學習/*learn*" and "中文/*Chinese*" respectively. Some features are not explicitly annotated in the Treebank, e.g., the semantic types of words and the morphological structure of verbs. We propose labeling methods for them in the next sub-section.

Feature Type	x	y
Word	w_1=學習	w_2=中文
PoS	t_1=VC	t_2=Na
Semantic	st_1=study|學習	st_2=language|語言
Context	t_{-2}=Nep; t_{-1}=VK; t_3=DE; t_4=Na	
Additional Information	Vmorph=VV	Nlen=2
Relation Type	rt = H/X	

Table 2. The feature labels of Vt-N pair in Figure 1

3.2 Unknown Word Processing

In Chinese documents, 3% to 7% of the words are usually unknown (Sproat and Emerson, 2003). By 'unknown words', we mean words not listed in the dictionary. More specifically, in this paper, unknown words means words without semantic type information (i.e., E-HowNet expressions) and verbs without morphological structure information. Therefore, we propose a method for predicting the semantic types of unknown words, and use an affix database to train a morph-structure classifier to derive the morphological structure of verbs.

Morph-Structure Predication of Verbs: We use data analyzed by Chiu et al. (2004) to develop a classifier for predicating the morphological structure of verbs. There are four types of morphological structures for verbs: the coordinating structure (VV), the modifier-head structure (AV), the verb-complement structure (VR), and the verb-object structure (VO). To classify verbs automatically, we incorporate three features in the proposed classifier, namely, the lexeme itself, the prefix and the suffix, and the semantic types of the prefix and the suffix. Then, we use training data from the affix database to train the classifier. Table 3 shows an example of the unknown verb "傳播到/disseminate" and the morph-structure classifier shows that it is a 'VR' type.

Feature	Feature Description
Word=傳播到	Lexicon
PW=傳播	Prefix word
PWST={disseminate|傳播}	Semantic Type of Prefix Word 傳播
SW=到	Suffix Word
SWST={Vachieve|達成}	Semantic Type of Suffix Word 到

Table 3. An example of an unknown verb and feature templates for morph-structure predication

Semantic Type Provider: The system exploits *WORD*, *PoS*, *affix* and *E-HowNet* information to obtain the semantic types of words (see Figure 2). If a word is known and its PoS is given, we can usually find its semantic type by searching the E-HowNet database. For an unknown word, the semantic type of its head morpheme is its semantic type; and the semantic type of the head morpheme is obtained from E-HowNet[1]. For example, the unknown word "傳播到/*disseminate*", its prefix word is "傳播/*disseminate*" and we learn that its semantic type is {disseminate|傳播} from E-HowNet. Therefore, we assign {disseminate|傳播} as the semantic type of "傳播到/*disseminate*". If the word or head morpheme does not exist in the affix database, we assign a general semantic type based on its PoS, e.g., nouns are {thing|萬物} and verbs are {act|行動}. In this matching procedure, we may encounter multiple matching data of words and affixes. Our strategy is to keep the ambiguous semantic type for future processing.

Input: *WORD, PoS*
Output: *Semantic Type (ST)*

```
procedure STP(WORD, PoS)
    (* Initial Step *)
    ST := null;
    (* Step 1: Known word *)
    if WORD already in E-HowNet then
        ST := EHowNet(WORD, PoS);
    else if WORD in Affix database then
        ST := EHowNet(affix of WORD, PoS);
    (* Step 2 : Unknown word *)
    if ST is null and PoS is 'Vt' then
        ST := EHowNet(prefix of WORD, PoS);
    else if ST is null and PoS is 'N' then
        ST := EHowNet(suffix of WORD, PoS);
    (* Step 3 : default *)
    if ST is null and PoS is 'Vt' then
        ST := 'act|行動';
    else if ST is null and PoS is 'N' then
        ST := 'thing|萬物'
    (* Finally *)
    STP := ST;
end;
```

Figure 2. The Pseudo-code of the Semantic Type Predication Algorithm.

[1] The E-HowNet function in Figure 2 will return a null ST value where words do not exist in E-HowNet or Affix database.

3.3 Learning World Knowledge

Based on the features discussed in the previous sub-section, we extract prior knowledge from Treebank to design the Vt-N classifier. However, the training suffers from the data sparseness problem. Furthermore most ambiguous Vt-N relations are resolved by common sense knowledge that makes it even harder to construct a well-trained system. An alternative way to extend world knowledge is to learn from large-scale unlabeled data (Wu, 2003; Chen et al., 2008; Yu et al., 2008). However, the unsupervised approach accumulates errors caused by automatic annotation processes, such as word segmentation, PoS tagging, syntactic parsing, and semantic role assignment. Therefore, how to extract useful knowledge accurately is an important issue.

To resolve the error accumulation problem, we propose two methods: unsupervised NP selection and supervised error correction. The NP selection method exploits the fact that an intransitive verb followed by a noun can only be interpreted as an NP structure, not a VP structure. It is easy to find such instances with high precision by parsing a large corpus. Based on the selection method, we can extend contextual knowledge about NP(V+N) and extract nouns that take adjectival verbs as modifiers. The error correction method involves a small amount of manual editing in order to make the data more useful and reduce the number of errors in auto-extracted knowledge. The rationale is that, in general, high frequency Vt-N word-bigram is either VP or NP without ambiguity. Therefore, to obtain more accurate training data, we simply classify each high frequency Vt-N word bigram into a unique correct type without checking all of its instances. We provide more detailed information about the method in Section 4.3.

4 Experiments and Results

4.1 Experimental Setting

We classify Vt-N structures into four types of syntactic structures by using the bracketed information (tree structure) and dependency relation (head-modifier) to extract the Vt-N relations from treebank automatically. The resources used in the experiments as follows.

Treebank: The Sinica Treebank contains 61,087 syntactic tree structures with 361,834 words. We extracted 9,017 instances of Vt-N structures from the corpus. Then, we randomly

selected 1,000 of the instances as test data and used the remainder (8,017 instances) as training data. Labeled information of word segmentation and PoS-tagging were retained and utilized in the experiments.

E-HowNet: E-HowNet contains 99,525 lexical semantic definitions that provide information about the semantic type of words. We also implement the semantic type predication algorithm in Figure 2 to generate the semantic types of all Vt and N words, including unknown words.

Affix Data: The database includes 13,287 examples of verbs and 27,267 examples of nouns, each example relates to an affix. The detailed statistics of the verb morph-structure categorization are shown in Table 4. The data is used to train a classifier to predicate the morph-structure of verbs. We found that verbs with a conjunctive structure (VV) are more likely to play adjectival roles than the other three types of verbs. The classifier achieved 87.88% accuracy on 10-fold cross validation of the above 13,287 verbs.

	VV	VR	AV	VO
Prefix	920	2,892	904	662
Suffix	439	7,388	51	31

Table 4. The statistics of verb morph-structure categorization

Large Corpus: We used a Chinese parser to analyze sentence structures automatically. The auto-parsed tree structures are used in Experiment 2 (described in the Sub-section 4.3). We obtained 1,262,420 parsed sentences and derived 237,843 instances of Vt-N structure as our dataset (called as ASBC).

4.2 Experiment 1: Evaluation of the Vt-N Classifier

In this experiment, we used the Maximum Entropy Toolkit (Zhang, 2004) to develop the Vt-N classifier. Based on the features discussed in Section 3.1, we designed five models to evaluate the classifier's performance on different feature combinations.

The features and used in each model are described below. The feature values shown in brackets refer to the example in Figure 1.

- **M1** is the baseline model. It uses PoS-tag pairs as features, such as (t_1=VC, t_2=Na).
- **M2** extends the M1 model by adding context features of (t_{-1}=VK, t_1=VC), (t_2=Na, t_3=DE), (t_{-2}=Nep, t_{-1}=VK, t_1=VC), (t_2=Na, t_3=DE, t_4=Na) and (t_{-1}=VK, t_3=DE).
- M3 extends the M2 model by adding lexicon features of (w_1=學習, t_1=VK, w_2=中文, t_2=Na), (w_1＝學習, w_2=中文), (w_1=學習) and (w_2=中文).
- M4 extends the M3 model by adding semantic features of (st_1=study|學習, t_1=VK , st_2=language|語言, t_2=Na), (st_1=study|學習, t_1=VK) and (st_2=language|語言, t_2=Na).
- M5 extends the M4 model by adding two features: the morph-structure of verbs; and the syllabic length of nouns (Vmorph='VV') and (Nlen=2).

Table 5 shows the results of using different feature combinations in the models. The symbol P1(%) is the 10-fold cross validation accuracy of the training data, and the symbol P2(%) is the accuracy of the test data. By adding contextual features, the accuracy rate of M2 increases from 59.10% to 72.30%. The result shows that contextual information is the most important feature used to disambiguate VP, NP and independent structures. The accuracy of M2 is approximately the same as the result of our PCFG parser because both systems use contextual information. By adding lexical features (M3), the accuracy rate increases from 72.30% to 80.20%. For semantic type features (M4), the accuracy rate increases from 80.20% to 81.90%. The 1.7% increase in the accuracy rate indicates that semantic generalization is useful. Finally, in M5, the accuracy rate increases from 81.90% to 83.00%. The improvement demonstrates the benefits of using the verb morph-structure and noun length features.

Models	Feature for Vt-N	P1(%)	P2(%)
M1	(t_1,t_2)	61.94	59.10
M2	+ (t_{-1},t_1) (t_2,t_3) (t_{-2},t_{-1},t_1) (t_2,t_3,t_4) (t_{-1},t_3)	76.59	72.30
M3	+ (w_1,t_1,w_2,t_2) (w_1,w_2) (w_2) (w_1)	83.55	80.20
M4	+ (st_1,t_1,st_2,t_2) (st_1,t_1) (st_2, t_2)	84.63	81.90
M5	+ (Vmorph) (Nlen)	85.01	83.00

Table 5. The results of using different feature combinations

Next, we consider the influence of unknown words on the Vt-N classifier. The statistics shows that 17% of the words in Treebank lack semantic type information, e.g., 留在/*StayIn*, 填飽/*fill*, 貼出/*posted*, and 綁好/*tied*. The accuracy of the Vt-N classifier declines by 0.7% without semantic type information for unknown words. In other words, lexical semantic information improves the accuracy of the Vt-N classifier. Regarding the problem of unknown morph-structure of words, we observe that over 85% of verbs with more than 2 characters are not found in the affix database. If we exclude unknown words, the accuracy of the Vt-N prediction decreases by 1%. Therefore, morph-structure information has a positive effect on the classifier.

4.3 Experiment 2: Using Knowledge Obtained from Large-scale Unlabeled Data by the Selection and Correction Methods.

In this experiment, we evaluated the two methods discussed in Section 3, i.e., unsupervised NP selection and supervised error correction. We applied the data selection method (i.e., *distance*=1, with an intransitive verb (Vi) followed by an object noun (Na)) to select 46,258 instances from the ASBC corpus and compile a dataset called Treebank+ASBC-Vi-N. Table 6 shows the performance of model 5 (M5) on the training data derived from Treebank and Treebank+ASBC-Vi-N. The results demonstrate that learning more nouns that accept verbal modifiers improves the accuracy.

	Treebank+ ASBC-Vi-N	Treebank
size of training instances	46,258	8,017
M5 - P2(%)	83.90	83.00

Table 6. Experiment results on the test data for various knowledge sources

We had also try to use the auto-parsed results of the Vt-N structures from the ASBC corpus as supplementary training data for train M5. It degrades the model's performance by too much error when using the supplementary training data. To resolve the problem, we utilize the supervised error correction method, which manually correct errors rapidly because high frequency instances (w_1, w_2) rarely have ambiguous classifications in different contexts. So we designed an editing tool to correct errors made by the parser in the classification of high frequency Vt-N word pairs. After the manual correction operation, which takes 40 man-hours, we assign the correct classifications (w_1, t_1, w_2, t_2, rt) for 2,674 Vt-N structure types which contains 10,263 instances to creates the ASBC+Correction dataset. Adding the corrected data to the original training data increases the precision rate to 88.40% and reduces the number of errors by approximately 31.76%, as shown in the Treebank+ASBC+Correction column of Table 7.

	Treebank+ ASBC+Correction	Treebank+ ASBC-Vi-N	Treebank
size of training instances	56,521	46,258	8,017
M5 - P2(%)	88.40	83.90	83.00

Table 7. Experiment results of classifiers with different training data

We also used the precision and recall rates to evaluate the performance of the models on each type of relation. The results are shown in Table 8. Overall, the Treebank+ASBC+Correction method achieves the best performance in terms of the precision rate. The results for Treebank+ASBC-Vi-N show that the unsupervised data selection method can find some knowledge to help identify NP structures. In addition, the proposed models achieve better precision rates than the PCFG parser. The results demonstrate that using our guidelines to design a disambiguation model to resolve the Vt-N problem is successful.

		H/X	X/H	X/X
Treebank	R(%)	91.11	67.90	74.62
	P(%)	84.43	78.57	81.86
Treebank+ ASBC-Vi-N	R(%)	91.00	72.22	71.54
	P(%)	84.57	72.67	85.71
Treebank+ ASBC+Correction	R(%)	98.62	60.49	83.08
	P(%)	86.63	88.29	93.51
PCFG	R(%)	90.54	23.63	80.21
	P(%)	78.24	73.58	75.00

Table 8. Performance comparison of different classification models.

4.4 Experiment 3: Integrating the Vt-N classifier with the PCFG Parser

Identifying Vt-N structures correctly facilitates statistical parsing, machine translation, infor-

mation retrieval, and text classification. In this experiment, we develop a baseline PCFG parser based on feature-based grammar representation by Hsieh et al. (2012) to find the best tree structures (*T*) of a given sentence (*S*). The parser then selects the best tree according to the evaluation score *Score(T,S)* of all possible trees. If there are *n* PCFG rules in the tree *T*, the *Score(T,S)* is the accumulation of the logarithmic probabilities of the *i*-th grammar rule (*RPi*). Formula 1 shows the baseline PCFG parser.

$$Score(T,S) = \sum_{i=1}^{n} (RP_i) \quad (1)$$

The Vt-N models can be easily integrated into the PCFG parser. Formula 2 represents the integrated structural evaluation model. We combine *RPi* and *VtNPi* with the weights w_1 and w_2 respectively, and set the value of w_2 higher than that of w_1. *VtNPi* is the probability produced by the Vt-N classifier for the type of the relation between Vt-N bigram determined by the PCFG parsing. The classifier is triggered when a [Vt, N] structure is encountered; otherwise, the Vt-N model is not processed.

$$Score(T,S) = \sum_{i=1}^{n} (w_1 \times RP_i + w_2 \times VtNP_i) \quad (2)$$

The results of evaluating the parsing model incorporated with the Vt-N classifier (see Formula 2) are shown in Table 9 and Table 10. The P2 is the accuracy of Vt-N classification on the test data. The bracketed *f*-score (BF^2) is the parsing performance metric. Based on these results, the integrated model outperforms the PCFG parser in terms of Vt-N classification. Because the Vt-N classifier only considers sentences that contain Vt-N structures, it does not affect the parsing accuracies of other sentences.

	PCFG + M5 (Treebank)	PCFG
P2(%)	80.68	77.09
BF(%)	83.64	82.80

Table 9. The performance of the PCFG parser with and without model M5 from Treebank.

[2] The evaluation formula is (BP*BR*2) / (BP+BR), where BP is the precision and BR is the recall.

	PCFG + M5 (Treebank+ASBC+Correction)	PCFG
P2(%)	87.88	77.09
BF(%)	84.68	82.80

Table 10. The performance of the PCFG parser with and without model M5 from Treebank+ASBC+Correction data set.

4.5 Experiment 4: Comparison of Various Chinese Parsers

In this experiment, we give some comparison results in various parser: 'PCFG Parser' (baseline), 'CDM Parser' (Hsieh et al., 2012), and 'Berkeley Parser' (Petrov et al., 2006). The CDM parser achieves the best score in Traditional Chinese Parsing task of SIGHAN Bake-offs 2012 (Tseng et al., 2012). Petrov's parser (as Berkeley, version is 2009 1.1) is the best PCFG parser for non-English language and it is an open source. In our comparison, we use the same training data for training models and parse the same test dataset based on the gold standard word segmentation and PoS tags. We have already discussed the PCFG parser in Section 4.4. As for CDM parser, we retrain relevant model in our experiments. And since Berkeley parser take different tree structure (Penn Treebank format), we transform the experimental data to Berkeley CoNLL format and re-train a new model with parameters "-treebank CHINESE -SMcycles 4" [3] from training data. Moreover we use "-useGoldPOS" parameters to parse test data and further transform them to Sinica Treebank style from the Berkeley parser's results. The different tree structure formats of Sinica Treebank and Penn Treebank are as follow:

```
Sinica Treebank:
S(NP(Head:Nh:他們)|Head:VC:散播
|NP(Head:Na:熱情))

Penn Treebank:
( (S (NP (Head:Nh (Nh 他們))) (Head:VC
(VC 散播)) (NP (Head:Na (Na 熱情)))))
```

The evaluation results on the testing data, i.e. in P2 metric, are as follows. The accuracy of PCFG parser is 77.09%; CDM parser reaches 78.45% of accuracy; and Berkeley parser is 70.68%. The results show that the problem of Vt-

[3] The "-treebank CHINESE -SMcycles 4" is the best training parameter in Traditional Chinese Parsing task of SIGHAN Bake-offs 2012.

N cannot be well solved by any general parser including CDM parser and Berkeley's parser. It is necessary to have a different approach aside from the general model. So we set the target for a better model for Vt-N classification which can be easily integrated into the existing parsing model. So far our best model achieved the P2 accuracy of 87.88%.

5 Concluding Remarks

We have proposed a classifier to resolve the ambiguity of Vt-N structures. The design of the classifier is based on three important guidelines, namely, adopting linguistically motivated features, using all available resources, and easy integration into parsing model. After analyzing the Vt-N structures, we identify linguistically motivated features, such as lexical words, semantic knowledge, the morphological structure of verbs, neighboring parts-of-speech, and the syllabic length of words. Then, we design a classifier to verify the usefulness of each feature. We also resolve the technical problems that affect the prediction of the semantic types and morph-structures of unknown words. In addition, we propose a framework for unsupervised data selection and supervised error correction for learning more useful knowledge. Our experiment results show that the proposed Vt-N classifier significantly outperforms the PCFG Chinese parser in terms of Vt-N structure identification. Moreover, integrating the Vt-N classifier with a parsing model improves the overall parsing performance without side effects.

In our future research, we will exploit the proposed framework to resolve other parsing difficulties in Chinese, e.g., N-N combination. We will also extend the Semantic Type Predication Algorithm (Figure 2) to deal with all Chinese words. Finally, for real world knowledge learning, we will continue to learn more useful knowledge by auto-parsing to improve the parsing performance.

Neural Networks Leverage Corpus-wide Information for Part-of-speech Tagging

Yuta Tsuboi
IBM Research - Tokyo
yutat@jp.ibm.com

Abstract

We propose a neural network approach to benefit from the non-linearity of corpus-wide statistics for part-of-speech (POS) tagging. We investigated several types of corpus-wide information for the words, such as word embeddings and POS tag distributions. Since these statistics are encoded as dense continuous features, it is not trivial to combine these features comparing with sparse discrete features. Our tagger is designed as a combination of a linear model for discrete features and a feed-forward neural network that captures the non-linear interactions among the continuous features. By using several recent advances in the activation functions for neural networks, the proposed method marks new state-of-the-art accuracies for English POS tagging tasks.

1 Introduction

Almost all of the approaches to NLP tasks such as part-of-speech tagging and syntactic parsing mainly use sparse discrete features to represent local information such as word surfaces in a size-limited window. The non-linearity of those discrete features is often used in many NLP tasks since the simple conjunction (AND) of discrete features represents the co-occurrence of the features and is intuitively understandable. In addition, the thresholding of these combinatorial features by simple counts effectively suppresses the combinatorial increase of the parameters. At the same time, although global information had also been used in several reports (Nakagawa and Matsumoto, 2006; Huang and Yates, 2009; Turian et al., 2010; Schnabel and Schütze, 2014), the non-linear interactions of these features were not well investigated since these features are often dense continuous features and the explicit non-linear expansions are counterintuitive and drastically increase the number of the model parameters. In our work, we investigate neural networks used to represent the non-linearity of global information for POS tagging in a compact way.

We focus on four kinds of corpus-wide information: (1) *word embeddings*, (2) POS tag distributions, (3) *supertag* distributions, and (4) context word distributions. All of them are continuous dense features and we use a feed-forward neural network to exploit the non-linearity of these features. Although all of them except (3) have been used for POS tagging in previous work (Nakamura et al., 1990; Schmid, 1994; Schnabel and Schütze, 2014; Huang and Yates, 2009), we propose a neural network approach to capture the non-linear interactions of these features. By feeding these features into neural networks as an input vector, we can expect our tagger can handle not only the non-linearity of the N-grams of the same kinds of features but also the non-linear interactions among the different kind of features.

Our tagger combines a linear model using sparse high-dimensional features and a neural network using continuous dense features. Although Collobert et al. (2011) seeks to solve NLP tasks without depending on the feature engineering of conventional NLP methods, our architecture is more practical because it integrates the neural networks into a well-tuned conventional method. Thus, our tagger enjoys both the manually explored combinations of discrete features and the automatically learned non-linearity of the continuous features. We also studied some of the newer activation functions: Rectified Linear Units (Nair and Hinton, 2010), Maxout networks (Goodfellow et al., 2013), and L_p-pooling (Gulcehre et al., 2014; Zhang et al., 2014).

Deep neural networks have been a hot topic in many application areas such as computer vi-

Proceedings of the 2014 Conference on Empirical Methods in Natural Language Processing (EMNLP), pages 938–950,
October 25-29, 2014, Doha, Qatar. ©2014 Association for Computational Linguistics

sion and voice recognition. However, although neural networks show state-of-the-art results on a few semantic tasks (Zhila et al., 2013; Socher et al., 2013; Socher et al., 2011), neural network approaches have not performed better than the state-of-the-art systems for traditional syntactic tasks. Our neural tagger shows state-of-the-art results: 97.51% accuracy in the standard benchmark on the Penn Treebank (Marcus et al., 1993) and 98.02% accuracy in POS tagging on CoNLL2009 (Hajič et al., 2009). In our experiments, we found that the selection of the activation functions led to large differences in the tagging accuracies. We also observed that the POS tags of the words are effectively clustered by the hidden activations of the intermediate layer. This observation is evidence that the neural network can find good representations for POS tagging.

The remainder of this paper is organized as follows. Section 2 introduces our deterministic tagger and its learning algorithm. Section 3 describes the continuous features that represent corpus-wide information and Section 4 is about the neural network we used. Section 5 presents our empirical study of the effects of corpus-wide information and neural networks on English POS tagging tasks. Section 6 describes related work, and Section 7 concludes and suggests items for future work.

2 Transition-based tagging

Our tagging model is a deterministic tagger based on Choi and Palmer (2012), which is a one-pass, left-to-right tagging algorithm that uses well-tuned binary features.

Let $\boldsymbol{x} = (x_1, x_2, \ldots, x_T) \in X^T$ be an input token sequence of length T and $\boldsymbol{y} = (y_1, y_2, \ldots, y_T) \in Y^T$ be a corresponding POS tag sequence of $\boldsymbol{x}$. We denote the predicted tags by a tagger as $\hat{\boldsymbol{y}}$ and the subsequence from r to t as $\boldsymbol{y}_r^t$. The prediction of the t-th tag is deterministically done by the classifier:

$$\hat{y}_t = \underset{y \in Y}{\operatorname{argmax}} f_{\boldsymbol{\theta}}(\boldsymbol{z}_t, y), \tag{1}$$

where $f_{\boldsymbol{\theta}}$ is a scoring function with arbitrary parameters, $\boldsymbol{\theta} \in \mathbb{R}^d$, that are to be learned and $\boldsymbol{z}_t$ is an arbitrary feature representation of the t-th position using $\boldsymbol{x}$ and $\hat{\boldsymbol{y}}_1^{t-1}$ which is the prediction history of the previous tokens.

We extend Choi and Palmer (2012) in three ways: (1) an online SVM learning algorithm with L_1 and L_2 regularization, (2) continuous features for corpus-wide information, and (3) the composite function of a linear model for discrete features and a non-linear model for continuous features. Since (2) and (3) are the main topics of this paper, they are explained in detail in Sections 3 and 4 and we describe only (1) here.

First, our learning algorithm trains a multi-class SVM with L_1 and L_2 regularization based on *Follow the Proximally Regularized Leader* (FTRL-Proximal) (McMahan, 2011). In the k-th iteration, the parameter update is done by

$$\boldsymbol{\theta}^k = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \sum_{l=1}^{k} \left(\boldsymbol{g}^l \cdot \boldsymbol{\theta} + \frac{1}{2\boldsymbol{\eta}^l} \left|\left| \boldsymbol{\theta} - \boldsymbol{\theta}^l \right|\right|_2^2 \right) + R(\boldsymbol{\theta}),$$

where $\boldsymbol{g}^k \in \mathbb{R}^d$ is a subgradient of the hinge loss function and $R(\boldsymbol{\theta}) = \boldsymbol{\lambda}_1 ||\boldsymbol{\theta}||_1 + \frac{\boldsymbol{\lambda}_2}{2} ||\boldsymbol{\theta}||_2^2$ is the composite function of the L_1 and L_2 regularization terms with hyper-parameters $\boldsymbol{\lambda}_1 \geq 0$ and $\boldsymbol{\lambda}_2 \geq 0$. To incorporate an adaptive learning rate scheduling, Adagrad (Duchi et al., 2010), we use per-coordinate learning rates for $\{i | 1 \leq i < d\}$:

$$\eta_i^k = \frac{\alpha_i}{\left(\beta_i + \sqrt{\sum_{l=1}^{k} (g_i^l)^2} \right)},$$

where $\alpha \geq 0$ and $\beta \geq 0$. Although the naive implementation may require $O(k)$ computation in the k-th iteration, FTRL-Proximal can be implemented efficiently by maintaining two length-d vectors, $\boldsymbol{m} = \sum_l^k \boldsymbol{g}^l - \frac{1}{2\boldsymbol{\eta}^l}\boldsymbol{\theta}^l$ and $\boldsymbol{n} = \sum_l^k (g_i^l)^2$ (McMahan et al., 2013).

Second, to overcome the error propagation problem, we train the classifier with a simple variant of the on-the-fly example generation algorithm from Goldberg and Nivre (2012). Since the scoring function refers to the prediction history, Choi and Palmer (2012) uses the gold POS tags, $\boldsymbol{y}_1^{t-1}$, to generate training examples, which means they assume all of the past decisions are correct. However, this causes error propagation problems, since each state depends on the history of the past decisions. Therefore, at the k-th iteration and the t-th position of the input sequence, we simply use the predictions of the previously learned classifiers to generate training examples, i.e.,

$$\hat{y}_{t-r} = \underset{y \in Y}{\operatorname{argmax}} f_{\boldsymbol{\theta}_{k-r}}(\boldsymbol{z}_{t-r}, y)$$

for all $\{r | 1 \leq r < t-1\}$. Although it is not theoretically justified, it empirically runs as a

stochastic version of DAGGER (Ross et al., 2011) or SEARN (Daumé III et al., 2009) with the speed benefit of online learning.

    ▷ Leaving all θ for inactive i unchanged
  end for
  return $\boldsymbol{u}$
end function

Algorithm 1 summarizes our training process where $\ell(\boldsymbol{z}_t, y_t, \tilde{y}) := \max(0, 1 - f_{\boldsymbol{\theta}}(\boldsymbol{z}_t, y) + f_{\boldsymbol{\theta}}(\boldsymbol{z}_t, \tilde{y}))$ is the multi-class hinge loss (Crammer and Singer, 2001). I in Algorithm 1 is a set of parameter indexes that correspond to the non-zero features, so the update is sparse for sparse features. In addition, for the parameter update of the neural networks, we also use an accelerated proximal method (Parikh and Boyd, 2013), which is considered as a variant of the momentum methods (Sutskever et al., 2013). Although $\boldsymbol{u}$ and $\boldsymbol{\theta}$ are the same when the acceleration is not used, $\boldsymbol{u}$ in Algorithm 1 is an extrapolation step in the accelerated method. Although we do not focus on the learning algorithm in this work, the algorithm converges quite quickly and the speed is important because the neural network extension described later requires a hyper-parameter search which is computationally demanding.

3 Corpus-wide Information

Since typical discrete features indicate only the occurrence in a local context and do not convey corpus-wide statistics, we studied four kinds of continuous features for POS tagging to represent the corpus-wide information.

3.1 Word embeddings

Word embeddings, or distributed word representations, embed the words into a low-dimensional continuous space. Most of the neural network applications for NLP use word embeddings (Collobert et al., 2011; Socher et al., 2011; Zhila et al., 2013; Socher et al., 2013), and even for linear models, Turian et al. (2010) highlights the benefit of word embeddings on sequential labeling tasks.

In particular, in our experiments, we used two recently proposed algorithms, *word2vec* (Mikolov et al., 2013) and *glove* (Pennington et al., 2014), which are simple and scalable, although our method could use other word embeddings. Word2vec trains the word embeddings to predict the words surrounding each word, and glove trains the word embeddings to predict the logarithmic count of the surrounding words of each word. Thus, these embeddings can be seen as the distributed versions of the distributional features since the word vectors compactly represent the distribution of the context in which a word appears. We normalized the word embeddings to unit length and used the average vector of training vocabulary for the unknown tokens.

3.2 POS tag distribution

In a way similar to Schmid (1994), we use POS tag distribution over a training corpus. Each word is represented by a vector of length $|Y|$ in which the y-th element is the conditional probabilities with which that word gets the y-th POS tag. We also use the POS tag distributions of the affixes and

spelling binary features used in Choi and Palmer (2012). We cite the definitions of these features.

1. Affix: $c_{:1}, c_{:2}, c_{:3}, c_{n:}, c_{n-1:}, c_{n-2:}, c_{n-3:}$ where c_* is a character string in a word. For example $c_{:2}$ is the prefix of length two of a word and $c_{n-1:}$ is the suffix of length two of a word.

2. Spelling: initial uppercase, all uppercase, all lowercase, contains 1/2+ capital(s) not at the beginning, contains a (period/number/hyphen).

The probabilities for a feature b is estimated with additive smoothing as

$$P(y|b) = \frac{C(b,y)+1}{C(b)+|Y|}, \quad (2)$$

where $C(b)$ and $C(b,y)$ are the counts of b and co-occurrences of b and y, respectively. In addition, an extra dimension for sentence boundaries is added to the vector for word-forms. In total, the POS tag distributions for each word are encoded by a vector of dimension $|Y|+1+|Y|\times 14$ ($|Y|$ for lowercase simplified word-forms, 1 for sentence boundaries, $|Y| \times 7$ for affixes, and $|Y| \times 7$ for spellings).

3.3 Supertag distribution

We also use the distribution of *supertags* for dependency parsing. Supertags are lexical templates which are extracted from the syntactic dependency structures and suppertagging is often used for the pre-processing of a parsing task. Since the supertags encode rich syntactic information, we expect the supertag distribution of a word to also provide clues for the POS tagging. We used two types of supertags: One is the dependency relation label of the head of the word and the other is that of the dependents of the word. Following Ouchi et al. (2014), we added the relative position, left (L) or right (R), to the supertags. For example, a word has its dependents in the left direction with a label "nn" and in the right direction with a label "amod", so its supertag set for dependents is {"nn/L", "amod/R"}. A special supertag "NO-CHILD" is used for a word that has no dependent. Note that, although the Model 2 supertag set of Ouchi et al. (2014) is defined as the combination of head and dependent tags, we used them separately. The feature values for each word are defined in the same way as Equation 2 in Section 3.2. Since a word can have more than one dependent, the dependent supertag features are no longer multinomial distributions but we used them in that way. Note that, since the feature values are calculated using the tree annotations from training set, our tagger does not require any dependency parser at runtime.

3.4 Context word distribution

This is the simplest distributional features in which each word is represented by the distributions of its left and right neighbors. Although the context word distribution is similar to word embeddings, we believe they complement each other, as reported by Levy and Goldberg (2014). Following Schnabel and Schütze (2014), we restricted the set of indicator words to the 500 most frequent words in the corpus, and used two special feature entries: One is the marginal probability of the non-indicator words and the other is the probabilities of neighboring sentence boundaries. The conditional probabilities for left and right neighbors are estimated in the same way as Equation 2 in Section 3.2, and there are a total of $1,004$ dimensions of this feature for a word.

4 Neural Networks

The non-linearity of the discrete features has been exploited in many NLP tasks, since the simple conjunction of the discrete features is intuitive and the thresholding of these combinatorial features by their feature counts effectively suppresses the combinatorial increase of the parameters.

In contrast, it is not easy to manually tune the non-linearity of the continuous features. For example, it is not intuitive to design the conjunction features of two kinds of word embeddings, word2vec and glove. Although kernel methods have been used to incorporate non-linearity in prior research, they are rarely used now because their tagging speed is too slow (Giménez and Màrquez, 2003). Our solution is to introduce feed-forward neural networks to capture the non-linearity of the corpus-wide information.

4.1 Hybrid model

We designed our tagger as a hybrid of a linear model and a non-linear model. Wang and Manning (2013) reported that a neural network using both sparse discrete features and dense (low-

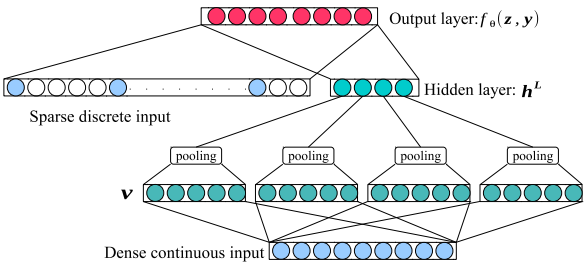

Figure 1: A hybrid architecture of a linear model and a neural network with a pooling activation function

dimensional) continuous features was worse than a linear model using the same two features. At the same time, they also reported that a neural network using only the dense continuous features outperformed a linear model using the same features. Based on their results, we applied neural networks only for the continuous features and used a linear model for the discrete features.

Formally, the scoring function (1) in Section 2 is defined as the composite function of two terms: $f(\boldsymbol{z}, y) := f_{\text{linear}}(\boldsymbol{z}, y) + f_{\text{nn}}(\boldsymbol{z}, y)$. The first f_{linear} is the linear model and the second f_{nn} is a neural network. Since this is a linear combination of two functions, the subgradient of the loss function required for Algorithm 1 is also the linear combination of subgradients of two functions, which means

$$\begin{aligned}\partial_{\boldsymbol{\theta}} \ell(\boldsymbol{z}_t, y_t, \tilde{y}) = \partial_{\boldsymbol{\theta}} f_{\text{linear}}(\boldsymbol{z}_t, \tilde{y}) + \partial_{\boldsymbol{\theta}} f_{\text{nn}}(\boldsymbol{z}_t, \tilde{y}) \\ - \partial_{\boldsymbol{\theta}} f_{\text{linear}}(\boldsymbol{z}_t, y_t) - \partial_{\boldsymbol{\theta}} f_{\text{nn}}(\boldsymbol{z}_t, y_t)\end{aligned}$$

if $f_{\boldsymbol{\theta}}(\boldsymbol{z}_t, y_t) - f_{\boldsymbol{\theta}}(\boldsymbol{z}_t, \tilde{y}) < 0$.

First, the linear model can be defined as

$$f_{\text{linear}}(\boldsymbol{z}, y) := \boldsymbol{\theta}_{\text{d}} \cdot \boldsymbol{\phi}_{\text{d}}(\boldsymbol{z}, y),$$

where $\boldsymbol{\phi}_{\text{d}}(\boldsymbol{z}, y)$ is a feature mapping for the discrete part of z and a POS tag, and $\boldsymbol{\theta}_{\text{d}}$ is the corresponding parameter vector. Since this is a linear model, the gradient of this function is simply $\partial_{\boldsymbol{\theta}} f_{\text{linear}}(\boldsymbol{z}, y) = \boldsymbol{\phi}_{\text{d}}(\boldsymbol{z}, y)$.

Second, each hidden layer of our neural networks non-linearly transforms an input vector $\boldsymbol{h}'$ into an output vector $\boldsymbol{h}$ and we can say $\boldsymbol{h}'$ is the continuous part of $\boldsymbol{z}$ at the first layer. Let $\boldsymbol{h}^L$ be a hidden activation of the top layer, which is the non-linear transformation of the continuous part of $\boldsymbol{z}$. The output layer of the neural network is defined as

$$f_{\text{nn}}(\boldsymbol{z}, y) := \boldsymbol{\theta}_{\text{o}} \cdot \boldsymbol{\phi}_{\text{o}}(\boldsymbol{h}^L, y),$$

where $\boldsymbol{\phi}_{\text{o}}(\boldsymbol{h}, y)$ is a feature mapping for the hidden variables and a POS tag, and $\boldsymbol{\theta}_{\text{o}}$ is the corresponding parameter vector.

4.2 Activation functions

The hidden variables $\boldsymbol{h}$ are computed by the recursive application of a non-linear activation function. Since new styles of the activation functions were recently proposed, we review several activation functions here. Let $\boldsymbol{v} \in \mathbb{R}^{|V|}$ be the input of an activation function and each element is $v_j = \boldsymbol{\theta}_{\text{nn},j} \cdot \boldsymbol{h}' + \theta_{\text{bias},j}$, where $\boldsymbol{\theta}_{\text{nn},j}$ is the parameter vector for v_j and $\theta_{\text{bias},j}$ is the bias parameter for v_j. We also assume $\boldsymbol{v}$ is divided into groups of size G, and denote the j-th element of the i-th group as $\{v_{ij} | 1 \leq i \leq |V|/G \wedge 1 \leq j \leq G\}$. We studied three activation functions:

1. Rectified linear units (ReLUs) (Nair and Hinton, 2010):

   $$h_j = \max(0, v_j) \text{ for all } \{j | 1 \leq j \leq |V|\}.$$

   Note that a subgradient of ReLUs is

   $$\frac{\partial h_j}{\partial \boldsymbol{\theta}} = \begin{cases} \frac{\partial v_j}{\partial \boldsymbol{\theta}} & \text{if } v_j > 0 \\ 0 & \text{otherwise.} \end{cases}$$

2. Maxout networks (MAXOUT) (Goodfellow et al., 2013):

   $$h_i = \max_{1 \leq j \leq G} v_{ij} \text{ for all } \{i | 1 \leq i \leq \frac{|V|}{G}\}.$$

   Note that a subgradient of MAXOUT is

   $$\frac{\partial h_i}{\partial \boldsymbol{\theta}} = \frac{\partial v_{i\hat{j}}}{\partial \boldsymbol{\theta}}, \text{ where } \hat{j} = \operatorname*{argmax}_{1 \leq j \leq G} v_{ij}$$

3. Normalized L_p-pooling (L_p) (Gulcehre et al., 2014):

   $$h_i = \left(\frac{1}{G} \sum_{j=1}^{G} |v_{ij}|^p \right)^{\frac{1}{p}} \text{ for all } \{i | 1 \leq i \leq \frac{|V|}{G}\}.$$

   Note that a subgradient of L_p is

   $$\frac{\partial h_i}{\partial \boldsymbol{\theta}} = \sum_{j=1}^{G} \frac{\partial v_{ij}}{\partial \boldsymbol{\theta}} \frac{v_{ij} |v_{ij}|^{p-2}}{G} \left(\frac{1}{G} \sum_{j=1}^{G} |v_{i,j}|^p \right)^{\frac{1}{p}-1}.$$

The activation inputs for each predefined group, $\{v_{1j}, \ldots, v_{Gj}\}$, are aggregated by a non-linear function in MAXOUT or L_p activation functions, while each input is transformed into a corresponding hidden variable in the ReLUs. When the number of parameters required for these activation functions is the same, the number of output variables $\boldsymbol{h}$ for MAXOUT and L_p is one-G-th smaller than that for ReLUs. Boureau et al. (2010) show pooling operations theoretically reduce the variance of hidden activations, and our experimental results also show MAXOUT and L_p perform better than the ReLUs with the same number of parameters. Note that MAXOUT is a special case of unnormalized L_p pooling when $p = \infty$ and $v_j > 0$ for all j (Zhang et al., 2014). Figure 1 summarizes the proposed architecture with a single hidden layer and a pooling activation function.

4.3 Hyper-parameter search

Finally, the subgradients of the neural network, $f_{\text{nn}}(\boldsymbol{z}, y)$, can be computed through standard back-propagation algorithms and we can apply them in Algorithm 1. However, many of the hyper-parameters have to be determined for the training of the neural networks, and two stages of random hyper-parameter searches (Bergstra and Bengio, 2012) are used in our experiments. Note that the parameters are grouped into three sets, $\boldsymbol{\theta}_d, \boldsymbol{\theta}_{\text{o}}, \boldsymbol{\theta}_{\text{nn}}$, and the same values for $\lambda_1, \lambda_2, \alpha, \beta$ are used for each parameter set.

In the first stage, we randomly select 32 combinations of λ_2 for f_{nn}, λ_1, λ_2 for f_{linear}, the epoch to start the L1/L2 regularizations, and the on and off the acceleration in Algorithm 1. Here are the candidates of three hyper-parameters:

1. λ_1: 0 for the update of f_{nn} and $\{0, 10^{-8}, 10^{-6}, 10^{-4}, 10^{-2}, 1\}$ for the update of f_{linear};
2. λ_2: $\{0.1, 0.5, 1, 5, 10\}$ for the update of f_{nn} and $\{1, 5, 10, 50, 100\}$ for the update of f_{linear}; and
3. Epoch to start the regularizations: $\{0, 1, 2\}$.

In the second stage with each hyper-parameter combination above, we select 8 random combinations of α, β for both f_{linear} and f_{nn} and initial parameter ranges R for f_{nn}. Here are the candidates of the three hyper-parameters:

1. α: $\{0.01, 0.05, 0.1, 0.5, 1, 5\}$;
2. β: $\{0.5, 1, 5\}$;
3. R: $\{[-0.1, 0.1], [-0.05, 0.05], [-0.01, 0.01], [-0.005, 0.005]\}$.

The values of $\boldsymbol{\theta}$ for f_{nn} are uniformly sampled in the range of the randomly selected R. Note that, according to Goodfellow et al. (2014), the biases $\boldsymbol{\theta}_{\text{bias}}$ are initialized as 0 for MAXOUT and L_p, and uniformly sampled from a range $R + \max(R)$, i.e., always initialized with non-negative values. The best combination for the development set is chosen after training that uses random 20% of the training set at the second stage, and Algorithm 1 is terminated when the all token accuracy of the development data has been declining for 5 epochs at the first stage. In other words, 32×8 random combinations of α, β, and $\boldsymbol{\theta}$ for f_{nn} were tested.

Table 1: Data set splits for PTB.

5 Experiments

5.1 Setup

Our experiments were mainly performed using the Wall Street Journal from Penn Treebank (PTB) (Marcus et al., 1993). We used tagged sentences from the parse trees (Toutanova et al., 2003) and followed the standard approach of splitting the PTB, using sections 0–18 for training, section 19–21 for development, and section 22–24 for testing (Table 1). In addition, we used the CoNLL2009 data sets with the training, development, and test splits used in the shared task (Hajič et al., 2009) for better comparison with a joint model of POS tagging and dependency parsing (Bohnet and Nivre, 2012).

Our baseline tagger was trained by Algorithm 1. As discrete features for our tagger, we used the same binary feature set as Choi and Palmer (2012) which is composed of (a) $1, 2, 3$-grams of the surface word-forms and their predicted/dominated POS tags, (b) the prefixes and suffixes of the words, and (c) the spelling types of the words. In the same way as Choi and Palmer (2012), we used lowercase simplified word-forms which appeared at least 3 times.

In addition to their binary features, we used continuous features which are the concatenation of the corpus-wide features in a context window. The window of size $w = 2s + 1$ is the local context centered around x_t: $x_{t-s}, \cdots, x_t, \cdots, x_{t+s}$. The experimental settings of each feature described in Section 3 are as follows.

Word embeddings

We used two word vectors: 300-dimensional vectors that were learned by word2vec using a part of the Google News dataset (around 100 billion tokens) [1], and 300-dimensional vectors that were learned by glove using a part of the Common Crawl dataset (840 billion tokens) [2]. For sentence boundaries, we use the vector of the special entry "</s>" for the word2vec embeddings and the zero vector for the glove embeddings.

POS tag distribution

The counts are calculated using training data.

Supertag distribution

In the experiments on PTB, we used the Stanford parser v2.0.4[3] to convert from phrase structures to dependency structures so that the dependency relation labels of the Stanford dependencies are used. The size of the supertag set is 85 for both heads and dependents in our experiments. In the experiments on CoNLL2009, the dependency structures and labels defined in CoNLL2009 are used and the size of supertag set is 99 for both heads and dependents.

Context word distribution

To count the neighboring words in our experiments, we used sections 0–18 of the Wall Street Journal and all of the Brown corpus from Penn Treebank (Marcus et al., 1993).

Since the training of the neural networks is computationally demanding, first, we trained the linear classifiers using Algorithm 1 to select the best window sizes for each corpus-wide information of Section 3. Then the best window size setting for the development set of PTB was used for training the neural networks described in Section 4.

Table 2: Feature and window size selection: development accuracies of all tokens (All) and unknown tokens (Unk.) of linear models trained on PTB (w2v: word2vec; glv: glove; pos: POS tag distribution; stg: supertag distribution; cw: context word distribution).

We fixed the group size at 8 for MAXOUT and L_p, and the number of hidden variables was chosen from $\{32, 48\}$ for MAXOUT and L_p and from $\{32, 64, 128, 256, 384\}$ for ReLUs according to all token accuracy on the development data of PTB. We report the POS tagging accuracy for both all of the tokens and only for the unknown tokens that do not appear in the training set.

5.2 Results

Table 2 shows the accuracies of the linear models on PTB with different window sizes for the continuous features. The window sizes of the word embeddings (word2vec and glove) in Section 3.1, POS tag distributions in Section 3.2, supertag distributions in Section 3.3, and context word distributions in Section 3.4 are shown in the columns of *w2v*, *glv*, *pos*, *stg*, and *cw*, respectively. Note that "-" denotes the corresponding feature was not used at all and the first row with all "-" denotes the results only using the original binary features from Choi and Palmer (2012). The window sizes in Table 2 are chosen mainly to investigate the effect of the word2vec embeddings, glove embeddings, and supertag distributions, since they had not previously been used for POS tagging.

The additions of the word embeddings improve all token accuracy by about 0.2 points according to the results shown in Nos. $1, 2, 3$. Although both word embeddings improved the accuracy of the unknown tokens, the gain of the glove embeddings (No. 3) is larger than that of the

word2vec (No. 2). The reason for this difference in the two embeddings may be because the training data for the glove vectors is 8 times larger than that for the word2vec vectors. The usage of the two word embeddings shows further improvement in the tagging accuracy over single word embeddings (No. 4).

The addition of the POS tag distributions and the context word distributions improves all token accuracy (Nos. $5, 8$). The comparison between the results with stag="-" (Nos. $5, 8$) and stag $= \{1, 3\}$ (Nos. $6, 7, 9$) indicates the minor but consistent improvement by using the supertag distribution features in Section 3.3. Finally, the 7th window-size setting in Table 2 achieves the best all token accuracy among the linear models, so we chose this setting for the experiments with the neural networks.

In Table 3, we compare the different settings of the neural networks with a single hidden layer [4] on the development set and test set from PTB. Neural networks with the MAXOUT and L_p (Nos. $3, 4, 5$) significantly outperform the best linear model (No. 1) [5], but the accuracy of the ReLUs (No. 2) was similar to that of the best linear model. According to these results, we argue that the activation function selection is important, although conventional research in NLP has used only a single activation function. It took roughly 7 times as long to learn the hybrid models than the linear model (No. 1). "$L_p(p=2)$ (w/o linear part)" (No. 6) shows the result for a $L_p(p=2)$ model which does not include the linear model f_{linear} for the binary features. Comparing the test results of No. 6 with that of No. 3, the proposed hybrid architecture of a linear model and a neural network enjoys the benefits of both models. Note that No. 6's accuracies of the unknown tokens are relatively competitive, and this may be because the continuous features for the neural network do not include word surfaces.

Since it shows the best accuracy for all tokens on the development set, we refer to $L_p(p=2)$ with 48 hidden variables and the group size of 8 (No. 3 in Table 3) as our representative tagger and denote it as $L_p(p=2)$ in the rest of discussion. In Table 4a, we compare our result with the previously reported results and we see that our tagger outperforms the current state-of-the-art systems on PTB for the accuracies of all tokens and unknown tokens.

In addition, since our tagger was trained using the dependency tree annotations as described in Section 3.3, we compare it with the results of Bohnet and Nivre (2012) which is also trained using both POS tag and dependency annotations. Although their focus is on the dependency pars-

[4] We leave the investigation of deeper neural networks as future work.

[5] For significance tests, we have used the *Wilcoxon matched-pairs signed-rank test* at the 95% confidence level dividing the data into 100 data pairs.

ing, they report state-of-the art POS accuracies for many languages. Note that Bohnet and Nivre (2012) also used external resources. Table 4b gives the results for CoNLL2009 data set[6]. Our tagger outperform Bohnet and Nivre (2012), so we believe this is the highest POS accuracy ever reported for a tagger trained on this data set.

Finally, to visualize the learned representations, we applied principal components analysis (PCA) to the hidden activations $\boldsymbol{h}^L$ of the first $10,000$ tokens of the development set from PTB. We also performed PCA to the raw continuous inputs of the same data set. Figure 2 shows the data plots for all the combinations among the first four principal components. We plots only the verb tokens to make the plots easier to see. Figures 2a and 2b show the PCA results of the raw features and the hidden activations of $L_p(p = 2)$, respectively. Compared to Figure 2a, the tokens with the same POS tag are more clearly clustered in Figure 2b. This suggests the neural network learned the good representations for POS tagging and these hidden activations can be used as the input of the succeeding processes, such as parsing.

[6]The accuracies of our tagger on the development set of CoNLL2009 data are 97.76% for all tokens and 93.42% for unknown tokens.

6 Related Work

There is some old work on the POS tagging by neural networks. Nakamura et al. (1990) proposed a neural tagger that predicts the POS tag using a previous POS predictions. Schmid (1994) is most similar to our work. The inputs of his neural network are the POS tag distributions of a word and its suffix in a context window, and he reports a 2% improvement over a regular hidden Markov model. However, his tagger did not use the other kinds of corpus-wide information as we used.

Most of the recent studies on POS tagging use linear models (Suzuki and Isozaki, 2008; Spoustová et al., 2009) or other non-linear models, such as k-nearest neighbor (kNN) (Søgaard, 2011). One trend in these studies is model combinations. Suzuki and Isozaki (2008) combined generative and discriminative models, Spoustová et al. (2009) used the combination of three taggers to generate automatically annotated corpus, and Søgaard (2011) used the outputs of a supervised tagger and an unsupervised tagger as the feature space of the kNN. Our work also follows this trend since neural networks can be considered as non-linear integration of several linear classifiers.

Apart from POS tagging, some previous studies in parsing used the discretization method to handle the combination of continuous features. Bohnet and Nivre (2012) binned the difference of two con-

tinuous features in discrete steps of a predefined small interval. Bansal et al. (2014) used the conjunction of discretized features and studied two discretization methods: One is the binning of real values into discrete steps and the other is a hard clustering of continuous feature vectors. It is not easy to determine the optimal intervals for the binning method, and the clustering method is unsupervised so that the clusters are not guaranteed for good representations of the target tasks.

To capture rich syntactic information for Chinese POS tagging, Sun and Uszkoreit (2012) used the ensemble model of both a POS tagger and a constituency parser. Sun et al. (2013) improved the efficiency of Sun and Uszkoreit (2012) in which a single tagging model is trained using automatically annotated corpus generated by the ensemble tagger. Although the supertag distribution feature in Section 3.3 is a simple way to incorporate syntactic information, automatically parsed large corpora may make the estimate of the supertag distributions more accurate.

7 Conclusion and Future Work

We are studying a neural network approach to handle the non-linear interaction among corpus-wide statistics. For POS tagging, we used word embeddings, POS tag distributions, supertag distributions, and context word distributions in a context window. These features are beneficial, even for linear classifiers, but the neural networks leverage these features for improving tagging accuracies. Our tagger with Maxout networks (Goodfellow et al., 2013) or L_p-pooling (Zhang et al., 2014; Gulcehre et al., 2014) show the state-of-the-art results on two English benchmark sets.

Our empirical results suggest further opportunities to investigate continuous features not only for POS tagging but also for other NLP tasks. An obvious use case for continuous features is the N-best outputs with confidence values, which were predicted by the previous process in a NLP pipeline, such as the POS tags used for syntactic parsing. Another interesting extension is the use of on-the-fly features which reflect previous network states, although the neural networks in our current work do not refer to the prediction history. Recurrent neural networks (RNNs) may be a solution to represent the prediction history in a compact way, and Mesnil et al. (2013) reported that RNNs outperform conditional random fields (CRFs) on a sequential labeling task. They also show the superiority of bi-directional RNNs on their task, so the bi-directional RNNs may also be effective on the POS tagging, since bi-directional inferences were also used in earlier work (Tsuruoka and Tsujii, 2005).

It has a clear benefit over kernel methods in that the test-time computational cost of neural networks is independent from training data. However, although the test-time speed of original kernel methods is proportional to the number of training data, recent development of kernel approximation techniques achieve significant speed improvements (Le et al., 2013; Pham and Pagh, 2013). Since this work shows the non-linearity of continuous features should be exploited, those approximated kernel methods may also improve the tagging accuracies without sacrifice tagging speed.

Independent from our work, Ma et al. (2014) and Santos and Zadrozny (2014) also recently proposed neural network approaches for POS tagging. Ma et al. (2014)'s approach is similar to our approach, with a combination of a linear model and a neural network, although a direct comparison is not easy since their focus is the Web domain adaptation of POS tagging. Remarkably, they report n-gram embeddings are better than single word embeddings. Santos and Zadrozny (2014) proposed character-level embedding to capture the morphological and shape information for POS tagging. Although the reported accuracy (97.32%) on PTB data is lower than state of the art results, their approach is promising for morphologically rich languages. We may study the integration of these embeddings into our approach as future work.
