This paper tackles sentence-level factual simplification (SLFS). The objective of SLFS is twofold. First, SLFS will process the syntactically complicated sentences. Second, while preserving the content meaning, SLFS outputs a sequence of simple sentences. SLFS is an instance of the broader spectrum of text-to-text generation problems, which includes summarization, sentence compression, paraphrasing, and sentence fusion. Comparing to sentence compression, sentence simplification requires the conversion to be lossless in sense of semantics. It is also different from paraphrasing in that it generates multiple sentences instead of one sentence with different constructions.

There are certain specific characteristics that complicate a sentence, which include length, syntactic structure, syntactic and lexical ambiguity, and an abundance of complex words. As suggested by its objective, sentence simplification outputs "simple sentences". Intuitively, a simple sentence is easy to read and understand, and arguably easily processed by computers. A more fine-tuned definition on a simple sentence is suggested in Klebanov et al. (2004), and is termed Easy Access Sentences (EAS). EAS in English is defined as 1) EAS is a grammatical sentence; 2) EAS has one finite verb; 3) EAS does not make any claims that were not present, explicitly or implicitly; 4) An EAS should contain as many named entities as possible.

While the last two requirements are difficult to quantify, the first two provide a practical guideline for sentence simplification. In this paper, we treat the sentence simplification process as a process of statistical machine translation. Given the input of a syntactically complicated sentence, we translate it into a set of EAS that preserves as much information as possible from the original sentence. We develop the algorithm that can generate a set of EAS from the original sentence and a model to incorporate features that indicate the merit of the simplified candidates. The model is discriminatively trained on a data set of manually simplified sentences.

We briefly review related work in the area of text-to-text generation in Section 2. The proposed model for statistical sentence simplification is presented in Section 3. In Section 4 we introduce the decoding algorithm. Section 5 and 6 describe the discriminative training method we use and the feature functions. Experi-

ments and analysis are present in Section 7, followed by the conclusion in Section 8.

2 Related Work

Given the problematic nature of text-to-text generation that takes a sentence or a document as the input and optimizes the output toward a certain objective, we briefly review state-of-art approaches of text-to-text generation methods.

Early approaches in summarization focus on extraction methods which try to isolate and then summarize the most significant sentences or paragraphs of the text. However, this has been found to be insufficient because it usually generates incoherent summaries. Barzilay and McKeown (2005) proposed sentence fusion for multi-document summarization, which produces a sentence that conveys common information of multiple sentences based upon dependency tree structures and lexical similarity.

Sentence compression generates a summary of a single sentence with minimal information loss, which can also be treated as sentence-level summarization. This approach applies word deletion, in which non informative words will be removed from the original sentence. A variety of models were developed based on this perspective, ranging from generative models (Knight and Marcu, 2002; Turner and Charniak, 2005) to discriminative models (McDonald, 2006) and Integer Linear Programming (Clarke, 2008). Another line of research treats sentence compression as machine translation, in which tree-based translation models have been developed (Galley and McKeown, 2007; Cohn and Lapata, 2008; Zhu et al., 2010). Recently, Woodsend and Lapata (2011) proposed a framework to combine tree-based simplification with ILP.

In contrast to sentence compression, sentence simplification generates multiple sentences from one input sentence and tries to preserve the meaning of the original sentence. The major objective is to transform sentences in complicated structures to a set of easy-to-read sentences, which will be easier for human to comprehend, and hopefully easier for computers to deal with.

Numerous attempts have been made to tackle the sentence simplification problem. One line of research has explored simplification with linguistic rules. Jonnalagadda (2006) developed a rule-based system that take into account the discourse information. This method is applied on simplification of biomedical text (Jonnalagadda et al., 2009) and protein-protein information extraction (Jonnalagadda and Gonzalez, 2010). Chandrasekar and Srinivas (1997) automatically induced simplification rules based on dependency trees. Additionally, Klebanov et al. (2004) develop a set of rules that generate a set of EAS from syntactically complicated sentences. Heilman and Smith (2010) proposed an algorithm for extracting simplified declarative sentences from syntactically complex sentences.

The rule-based systems performs well on English. However, in order to develop a more generic framework for other languages, a statistical framework is preferable. In this work, we follow this direction to treat the whole process as a statistical machine translation task with an online large-margin learning framework. The method is generalizable to other languages given labeled data. To ensure the information is preserved, we build a table of EAS for each object, and use stack decoding to search for the optimal combination of EAS. A feature vector is assigned to each combination and we use an end-to-end discriminative training framework to tune the parameters given a set of training data. Our method is different from Klebanov et al. (2004) in the way that we applied statistical model to rank the generated sentences. And the difference between our method and Heilman and Smith (2010) is that we integrate linguistic rules into the decoding process as soft constraints in order to explore a much larger search space.

3 Statistical Sentence Simplification with Log-linear Models

Assume that we are given an English sentence e, which is to be simplified into a set $\mathcal{S}$ of k simple sentences $\{s_1, ..., s_i, ..., s_k\}$. Among all possible simplified sets, we will select the set with the highest probability $\hat{\mathcal{S}}(e) = \arg\max_{\forall \mathcal{S}} Pr(\mathcal{S}|e)$. As the true probability distribution of $Pr(\mathcal{S}|e)$ is unknown, we have to approximate $Pr(\mathcal{S}|e)$ by developing a log-linear model $p(\mathcal{S}|e)$. In contrast to noisy-channel models (Knight and Marcu, 2002; Turner and Charniak, 2005) we directly compute simplification probability by a conditional exponential model as follow:

$$p(\mathcal{S}|e) = \frac{exp[\sum_{m=1}^{M} w_m f_m(\mathcal{S}, e)]}{\sum_{\mathcal{S}'} exp[\sum_{m=1}^{M} w_m f_m(\mathcal{S}', e)]} \quad (1)$$

where $f_m(\mathcal{S}, e), m = 1, ..., M$ are feature functions on each sentence; there exists a model parameter w_m are feature weights to be learned.

In this framework, we need to solve decoding, learning, and modeling problems. The *decoding problem*, also known as the search problem, is denoted by the $\arg\max$ operation which finds the optimal $\mathcal{S}$ that maximize model probabilities. The *learning problem* amounts to obtaining suitable parameter values w_1^M subject to a loss function on training samples. Finally, the *modeling problem* amounts to developing suitable feature functions that capture the relevant properties of the sentence simplification task. Our sentence simplification model can be viewed as English-to-English log-linear translation models. The defining characteristic that makes the problem difficult is that we need to translate from one syntactically complicated sentence to k simple sentences, and k is not predetermined.

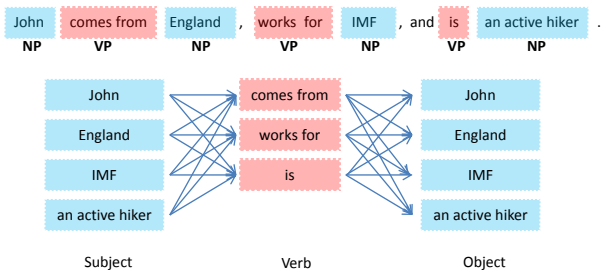

Figure 1: Constructing simple sentences

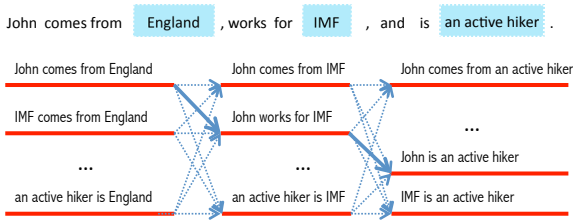

Figure 2: Left-right decoding by objects

4 Decoding

This section presents a solution to the *decoding problem*. The solution is based on a stack decoding algorithm that finds the best $\mathcal{S}$ given an English sentence e. Our decoding algorithm is inspired by the decoding algorithms in speech recognition and machine translation (Jelinek, 1998; Koehn et al., 2007). For example, with a sentence e "*John comes from England, works for IMF, and is an active hiker*", the stack decoding algorithm tries to find $\mathcal{S}$, which is a set of three sentences: "*John comes from England*", "*John works for IMF*" and "*John is an active hiker*". Note that $\mathcal{S}$ is a set of k simple sentences $\mathcal{S} = \{s_1, ..., s_i, ..., s_k\}$. We can assume the items s_i are drawn from a finite set $\mathbb{S}$ of grammatical sentences that can be derived from e. Therefore, the first step is to construct the set $\mathbb{S}$.

4.1 Constructing simple sentences

We define a simple English sentence as a sentence with SVO structure, which has one subject, one verb and one object. Our definition is similar to the definition of EAS, mentioned in section 1. However, we only focus on the SVO structure and other constraints are relaxed. We assume both subjects (S) and objects (O) are noun phrases (NP) in the parse tree. For a given English sentence e, we extract a list S_{NP} of NPs and a list S_V of verbs. S_{NP} has an additional empty NP in order to handle intransitive verbs. A straightforward way to construct simple sentences is to enumerate all possible sentences based on S_{NP} and S_V. That results in $|S_{NP}|^2|S_V|$ simple sentences.

Figure 1 illustrates the constructions for "*John comes from England, works for IMF, and is an active hiker*". The system extracts a noun phrase list S_{NP} {*John, England, IMF, an active hiker*} and a verb list S_V {*comes from, works for, is*}. Our model constructs simple sentences such as "*John comes from England*" , "*John comes from IMF*" and "*John comes from an active hiker*". The total number of simple sentences, $|\mathbb{S}|$, is 48.

4.2 Decoding algorithm

Given a list of simple sentences $\mathbb{S}$, the decoder's objective is to construct and find the best simplification candidate $\mathcal{S} \subset \mathbb{S}$. We call $\mathcal{S}$ a *hypothesis* in the context of the decoder. The rationale behind our left-right stack decoding algorithm is to construct a hypothesis that covers all noun phrases and verb phrases of the original sentence.

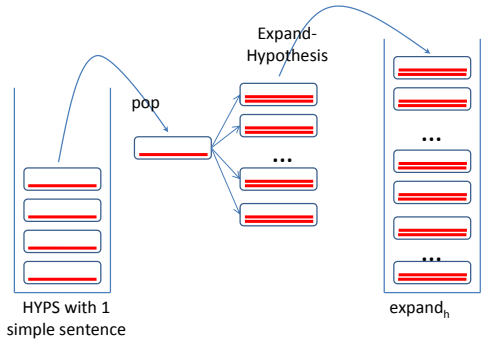
The decoding task is to find the optimal solution over all possible combinations of simple sentences, given the feature values and learned feature weights. Depending on the number of simple sentences per hypothesis, the search space grows exponentially. Since each simple sentence contains an object, we can group the candidate sentences by the object noun phrase. As a result, it is not necessary to evaluate all combinations; we can look at one object at a time from left to right. Figure 2 demonstrates the idea of decoding via objects. We have three objects "*England*", "*IMF*" and "*an active hiker*". The algorithm first finds potential simple sentences which have "*England*" as object. After finishing "England", the algorithm expands to "*IMF*" and "*an active hiker*". In this example the optimal path is the path with bold arrows.

Algorithm 1 : K-Best Stack Decoding

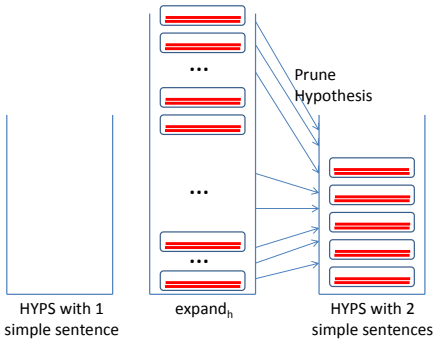
1: Initialize an empty hypothesis list *HypList*
2: Initialize *HYPS* is a stack of 1-simple-sentence hypotheses
3: **for** $i = 0$ to $|S_V|$ **do**
4: Initialize stack $expand_h$
5: **while** *HYPS* is not empty **do**
6: pop h from *HYPS*
7: $expand_h \leftarrow$ Expand-Hypothesis(h)
8: **end while**
9: $expand_h \leftarrow$ Prune-Hypothesis($expand_h$, *stack-size*)
10: *HYPS* $\leftarrow expand_h$
11: Store hypotheses of $expand_d$ into *HypList*
12: **end for**
13: *SortedHypList* $\leftarrow$ Sort-Hypothesis(*HypList*)
14: Return K-best hypotheses in *SortedHypList*

Algorithm 1 is a version of stack decoding for sentence simplification. The decoding process advances by extending a state that is equivalent to a stack of hypotheses. Line 1 and 2 initialize *HYPS* stack and *HypList*. A *HYPS* stack maintains a current search state, meanwhile *HypList* stores potential hypotheses after each state. *HYPS* is initialized with hypotheses containing one simple sentence. Line 3 starts a loop over states. The number of maximum states is equal to the

size of S_V plus one. Lines 4-8 represent the hypothesis expansion.



(a) Pop and Expand



(b) Hypothesis pruning

Figure 3: A visualization for stack decoding

Figure 3a illustrates the pop-expand process of *HYPS* stack with 1-simple-sentence hypotheses. The expansion in this situation expands to a 2-simple-sentence hypotheses-stack $expand_h$. The size of $expand_h$ will exponentially increase according to the size of S_V and S_{NP}. Therefore, we prefer to maintain $expand_h$ within a limit number (*stack-size*) of hypotheses. Line 9 helps the decoder to control the size of $expand_h$ by applying different pruning strategies: word coverage, model score or both. Figure 3b illustrates the pruning process on $expand_h$ with 2-simple-sentence hypotheses. Line 10 replaces the current state with a new state of the expanded hypotheses. Before moving to a new state, *HypList* is used to preserve potential hypotheses of the current state. Line 13 sorts hypotheses in *HypList* according to their model scores and a K-best list is returned in line 14.

5 Learning

Since defining a log-linear sentence simplification model and decoding algorithm has been completed, this section describes a discriminative learning algorithm for the *learning problem*. We learn optimized weight vector w by using the Margin Infused Relaxed Algorithm or MIRA (Crammer and Singer, 2003), which is an online learner closely related to both the support vector machine and perceptron learning framework. In general, weights are updated at each step time i according to:

$$w_{i+1} = \arg\min_{w_{i+1}} ||w_{i+1} - w_i|| \quad \text{s.t.} \quad score(\mathcal{S}, e) \geq score(\mathcal{S}', e) + L(\mathcal{S}, \mathcal{S}') \tag{2}$$

where $L(\mathcal{S}, \mathcal{S}')$ is a measure of the loss of using $\mathcal{S}'$ instead of the simplification reference $\mathcal{S}$; $score()$ is a cost function of e and $\mathcal{S}$ and in this case is the decoder score.

Algorithm 2 : MIRA training for Sentence Simplifier

training set $\tau = \{f_t, e_t\}_{t=1}^{T}$ has T original English sentences with the feature vector f_t of e_t.
ε is the simplification reference set.
m-oracle set $O = \{\}$.
The current weight vector w^i.

1: i=0
2: **for** $j = 1$ to Q **do**
3: **for** $t = 1$ to T **do**
4: $H \leftarrow$ get_K_Best($\mathcal{S}_t$; w^i)
5: $O \leftarrow$ get_m_Oracle(H ; ε_t)
6: $\gamma = \sum_{o=1}^{m} \sum_{h=1}^{K} \alpha(e_o, e_h; \varepsilon_t)(f_{e_o} - f_{e_h})$
7: $w^{i+1} = w^i + \gamma$
8: $i = i + 1$
9: **end for**
10: **end for**
11: Return $\frac{\sum_{i=1}^{Q*T} w^i}{Q*T}$

Algorithm 2 is a version of MIRA for training the weights of our sentence simplification model. On each iteration, MIRA considers a single instance from the training set $(\mathcal{S}_t, e_t)$ and updates the weights so that the score of the correct simplification ε_t is greater than the score of all other simplifications by a margin proportional to their loss. However, given a sentence there are an exponential amount of possible simplification candidates. Therefore, the optimizer has to deal with an exponentially large number of constraints. To tackle this, we only consider K-best hypotheses and choose m-oracle hypotheses to support the weight update decision. This idea is similar to the way MIRA has been used in dependency parsing and machine translation (McDonald et al., 2005; Liang et al., 2006; Watanabe et al., 2007).

On each update, MIRA attempts to keep the new weight vector as close as possible to the old weight vector. Subject to margin constraints keep the score of the correct output above the score of the guessed output by updating an amount given by the loss of the incorrect output. In line 6, α can be interpreted as an update step size; when α is a large number we want to update our weights aggressively, otherwise weights are

updated conservatively. α is computed as follow:

$$\alpha = \max(0, \delta)$$
$$\delta = \min\left\{C, \frac{L(e_o, e_h; \varepsilon_t) - [score(e_o) - score(e_h)]}{||\mathcal{S}_{e_o} - f_{e_h}||_2^2}\right\} \quad (3)$$

where C is a positive constant used to cap the maximum possible value of α; $score()$ is the decoder score; and $L(e_o, e_h; \varepsilon_t)$ is the loss function.

$L(e_o, e_h; \varepsilon_t)$ measures the difference between oracle e_o and hypothesis e_h according to the gold reference ε_t. L is crucial to guide the optimizer to learn optimized weights. We defined $L(e_o, e_h; \varepsilon_t)$ as follow

$$L(e_o, e_h; \varepsilon_t) = AveF_N(e_o, \varepsilon_t) - AveF_N(e_h, \varepsilon_t) \quad (4)$$

where $AveF_N(e_o, \varepsilon_t)$ and $AveF_N(e_h, \varepsilon_t)$ is the average n-gram (n=[2:N]) cooccurrence F-score of (e_o, ε_t) and (e_h, ε_t), respectively. In this case, we optimize the weights directly against the $AveF_N$ metric over the training data. $AveF_N$ can be substituted by other evaluation metrics such as the ROUGE family metric (Lin, 2004). Similar to the perceptron method, the actual weight vector during decoding is averaged across the number of iterations and training instances; and it is computed in line 11.

6 Modeling

We now turn to the *modeling problem*. Our fundamental question is: given the model in Equation 1 with M feature functions, what linguistic features can be leveraged to capture semantic information of the original sentence? We address the question in this section by describing features that cover different levels of linguistic structures. Our model incorporates 177 features based on information from the original English sentence e which contains chunks, syntactic and dependency parse trees (Ramshaw and Marcus, 1995; Marneffe et al., 2006).

6.1 Simple sentence level features

A simplification hypothesis s contains k simple sentences. Therefore, it is crucial that our model chooses reasonable simple sentences to form a hypothesis. For each simple sentence s_i we incorporated the following feature functions:

Word Count These features count the number word in subject (S), verb (V) and object (O), also counting the number of proper nouns in S and the number of proper nouns in O.

Distance between NPs and Verbs These features focus on the number of NPs and VPs in between S, V and O. This feature group includes the number of NPs between S and V, the number of NPs between V and O, the number of VPs between S and V, the number of VPs between V and O.

Dependency Structures It is possible that the decoder constructs semantically incorrect simple sentences, in which S, V, and O do not have any semantic connection. One way to possibly reduce this kind of mistake is analyze the dependency chain between S, V, and O on the original dependency tree of e. Our dependency structure features include the minimum and maximum distances of (S:O), (S:V), and (V:O).

Syntactic Structures Another source of information is the syntactic parse tree of e, which can be used to extract syntactic features. The sentence-like boundary feature considers the path from S to O along the syntactic parse tree to see whether it crosses the sentence-like boundary (e.g. relative clauses). For example in the original sentence "*John comes from England and works for IMF which stands for International Monetary Funds*", the simple sentence "*IMF stands for International Monetary Funds*" has sentence-like boundary feature is triggered since the path from "*IMF*" to "*International Monetary Funds*" on the syntactic tree of the original sentence contains an SBAR node.

Another feature is the PP attachment feature. This checks if the O contains a prepositional phrase attachment or not. Moreover, the single pronoun feature will check if S and O are single pronoun or not. The last feature is VO common ancestor, which looks at the syntactic tree to see whether or not V and O share the same VP tag as a common ancestor.

6.2 Interactive simple sentence features

A collection of grammatically sound simplified sentences does not necessarily make a good hypothesis Dropping words, unnecessary repetition, or even wrong order can make the hypothesis unreadable. Therefore, our model needs to be equipped with features that are capable to measure the interactiveness across simple sentences and are also able to represent s in the best possible manner. We incorporated the following features into our model:

Sentence Count This group of features consider the number of sentences in the hypothesis. It consists of an integral feature of sentence count $sci = |S|$, and a group of binary features $scb_k = \delta(|S|) = k$ where $k \in [1, 6]$ is the number of sentence.

NP and Verb Coverage The decoder's objective is to improve the chance of generating hypotheses that cover all NP and verbs of the original sentence e. These features count the number of NPs and verbs that have been covered by the hypothesis, by the 1st and 2nd simple sentences. Similarly, these features also count the number of missing NPs and verbs.

S and O cross sentences These features count how many times S of the 1st simple sentence is repeated as S of the 2nd simple sentence in a hypothesis. They also count the number of times O of the 1st sentence is the S of 2nd sentence.

Readability This group of features computes statistics related to readability. It includes Flesch, Gunning-Fog, SMOG, Flesch-Kincaid, automatic readability index, and average all scores (Flesch, 1948; Gunning, 1968; McLaughlin, 1969; Kincaid et al.,

1975). Also, we compute the edit-distance of hypothesis against the original sentence, and the average word per simple sentence.

Typed Dependency At simple sentence level we examine dependency chains of S, V and O, while at the hypothesis level we analyze the typed dependency between words. Our model has 46 typed dependencies which are represented by the 92 count features for the 1st and 2nd simple sentence.

7 Experiments and Analysis

7.1 Data

To enable the study of sentence simplification with our statistical models, we search for *parallel* corpora, in which the sources are original English sentences and the target is its simplification reference. For example, the source is "*Lu is married to Lian Hsiang , who is also a vajra master , and is referred as Grand Madam Lu* ". The simplification reference contains 3 simple sentences which are "*Lu is married to Lian Hsiang*"; "*Lian Hsiang is also a vajra master*"; "*Lu is referred as Grand Madam Lu*". To the best of our knowledge, there is no such publicly available corpora under these conditions[1].

Our first attempt is to collect data automatically from original English and Simple English Wikipedia, based on the suggestions of Napoles and Dredze (2010). However, we found that the collected corpus is unsuitable for our model. For example, consider the original sentence "*Hawking was the Lucasian Professor of Mathematics at the University of Cambridge for thirty years, taking up the post in 1979 and retiring on 1 October 2009*". The Simple Wikipedia reads "*Hawking was a professor of mathematics at the University of Cambridge (a position that Isaac Newton once had)*" and "*He retired on October 1st 2009*". The problems with this are that "*(a position that Isaac Newton once had)*" did not appear in the original text, and the pronoun "*He*" requires our model to perform anaphora resolution which is out of scope of this work.

We finally decided to collect a set of sentences for which we obtained one manual simplification per sentence. The corpus contains 854 sentences, among which 25% sentences are from the New York Times and 75% sentences are from Wikipedia. The average sentence length is 30.5 words. We reserved 100 sentences for the unseen test set and the rest is for the development set and training data. The annotators were given instructions that explained the task and defined sentence simplification with the aid of examples. They were encouraged not to introduce new words and try to simplify by restructuring the original sentence. They were asked to simplify while preserving all important information and ensuring the simplification sentences remained grammatically correct[2]. Some examples from our corpus are given below:

Original: "*His name literally means Peach Taro ; as Taro is a common Japanese boy 's name , it is often translated as Peach Boy* ."
Simplification: "*His name literally means Peach Taro*" ; "*Taro is a common Japanese boy 's name*" ; "*Taro is often translated as Peach Boy*"

Original: "*These rankings are likely to change thanks to one player , Nokia , which has seen its market share shrink in the United States* ."
Simplification: "*These rankings are likely to change thanks to one player , Nokia*" ; "*Nokia has seen its market share shrink in the United States*"

7.2 Evaluation methods

Evaluating sentence simplification is a difficult problem. One possible way to overcome this is to use readability tests. There have been readability tests such as Flesch, Gunning-Fog, SMOG, Flesch-Kincaid, etc. (Flesch, 1948; Gunning, 1968; McLaughlin, 1969; Kincaid et al., 1975). In this work, we will use Flesch-Kincaid grade level which can be interpret as the number of years of education generally required to understand a text.

Furthermore, automatic evaluation of summaries has also been explored recently. The work of Lin (2004) on the ROUGE family metric is perhaps the best known study of automatic summarization evaluation. Other methods have been proposed such as Pyramid (Nenkova et al., 2007). Recently, Aluisio et al. (2010) proposed readability assessment for sentence simplification.

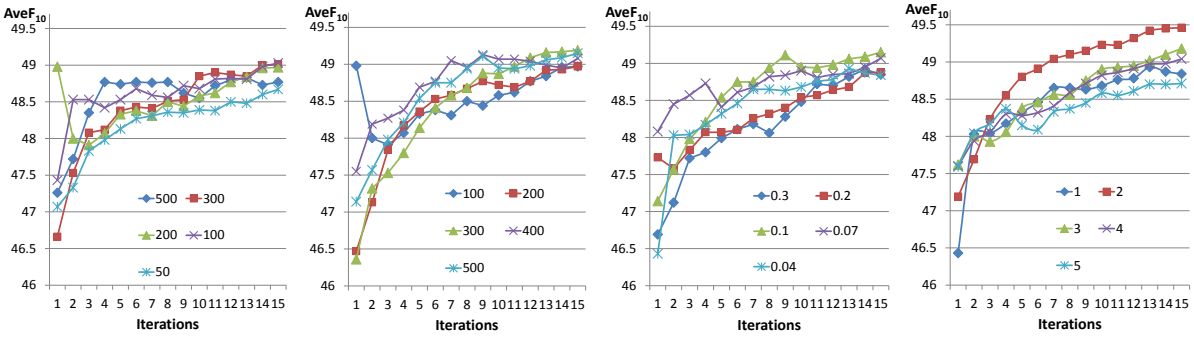
Our models are optimized toward $AveF_{10}$, which is the average F-score of n-gram concurrence between hypothesis and reference in which n is from 2 to 10. Besides $AveF_{10}$, we will report automatic evaluation scores on the unseen test set in Flesch-Kincaid grade level, ROUGE-2 and ROUGE-4. When we evaluate on a test set, a score will be reported as the average score per sentence.

7.3 Model behaviors

How well does our system learn from the labeled corpus? To answer this question we investigate the interactions of model and decoder hyper parameters over the training data. We performed controlled experiments on *stack-size*, K-best, C, and m-oracle parameters. For each parameter, all other model and decoder values are fixed, and the only change is with the parameter's value of interest. Figure 4 illustrates these experiments with parameters over the training data during 15 MIRA training iterations with $AveF_{10}$ metric. The weight vector w is initialized randomly.

[1] We are aware of data sets from (Cohn and Lapata, 2008; Zhu et al., 2010), however, they are more suitable in sentence compression task than in our task.

[2] Our corpus will be made publicly available for other researchers.



(a) *stack-size* (b) K-best (c) Constant C (d) m-oracle

Figure 4: Performance of the sentence simplifier on training data over 15 iterations when optimized toward $AveF_{10}$ metric and under various conditions.

In Figure 4a, we experimented with 5 different values from 100 to 500 hypotheses per stack. The expected outcome is when we use a larger *stack-size* the decoder may has more chance to find better hypotheses. However, a larger *stack-size* will obviously cost more memory and run time is slower. Therefore, we want to find a *stack-size* that compromises conditions. These experiments show that with a *stack-size* of 200, our model performed reasonably well in comparison with 300 and 500. A *stack-size* of 100 is no better than 200, while a *stack-size* of 50 is much worse than 200.

In Figure 4b, we experimented with 5 different values of K-best list with K from 100 to 500. We observed a K-best list of 300 hypotheses seems to perform well compare to other values. In terms of stability, the curve of 300-best list appears less fluctuation than other curves over 15 iterations.

C is the hyper-parameter which is used in Equation 3 for weight updating in MIRA. Figure 4c shows experiments with different constant C. If C is a large number, it means our model prefers an aggressive weight updating scheme, otherwise, our model updates weights conservatively. When C is 0.3 or 0.2 the performance is worse than 0.1 or 0.07 and 0.04.

The last controlled experiments are shown in Figure 4d, in which we test different values of m ranging from 1 to 5. These experiments show that using 2 oracle hypotheses consistently leads to better performances in comparison with other values.

7.4 Performance on the unseen test set

After exploring different model configurations we trained the final model with *stack-size* = 200; K-best = 300; C = 0.04; and m-oracle = 2. $AveF_{10}$ score of the final system on the training set is 50.69 which is about one $AveF_{10}$ point better than any system in Figure 4. We use the final system to evaluate on the unseen test set. Also, we compare our system with the rule-based system (henceforth H&S) proposed by Heilman and Smith (2010).[3,4]

Original	Reference	H&S	Our system
9.6	8.2	8.3	7.9

Table 1: Flesch-Kincaid grade level of original, reference, H&S, and our proposed simplification on the unseen test set.

System	$AveF_{10}$	ROUGE-2	ROUGE-4
H&S	51.0	82.2	72.3
Our system	55.5	82.4	72.9

Table 2: Results on the unseen test set with $AveF_{10}$, ROUGE-2 and ROUGE-4 scores. Our system outperforms the rule-based system proposed by Heilman and Smith (2010).

We first compare our system with H&S in the Flesch-Kincaid grade level, which indicates comprehension difficulty when reading an English text. The higher the number the more difficult the text. Table 1 shows the original text requires a reader of grade level 9 or 10. Both H&S and us provided simplification candidates, which are easier to read compared to the original text. Our model generated simpler hypotheses than the reference, while H&S outputs were slightly more difficult to read than the reference.

Next, we compare our system with H&S in ngram-based metrics such as $AveF_{10}$, ROUGE-2 and ROUGE-4 as shown in Table 2. Our results are better than H&S by 0.2 and 0.6 point in ROUGE-2 and ROUGE-4, respectively. More interestingly, our system outperformed H&S by 4.5 points in $AveF_{10}$,

[3] We thank Michael Heilman for providing us his code.

[4] We could not reach the authors of (Zhu et al., 2010) in order to obtain outputs. Kristian Woodsend kindly provided us **partial outputs** of (Woodsend and Lapata, 2011), therefore we did not include their outputs in this section.

R	An elderly Georgian woman was scavenging for copper to sell as scrap . she accidentally sliced through an underground cable . she cut off Internet services to all of neighbouring Armenia . it emerged on Wednesday .

Table 3: We show the original sentence (O), our simplification (S), and simplification reference (R). Positive examples are cases when our simplifications closely match with the reference. Meanwhile, negative examples show cases when our model can not produce good simplifications.

which is a metric considering both precision and recall up to 10-gram. Over 100 sentences of the unseen test set, H&S outperforms us in 43 sentences, but is worse than our system in 51 sentences.

Table 3 shows examples of our system on the unseen test set. We present examples in cases where the proposed model works well and does not work well.

7.5 Discussions

This work shares the same line of research with (Klebanov et al., 2004; Heilman and Smith, 2010) in which we all focus on sentence-level factual simplification. However, a major focus of our work is on log-linear models which offer a new perspective for sentence simplification on decoding, training, and modeling problems. To contrast, consider rule-based systems (Klebanov et al., 2004; Daelemans et al., 2004; Siddharthan, 2006; Heilman and Smith, 2010), in which sentence simplification processes are driven by hand-written linguistic rules. The linguistic rules represent prior information about how each word and phrase can be restructured. In our model, each linguistic rule is encoded as a feature function and we allow the model to learn the optimized feature weights based on the nature of training data.

A potential issue is the proposed model might be susceptible to the sparseness issue. We alleviated this issue by using structure level and count feature functions which are lexically independent.

There are some limitations in this work. First, the proposed model does not introduce new words which may lead to generate grammatically incorrect simple sentences. Second, we focus on structure simplification and not on lexical simplification. Finally, the proposed model does not deal with anaphora resolution, which means our model can generate repeatedly noun phrases repeatedly in multiple simple sentences.

8 Conclusions

In this paper we proposed a novel method for sentence simplification based on log-linear models. Our major contributions are the stack decoding algorithm, the discriminative training algorithm, and the 177 feature functions within the model. We have presented insight the analyses of our model in controlled settings to show the impact of different model hyper parameters. We demonstrated that the proposed model outperforms a state-of-the-art rule-based system on ROUGE-2, ROUGE-4, and $AveF_{10}$ by 0.2, 0.6, and 4.5 points, respectively.

Another way to improve our model is feature engi-

neering, which can be applied in future work. To address the data sparsity issue, we plan to use crowdsourcing such as Amazon Mechanical Turk to collect more training data. We plan to incorporate an n-gram LM to improve the grammaticality of hypotheses.

Acknowledgments

We would like to thank Colin Cherry for fruitful discussions and anonymous reviewers for helpful comments. We also thank Julianne Mentzer for proofreading the final version of the paper.

Abstract

Heavy research has been done in recent years on tasks of traditional summarization. However, social context, which is critical in building high-quality social summarizer for web documents, is usually neglected. To address this issue, we propose a novel summarization approach based on social context. In this approach, social summarization is implemented by first employing the tripartite clustering algorithm to simultaneously discover document context and user context for a specified document. Then sentence relationships intra and inter documents plus intended user communities are taken into account to evaluate the significance of each sentence in different context views. Finally, a few sentences with highest overall scores are selected to form the summary. Experimental results demonstrate the effectiveness of the proposed approach and show the superior performance over several baselines.

1 Introduction

Now, an increasing number of Web 2.0 applications (e.g. Del.icio.us, CiteULike, LinkedIn) are allowing users to play more active roles such as annotating online documents with free-form tags, submitting opinions on the items they are interested in, or participating in social networks, etc.

Despite their focus on different resources, all of them have the common purpose of helping users organize, retrieve and share knowledge. The rich information offered by these systems provides additional clues for collaboratively summarizing online documents in a social context. However, most existing methods generate a summary based only on the information within each document or its neighboring documents, while the social context is usually ignored. This is an important issue that has not been extensively investigated in the summarization's literature.

In this study, different user's social tagging history and their tagged documents are employed and a novel social summarization approach is proposed by considering both document context and user context in the sentence evaluation process. The intuition is that if an appropriate social context is available, then integration of social context knowledge into the existing sentence evaluation process will improve the performance of traditional summarization methods.

The proposed approach takes into account both the mutual influences between documents and the impact from different user communities, which consists of the following phases.

Firstly, the tripartite clustering algorithm is adopted to discover document context and user context by clustering documents, users and tags simultaneously, which is based on the inherent structure of the three kinds of objects. In the clustering result, each document cluster is regarded as a context for each document in the cluster and all the user clusters are regarded as user communities with diverse information preferences.

Secondly, the context-sensitive ranking algorithm is applied for evaluating the significance of each sentence in different context views respectively.

Thirdly, a few significant sentences with highest overall scores are extracted from the specified document to generate the summary.

The main contribution of this paper is summarized as follows:

1) We examine an important factor called social context for document summarization.

2) We propose a novel social summarization approach by incorporating both document context and user context in the sentence evaluation process.

3) We conduct experiments to validate the effectiveness of the proposed approach on the

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 483–490,
Chiang Mai, Thailand, November 8 – 13, 2011.

dataset sampled from del.icio.us and investigate how the parameters influence the summarization performance.

The paper is organized as follows: Section 2 introduces related work. Section 3 describes the details of the proposed social summarization approach. Section 4 presents experimental results and analysis. Lastly we conclude our paper in Section 5.

2 Related Work

Document summarization aims to automatically create a concise representation of a given document that delivers the main content of it. To date, a variety of methods have been developed, which can be roughly divided into two types: extractive approach and abstractive approach.

The former directly assigns each sentence a significance score and extracts a few sentences of highest scores from the original document, which depends on the combination of implicit or explicit statistical or linguistic features, while the latter usually makes use of advanced natural language understanding or generation technique to fuse, compress or reformulate information. In this paper, we focus on the extractive approach.

Much work has been done on extractive summarization including classification-based methods (Conroy and O'leary, 2001), regression-based methods (You et al., 2011), NMF-based methods (Lee et al., 2009), MMR-based methods (Carbonell and Goldstein, 1998), clustering-based methods (Nomoto and Matsumoto, 2001), etc. Recently, graph-based ranking methods are becoming more and more popular. LexRank (Erkan and Radev, 2004), TextRank (Mihalcea and Tarau, 2004), mutual reinforcement based ranking (Zha, 2002), and manifold ranking (Wan et al., 2007) are such methods using algorithms similar to PageRank and HITS to compute sentence's significance.

When summarizing a specified document, most methods employ only the information contained in the document while ignore its context. One exception is the collaborative approach proposed by Wan and Yang (2007), which improves news document summarization by use of the content from neighboring documents. This motivates us to further consider how social context knowledge might be incorporated in the sentence evaluation process to improve the performance of traditional summarization systems.

To date, much work on summarization tends to focus on a specific type of document, such as news articles (McKeown and Radev, 1995), academic papers (Qazvinian and Radev, 2010) or medical records (Afantenos et al., 2005). With the rapid growth of documents over the Internet, a large number of web documents need to be summarized. However, the content contained in a web document is observed to be sparser and noisier, and it is difficult for the traditional summarization methods that only focus on the local content of a document to capture the true meaning of web documents in a richer context environment. So it is more reasonable to summarize the web document by taking advantage of its social context (i.e. document context and user context).

Relevant work on web document summarization includes harnessing the search engine's click-through data to guide summarization (Sun et al., 2005), producing summaries by using query-result selection pairs according to their relative importance (Boydell and Smyth, 2007), etc.

The work described in this paper is concerned with producing an extractive summary for a Web document. Different from existing summarization methods that use document content or document context alone, the novelty of our approach stems from the integration of an important factor (i.e. social context) for sentence evaluation. We focus on how the richer information from social context can be utilized to improve the summarization performance, which is an interesting issue that needs to be carefully investigated.

3 The Proposed Social Summarization Approach

3.1 Overview

The main idea of the proposed summarization approach is to incorporate an important factor into sentence evaluation process by discovering social context knowledge from online bookmarking services and utilizing the discovered knowledge to collaboratively evaluate each sentence’s significance.

Given a document to be summarized, the approach first clusters three types of objects (i.e. documents, users, and tags) simultaneously in a unified framework so that social context can be identified automatically. The identified document context is a cluster of documents, which are topically close to the specified document and are tagged by like-minded users. The identified user contexts include multiple user clusters with each

representing a unique user community with different information preference. The discovered social context knowledge is deemed beneficial to evaluating sentences' significance from diverse views since they can provide richer external knowledge and more complementary clues to help rank sentences comprehensively.

Then the context-sensitive ranking algorithm is adopted to score all the sentences in the document context that the specified document belongs to by differentiating inter-sentence relationships in document context view and considering the impact of different user communities in user context view.

Finally, each sentence's overall significance is computed by fusing their scores from different views and a few sentences with highest overall scores are extracted from the specified document to generate the final summary.

3.2 Social Context Discovery

Social context discovery aims to find not only a set of neighboring documents similar to the specified document but also a group of intended user communities with different information preferences. Figure 1 shows an example of the social context for document d.

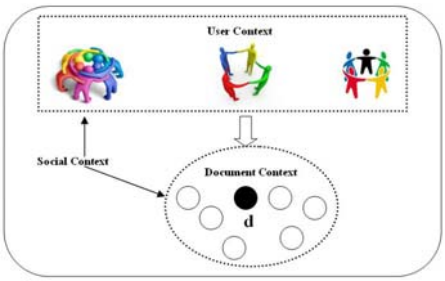

Figure 1. An Example of the Social Context for Document d.

A major characteristic of the social context knowledge acquired from bookmarking services is the tripartite relationships formed through users' social tagging behaviors, which can be illustrated through the example shown in Figure 2.

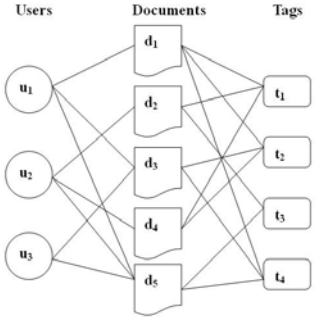

Figure 2. An Example of Tripartite Relationships among Users, Documents, and Tags.

In Figure 2, whenever a user annotates a document with a tag, a ternary relationship is built among the three kinds of objects. The tripartite nature among documents, users, and tags provides valuable information for discovering the topic-related documents, the intended user communities, and the semantics of tags. Besides, in the del.icio.us bookmarking service, it can be observed that topic-related documents are usually annotated with semantically-related tags by like-minded users with common interests, so in this study, the tripartite clustering algorithm (Lu et al., 2009) is employed to cluster documents, users, and tags simultaneously based on the inherent structure of the three kinds of objects to automatically discover the social context for a specific document.

The tripartite relationships among documents, users, and tags can be formally represented by a graph denoted as: $G=(D, U, T, E_{UD}, E_{UT}, E_{DT})$, where D, U, and T are the sets of documents, users and tags respectively, and E_{UD}, E_{UT}, and E_{DT} denote the relationships between user-document, user-tag, and document-tag respectively.

In the tripartite graph, each kind of object can be represented by a combined vector. For example, a document is naturally related to the users who have tagged it and the tags which have been used to tag it, so a document d_i can be represented by a combined vector D_i consisting of two components with one denoting user link vector and the other denoting tag link vector. i.e. $D_i=(D_i^{(U)}, D_i^{(T)})$, $D_i^{(U)}= (y_{ih}^{(U)} \mid h=1,2,...,|U|)$, $D_i^{(T)} =(y_{ij}^{(T)} \mid j=1,2,...,|T|)$, where $y_{ih}^{(U)}$ denotes the times that d_i is annotated by user u_h, $|U|$ denotes the total number of users, $y_{ij}^{(T)}$ denotes the times that d_i has been annotated with tag t_j, and $|T|$ denotes the total number of tags. Likewise, user and tag can be represented in the similar way.

Assuming $C_m(D)$ represent a document cluster, we can calculate the value of the centroid vector at user dimension by formula (1).

$$Centroid_{mu}^{(U)} = \frac{\sum_{d_i \in C_m^{(D)}, u_h \in C_l^{(U)}} y_{ih}^{(U)}}{|C_m^{(D)}| * |C_l^{(U)}|}, (u_u \in C_l^{(U)}) \quad (1)$$

where $C_l^{(U)}$ is a user cluster which user u_u belongs to, u_h is any user in $C_l^{(U)}$, and d_i is any document in $C_m^{(D)}$. It can be seen that the value of a document cluster's centroid at user dimension does not only depends on the links from u_u to all the cluster's documents, but also relies on the links from other users belonging to the same cluster as u_u to the cluster's documents. Likewise, the value of the centroid vector at tag dimension can be

calculated in the similar way and the similarity value between a document d_i and the centroid of a document cluster $C_m^{(D)}$ can be calculated as follows,

$$Similarity(d_i, Centroid_m^{(D)}) = \alpha * Simlarity(D_i^{(U)}, Centorid_m^{(U)}) + (1-\alpha) * Simlarity(D_i^{(T)}, Centroid_m^{(T)}) \quad (2)$$

where $Simlarity(D_i^{(U)}, Centorid_m^{(U)})$ denotes the similarity between d_i and the centroid of $C_m^{(D)}$ based on the user link vector, $Simlarity(D_i^{(T)}, Centroid_m^{(T)})$ denotes the similarity of them based on the tag link vector, and α is a weighting adjusting parameter usually set to 0.5.

In this study, social context can be discovered by the tripartite clustering algorithm described in Table 1 (Lu et al., 2009).

Algorithm: Tripartite clustering based social context discovery
Input: The tripartite graph G=(D, U, T, E_{UD}, E_{UT}, E_{DT}) encoding the relationships among documents, users, and tags, the predefined number of document clusters N_{dc}, the predefined number of user clusters N_{uc}, and the predefined number of tag clusters N_{tc}. **Output:** The social context, which includes not only the document context but also the user context. 1: Assign each document (user or tag) to a random document cluster (user cluster or tag cluster); 2: **Repeat:** 3: **For** each type of objects **do** 4: Compute the centroid of each cluster based on the link features of its cluster members and the cluster structures of other two types of objects from last iteration; 5: **For** each document (user or tag) **do** 6: Compute the similarity between the object and the centroid of each document (user or tag) cluster; 7: Reassign the current object to the closest cluster based on the similarity. 8: **End For** 9: **End For** 10: **Until** the assignments no longer change.

Table 1. Tripartite Clustering Based Social Context Discovery

After that, we can discover all the document clusters. Each document cluster is regarded as a document context for any document in the cluster. At the same time, all user communities with varied information preferences can be also found. Since the 'true' numbers of document clusters, user cluster, and tag clusters are hard to predict, in this study we simply set them to the square root of the total number of documents, users, and tags respectively.

The potential benefit of adopting the tripartite clustering algorithm for social context discovery is that it can incorporate the social tagging information in a unified framework and all social context information can be simultaneously obtained by making use of the interactions among the cluster structures of different types of objects.

3.3 Social Context Based Summarization

In this study, for summarizing a single document, all the documents in its document context are firstly segmented into sentences and each sentence is evaluated in document context view and user context view respectively. Then the two scores are fused to evaluate the overall significance of a sentence. Lastly, a few sentences with highest overall scores are extracted from the specified document to generate the summary.

Sentence Scoring in Document Context View

The document-context-sensitive ranking algorithm is applied on the document context of the specified document for scoring sentences collaboratively (Wan, 2008).

In document context view, inter-sentence relationships are described by sentence affinity graph G_s with each vertex s_i representing a sentence and each edge e_{ij} representing the relationship between sentence s_i and s_j ($i \neq j$) whose weight is the similarity between the pair of sentences. G_s can be encoded by either the matrix M_{intra} or the matrix M_{inter} with each entry corresponding to the edge's weight of G_s's sub-graph G_{intra} and G_{inter}, which describe either the within-document relationships or the cross-document relationships among sentences. Then M_{intra} and M_{inter} are normalized to $\widetilde{M}_{intra}$ and $\widetilde{M}_{inter}$ by making the sum of each row equal to 1.

The document-context-sensitive score of sentence s_i is denoted as $DCScore(s_i)$ that can be computed as follows:

$$DCScore(s_i) = \lambda * DCScore_{intra}(s_i) + (1-\lambda) * DCScore_{inter}(s_i) \quad (3)$$

$$DCScore_{intra}(s_i) = \delta * \sum_{all\ j \neq i} DCScore_{intra}(s_j) * (\widetilde{M}_{intra})_{j,i} + \frac{(1-\delta)}{n} \quad (4)$$

$$DCScore_{inter}(s_i) = \delta * \sum_{all\ j \neq i} DCScore_{inter}(s_j) * (\widetilde{M}_{inter})_{j,i} + \frac{(1-\delta)}{n} \quad (5)$$

where n is the number of sentences in the document context, s_j is any other sentence linked with s_i, $DCScore_{intra}$ and $DCScore_{inter}$ are the sentence scores by considering either the within-document relationship or the cross-document relationship. δ is a damping factor usually set to 0.85 as in PageRank and λ is a weight adjusting parameter specifying the relative contribution to the score from the within-document relationship and the cross-document relationship. Since the previous research (Wan, 2008) has demonstrated

that the use of cross-document relationships between sentences can much improve the performance of summarization, in this study λ is set to 0.4 to enhance the contribution from cross-document relationship.

Sentence Scoring in User Context View

Since the discovered user contexts represent different user communities, when evaluating the sentence's significance within the specified document, we should take into account the recommendation from diverse user communities. However, how to evaluate the recommendation strength becomes a difficult problem. In this paper, we propose a relevance measurement to evaluate it by computing the affinity between the document context of the specified document and the profile of each user community. The reason of using the document context instead of the document is that the expanded document context includes richer information than the single document, which can be used to match the community profile better.

In delicious, the documents annotated by a user can reflect the user's information preference to certain extent. Therefore, for a user community and two documents x and y, if the number of users in the community who annotate document x is greater than that of users who annotate document y, we may assume that the community is more interested in the content of document x than that of document y. Based on this assumption, we model the user community profile by choosing a certain number of representative documents that have been annotated by the most of users in this community. In this study, twenty percent of documents have been selected.

For scoring sentence in the user context view, each user context UC_k is firstly transformed into a pseudo-query q_k that is represented by the centroid vector of all the sentences in the user community profile. The affinity graph G_{uk} is constructed in which the vertexes include all the sentences in the specified document's context and the k^{th} pseudo-query associated with the k^{th} user context, and the edges encode both the relationships among the sentences and the relationship between the k^{th} pseudo-query and the sentences. Here q_k can be processed in the same way as other sentences.

The user-context-sensitive score $UCScore_k(s_i)$ for sentence s_i in the k^{th} user context view can be deduced from those of other sentences linked with it and the k^{th} user context, which can be computed by the query-sensitive ranking algorithm as follows:

$$\mathrm{UCScore_k}(\mathrm{s_i}) = \beta * \sum_{all\ j \neq i} \mathrm{UCScore_k}(\mathrm{s_j}) * (\widetilde{M}_{uk})_{j,i} + (1-\beta) * Rel(\mathrm{s_i}, q_k) \quad (6)$$

where $\widetilde{M}_{uk}$ is the normalized affinity matrix of G_{uk}, $Rel(\mathrm{s_i}, q_k)$ denotes the Cosine relevance of the sentence s_i to the pseudo-query q_k, and β is a damping factor usually set to 0.85. The user-context-sensitive score for sentence s_i in the rest of user contexts can be deduced in the same way.

The final score of sentence s_i assigned in the user context view can be denoted as $UCScore(s_i)$, which is calculated by the combination of all scores from different user contexts.

$$\mathrm{UCScore}(\mathrm{s_i}) = \frac{\sum_{k=1}^{N_{uc}} \mathrm{RS}(\mathrm{UC_k}, \mathrm{DC}_{s_i}) * \mathrm{UCScore_k}(\mathrm{s_i})}{\sum_{k=1}^{N_{uc}} \mathrm{RS}(\mathrm{UC_k}, \mathrm{DC}_{s_i})} \quad (7)$$

where N_{uc} is the number of user contexts, $\mathrm{RS}(\mathrm{UC_k}, \mathrm{DC}_{s_i})$ denotes the recommendation strength of the user context UC_k to the document context DC_{s_i} of sentence s_i.

Summary Generation

In order to evaluate the overall score of each sentence s_i in the social context view, we fuse both document-context-sensitive score $DCScore(s_i)$ and user-context-sensitive score $\mathrm{UCScore}(\mathrm{s_i})$ in a unified way as follows:

$$\mathrm{Score}(\mathrm{s_i}) = \eta * \mathrm{UCScore}(\mathrm{s_i}) + (1-\eta) * DCScore(s_i) \quad (8)$$

where $\eta \in [0,1]$ is a weight adjusting parameter, specifying the relative contribution to the overall scores from user context view and document context view. If η=1, only the user context's impact is considered and the score of sentence s_i equals to $\mathrm{UCScore}(\mathrm{s_i})$; if η=0, only the document context's impact is considered and the score of sentence s_i equals to $DCScore(s_i)$; and if η=0.5, the two context view's impacts are considered equally.

Finally, a few sentences with highest overall scores and least redundancy are chosen into the summary according to the summary length limit.

4 Experiments

4.1 Experimental Setup

Because there is no existing benchmark dataset for social summarization, we construct a real-world dataset to evaluate the proposed method by downloading 200 bookmarked CNN news web documents from del.icio.us website on diverse topics (e.g. financial crisis, accidents and natural disasters, health, sports, etc). The "Story

Highlights" texts are extracted from each CNN news document to form the gold-standard (model) summary, which contains about 50-100 words.

The detailed statistical result of the dataset is shown in Table 2.

Summary of the Dataset	
Number of documents	200
Number of users	1194
Number of tags	2186

Table 2. The Statistical Result of the Dataset

Both intrinsic and extrinsic methods are proposed for summarization evaluation. In this paper, we employ the intrinsic method to evaluate the proposed summarization approach and all the baselines.

To date, various intrinsic evaluation methods such as ROUGE (Lin and Eduard, 2003) and Pyramid (Nenkova and Passonneau, 2004) have been proposed. In the study, The ROUGE-1.5.5 toolkit is adopted because it was officially adopted by DUC (Now TAC) for automatic summarization evaluation and has been shown to correlate with human evaluations well. ROUGE metrics measure a summary's content quality by counting overlapping units such as n-gram, word sequences, and word pairs between the automatically generated summary and the gold-standard summaries. Formally, ROUGE-N is an n-gram recall based measurement between a candidate summary and a set of reference summaries, which is computed as follows (Lin and Eduard, 2003):

$$ROUGE-N=\frac{\sum_{S\in\{reference\ summaries\}}\sum_{gram_n\in S}Count_{match}(gram_n)}{\sum_{S\in\{reference\ summaries\}}\sum_{gram_n\in S}Count(gram_n)} \quad (9)$$

where n stands for the length of the n-gram, $gram_n$, and $Count_{match}(gram_n)$ is the maximum number of n-grams co-occurring in a candidate summary and a set of reference summaries.

A few recall-oriented ROUGE metrics have been employed such as ROUGE-1 (unigram based metric), ROUGE-2 (bigram based metric), and ROUGE-SU4 (skip bigram and unigram based metric with maximum skip distance 4), etc. We report the metric scores of ROUGE-1, ROUGE-2 and ROUGE-SU4 at the confidence level of 95% in the following experiments.

4.2 Experimental Results

As a preprocessing step, in the following experiments, all the documents were segmented into sentences, stop-words were removed and the remaining words were stemmed by the Porter Stemmer. All the sentences were represented as the term vectors according to TF*ISF scheme. The process of redundancy removing and the setup of the corresponding parameters of the following baselines are also the same as that of the proposed approach.

For comparison, given a document and its document context discovered by the tripartite clustering algorithm, we implement the following methods as the baselines and each method generates a summary for each document in accordance to the length of the corresponding model summary. Since the good performance of the tripartite clustering algorithm adopted in this paper has been validated in the previous study (Lu et al., 2009), which shows that it can be applied to cluster different types of objects simultaneously and significantly outperforms the content-based K-means algorithm. In this study, we don't compare it again with the K-means algorithm in the discovery of document context.

Baseline 1 (RANDSum): RANDSum selects sentences randomly from the specified document to generate a summary.

Baseline 2 (DCISum): DCISum is a document-context-independent method which computes the significance score of a sentence based only on the within-document relationships while ignoring the document context. In this study, it is realized according to formula (4).

Baseline 3 (DCDSum): DCDSum is a document-context-dependent method which computes the significance score of a sentence based on both the cross-document relationships and the within-document relationships. In this study, it is realized according to formula (3).

Note that all the above baseline methods depend either on the internal information of the specified document or the external information of the document context, yet the user context information is entirely neglected. The proposed social context based approach **(*abbr.* SCSum)** considers not only document context but also user context in a unified framework.

We show the summarization evaluation results of different approaches in Tables 3.

Method	ROUGE-1	ROUGE-2	ROUGE-SU4
RANDSum	0.25532	0.02174	0.05634
DCISum	0.33961	0.05576	0.09039
DCDSum	0.34273	0.05522	0.09113
SCSum	**0.35880**	**0.07130**	**0.11417**

Table 3. The Summarization Evaluation Results of Different Approaches

In Table 3, the best result of our approach is achieved when the weight adjusting parameter η specifying the relative contribution from user context and document context is set to 0.4.

Seen from Table 3, our proposed approach SCSum using the discovered social context knowledge achieves the best performance on all ROUGE metrics comparable to that of the baseline approaches (i.e. RANDSum, DCISum, and DCDSum), which demonstrates that both document context and user context are very important for improving the performance of document summarization if richer context information is available for a specific document.

We also observe that the DCDSum that uses the document context information performs better than the DCISum, and RANDSum that use only the local information within the specified document. It shows the expanded document context from like-minded users can benefit the sentence's evaluation process by proving more external document information related to the specified document.

To discover how the relative contribution from user context and document context influences the summarization performance, we set the weight adjusting parameter η from 0.2 to 0.9, and Figure 3 shows the ROUGE-1 evaluation results of the proposed approach with different η value.

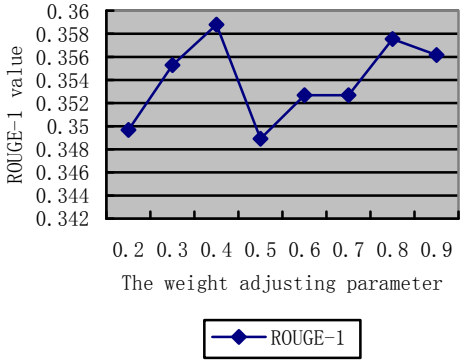

Figure 3. The ROUGE-1 evaluation results of the proposed approach with different η value

Seen from Figure 3, it is clear that the summarization performance on ROUGE-1 first increases with η, when η is larger than 0.4, the performance tends to decrease. It shows that considering appropriate user context knowledge is critical for improving summarization performance.

The reason underlying the above observations that the proposed social context summarization approach can improve the performance of document summarization is that there are many different documents on the Internet to discuss the same topic from various perspectives, and the discovered appropriate social context would guarantee that the influences through the different documents and different user communities are reliable.

5 Conclusion and Future Work

This paper examines an important factor called social context and proposes a novel social summarization approach for incorporating both document context and user context for collaborative generation of summaries. Experimental results on the dataset sampled from del.icio.us demonstrate the effectiveness of our method and show the superior performance over several baselines.

In future work, it would be interesting to investigate the performance of the approach on larger data sets with richer social annotation information. Besides, we will explore the optimization-based estimation strategy to automatically determine the parameters of our approach in an adaptive way. We also plan to make use of more implicit or explicit user feedback information, meta-content information, and hyperlink information to acquire richer social context knowledge to improve the summarization performance.

Abstract

Multi-document summarization aims to produce a concise summary that contains salient information from a set of source documents. Since documents often cover a number of topical themes with each theme represented by a cluster of highly related sentences, sentence clustering plays a pivotal role in theme-based summarization. Moreover, noting that real-world datasets always contain noises which inevitably degrade the clustering performance, we incorporate noise detection with spectral clustering to generate ordinary sentence clusters and one noise sentence cluster. We are also interested in making the theme-based summaries biased towards a user's query. The effectiveness of the proposed approaches is demonstrated by both the cluster quality analysis and the summarization evaluation conducted on the DUC generic and query-oriented summarization datasets.

1 Introduction

The exponential growth in the volume of documents available on the Internet brings the problem of finding out whether a single document can meet a user's complex information need. In order to solve this problem, multi-document summarization, which reduces the size of documents while preserves their important semantic content is highly demanded. Most of the summarization work done till date follow the sentence extraction framework, which ranks sentences according to various pre-specified criteria and selects the most salient sentences from the original documents to form summaries.

In addition to sentence salience, the other fundamental issues that must be concerned in summarization are information redundancy and information diversity (Radev et al., 2002). When the given documents are all supposed to be about the same topic, they are very likely to repeat some important information in different documents or in different places of the same document. Therefore, effectively recognizing the sentences with the same or very similar content is necessary for reducing redundancy and covering more diverse informative content in a summary. This is normally achieved by clustering highly related sentences into topical themes. Summaries can then be produced, e.g., by extracting the representative sentence(s) from each theme cluster. Thus, good sentence clusters are the guarantee of good summaries in theme-based summarization.

It is also important to stress that the noise sentences are clearly observed in the DUC datasets, i.e., the benchmark datasets for use by the summarization community (Wei et al., 2009). Take the DUC2005 d301i document set, which talks about 'International Organized Crime', as an example. The sentence like 'This well-educated, well-spoken, cosmopolitan businessman is laughing all the way.' absolutely goes too far off the point, and it is considered as a noise sentence in the context of our study. The existence of noises will inevitably degrade the clustering performance. Noise detection for summarization which has been ignored previously is emphasized in this work. Our strategy is to detect the noises by mapping the textual objects (either sentences or words) to a new representation space where the features are more discriminative. Then all the identified noises are thrown into a single cluster called noise cluster and the summaries are generated from the other regular clusters alone.

Topical themes and noises are the inherent characteristics of documents. Without doubt, effective recognition of them provides a good basis for theme-based summarization. However, summaries generated in such a way are not guaran-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 491–499,
Chiang Mai, Thailand, November 8 – 13, 2011.

teed to cater to the user's information need and therefore may not always be in line with his/her expectations. For example, if a user asks to "identify and describe types of organized crime that crosses borders or involves more than one country", the cases of international drug trafficking and international smuggling are definitely more relevant than the origin and the means of organized crime or the government's precautions, even though all of them are extractable main themes in the documents. That is why query-oriented summarization which requires concise information corresponding to a specific query has drawn much attention in recent years. Its challenge to theme-based summarization is how to better make use of the query information to guide the necessary clustering and ranking processes. We explore three approaches to incorporate the query information in theme-based summarization, including query-driven cluster ranking, query-embedding similarity measure and semi-supervised clustering.

The main contributions of this paper are threefold. (1) Noisy detection is incorporated into clustering for theme-based generic summarization. (2) Three approaches are explored to incorporate the query information into query-oriented theme-based summarization. (3) Thorough experimental studies are conducted to verify the effectiveness and robustness of the proposed frameworks and approaches.

The rest of the paper is organized as follows. Section 2 reviews the related work. Section 3 explains the noise detection enhanced sentence clustering approach. Section 4 then addresses the other necessary issues in generic and query-oriented theme-based summarization. Section 5 presents experiments and evaluation results. Section 6 concludes the paper.

2 Related Work

Depending on the purpose and the target user, summarization can be either generic or query-oriented. While a generic summary reflects the author's point of view with respect to the most important information in the documents, a query-oriented summary presents the information in the documents that is most responsive to a given query.

Normally, sentence ranking is the issue of most concern in summarization (either generic or query-oriented). With the advancement of information technologies and the explosion of information on the Internet, clustering has become increasingly important in text mining and knowledge discovery. Recently it has been successfully applied in theme-based (a.k.a. clustering-based) summarization.

In terms of the roles of clustering in summarization, one could take the advantage of the clustering results to select the representative sentences in order to generate diverse summaries. The typical examples of such use are C-RR and C-LexRank proposed by Qazvinian and Radev (Qazvinian and Radev, 2008), which selected the important citation sentences from the sentence clusters generated by a hierarchical agglomeration algorithm. Alternatively, the clustering results could be used to improve or refine the sentence ranking results. Most of the clustering-based summarization approaches are of this nature. For example, Wan and Yang (Wan and Yang, 2008) presented a cluster-based conditional Markov random walk model and a cluster-based HITS model to incorporate the cluster-level information into the process of sentence ranking. Wang et al. (Wang et al., 2008a) also proposed a language model to cluster and summarize documents simultaneously using non-negative factorization. In addition, Wang et al. (Wang et al., 2008b) applied symmetric matrix factorization to generating sentence clusters. Each sentence's score is based on the linear combination of two elements. One is the average similarity score between a sentence and all the other sentences in the same cluster. The other is the similarity between the sentence and the given query. Notice that this is the only work we could find that explored clustering for query-oriented summarization.

Another important problem that we'd like to emphasize here is the existence of noisy data in any real-world dataset. To the best of our knowledge, no related work in summarization has attempted to solve this problem. In this paper, we try to address this issue by borrowing ideas from the noise detection research in the data mining literature. Existing noise detection approaches fall into two main types. One considered the data points whose distances to all cluster centers exceeded a certain threshold as noises after clustering (Dave, 1999). This type of approaches mainly focused on reducing the influence of noises on the regular clusters, but not exactly on identifying and removing noises. In this sense, the clusters output were still the noisy clusters. The other type managed to obtain one or more regular clusters and a single noise cluster that contained all noises simultaneously during clus-

tering (Li et al., 2007). Therefore, this type of approaches was able to provide noise-free clusters. The approach we are interested in this work is of the second type.

3 Spectral Clustering with Noise Detection

Compared to the traditional clustering algorithms such as K-means and agglomerative clustering, the new clustering algorithms that emerged over the last few years such as spectral clustering have demonstrated excellent performance on some challenging tasks (Ding and Zha, 2011). The spectral clustering has many fundamental advantages. For example, it is able to obtain global optimal solution and adapt to sample spaces with any shape (Ng, Jordan and Weiss, 2001; Bach and Jordan, 2004; Yu and Shi, 2003). The algorithm is also very simple to implement. It can be solved efficiently by standard linear algebra methods (Luxburg, 2007) and can be applied on a dataset of high dimensions in the feature space and data space (Dhillon et al., 2004). Taking into account these advantages, we choose to use spectral clustering in this study.

Without exception, spectral clustering is also sensitive to noises like all the other clustering algorithms. The main reason leading to its failure on the noisy dataset is that the block structure of the affinity matrix is destroyed by noises (Li et al., 2007). A possible solution is to reshape the noisy dataset so that the block structure of the new affinity matrix can be recovered. In this paper, we incorporate noise detection with spectral clustering by mapping the text data points from their original feature space into a new feature space such that a noise cluster formed by all the noisy data points can be separated from the other regular clusters. Basically, noise detection enhanced spectral clustering involves normalized graph Laplacian construction, data re-representation and spectral embedding.

3.1 Normalized Graph Laplacian Construction

Let *G*=(*S*, *A*) be an undirected weighted graph. $S = \{s_1, s_2, \cdots, s_n\}$ is the set of nodes corresponding to the text points represented as the *m*-dimensional feature vectors, *m* is the total number of the words and *n* is the total number of the sentences in a given document collection. $A = [a_{ij}]_{n \times n}$ is a symmetric matrix where a_{ij} is the weight of the edge connecting the two nodes s_i and s_j in G ($i, j = 1,2,\ldots,n$), and it is measured by the cosine similarity between the s_i and s_j vectors. The graph Laplacian L of G is defined as $L = I - A$, where I is the identity matrix, and the normalized graph Laplacian $\bar{L}$ of G is defined as

$$\bar{L} = D^{-1/2} L D^{-1/2} = I - D^{-1/2} A D^{-1/2} \quad (1)$$

where $D = [d_{ij}]_{n \times n}$ is a diagonal matrix with $d_{ii} = \sum_j a_{ij}$. A is called the affinity matrix and $\bar{A} = D^{-1/2} A D^{-1/2}$ the normalized affinity matrix.

3.2 Data Re-Representation

In order to achieve relatively compact sentence clusters and meanwhile separate the noises from them, we map the sentence nodes $\{s_i, s_2, \cdots, s_n\}$ to $\{p_1, p_2, \ldots, p_n\}$ in a new feature space with dimension equal to *n*. It is expected that the block structure of the new affinity matrix built on this new graph can be recovered. Now let's consider the following regularization framework

$$\Omega(P) = \| P - I \|_F^2 + \alpha \cdot \mathrm{tr}(P^T K_r^{-1} P) \quad (2)$$

where $\| \cdot \|_F$ denotes the Frobenious norm of a matrix, $\mathrm{tr}(\cdot)$ denotes the trace of a matrix, α is a positive regularization parameter controlling the trade-off between the two terms. K_r is a graph kernel (e.g., $K_r = \bar{L}^{-1}$). K_r^{-1} is the inverse of K_r if it is non-singular or is the pseudo-inverse of K_r if it is singular. $P = [p_1, p_2, \ldots, p_n]_{n \times n}^T$ is the new representation of the sentence set we would like to have after mapping. The optimal P can be obtained by minimizing $\Omega(P)$, i.e., $P^* = \arg\max_P \Omega(P)$. It is easy to see that the Equation (2) is strictly convex, so we could use the derivative of Equation (2) with respect to P to get the minimum of $\Omega(P)$, i.e.,

$$P^* = (I + \alpha K_r^{-1})^{-1} \quad (3)$$

Then the new representation of s_i is p_i^* (i.e. $P^*(i,\cdot)^T$, the *i*-th row vector of P^*).

3.3 Spectral Embedding

Given $P^* = \{p_1^*, p_2^*, \cdots, p_n^*\}$, i.e., the optimal representation of $S = \{s_i, s_2, \cdots, s_n\}$ in the new feature space, we can construct a new normalized

sentence graph Laplacian $\tilde{L}$. Let $\lambda_1 \le \lambda_2 \le \ldots \le \lambda_n$ be the eigenvalues of $\tilde{L}$ with the corresponding eigenvectors $v_1, v_2, \ldots, v_n$. Assume the cluster number k is known, let $V = [v_1, v_2, \ldots, v_k]_{n \times k}$. We normalize each row of V to unit length, resulting in a new matrix $\overline{V}$. The resultant row vectors correspond to the original sentence points and K-means clustering is performed on them. Then s_i is assigned to the cluster l $(1 \le l \le k)$ if and only if the i-th row vector in $\overline{V}$ (i.e., $\overline{V}(i,\cdot)$) is assigned to cluster l.

For each generated cluster, we compute the average distance between the sentence points in it and the origin. The cluster with the smallest average distance is taken as the noise cluster. The other clusters are considered as the regular clusters.

3.4 Cluster Number Estimation

Recall that spectral clustering requires a predefined cluster number k. To avoid exhaustive search for a proper cluster number for each document set, we employ the automatic cluster number estimation approach introduced in (Li et al., 2007) to predict the number of the expected clusters. Given the new normalized sentence graph Laplacian matrix $\tilde{L}$ and its eigenvalues $\lambda_1 \le \lambda_2 \le \ldots \le \lambda_n$, the optimal number of clusters k^* is defined as

$$k^* = \arg\max_k \{\lambda_{k+1}(\tilde{L}) - \lambda_k(\tilde{L})\} \quad (4)$$

where $\lambda_i(\tilde{L})$ is the i-th smallest eigenvalue of $\tilde{L}$.

4 Theme-based Summarization

4.1 Generic Theme-based Summarization

Once the sentence clusters are obtained, the summary sentences are then extracted from the original documents according to the ranks of the ordinary clusters they belong to and their ranks within the assigned clusters.

The ranking score of each regular sentence cluster is formulated as:

$$\gamma(C_{S_i}) = \frac{Score(C_{S_i})}{\sum_{i=1}^{K} Score(C_{S_i})} \quad (5)$$

$$Score(C_{S_i}) = \frac{\sum_{j=1}^{m} C_{S_i}(j) \cdot S(j)}{\sqrt{\sum_{j=1}^{m} (C_{S_i}(j))^2} \cdot \sqrt{\sum_{j=1}^{m} (S(j))^2}} \quad (6)$$

where $Score(C_{S_i})$ indicates the cosine similarity between an regular sentence cluster C_{S_i} and the whole document set S for generic summarization. K is the total number of the ordinary sentence clusters identified; m is the number of the words in the whole document set. $\gamma(C_{S_i})$ is the normalized value of $Score(C_{S_i})$, where $\gamma(C_{S_i}) \in [0,1]$ and $\sum_{k=1}^{K} \gamma(C_{S_i}) = 1$.

Within each regular sentence cluster, any reasonable ranking algorithm, can be applied to rank the sentences. In view of the successful application of PageRank-like algorithms in sentence ranking, LexRank (Qazvinian and Radev, 2008) is adopted in our work. Considering sentence position also provides important information for generic summarization, we multiply a weight to the rank score of each sentence. The weight of a sentence in a document is 1/n, where n is the total number of the sentences in the document. This is a normal practice in generic summarization, which follows the hypothesis that the first sentence in a document is the most important and the importance decreases as the sentence gets further away from the beginning. The summaries are then generated by choosing the most salient sentence from the most salient regular cluster to the least salient regular cluster, then the second most salient sentences from the regular clusters in descending order of rank, and so on.

4.2 Query-Oriented Theme-based Summarization

For query-oriented summarization, the query's influence can be reflected in any process of ranking or clustering. Considering the focus of this study is the application of clustering in summarization, we explore three query-based approaches that center on the ranking process or the result of clustering.

4.2.1 Query-Driven Cluster Ranking

The process of it is similar to the generic theme-based summarization, except that the $Score(C_{S_i})$ is formulated as

$$Score(C_i) = \frac{\sum_{j=1}^{m} C_{S_i}(j) \cdot Q(j)}{\sqrt{\sum_{j=1}^{m} (C_{S_i}(j))^2} \cdot \sqrt{\sum_{j=1}^{m} (Q(j))^2}} \quad (7)$$

which indicates the cosine similarity between a sentence cluster and a given query *Q*. Moreover, the sentence position information can not be considered in query-oriented summarization.

As the query's influence is only reflected in the process of ranking in this approach, we argue that the query's influence can be not only reflected in the process of ranking, but also reflected in the process of clustering. We explore two query-based approaches that center on the result of clustering.

4.2.2 Query-Embedding Similarity Measure

Sentence clustering requires the affinity matrix that is built upon the cosine similarity between the two sentences. On top of query-driven cluster ranking, we further consider the query-driven sentence clustering by defining a new query-embedding similarity measure that biases inter-sentence relationships towards pairs of sentences possessing the same concepts expressed in the query.

The idea is intuitive. The *m*-dimensional sentence vector $s_i = (s_{i1}, s_{i2}, \ldots, s_{im})$ is mapped onto the *l*-dimensional query vector $Q = (q_1, q_2, \ldots, q_l)^T$ (l is the number of query terms). As the number of the words contained in query is much smaller than the number of the words contained in the document collection, to avoid problems resulting from exact word match, we propose to use the synsets in WordNet to map the sentence vector onto the query vector. Given a sentence s_i, for each q_t ($1 \le t \le l$), the weights of s_{ij} ($1 \le j \le m$) that are in the same synset as q_t are accumulated and contribute to be the weight of q_t. Consequently, the cosine similarity between the two sentences can be defined in the query vector space. We call it the query-embedding similarity.

4.2.3 Query-Supervised Clustering

Clustering is typically unsupervised. In the case that some limited prior knowledge is available, one can use the knowledge to "guide" the clustering process. This is called semi-supervised clustering. Inspired by this idea, we make use of the query information to supervise sentence clustering. It is expected that the sentences that correspond to certain aspects of the query will be grouped together forming the query-relevant clusters and the query-non-relevant sentences will be grouped together while the other noisy sentences fall into the noise cluster.

For this purpose, we adopt semi-supervised spectral clustering with pairwise constraints proposed by (Kamvar, Klein and Manning, 2003). We regard each query sentence as a seed for a query-relevant cluster and a sentence from the document collection which does not contain any word in the query sentences is selected to be a seed of the noise cluster. Then from the remaining sentences in the document collection, the one that has the highest cosine similarity to a seed is selected to construct a must-link constraint with that seed. Once a sentence is selected for a cluster, it cannot be assigned to the other clusters any more. Thus it can be naturally used to construct the cannot-link constraints with the other seeds.

As the query sentences are involved in clustering with this approach, the affinity matrix becomes $A = (a_{ij})_{(n+r)\times(n+r)}$, where r is the number of the sentences in the given query. Normally a_{ij} is defined as the cosine similarity between the two sentences s_i and s_j. Specially, $a_{ij} = 1$ is assigned to each pair of must-link constraint, indicating that the corresponding two sentences have to be in the same cluster. Similarly, $a_{ij} = 0$ is assigned to each pair of cannot-link constraint, indicating that the corresponding two sentences must not be in the same cluster. Then spectral clustering is applied based on this constrain-affinity matrix. We generate summaries from those clusters containing the query sentence(s). Other clusters are assumed to be either the query-non-relevant cluster(s) or the noise cluster.

4.3 Redundancy Control in Summary Generation

Since the number of documents to be summarized can be very large, information redundancy can be quite serious in the generated summaries. Redundancy control is necessary. We apply a simple yet effective way to choose summary sentences. Each time, we compare the current candidate sentence to the sentences already included in the summary. Only the sentence that is not too similar to any sentence already in the summary (i.e., the cosine similarity between them is lower than a threshold) is selected into the summary. The iteration is repeated until the length of sentences in the summary reaches the length limitation. In our experiment, the threshold is set to 0.9.

5 Experiments and Evaluation

We conduct a series of experiments on the DUC2004 generic summarization dataset and the DUC2007 query-based summarization dataset. According to task definitions, systems are required to produce a concise summary for each document set (without or with a given query description) and the length of summaries is limited to 665 bytes in DUC 2004 and 250 words in DUC2007.

A well-recognized automatic evaluation toolkit ROUGE (Lin and Hovy, 2003) is used for evaluation. We report two common ROUGE scores in this paper, namely ROUGE-1 and ROUGE-2, which base on the Uni-gram match and the Bi-gram match, respectively. Documents and queries are pre-processed by segmenting sentences and splitting words. Stop words are removed and the remaining words are stemmed using Porter stemmer.

5.1 Summarization Evaluation

To evaluate the performance of the noise detection enhanced spectral clustering approach, we compare the ROUGE scores of it with the ROUGE scores of the LexRank approach for generic summarization and query-oriented LexRank approach, which is a direct extension of LexRank in our clustering and ranking frameworks. That is, the sentence clusters are generated by the traditional spectral clustering algorithm first and then the sentences within each cluster are ranked with LexRank. With this approach, the cluster ranking and the summarization generation processes are exactly the same way as in our approaches. For LexRank and query-oriented LexRank approaches, we obtain the cluster number based on the normalized sentence graph Laplacian directly.

We choose $K_r = \overline{L}^{-1}$ and set α to 1000 for noise detection. Table 1 and Table 2 below illustrate the ROUGE results on the DUC2004 and DUC2007 datasets.

DUC2004	ROUGE-1	ROUGE-2
Noise Detection Enhanced	0.36325	0.07847
LexRank	0.36294	0.07351

Table 1. ROUGE Evaluation of Two approaches on DUC2004

DUC2007	ROUGE-1	ROUGE-2
Query-Driven Cluster Ranking	0.39351	0.09223
Query-Oriented LexRank	0.37589	0.07858

Table 2. ROUGE Evaluation of Two approaches on DUC2007

It is delighted to see that the noise detection enhanced clustering approaches consistently outperform the clustering approaches without noise detection in the both datasets. This demonstrates that removing noises can indeed benefit producing better sentence clusters that in turn can further enhance the performance of summarization.

5.2 Analysis of Cluster Quality

Our original intention to utilize noise detection enhanced spectral clustering is to hope to generate more accurate sentence clusters results by eliminating the negative impact of noises. In order to examine the quality of the generated sentence clusters, we define the following measure

$$quan = \sum_{k=1}^{K} \left(\frac{\min_{s_i \in C_k} sim(s_i, CC_{S_k})}{\sum_{l=1, l \neq k}^{K} \min_{s_i \in C_{S_l}, s_j \in C_{S_l}} sim(s_i, s_j)} \right) \quad (8)$$

where $\min_{s_i \in C_k} sim(s_i, CC_{S_k})$ denotes the distance between the cluster center and the border sentence in a cluster that is the farthest away from the center. The larger it is, the more compact the cluster is. $CC_{S_k} = \sum_{s_i \in C_{S_k}} s_i \Big/ |C_{S_k}|$ where $|C_{S_k}|$ is the size of C_{S_k}. $\min_{s_i \in C_{S_l}, s_j \in C_{S_l}} sim(s_i, s_j)$, on the other hand, denotes the distance between the most distant pair of sentences, one from each cluster. The smaller it is, the more separated the two clusters are. The distance is measured by cosine similarity. As a whole, the larger *quan* means the better cluster quality.

Table 3 and Table 4 below indeed clearly indicate the improved cluster qualities by removing noises and/or by making better use of the relationships among sentences and words. The ranges of the sentence clusters are also provided for reference.

DUC2004	*Quan*	*Cluster no.*
Noise Detection Enhanced	5.26	2-6
LexRank	4.73	2-7

Table 3. Cluster Quality Evaluation on DUC2004

DUC2007	*Quan*	*Cluster no.*
Query-Driven Cluster Ranking	4.79	3-6
Query-Oriented LexRank	4.18	3-7

Table 4. Cluster Quality Evaluation on DUC2007

5.3 Example of Effective on Noise Detection

Besides the quantitative evaluation, we also select the DUC2004 D30006 document set and DUC2007 D0702A document set to illustrate the advantages of enhancement with noise detection in generic and query-oriented summarization, respectively. The former document set contains 10 documents about 'Labor Dispute in National

Basketball Association', while the latter one contains 25 documents about 'Art and music in public schools' and the corresponding query is to 'Describe the state of teaching art and music in public schools around the word, indicate problems, progress and failures'.

Three relevant topical themes, including 'Employers' attitude', 'Employees' attitude' and 'Game Canceling' are mentioned in DUC2004 D30006 human summaries, 'Music and art education in the world', 'The problems of music and art education' and 'the progress and failure in the music and art education' are mentioned in DUC2007 D0702A, respectively.

For illustration, we compare the summaries generated by noise detection enhanced spectral clustering/query-driven cluster ranking and LexRank/query-oriented LexRank without noise detection. In order to provide better coherence of the generated summary, we group the sentences in the same cluster together in a paragraph and order them according to their ranking scores in that cluster.

If Feerick finds in favor of the owners, the reality of not being paid may spur the players to reach an agreement more quickly. In return for the concessions, the players want an increase in the minimum salary currently $ 272,500. **(Cluster 1: Employees' attitude)**
Larry Bird, in the Indiana countryside or inside Boston Garden, was a luminous exception to the governing rule. The proposal is similar to the luxury tax proposed by the union in 1995 during negotiations, but it would not be nearly as liberal. **(Cluster 2: Topic non-relevant)**
The National Basketball Association, embroiled in a labor dispute with its players, Tuesday canceled the first two weeks of the 1998 - 99season.**(Cluster 3: Game canceling)**

Table 5. System generated summary of DUC2004 D30006 using LexRank

But neither the players nor the owners are counting on the ruling by the arbitrator, John Feerick, to speed up negotiations, especially if Feerick finds in favor of the players, an award that could approach $800 million in salaries. **(Cluster 1: Employers' attitude)**
Next week, it will consider canceling the first-ever regular season games in league history. The NBA has already canceled the first two weeks of the regular season because of the labor dispute. **(Cluster 2: Game canceling)**
In return for the concessions, the players want an increase in the minimum salary currently $272,500 and creation of an average salary exception. More than 220 National Basketball Association players with guaranteed contracts will find out **(Cluster 3: Employees' attitude)**

Table 6. System generated summary of DUC2004 D30006 using noise enhanced spectral clustering

Yet many schools have overflowing classes, outdated textbooks, insufficient supplies and cuts in arts and sports. This is Inner City Arts, a nonprofit arts school that is both an enlightened model for arts education and a design landmark where education is embellished by architectural example. The Bingham Academy, in its third year, offers a five-week program for five disciplines: creative writing, dance, instrumental and vocal music, theater and visual arts. Given the national obsession with high-stakes tests, they reasoned, it made sense to promote art and music classes as a way to boost test scores. **(Cluster 1: The progress and failure in the music and art education)**
The design is also an object lesson in construction. Results of the study were released. In a variety of ways. Flamenco, for example, ties into social studies and language arts lessons on the history and culture of Spain. Test scores are rising. People want schools to teach conflict resolution by negotiation, not violence. Standardized tests have improved many American schools. And classical music in Cuba could, from this point of view, use a little rescuing. The last argument may be in trouble. **(Cluster 2: Topic non-relevant sentences)**
The requirements include four years of English; three years of math; two years of social science; two years of lab science, two years of foreign language; one year of visual or performing arts and one year of electives. Centralizing information about the arts is another matter. By some estimates, only 25 percent of American schools offer music programs as a basic part of the curriculum. Arts exchanges are only part of the business. **(Cluster 3: The problems of music and art education)**

Table 7. System generated summary of DUC2007 D0702A using query-oriented LexRank

Most had participated in Carnegie Hall's Linkup music education program, and it showed. The Roundabout Theater sends teaching artists to 40 classrooms in the city for 10 visits each. Artists from Lotus Music and Dance Studios in Chelsea work intensively with six schools across the city, including Public School 156, teaching students about the music and dance of different cultures. Delaine Easton, the State Superintendent of Public Instruction, has called for the restoration of arts education in California public schools. All arts curriculum was eliminated from the public schools. **(Cluster 1: The progress and failure in the music and art education)**
Given the national obsession with high-stakes tests, they reasoned, it made sense to promote art and music classes as a way to boost test scores. By some estimates, only 25 percent of American schools offer music programs as a basic part of the curriculum. The more prestigious University of California schools consider only the top one-eighth of the state's high school seniors, while California State University, dubbed the people's university, takes the top one-third. **(Cluster 2: The problems of music and art education)**
The rhythm, harmony and melodies of the music all create different perceptions and sensations within different regions of the brain. Areas of research will include new digital techniques for music, dance, storytelling and the visual arts. The theory that classical music makes the brain work better and they have some high-profile allies. To schedule this extra drill, students must drop an elective, like fine arts or gym. **(Cluster 3: The problems of music and art education, Benefit from the education)**

Table 8. System generated summary of DUC2007 D0702A using query-driven spectral cluster rankings

It is not difficult to conclude that the generated summaries using noise detection looks more informative than without using noise detection. We interpret the sentences of cluster 2 in Table 5 and the sentence of cluster 2 in Table 7 as the noise

sentences, considering they are not relevant to any main topical theme in the corresponding document set. Such kind of sentence is not observed in Table 6 and Table 8.

5.4 Comparison of Different Approaches to Integrating the Query Information

Different from generic summarization, the query information plays an important role in query-oriented summarization. In order to examine which way is more effective to integrate the query's influence into the clustering or ranking process, we further compare the query-based cluster-ranking and clustering approaches as introduced in Section 4.2. Meanwhile, we also implement the query-sensitive similarity measure introduced in (Tombros and Rijsbergen, 2001) for comparison, which calculates the similarity between s_i and s_j as

$$Sim(s_i, s_j) = \frac{\sum_{b=1}^{m} s_{ib} \cdot s_{jb}}{\sqrt{\sum_{b=1}^{m} s_{ib}^2 \cdot \sum_{b=1}^{m} s_{jb}^2}} \cdot \frac{\sum_{b=1}^{\max(l_m, l_Q)} c_b \cdot q_b}{\sqrt{\sum_{b=1}^{l_m} c_b^2 \cdot \sum_{b=1}^{l_Q} q_b^2}} \quad (9)$$

where l_Q is the query length of the query Q, l_m is the number of common words between s_i and s_j.

Table 9 below illustrates the ROUGE results on the DUC2007 dataset.

	ROUGE-1	ROUGE-2
Query-Driven Cluster Ranking	0.39351	0.09223
Query-Sensitive Similarity	0.39644	0.09537
Query-Embedding Similarity	0.39803	0.09698
Query-Supervised Clustering	0.40118	0.10125

Table 9. ROUGE Evaluation of Query-based Noise Detection Enhanced Approaches on DUC2007

We can observe from the above table that the query-embedding similarity approach and the query-supervised clustering approach clearly outperform the query-driven cluster ranking approaches. These results are expected. While the query-driven approach makes use of the query information in cluster ranking only, the other three approaches integrate the query information in both clustering and cluster ranking.

Beyond this, as a whole, the query-supervised clustering approach performs better than the query-embedding similarity approach. It can be interpreted if we look at the cluster generated. The query-supervised clustering approach is able to generate three types of clusters, i.e., query-relevant clusters, query-irrelevant clusters and a noise cluster and the summaries are generated merely from the query-relevant clusters. So the summaries generated are truly both query-relevant and theme-focused. In contrast, the query-embedding similarity approach can only differentiate the regular clusters from the noise cluster. Though the summaries are influenced by the query in some extent, the sentences in the generated regular clusters are not guaranteed to be relevant to the query.

It is also shown that the proposed query-embedding similarity measure has the advantage over the existing query-sensitive similarity measure, which simply multiplied the sentences-query similarity with the sentence-sentence similarity and thus the role of query is not as explicit as in query-embedding similarity.

To summarize, we believe that the high performance benefits from (1) Detecting and Removing Noise during Clustering i.e. removing noise sentences to enhance the clustering results and thus consequently improve the summarization performance; and (2) Guiding Sentence Clustering with Query for Query-oriented summarization, i.e., using the query information as the prior knowledge to supervise sentence clustering.

6 Conclusion

In conclusion, we propose noise detection enhanced spectral clustering to generate sentence clusters in this study. Moreover, we test the influence of query information for summarization generation. The experimental results on the DUC summarization datasets demonstrate the effectiveness and the robustness of the proposed approach. In particular the contribution of noise detection and the query information in the clustering process are clearly observed. In the future, we will add contextual information to sentences to further enhance the sentence clustering performance.

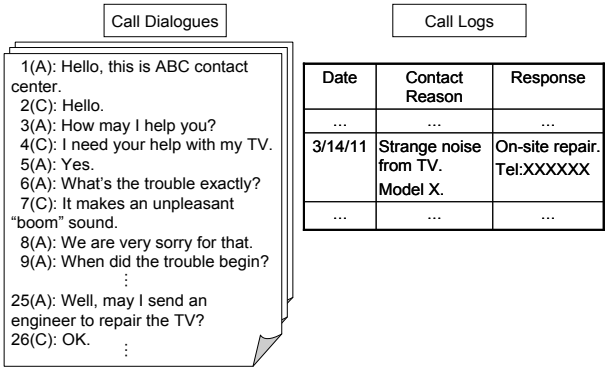
Abstract

This paper proposes a novel extractive summarization method for speech dialogues between agents and customers in contact centers. The proposed method does not require any extra cost for applying the method such as preparing rules or creating training data. Conventional methods such as the tf*idf method, which gives importance to characteristic words in an input text, can miss the essential points for contact center work. Our proposed method evaluates the importance of each utterance from the standpoint of call agents who report calls for managing or analyzing calls. Specifically, the proposed method includes information frequently reported by call agents in summaries using past call logs commonly recorded in the contact center. Evaluation using real data (call dialogues and call logs) shows that the proposed method can extract essential points in terms of contact center work and outperforms the conventional method.

1 Introduction

In recent years, the role of contact centers has become more important in many companies. This is because each contact center is a main channel for individual customers to directly access a company and the voice of the customers can be used to improve the quality of the company's products and services.

Many contact centers have two problems of human cost. The first one is that agents spend much time documenting logs. Logs are usually generated by agents based on their memories or handwritten memos after a call. Such logs are used for reporting, managing, and analyzing their calls. Figure 1 shows an example of a call dialogue and its corresponding call log (We simply refer to these as a dialogue and a log hereafter).



※leftmost number: utterance ID, A: agent, C: customer

Figure 1: Example of a call dialogue and a call log

The other cost is that managers also spend much time understanding the details of calls. This is because managers must listen to speech data or browse dialogue texts generated by automatic speech recognition (ASR), which are lengthy and include many uninformative parts.

Accordingly, automatic summarization of dialogues is required as an effective solution to the above problems. For the first problem, the summary can be an alternative to the logs or draft for agents. Byrd et al. (2008) have shown that automatic summarization helps to reduce the time for documenting calls. For the second one, the summary can help to reduce the time spent listening to the speech data or browsing the dialogue texts.

In previous works (Zechner, 1996; Edmundson, 2004; Orasan et al., 2004; Murray et al., 2007; Higashinaka et al., 2010), the methods summarize an input text without considering the

*This work was done when the author was at NEC Corporation.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 500–508,
Chiang Mai, Thailand, November 8 – 13, 2011.

requirements for contact center work such as reporting, managing, and analyzing calls. Some other works (Hirao et al., 2002; Iwasaki et al., 2005; Murray et al., 2005; Shen et al., 2007; Byrd et al., 2008; Fujii et al., 2008) can generate summaries satisfying such requirements. However, these methods generally require manual work of creating rules or training data.

In this paper, we propose a novel method that can summarize dialogues satisfying the requirements for contact center work without incurring the cost of manual works. The proposed method preferentially extracts sentences (or utterances) consisting of phrases described in logs of past calls. Such logs have been recorded through daily operation and are readily available in most contact centers. Moreover, we propose a method that bridges the gaps between the expressions in dialogues and logs to improve performance.

The main contributions of this paper are as follows.

1. We propose a method that preferentially extracts sentences consisting of phrases frequently written in logs of past calls. In our experiment using real data, we confirm that the proposed method outperforms the conventional methods ($\mathrm{tf} * \mathrm{idf}$ method and ridf method), baseline methods without considering the requirements for contact center work.
2. We propose a method that extracts sentences based on association strength with contents of the past logs so as to bridge gaps between the expressions in dialogues and logs, and confirm experimentally its effectiveness in summarization to improve performance.

This paper is organized as follows. In Section 2, we explain previous works and their problems. In Section 3, we propose our method. In Section 4, we describe the experiment using real contact center data. In Section 5, we discuss the experimental results. In Section 6, we summarize this paper.

2 Related Work

We describe conventional summarization methods for contact center dialogues and their problems. To reduce the burden of agents, Iwasaki et al. (2005) have proposed a method that generates a log of the input dialogue automatically. The method selects important sentences using different approaches according to sentence type (e.g. "contact reason", "response"), where the $\mathrm{tf} * \mathrm{idf}$ method or lead method is used. However, the method requires training data to identify the sentence type of each sentence. Hence, it takes effort to prepare the training data.

Byrd et al. (2008) built a system, Contact-Center Agent Buddies, which generates a candidate log from dialogues, and demonstrated its effectiveness in an actual contact center environment. The system normalizes the dialogue text generated by ASR, calculates the importance of each normalized sentence using a number of heuristic rules, and then extracts important sentences. However, some of the heuristic rules depend on the individual contact center (e.g. rules for annotating *cues* typically found in questions by agents). Hence, it takes effort to create rules for each contact center.

On the other hand, there are methods that do not require preparing training data or creating rules. Higashinaka et al. (2010) have proposed an extractive summarization method for contact center dialogues categorized into multiple domains (e.g. finance, mail order, PC support). The method extracts utterances that are characteristic of the input dialogue domain in relation to other domains using a particular type of hidden Markov model. However, the method cannot be applied to contact centers that do not deal with multiple domains. Additionally, the method seems to have difficulty extracting important information occurring in any domain (e.g., "a customer urgently requests support").

Other notable methods are the lead method proposed by Edmundson (1969) and the $\mathrm{tf} * \mathrm{idf}$ method proposed by Zechner (1996). The lead method extracts sentences from the top in order under the assumption that the important points are described first. However, important parts such as the customer's requirements and agent's responses can be located anywhere because the customer's requirements are identified through conversation interactions, which differ according to customers. Therefore, the lead method is not suitable for summarizing contact center dialogues.

The $\mathrm{tf} * \mathrm{idf}$ method uses word frequencies. First, the method calculates the following weight for each word w in the input text:

$$\mathrm{tf} * \mathrm{idf}(\mathrm{w}) = \mathrm{tf}(\mathrm{w}) \times \log\left(\mathrm{N}_{\mathrm{all}}/\mathrm{N}(\mathrm{w})\right),$$

where $\mathrm{tf}(\mathrm{w})$ is the frequency of w in the input, $\mathrm{N}_{\mathrm{all}}$ is the total number of texts, and $\mathrm{N}(\mathrm{w})$ is the number of texts containing w. Next, the method calculates the average of the weights for words in each sentence as importance of the sentence. Finally, the method extracts sentences in the order

of the importance from the highest. The method extracts utterances including characteristic words that are frequent in the input text and infrequent in other texts. However, there are essential words for contact center work, although the words are frequent in other texts (e.g. words in frequent customer requests). The method does not include the words in summaries. Moreover, there are uninformative sentences including characteristic words such as the customer's speaking habits (e.g. "kind of" being frequently used by the customer). The method can extract these uninformative sentences.

Orasan et al. (2004) and Murray et al. (2007) experimentally showed that ridf(w) defined as the following function is most effective for summarizing texts in several term weighting functions including the $\mathrm{tf} * \mathrm{idf}(w)$.

$\mathrm{ridf}(w) = \log(N_{all}/N(w)) - \log(1 - p(0;\lambda_w))$,

where N_{all} and $N(w)$ have the same definitions as those in the $\mathrm{tf} * \mathrm{idf}(w)$, and p is the Poisson distribution with parameter λ_w, the average number of occurrence of w per text, and $1 - p(0;\lambda_w)$ is the probability of w appearing in a text at least once. However, the method using the ridf(w) also cannot generate summaries from the viewpoint of contact center work.

3 Proposed Method

We propose a novel summarization method for contact center dialogues without the problems described in Section 2. In this work, we assume that essential information for contact center work should be frequently written in past logs. First, the proposed method calculates the likelihood of being reported by agents for each utterance using past logs recorded in the contact center. Hereafter, we refer to the likelihood as *report score*. Next, the proposed method extracts utterances in the order of the report score from the highest and then outputs the extracted utterances in the order of appearance in the input dialogue as its summary.

The proposed method does not require any extra cost for applying the method because the method exploits past logs automatically accumulated in the contact center through daily operation. Additionally, the proposed method includes the essential points in terms of contact center work in summaries because the logs are described to report, manage, and analyze the contacts. Note that there is no corresponding log of an input dialogue when the method summarizes the dialogue.

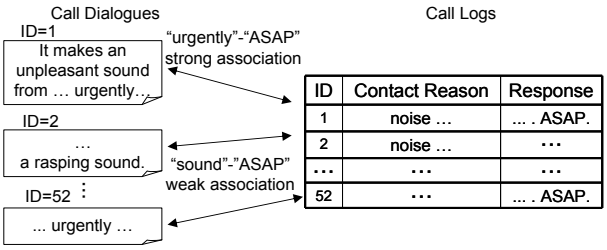


Figure 2: Association strength between words

The rest of this section is organized as follows. In Section 3.1, we first describe a method that simply calculates the report score based on frequency in past logs, and explain the problem with the simple method. In Section 3.2, we propose a method that calculates the report score based on past pairs of a dialogue and its corresponding log so as to handle the problem with the simple method.

3.1 Call Log Frequency Method (LF Method)

The LF method regards high frequency words in past logs as important, and then extracts utterances that have the high frequency words. The LF method proceeds as follows.

Step 1. $\mathrm{R\_Score}(w)$, the report score of a word w, for each word in an input dialogue is calculated by the following equation (1). Here, equation (1) is the document frequency of the word w, where a set of documents is a set of past logs (Call Log Frequency; LF).

$$\mathrm{R\_Score}(w) = L(w)/L_{all} \cdots (1).$$

Let $L(w)$ be the number of past logs containing the word w, and let L_{all} be the total number of past logs.

Step 2. $\mathrm{R\_Score}(U)$, the report score of an utterance U, for each utterance in the input dialogue is calculated as the average[1] of the report scores of the words in the utterance U as follows:

$$\mathrm{R\_Score}(U) = \frac{\sum_{w \in W(U)} \mathrm{R\_Score}(w)}{|W(U)|} \cdots (2).$$

Let $W(U)$ be a set of all words in an utterance U.

Step 3. Top-K utterances in the order of the report score from the highest are extracted.

3.1.1 Problem with LF Method

In logs, concise expressions, abbreviations, and specialized terminology tend to be frequently used because the logs are generated so as to report to managers or persons involved. On the

[1] We regard sentences that express content compactly as important to summarization. Hence, we do not use the total but the average.

other hand, an agent usually uses multiple expressions in a dialogue according to the situation or customer's level of understanding. Therefore, there is a gap between the expressions in the dialogue and in its corresponding log even though those are the same in meaning.

In Figure 1, "an unpleasant 'boom' sound" in the dialogue is concisely described as "strange noise" in its corresponding log, and in Figure 2, "urgently" in a dialogue is described with the abbreviation "ASAP" in the log. However, the LF method cannot handle the differences between the expressions in dialogues and logs. Concretely, the LF method cannot select important information that is not described with the same expression in the logs.[2] Consider Figure 1, for example; the LF method cannot regard as important the words not appearing in the log such as "unpleasant", "boom" and "sound". Therefore, the LF method may not include ID 7, which is important for contact center work, in the summary.

3.2 Proposed Method

In Section 3.2.1, we propose a method that can handle the problem described in Section 3.1.1. In Section 3.2.2, we introduce a component that removes frequent utterances from the summary to improve performance of our method.

3.2.1 Association Strength Method (AS Method)

To handle differences between the expressions in dialogues and logs, we have based our proposed method on the following assumption: association strength (AS) between each occurrence of two words in past pairs of a dialogue and its corresponding log indicates semantic similarity between the two words.

Consider, for example, Figure 2. "Urgently" in dialogues and "ASAP" in logs have the same meaning. When "urgently" appears in a dialogue, "ASAP" also appears in its corresponding log (ID=1,52). Moreover, when "urgently" does not appear in a dialogue, "ASAP" also does not appear in its corresponding log (ID=2). In short, Figure 2 shows that association strength between "urgently" and "ASAP" is strong. On the other hand, "sound" and "ASAP" have different meanings. Figure 2 shows that the association strength between "sound" and "ASAP" is weak.

[2] Not only the LF method but any supervised methods using logs as training data have the same problem.

Under the above assumption, we propose the AS method, which estimates semantic similarity between a word w in dialogues and a word v in logs as $\mathrm{AS}(w, v)$, the association strength between each occurrence of w and v. $\mathrm{AS}(w, v)$ is calculated by association measures such as mutual information, chi-square value, and z-value.

We calculate the likelihood that a word w in a dialogue is reported in past logs as a word v, by the following expression (3). The expression is the product of $\mathrm{AS}(w, v)$, the semantic similarity between w and v, and the likelihood that the word v is reported in past logs.

$$\mathrm{AS}(w, v) \cdot \mathrm{L}(v)/\mathrm{L}_{\mathrm{all}} \cdots (3).$$

$\mathrm{L}(v)$ and $\mathrm{L}_{\mathrm{all}}$ in the expression (3) have the same definitions as $\mathrm{L}(w)$ and $\mathrm{L}_{\mathrm{all}}$ in equation (1) respectively.

Some of the words in dialogues have multiple synonymous expressions in logs. For example, "noise" in dialogues can sometimes be described as "noise" and other times as "sound" in logs. Additionally, the meaning of a word in a dialogue is often expressed with multiple words in its corresponding log. For example, the meaning of "boom" in the dialogue in Figure 1 is expressed with "strange noise" in its log. To deal with the above paraphrases, we expand expression (3). Specifically, the likelihood that the meaning of a word w in a dialogue is reported in past logs as a set of words V is calculated as the sum of expression (3) for each word v in V as follows:

$$\sum_{v \in V} \mathrm{AS}(w, v) \cdot \mathrm{L}(v)/\mathrm{L}_{\mathrm{all}} \cdots (4).$$

In conclusion, $\mathrm{R\_Score}(w)$, the report score of a word w, is estimated by expression (4), where V is the set of all words in past logs. Here, the amount of calculation is enormous. Therefore, we limit V in expression (4) to N words in order of $\mathrm{AS}(w, v)$ from the highest. We denote the set of such N words for a word w by $\mathrm{V_N}(w)$. The AS method estimates $\mathrm{R\_Score}(w)$ by the following equation (5).

$$\mathrm{R}_{\mathrm{Score}(w)} = \sum_{v \in \mathrm{V_N}(w)} \mathrm{AS}(w, v) \cdot \frac{\mathrm{L}(v)}{\mathrm{L}_{\mathrm{all}}} \cdots (5).$$

Here, association strength between unrelated words should be close to zero, and the number of association words for one word is limited. Accordingly, equation (5) is not sensitive to larger N, and we assume that the AS method is effective with little or no tuning of N. We examine this point in Section 4. Hereafter, the AS method performs steps 2 and 3 in Section 3.1 in sequence.

Table 1: Performance of ASR

Speaker	Agent	Customer
P.C. (%)	91.5	89.9
W.A. (%)	87.7	84.8

Table 2: Test data

Data type	SR	MT	Log
Avg. number of utterances	175	111	-
Avg. number of characters	1,207	1,320	166

3.2.2 Removal of Frequent Utterances (RFU)

Contact center dialogues include many uninformative utterances that do not have important contents such as back-channel feedback (e.g. "Yes", "Well"), set phrases (e.g. "This is XX contact center."), and greetings (e.g. "Hello", "Good morning"). These uninformative utterances must not be included in a summary. We aim to improve performance of our method by directly detecting these uninformative utterances.

We assume that such uninformative utterances frequently occur in any dialogue. Hence, the proposed method calculates the occurrence rate for each utterance U defined as "the number of dialogues containing utterance U / total number of dialogues", and then identifies the utterances whose occurrence rates are higher than threshold θ as uninformative utterances. Finally, the proposed method removes the identified utterances from a summary.

4 Experiment

In this section, we describe the experiments using dialogues and logs in a real Japanese contact center and show their results, where we examine the following effects of our proposal.

- By preferentially including information frequently reported in past logs, the performance of automatic text summarizers for contact center works can be improved.
- Association strength between two words enables our method to handle differences between the expressions in dialogues and logs, and improves performance.
- RFU improves performance of our method.

4.1 Experimental Settings

4.1.1 Experimental data

We collected 4,596 call speech data and their corresponding logs in a real Japanese contact center, and generated the following two types of texts from the call speech data. We used the texts as dialogue data in the experiments.

1. Speech Recognition Text (SR):

The texts were generated by ASR from the read speech data. Table 1 shows the accuracy of ASR. In Table 1, P.C. is percent correct calculated by (T-S-D)/T, and W.A. is word accuracy calculated by (T-S-D-I)/T. Let T be the total number of words, S be the number of substitutions, I be the number of insertions, and D be the number of deletions.

2. Manual Transcription Text (MT):

The texts were transcribed manually from the speech data and divided manually into utterances.

4.1.2 Test Data

We used 40 pairs of dialogue data and their corresponding logs as test data, which were selected randomly from a total of 4,596 data. The average length of the dialogue data and the logs are shown in Table 2, which shows that the log corresponds to 12.6% (=166/1,320) of compressed text of the call speech data.

We used the following two types of summaries with different compression rates as the references in the experiments so as to examine the effectiveness for various types of contact center work such as reporting, managing, and analyzing contacts. The references were manually generated from the MT of the test data. Note that logs themselves are not suitable for references because there are differences between the expressions in dialogues and logs.

1. Indicative Summary:

We generated summaries with a 30% compression rate by manually extracting utterances on the assumption that these are used as alternatives to the logs or drafts for agents, and for managers to grasp the gist of calls at a glance. Here, the compression rate is defined as "number of characters in a summary / number of characters in a dialogue data". Note that we set the compression rate to 30%, which is higher than that of the logs (12.6%), because the expressions in dialogues tend to be lengthy compared to those in logs.

2. Informative Summary:

We generated summaries that are sufficient to obtain all contents by manually extracting utterances without thinking of compression rate on the assumption that these are used for managers to grasp the details of calls, and as cleansed texts for analysis of calls such as information retrieval and text mining. The average compression rate is 65.2%.

Table 3: Experiments with different N in equation (5)

N	1	2	4	8	16
F-measure	0.526	0.528	0.527	0.529	0.519
ROUGE-1	0.565	0.572	0.571	0.576	0.567
ROUGE-2	0.567	0.574	0.578	0.584	0.575
N	32	64	128	LF Method	
F-measure	0.504	0.497	0.494	0.478	
ROUGE-1	0.563	0.549	0.546	0.527	
ROUGE-2	0.568	0.550	0.548	0.543	

4.1.3 Competing Methods

We evaluate the following five methods in the experiments. For MT, each method judges each utterance manually detected as to whether it is necessary for the summary or not, and for SR, each method judges each utterance detected by the ASR engine.

1. $\mathrm{tf} * \mathrm{idf}$ method and ridf method:

The methods are described in Section 2. Using a total of 4,556 dialogue data, the $\mathrm{tf} * \mathrm{idf}$ method calculated the $\mathrm{tf} * \mathrm{idf}$ score for each word and the ridf method calculated the ridf score.

2. LF method:

The method is described in Section 3.1. In calculating the report score for each word, the method used a total of 4,556 logs.

3. AS method:

The method is described in Section 3.2.1. Note that the method does not introduce RFU. In calculating the report score for each word, the method used a total of 4,556 pairs of the dialogue data and its corresponding logs, and used z-value as the association measure. We used various numbers as N in equation (5) to investigate the dependency of N on the performance of the AS method.

4. AS with RFU method:

The method introduces RFU into the AS method. The settings in the AS method are the same as the above. In RFU, we used 0.5 as a threshold, which was determined by the preliminary experiment. Additionally, RFU calculated the occurrence rate using a total of 4,556 dialogue data. Here, RFU regards an utterance as the bag of content-word bigrams so as to relieve differences of the expressions between utterances (e.g. "This is XX speaking." and "This is XX."). RFU calculates the average of the occurrence rate of the bigrams in the utterance as the occurrence rate of the utterance.

4.1.4 Evaluation Measure

We used the following evaluation measures.

1. Sentence recall, precision, and F-measure:

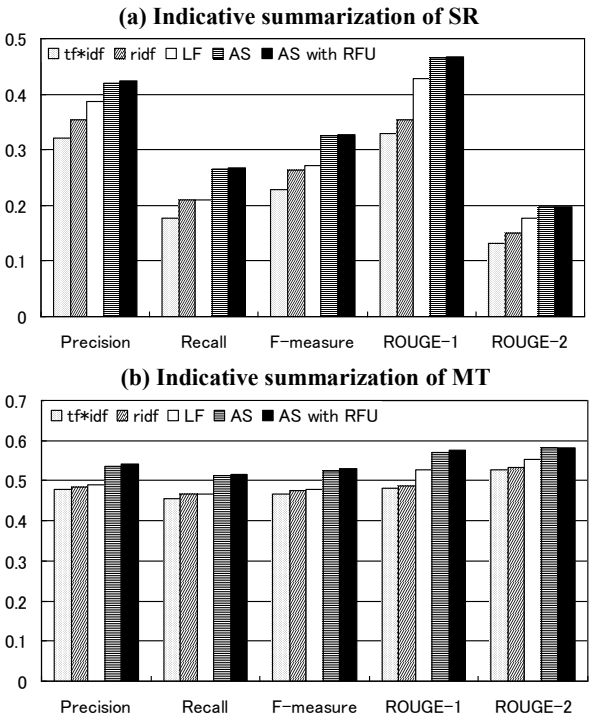

Fig 3: Result of indicative summarization

Sentence recall is the number of sentences correctly extracted by a method over the number of sentences in the reference. Sentence precision is the number of sentences correctly extracted over the number of sentences extracted by the method. F-measure is defined as follows;

$$2 \times \mathrm{Recall} \times \mathrm{Precision} / (\mathrm{Recall} + \mathrm{Precision}).$$

When SR is summarized, estimated sentence (or utterance) boundaries based on ASR results do not always agree with those in the references. In this paper, extraction of a sentence in the SR is considered as extraction of one or multiple sentences in the reference with an overlap of 50% or more words as in Hirohata et al. (2005).

2. $\mathrm{ROUGE_N}$ (Lin et al., 2003):

$\mathrm{ROUGE_N}$ is an N-gram recall between reference (R) and the summary generated by a method (C), which indicates similarity between them. $\mathrm{ROUGE_N}$ is calculated as follows:

$$\mathrm{ROUGE_N}(\mathrm{C}, \mathrm{R}) = \frac{\mathrm{C_m}(\mathrm{N\text{-}gram})(\mathrm{C}, \mathrm{R})}{\mathrm{C}(\mathrm{N\text{-}gram} \in \mathrm{R})},$$

where $\mathrm{C_m}(\mathrm{N\text{-}gram})(\mathrm{C}, \mathrm{R})$ is the number of co-occurrences of N-gram in C and R, and $\mathrm{C}(\mathrm{N\text{-}gram} \in \mathrm{R})$ is the number of N-grams in R. In our experiments, 1-grams (ROUGE-1) and 2-grams (ROUGE-2) are used, where the words are only content words.

4.2 Experimental Results

First, we investigated the dependency of the number of association strength in estimating the

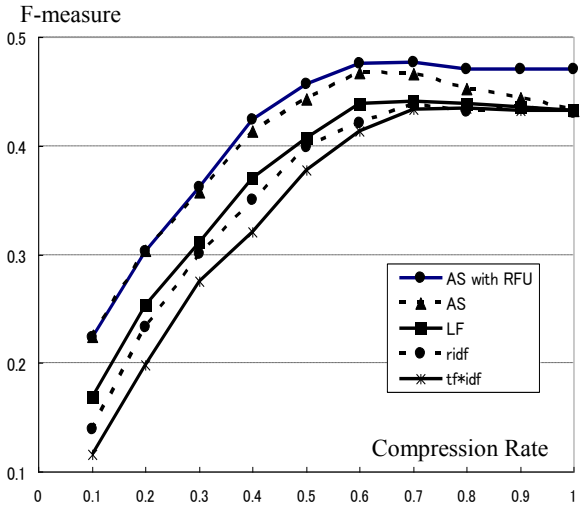

Fig 4: F-measure of informative summarization

report score (N in equation (5)) on the performance of the AS method. Table 3 shows the performance of indicative summarization with different N for MT. Table 3 shows that there is not much difference between N=64 and N=128. The result indicates that the number of related words for one word is limited and association strength between unrelated words is close to zero. Accordingly, the performance of the AS method is not sensitive to larger N. Table 3 also shows that the performance with N = 8 is best. Hereafter, let N be 8 with regard to the AS method.

Next, we examined the performance of indicative summarization for each competing method. Specifically, we summarized the dialogues in the test data by each method at a 30% compression rate, and then evaluated their results. Figure 3 shows the results. Moreover, we examined the performance of informative summarization for each competing method. Unfortunately, we cannot get the compression rate suitable for the informative summarization in each competing method. In the examination, we summarized the dialogues in the test data by each method, where the compression rate was changed from 0.1 to 1.0 at 0.1 intervals, and then evaluated their results. Figure 4 shows the F-measure for SR. Other evaluation measures and the results for MT are omitted in this paper because the results indicate a similar tendency to Figure 4, and the conclusions in this paper do not change.

Figures 3 and 4 show that the LF method, the AS method, and the AS with RFU method outperform the tf ∗ idf method and the ridf method. The results show that preferentially selecting information frequently reported in past logs is effective for summarizing dialogues from the viewpoint of contact center work regardless of compression rate.

Figures 3 and 4 also show that the AS method outperforms the LF method, and Table 3 shows that the performance of the AS method with N = 128 is better than that of the LF method. These results show that using association strength between two words in the past pairs of a dialogue and its corresponding log improves the performance of our method. This means the association measure helps to handle differences between the expressions in dialogues and logs. We discuss the point in Section 5.1 in detail. Additionally, Table 3 shows that the AS method is effective with little or no tuning of N.

Figure 4 shows that the AS with RFU method outperforms the AS method when the compression rate is high. The result shows that RFU is effective for summarization with a high compression rate. However, Figures 3 and 4 also show that when compression rate is low, there is not much difference between performance of the AS method and that of the AS with RFU method. We discuss this point in Section 5.2 in detail.

5 Discussion

5.1 Effectiveness of Association Strength between Two Words

We discuss whether the assumption described in Section 3.2.1, that the association strength between two words indicates semantic similarity, is correct or not. We examined relationships of the 500 pairs of two words with strong association in the experimental data. The result is that 67.8% are synonymous, 15.2% are *related*, and 17% are *unrelated*. Here, *related* is when the two words are associated with one another including is-a relations and part-of relations (e.g. "freeze" and "break", "ATM" and "cash"). *Unrelated* is when the two words are irrelevant to one another. The result shows that accuracy of identifying two words with the same meaning using the word pairs with high association strength is 67.8%.

Table 3 shows that the performance with N = 8 is best although the number of synonymous expressions for one word is supposed to be smaller than 8. We suppose that *related* helps to find utterances reported in the logs and 83% (total of *synonymous* and *related*) strong association is an efficient clue for summarization.

Most *unrelated* words belong to different types of information (e.g. "CUSTOMER X" and "MODEL Y", which should be respectively described in the "customer's name" and "contact

Table 4: Rate of eliminated utterances by RFU

Data Type	Compression Rate	Rate of eliminated utterances by RFU
SR	30%	1.9% (23/1,213)
	50%	2.4% (51/2,098)
	65%	9.3% (269/2,879)
	80%	35.9% (1,500/4,182)
MT	30%	0.6% (4/715)
	50%	2.3% (27/1,168)
	65%	8.0% (129/1,617)
	80%	53.8% (1,239/2,305)

reason" parts of the logs). By calculating the association measure of two words in corresponding parts of a dialogue and its log after topic segmentation of the dialogue, we can further improve our method.

5.2 Effectiveness of RFU

We examined whether the frequent utterances identified by RFU in the test set are unnecessary for the summaries (uninformative) or not. In a total of 6,985 utterances in SR, 2,102 utterances (161 varieties) are identified by RFU, and 99.4% (=2,090/2,102) are uninformative. In a total of 4,436 utterances in MT, 1,985 utterances (156 varieties) are identified by RFU, and 99.7% (=1,979/1,985) are uninformative. The results show that RFU can eliminate uninformative utterances from the summaries with high accuracy.

Additionally, we examined the rate of eliminated utterances by introducing RFU into the AS method, which is the number of frequent utterances in the summary generated by the AS method over the total number of utterances in the summary. Table 4 shows the result. Table 4 shows that there are few frequent utterances in the summary generated by the AS method when the compression rate is low. In other words, the result indicates that the AS method (without RFU) can eliminate uninformative frequent utterances when generating an indicative summary or informative summary with a low compression rate. As a result, there is not much difference between the performance of the AS method and that of the AS with RFU method in Figures 3 and 4 with a low compression rate.

On the other hand, Table 4 shows that there are a lot of frequent utterances in the summary generated by the AS method when the compression rate is high. The results indicate that when the compression rate is high, it is difficult to judge whether an utterance is important or not using only the report score based on the association strength. This is because the input dialogue can include detailed information not described in the logs, and also subjects not occurring in past calls. In the above situation, suitable utterances can be included in a summary by eliminating frequent utterances preferentially. As a result, the AS with RFU method enables maintaining the quality of summarization with a high compression rate.

5.3 Robustness to ASR errors

Figure 3 shows that performance on summarization of SR is lower than that of MT in every method. This is because the words that should be ideally included in the summary are missing in SR due to substitutions or deletions in ASR.

To examine the robustness to ASR errors, we calculated the reduction rate[3] of F-measure by comparing the performance to SR with that to MT. As a result, the reduction rate of the AS method is 37.9% and the rate of the LF method is 43.1%. The result shows that the AS method is more robust to ASR errors than the LF method.

6 Conclusions

We proposed a novel method that can summarize contact center dialogues satisfying the requirements for contact center work without any extra cost for applying the method. We proposed the idea of preferentially selecting information frequently reported in past logs so as to include the essential information for contact center work in summaries. Moreover, we proposed a method that extracts utterances based on association strength between each sentence and the past logs so as to bridge the gaps between the expressions in logs and dialogues.

In the evaluation using real data, experimental results showed that our proposed method outperforms the conventional methods (the $\mathrm{tf} * \mathrm{idf}$ method and the ridf method), and association strength between two words improves the performance of automatic text summarizers for contact center works. Additionally, we improved our method by removing frequent utterances from the summaries.

We are planning to prove the effectiveness of our proposed method for actual contact center work according to the cost reduction effect in the call log documentation process.

Abstract

This paper addresses a semantic tree-to-string alignment problem: indexing spoken documents with known hierarchical semantic structures, with the goal to help index and access such archives. We propose and study a number of alignment models of different modeling capabilities and time complexities to provide a comprehensive understanding of these unsupervised models and hence the problem itself.

1 Introduction

The inherent difficulties in efficiently accessing spoken documents raise the need for ways to better organize such archives. Such a need parallels with the consistently increasing demand for and availability of audio content on web pages and other digital media, which, in turn, should come as no surprise, with speech being one of the most basic, most natural forms of human communication.

When intended to be read, written documents are almost always presented as more than uninterrupted text strings; e.g., indicative structures such as section/subsection headings and tables-of-contents are standard constituents created manually to help readers, whereas structures of this kind are rarely aligned with spoken documents, which has raised little concern—in most time of history, speech has not been ready for *navigation*, until very recently, when recording, delivering, and even automatic transcription were possible.

Navigating audio documents is often inherently much more difficult than browsing text. An obvious solution, in relying on human beings' ability of reading text, is to conduct a speech-to-text conversion through ASR, which in turn raises a new set of problems to be considered. First, the convenience and efficiency of reading transcripts are affected by errors produced in transcription channels, though if the goal is only to browse the most salient parts, recognition errors in excerpts can be reduced by considering ASR confidence (Xie and Liu, 2010; Hori and Furui, 2003; Zechner and Waibel, 2000) and the quality of excerpts can be improved from various perspectives (Zhang et al., 2010; Xie and Liu, 2010; Zhu et al., 2009; Murray, 2008; Zhu and Penn, 2006; Maskey and Hirschberg, 2005). Even if transcription quality were not a problem, browsing lengthy transcripts is not straightforward, since, as mentioned above, indicative browsing structures are barely manually created for and aligned with spoken documents. Ideally, such semantic structures should be inferred directly from the spoken documents themselves, but this is known to be difficult even for written texts, which are often more linguistically well-formed and less noisy than automatically transcribed text. This paper studies a less ambitious problem: we align an already-existing hierarchical browsing structure, e.g., the electronic slides of lecture recordings, with the sequential transcripts of the corresponding spoken documents, with the aim to help index and access such archives. Specifically, we study a number of semantic tree-to-string alignment models with different modeling capabilities and time complexities in order to obtain a comprehensive understanding of these models and hence the indexing task itself.

Semantic Structures of Spoken Documents Much previous work, similar to its written-text counterpart, has attempted to find certain *flat* structures of spoken documents such as topic and slide boundaries (Malioutov et al., 2007; Zhu et al., 2008), which, however, involve no hierarchical structures of a spoken document, thought as will be shown in this paper, topic-segmentation models can be considered in our alignment task. Research has also resorted to other multimedia channels, e.g., video (Fan et al., 2006), to detect slide

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 509–517,
Chiang Mai, Thailand, November 8 – 13, 2011.

transitions. This type of approaches, however, are unlikely to recover semantic structures more detailed than slide boundaries.

Zhu et al. (2010) investigate the problem of aligning electronic slides with lecture transcripts by first sequentializing bullet trees on slides with a pre-order walk before conducting alignment, through which the problem is reduced to a string-to-string alignment problem and conventional methods such as DTW (dynamic time warping) based alignment can then be directly applicable. A pre-order walk of bullet tree on slides is actually a natural choice, since speakers of presentations often follow such an order to develop their talks, i.e., they discuss a parent bullet first and then each of its children in sequence. However, although some remedies may be taken (Zhu et al., 2010), sequentializing the hierarchies before alignment, in principle, enforces a full linearity/monotonicity between transcripts and slide trees, which violates some basic properties of the problem that we will discuss. More recently, the work of (Zhu, 2011) proposes a graph-partitioning based model (revisited in Section 4) and shows that the model outperforms a bullet-sequentializing model.

With this previous work available, several important questions, however, are still open in obtaining a comprehensive understanding of the semantic tree-to-string alignment task. First of all, a basic question is associated with different ways of exploiting the semantic trees when performing alignment, which, as will be studied comprehensively in this paper, results in models of different modeling capabilities and time complexities. Second, all the models discussed above consider only similarities between bullets and transcribed utterances, while similarities among utterances, which directly underline a cohesion model, are generally ignored. We will show in this paper that the state-of-the-art topic-segmentation model (Malioutov and Barzilay, 2006) can be inherently incorporated into the graph-partitioning-based alignment models. Third, the different alignment objectives, e.g., that of the graph-partitioning models versus that of basic DTW-based models, are entangled together with different ways of exploiting the bullet tree structures in (Zhu, 2011). In this paper, we discuss two more quadratic-time models to bridge the gap.

Specifically, this paper studies nine different models, with the aim to provide a comprehensive understanding of the questions discussed above. In the remainder of the paper, we will first review the related work (Section 2) and more formally describe our problem (Section 3). Then we revisit the graph-partitioning alignment model (Section 4), before present all the alignment models we will study (Section 5). We describe our experiment setup in Section 7 and results in Section 8, and draw our conclusions in Section 9.

2 Related Work

Alignment of parallel texts In general, research on finding correspondences between parallel texts pervades both spoken and written language processing, e.g., in training statistical machine translation models, identifying relationship between human-written summaries and their original texts (Jing, 2002), force-aligning speech and transcripts in ASR, and grounding text with database facts (Snyder and Barzilay, 2007; Chen and Mooney, 2008; Liang et al., 2009). Our problem here, however, is distinguished in several major aspects, which need to be considered in our modeling. First, it involves segmentation—alignment is conducted together with the decision of the corresponding segment boundaries on transcripts; in other words, we are not finally concerned with the specific utterances that a bullet is aligned to, but the region of utterances. In such a sense, graph partitioning seems intuitively to be more relevant than models optimizing a full-alignment score. Second, unlike a string-to-string alignment task, the problem involves hierarchical tree structures. This allows for different ways of combining tree traversal with the alignment process, as will be studied in detail in this paper. Third, the hierarchical structures as well as the texts on them are fixed and unique to each document (here a lecture) and knowledge is little generalizable across different documents. We accordingly keep our solution in an unsupervised framework. Fourth, the length of transcripts and that of the hierarchies are very imbalanced, and the former can be as long as tens of thousands of utterances or hundreds of thousands of words, which requires a careful consideration of a model's time complexity.

Building Tables-of-contents on Written Text Learning semantic structures of written text has been studied in a number of specific tasks, which include, but not limited to, those finding semantic representations for individual sentences and

those constructing hierarchical structures among sentences or larger text blocks. A notable effort of the latter kind, for example, is the work of (Branavan et al., 2007), which aims at the ultimate goal of building tables-of-contents for written texts, though the problem was restricted to generating titles for each text span by assuming the availability of the structures of tables-of-contents and their alignments with text spans. Our work here can be thought of as an inverse problem, in which a specific type of semantic hierarchical structures are known, and we need to establish their correspondence with the spoken documents.

Rhetoric Analysis In general, analyzing discourse structures can provide thematic skeletons (often represented as trees) of a document as well as relationship between the nodes in the trees. Examples include the widely known discourse parsing work of (Marcu, 2000). However, when the task involves the understanding of high-level discourse, it becomes more challenging than finding local discourse conveyed on small spans of text; e.g., the latter is more likely to benefit from the presence of discourse markers. Specifically for spoken documents, speech recognition errors, absence of formality and thematic boundaries, and less linguistically well-formedness of the spoken language, will further impair the conditions on which an reliable discourse-analysis algorithm is often built. In this paper, we study a less ambitious but naturally occurring problem.

3 Problem

We are given a speech sequence $U = u_1, u_2, ..., u_N$, where u_i is an utterance, and the corresponding hierarchical structure, which, in our work here, is a sequence of lecture slides containing a set of slide titles and bullets, $B = \{b_1, b_2, ..., b_M\}$, organized in a tree structure $T(\Re, \aleph, \Psi)$, where $\Re$ is the root of the tree that concatenates all slides of a lecture; i.e., each slide is a child of the root $\Re$ and each slide's bullets form a subtree. In the rest of this paper, the word *bullet* means both the title of a slide (if any) and any bullet in it. $\aleph$ is the set of nodes of the tree (both terminal and non-terminals, excluding the root $\Re$), each corresponding to a bullet b_m in the slides. Ψ is the edge set. With the definitions, our task is herein to find the triple (b_i, u_j, u_k), denoting that a bullet b_i is mapped to a region of lecture transcripts that starts from the jth utterance u_j and ends at the kth, inclusively. Constrained by the tree structure, the transcript region corresponding to an ancestor bullet contains those corresponding to its descendants; i.e., if a bullet b_i is the ancestor of another bullet b_n in the tree, the acquired boundary triples (b_i, u_{j_1}, u_{k_1}) and (b_n, u_{j_2}, u_{k_2}) should satisfy $j_1 \leq j_2$ and $k_1 \geq k_2$.

4 Graph-partitioning Models: A Revisit

To facilitate our discussion later in this paper, we briefly revisit the graph-partitioning alignment model proposed in (Zhu, 2011), which, inspired by (Malioutov and Barzilay, 2006; Shi and Malik, 2000), extended a graph-partitioning model to find the correspondence between the bullets on electronic slides and transcribed utterances.

Consider a general, simple two-set partitioning case, in which a boundary is placed on a graph $G = (V, E)$ to separate its vertices V into two sets, A and B, with all the edges between these two sets being removed. The objective, as we have mentioned above, is to minimize the following normalized-cut score:

$$Ncut(A, B) = \frac{cut(A, B)}{assoc(A, V)} + \frac{cut(A, B)}{assoc(B, V)} \quad (1)$$

In equation (1), $cut(A, B)$ is the total weight of the edges being cut, i.e., those connecting A with B, while $assoc(A, V)$ and $assoc(B, V)$ are the total weights of the edges that connect A with all vertices V, and B with V, respectively. In general, minimizing such a normalized-cut score has been shown to be NP-complete. In our problem, however, the solution is constrained by the linearity of segmentation on transcripts, similar to that in topic segmentation (Malioutov and Barzilay, 2006). In such a situation, a polynomial-time algorithm exists (Zhu, 2011).

Consider a set of sibling bullets, $b_1, ..., b_m$, that appear on the same level of a bullet tree and share the same parent b_p. For the time being, we assume the corresponding region of transcripts has already been identified for b_p, say $u_1, ..., u_n$. We connect each bullet in $b_1, ..., b_m$ with utterances in $u_1, ..., u_n$ by their similarity, which results in a bipartite graph. Our task here is to place $m - 1$ boundaries onto the bipartite graph to partition the graph into m bipartite graphs and obtain triples, e.g., (b_i, u_j, u_k), to align b_i to $u_j, ..., u_k$, where $b_i \in \{b_1, ..., b_m\}$ and $u_j, u_k \in \{u_1, ..., u_n\}$ and $j <= k$. Since we have all descendant bullets to

help the partitioning, when constructing the bipartite graph, we actually include also all descendant bullets of each bullet b_i, but ignoring their orders within each b_i. We find optimal normalized cuts in a dynamic-programming process with the following recurrence relation:

$$C[i,k] = \min_{j \leq k} \{C[i-1,j] + D[i,j+1,k]\} \quad (2)$$

In equation (2), $C[i,k]$ is the optimal/minimal normalized-cut value of aligning the first i sibling bullets, $b_1, ..., b_i$, with the first k utterances, $u_1, ..., u_k$. It is computed by updating $C[i-1,j]$ with $D[i,j+1,k]$, for all possible j s.t. $j \leq k$, where $D[i,j+1,k]$ is a normalized-cut score for the triple (b_i, u_{j+1}, u_k) and is defined as follows:

$$D[i,j+1,k] = \frac{cut(A_{i,j+1,k}, V \setminus A_{i,j+1,k})}{assoc(A_{i,j+1,k}, V)} \quad (3)$$

where $A_{i,j+1,k}$ is the vertex set that contains the bullet b_i (including its descendant bullets, if any, as discussed above) and the utterances $u_{j+1}, ..., u_k$; $V \setminus A_{i,j+1,k}$ is its complement set.

Different from the topic segmentation problem (Malioutov and Barzilay, 2006), the graph-partitioning alignment model needs to remember the normalized-cut values between any region $u_j, ..., u_k$ and any bullet b_i in our task, which requires to use the additional subscript i in $A_{i,j+1,k}$, while in topic segmentation, the computation of both $cut(.)$ and $assoc(.)$ is only dependant on the left boundary j and right boundary k. Also, the similarity matrix here is not symmetric as in topic segmentation, but m by n, where m is the number of bullets, while n is the number of utterances.

As far as time complexity is concerned, the graph-partitioning models discussed above are quadratic with regards to N, i.e., $O(MN^2)$, where $M \ll N$; M and N denoting the number of bullets and utterances, respectively, with the loop kernel computing and filling $D[i,j,k]$ in equation 3, which is a $M \times N \times N$ matrix. Zhu (2011) applied the algorithm deterministically in traversing a bullet tree top-down: starting from the root, the normalized-cut algorithm finds the corresponding regions of transcripts for all the direct children of the root, fixes the regions, and repeats this process recursively to partition lower-level bullets. This whole algorithm is still quadratic $O(MN^2)$ but outperforms a bullet-sequentializing baseline.

5 Alignment Models

Now, we discuss the models that we will study further in this paper to address the problems rise earlier in the introduction section.

5.1 The $O(MN^4)$ Models

As discussed, Zhu (2011) proposed a graph-partitioning alignment model and applied it in a deterministic way along with a top-down traversal of bullet trees. Though such models could be very competitive in performance, an important question, however, is with regard to the performance of models that can optimize a global score rather than local ones on each set of sibling bullets, which requires a study of models with more modeling capability (containing the deterministic hierarchical models as a special case) and with higher time complexities.

Naively, searching all possible partitions to optimizing a global score needs to consider an exponential space in terms of the number of transcribed utterances, while applying dynamic programming similar to those used in syntactic parsing would keep the solution to be polynomial. In this section, we introduce such alignment models; or in another viewpoint, we formulate the alignment task in a parsing-like setting. A dynamic programming approach, e.g., that used in a conventional CYK parser, can be adapted to solve this problem, in which one can replace the splitter moving in each text span in the classic CYK with the quadratic bipartite-graph partitioning model discussed above. However, in our task here, the trees, unlike in a general parsing task, are given and fixed, meaning that the cells of a parsing table can be filled in a fixed order, i.e., a post order, so that the search speed can be improved by some constant.

Figure 1 shows an algorithm, in which we insert the bipartite graph partitioning model that works on sibling bullets (as discussed in Section 4) into a parsing search process (line (12)). We call this model **PrsCut**. Note that there are more than one way to conducting such a search, but they should yield the same results once the objective function, e.g., the normalized-cut score here, is the same.

Specifically, the *Main* function in Figure 1 takes as input an $M \times N$ similarity matrix, where, same as before, M and N denote the number of bullets and transcribed utterances in a lecture, respectively. The $Main$ function first computes the

```
Main
Input: simMat, an MxN similarity matrix
       root, the root of a bullet tree
Output: boundPos, bullets' boundaries on transcripts
1: cutCostTab = Cal_CutCostTab(simMat);
2: Build_Parsing_Tab(root, cutCostTab, prsTab);
3: boundPos = Decoding(root, prsTab);

Build_Parsing_Tab(curNd, cutCostTab, prsTab)
Input: curNd, current node/bullet in concern
       cutCostTab, an MxNxN normalized-cut cost table
Output: prsTab, an MxNxN parsing table
4: If current node curNd is a leaf then
5:    prsTab[curNd,:,:] = cutCostTab[curNd,:,:];
6: else
7:    for each child c^i of curNd do
8:       Build_Parsing_Tab(c^i, cutCostTab, prsTab);
9:    end for
10:   for i = 1...N do
11:      for j = i...N do
12:         bestScr = Bigraph_Alignment(curNd, prsTab, i, j);
13:         prsTab[curNd,i,j] = cutCostTab[curNd,i,j]+w*bestScr;
14:      end for
15:   end for
16: end if
```

Figure 1: An algorithm of optimizing a global normalized-cut score.

$cutCostTab$, which saves the $D[i, j+1, k]$ values defined by equation (3). Then the parsing table $prsTab$ is built with a post-order traversal algorithm *Build-Parsing-Tab*, followed by a decoding process that finds the optimal partitioning tree. As sketched in Figure 1, the *Build-Parsing-Tab* algorithm builds a 3-dimensional table $prsTab$, each cell saving a value that linearly combines the corresponding $cutCostTab$ value of the current node/bullet *curNd* and the optimal partitioning score $bestScr$ value calculated on its descendent, if any (see line (13)); or if the current node $curNd$ is a leaf itself, its $bestScr$ score is zero; in such case, the $prsTab$ value is initialized with the $cutCostTab$ value (line (5)). The recursive algorithm traverse the bullet tree in a post-order walk, which, as discussed above, utilizes the given, fixed bullet tree structures to fill the parsing table $prsTab$. The weight w in line (13) is set in a held-out data and note that if w is set to be 0, the model degrades to be the deterministic hierarchical model discussed in (Zhu, 2011) and referred to as $HieCut$ below in Section 5.2, since in this case the $prsTab$ is same as $costCustTab$. As far as time complexity is concerned, the whole algorithm is $O(MN^4)$, shown by the nested *for*-loops of line (10)-(15) that contain the $O(MN^2)$ bigraph-partitioning alignment in line (12). Similarly, we can insert a standard DTW-based alignment model into the line (12) here, which we call the **PrsBase** model. Note that the real algorithm is a little more complicated; e.g., we need to allow a parent bullet to have a different starting position than its first child, same as in (Zhu, 2011).

5.2 The $O(MN^2)$ models

Sequential Alignment Models As discussed earlier, in a simplified situation, our problem here can be formulated as a sequential alignment problem, based on a fairly reasonable assumption (Zhu et al., 2010): a speaker follows a pre-order walk of a bullet tree to develop the talk, i.e., discussing a parent bullet first, followed by each of its children in sequence. Accordingly, the models first sequentialize bullet trees with a pre-order walk before conducting alignment, through which the problem is reduced to a string-to-string alignment problem and conventional methods such as DTW-like alignment can then be applicable. Such a pre-order walk has also been assumed by (Branavan et al., 2007) to reduce the search space in their table-of-contents generation task, a problem in which a tree hierarchy has already been aligned with a span of written text, while the title of each node on the tree needs to be generated.

With this formulation, we first included here the baseline model in (Zhu et al., 2010), which applies a typical DTW-based alignment. We refer to the model as **SeqBase**. In addition, we applied the graph-partitioning based models discussed in (Zhu, 2011) to align the sequentialized bullets and the corresponding transcribed utterances, and we call this model **SeqCut**. The motivation of studying $SeqCut$ is to further understand the benefit of graph-partitioning based models. For example, it allows us to disentangle the benefit of the deterministic graph-partitioning models in (Zhu, 2011): whether the benefit is due to the modeling advantage of the proposed partitioning objective or its avoiding sequentializing bullet trees.

In principle, sequentializing bullet trees before alignment enforces a full linearity/monotonicity between transcripts and these bullet trees, which, though based on a reasonable assumption and is fairly effective (as will be shown in our comprehensive comparison later), misses some basic properties of the problem. For example, the generative process of lecture speech, with regards to a hierarchical structure (here, bullet trees), is char-

acterized in general by a speaker's producing detailed content for each bullet when discussing it, during which sub-bullets, if any, are talked about recursively. By the nature of the problem, words in a bullet could be repeated multiple times, even when the speaker traverses to talk about the descendant bullets in the depth of the sub-trees. That is, the content of a bullet could be mentioned not only before its children but also very likely when the speaker traverses to talk descendant bullets, if any, which violate the pre-order-walk assumption.

Though with shortcomings, an important benefit of formulating the task as a sequential-alignment problem is its computational efficiency: solutions can be acquired in quadratic time. This is of particular importance for this task, considering that the length of a document, such as a lecture or a book, is often long enough to make less efficient algorithms practically intractable. A natural question to be ask is therefore whether we can, in principle, model the problem better, but still keep the time complexity quadratic, i.e., $O(MN^2)$.

Deterministic Hierarchical Models Deterministically deciding bullets' boundaries on transcribed utterances when traversing the bullet tree can keep the solution within a quadratic time complexity and avoid a sequentialization of bullet trees beforehand. For example, in (Zhu, 2011), the graph-partitioning alignment model, as discussed above, is applied in such a deterministic way; the model recursively traverses a bullet tree by first determining transcript boundaries of the direct children of the root, fixing the boundaries found, and then determining boundaries for the descendant bullets recursively[1]. We refer to this model as $HieCut$ in this paper. Note that though working deterministically, this models utilize the similarities associated with all descendant bullets of the current sibling bullets under concern, to find the optimal boundaries between these siblings. In addition, we include a standard DTW-based alignment model in such a deterministic-decision process, called the **HieBase** model in the remainder of this paper.

One major benefit of the deterministic hierarchical alignment models is their time complexity: still quadratic, same as the sequential alignment model discussed above, though models like $HieCut$ can achieve a very competitive performance, which we will discuss in detail later. Also, the deterministic hierarchical models need less memories than the corresponding $O(MN^4)$ models and even the sequential models. For example, the memory needed by $HieCut$ is proportional to the maximal number of sibling bullets in a tree, not the total number of bullets.

[1] A pre-order walk can be used here (not for sequentializing bullet trees though); other top-down transversing methods are also applicable, e.g., a breadth-first search, once a parent bullet is visited before its children.

6 The Topic-segmentation Model

Up to now, we have discussed a variety of alignment models with different model capabilities and time complexities, which, however, consider only similarities between bullets and utterances. Cohesion in text or speech, by itself, often evidenced by the change of lexical distribution (Hearst, 1997), can also indicate topic or subtopic transitions, even among subtle subtopics (Malioutov and Barzilay, 2006). In our problem here, when a lecturer discusses a bullet, the words used are likely to be different from those used in another bullet, suggesting that the spoken documents themselves, when ignoring the alignment model above for the time being, could potentially indicate the semantic boundaries that we are interested in here. Particularly, the cohesion conveyed by the repetition of the words that appear in transcripts but not in slides could be additionally helpful; this is very likely to happen considering the significant imbalance of text lengths between bullets and transcripts, from which the alignment models by themselves may suffer.

$$C[i,k] = \min_{j \le k} \{C[i-1,j] + \lambda_1 D[i,j+1,k] + (1-\lambda_1) S[j+1,k]\} \quad (4)$$

where,

$$S[j+1,k] = \frac{cut(A_{j+1,k}, V \setminus A_{j+1,k})}{assoc(A_{j+1,k}, V)} \quad (5)$$

In fact, a state-of-the-art topic-segmentation model (Malioutov and Barzilay, 2006) (also called a cohesion model in this paper) can be naturally incorporated into the graph-partitioning alignment models that we have discussed. That is, we can augment the $SeqCut$, $HieCut$, and $PrsCut$ models with the cohesion models to form three new models **SeqCutTpc**, **HieCutTpc**, and **PrsCutTpc**, respectively. To achieve this, we modify equation (2) to equation (4), where $S[j+1,k]$ is calculated as in (Malioutov and Barzilay,

2006), which denotes the normalized partition cost of the segment from utterance u_{j+1} to u_k, inclusively. For complexity, since the cohesion model is $O(MN^2)$, linearly combining it would not increase the time complexities of the corresponding polynomial alignment models, which are at least $O(MN^2)$ by themselves.

7 Experiment Set-up

Corpus Our experiment uses a corpus of four 50-minute university lectures taught by the same instructor, which contain 119 slides composed of 921 bullets. The automatic transcripts of the speech contain approximately 30,000 word tokens, roughly equal to a 120-page double-spaced essay in length. The lecturer's voice was recorded with a head-mounted microphone with a 16kHz sampling rate and 16-bit samples, while students' comments and questions were not recorded. The speech is split into utterances by pauses longer than 200ms, resulting in around 4000 utterances. The slides and automatic transcripts of one lecture were used as the development set. In practice, each lecture is divided into three roughly equally-long pieces in all our experiments discussed below, for pragmatic computational consideration of calculating the $O(MN^4)$ models quickly enough.

Building the Graphs The transcripts were generated with the SONIC toolkit (Pellom, 2001), with the models trained as suggested by (Munteanu et al., 2007), in which one language model was trained on SWITCHBOARD and the other used also corpus obtained from the Web through searching the words on slides. Both bullets and automatic transcripts were stemmed with the Porter stemmer and stopwords were removed. The similarities between bullets and utterances and those between utterances were calculated with different distance metrics, i.e., cosine, exponential cosine (Malioutov and Barzilay, 2006) for topic segmentation, and a normalized word-overlapping score used in summarization (Radev et al., 2004), from which we chose the one (regular cosine) that optimizes our baseline. Our graph-partitioning models then used exactly the same setting. The lexical weighting is same as in (Malioutov et al., 2007), for which we split each lecture into M chunks, the number of bullets. Finally, we obtained a M-by-N bullet-utterance similarity matrix and a N-by-N utterance-utterance matrix to optimize the alignment model and topic-segmentation model, respectively, while M and N, as already mentioned, denote the number of bullets and utterances of a lecture, respectively.

Evaluation Metric The metric used in our evaluation is straightforward—automatically acquired boundaries on transcripts for each slide bullet are compared against the corresponding gold-standard boundaries to calculate offsets measured in number of words, counted after stopwords having been removed, which are then averaged over all boundaries to evaluate model performance. Though one may consider that different bullets may be of different importance, in this paper we do not use any heuristics to judge this and we treat all bullets equally in our evaluation. Note that topic segmentation research often uses metrics such as P_k and *WindowDiff* (Malioutov and Barzilay, 2006; Beeferman et al., 1999; Pevsner and Hearst, 2002). Our problem here, as an alignment problem, has an exact 1-to-1 correspondence between a gold and automatic boundary, in which we can directly measure the exact offset of each boundary.

8 Experimental Results

Alignment Models Table 1 presents the experimental results obtained on the automatic transcripts generated by the ASR models discussed above, with WERs of 0.43 and 0.48, respectively, which are typical for lectures and conference presentations in realistic and less controlled situations (Leeuwis et al., 2003; Hsu and Glass, 2006; Munteanu et al., 2007).

The results show that among the four quadratic models, i.e., the first four models in the table, $HieCut$ achieves the best performance. The results also suggest that the improvement of $HieCut$ over $SeqBase$ comes from two aspects. First, the normalized-cut objective used in the graph-partitioning based model seems to outperform that used in the baseline, indicated by the better performance of $SeqCut$ over $SeqBase$, since both take as input the same, sequentialized bullet sequence and the corresponding transcribed utterances. The DTW-based objective used in $SeqBase$ corresponds to finding the optimal path that maximizes the similarity score between the bullet sequence and the transcripts. Second, the better performance of $HieCut$ and $SeqCut$ shows that $HieCut$ further benefits from avoiding sequentializing the bullet trees. However, this two

aspects of benefit do not come independently, since the former (performance of an alignment objective) can significantly affect the latter (whether a model can benefit from avoiding sequentializing bullets). This is evident in the inferior performance of $HieBase$. Manual analysis of its errors shows that $HieBase$ is less accurate than $HieCut$ on higher-level bullets and the errors in turn severely impair the decisions made on lower-level bullets in the deterministic decision process: the errors propagate severely in such a deterministic process.

Models	WER=0.43	WER=0.48
SeqBase	15.19	18.44
SeqCut	12.87	16.16
HieBase	21.06	24.25
HieCut	12.13	15.95
PrsBase	15.05	18.18
PrsCut	12.05	15.20

Table 1: The performances of different alignment models.

A closer examination of errors made by $HieBase$ suggests that in a DTW-based alignment, a large subtree is likely to be aligned to a region larger than it should be, particularly for higher-level bullets (e.g., slides), where the subtree sizes vary more, e.g., some slides containing much textual content and others containing little. It seems that $HieCut$ could counteract this effect with its capability of normalizing partition sizes (see the denominators in both equation (1) and (3)). The usefulness of the normalization has also been discussed in other tasks such as image segmentation (Shi and Malik, 2000). Compared with those of $HieBase$, segments in the $SeqBase$ model are smaller (all non-leaf bullets do not include its descendants after being sequentialized) and the pre-order walk constrains the alignment range of bullets, which often avoid errors of long offsets. Again, the $HieCut$ model is quadratic in time, it uses less memories than the $O(MN^4)$ models and even the $SeqCut$ model, and it achieves a very competitive overall performance.

The results in Table 1 also shows that the ($O(MN^4)$) models, which conduct a more thorough search, improve the performance in all situations.

Effect of Topic-segmentation Models The effect of the topic-segmentation model is presented in Table 2. To facilitate reading, we also copy here the relevant results from Table 1. The results show that incorporating text cohesion additionally reduces the errors consistently for all models, though the specific improvement varies.

Models	WER=0.43	WER=0.48
SeqCut	12.87	16.16
SeqCutTpc	12.77	15.14
HieCut	12.13	15.95
HieCutTpc	11.82	15.28
PrsCut	12.05	15.20
PrsCutTpc	11.34	14.62

Table 2: The effect of topic-segmentation models.

9 Conclusions

In addressing the semantic tree-to-string alignment problem described, this paper proposes and studies a number of models with different modeling capabilities and time complexities. Experimental results show that among the quadratic alignment models ($O(MN^2)$), $HieCut$ consistently achieves the best performance, while the $O(MN^4)$ models that optimize a global objective score further improve the performance, though such models are, pragmatically, much more computationally expensive. This paper also relates alignment models with topic-segmentation models by showing that a state-of-the-art topic-segmentation models can be inherently incorporated into the graph-partitioning based alignment models. The experimental results show the benefit of considering such cohesion knowledge.

Abstract

The evaluation of named entity recognition (NER) methods is an active field of research. This includes the recognition of named entities in speech transcripts. Evaluating NER systems on automatic speech recognition (ASR) output whereas human reference annotation was prepared on clean manual transcripts raises difficult alignment issues. These issues are emphasized when named entities are structured, as is the case in the Quaero NER challenge organized in 2010. This paper describes the structured named entity definition used in this challenge and presents a method to transfer reference annotations to ASR output. This method was used in the Quaero 2010 evaluation of extended named entity annotation on speech transcripts, whose results are given in the paper.

1 Introduction

Named Entity Detection has been studied since the MUC conferences in 1987. The notion has been extended to deal with mono- or multi-word expressions that belong to a potentially interesting class for an application. Given a set of entity definitions and a natural language corpus, systems try to extract and categorize all the relevant occurring entities. These entities can be used to feed further systems such as Information Retrieval, Question-Answering, Distillation, Terminology studies, etc.

Traditional Named Entity Recognition (NER) is a task where proper nouns and numerical expressions are extracted from documents and classified into categories (person, location, organization, date, etc.). As shown by Voorhees and Harman (2000), it is a key technology of Information Extraction (IE) and Open-Domain Question Answering. NER is also used as a fundamental component in a variety of language processing applications such as text clustering, topic detection, and summarization.

While significant progress has been reported on the NER task, most of these approaches have generally focused on clean textual data such as Sang and Meulder (2003). In the mean time, Kubala et al. (1998), Palmer et al. (1999), Turmo et al. (2009) and many others have focused on speech data. Named Entity detection evaluation over French spoken data has been proposed within the Ester II project, as described by Galliano et al. (2009).

Within the framework of the *Quaero* project,we proposed an extended named entity definition with compositional and hierarchical structure. This extension raises new issues and challenges in NER evaluation. First, as we shall explain below in more detail, the usual evaluation methods cannot compute the Slot Error Rate (SER) metric when named entities are compositional and recursive. Second, following Burger et al. (1998) and Hirschman et al. (1999), we consider that the evaluation of named entity recognition on noisy text output by automatic speech recognition (ASR) systems should take as reference the named entities found in the human annotation of a human-transcribed text: what *should have been there* in the ASR output. This requires to project the clean reference to the noisy text, which is made all the more difficult because of the compositional and hierarchical structure of the named entities.

The remainder of the paper is structured as follows. We first present the extended named entities in Section 2, then the evaluation protocol in Section 3 with specific metrics adapted to the structure of the evaluated objects and data. Section 4 illustrates their use in a challenge and discusses system results in this challenge. Finally in Section 5 we conclude and draw perspectives for further work.

2 Extended Named Entities

In this section, we present our extension to named entities, starting with related work (Section 2.1) and specifying their scope (Section 2.2). Our entities are hierarchical (Section 2.3) and compositional (Section 2.4). Section 2.5 provides a discussion of the issues they raise in the evaluation of named entity recognition from speech transcripts.

2.1 Named Entity Types

Named Entity recognition was initially defined as recognizing proper names (Coates-Stephens, 1992). Since MUC-6 (Grishman and Sundheim, 1996), named entities are proper names categorized into three major classes: persons, locations and organizations. Proposals have been made to sub-divide these entities into finer-grained classes. For example, politicians for the person class by Fleischman and Hovy (2002) or cities for the location class by Fleischman (2001) as well as Lee and Lee (2005).

The CONLL conference added a miscellaneous type which includes proper names outside the previous classes. Some classes are sometimes added, e.g. product by Bick (2004). Some numerical types are also often described and used in the literature: date, time, and amounts (money and percents in most cases).

Specific entities have been proposed and handled for some tasks, e.g. language and shape by Rosset et al. (2007), or email address and phone number (Maynard et al., 2001). In specific domains, entities such as gene, protein, DNA etc. are also addressed (Ohta, 2002) and campaigns are organized for gene/protein detection (Kim et al., 2004; Galibert et al., 2010)). More recently larger extensions have been proposed: Sekine (2004) defined a complete hierarchy of named entities containing about 200 types.

2.2 Scope

Named Entities often include four major groups: name, quantity, date and duration. The overall task in which we frame information extraction is the extraction of entities and relations to build a fact base from news sources. We thus decided to start from the traditional named entities used in information extraction from newspaper corpora. We then included named entities extensions proposed by Sekine (2004) for products and Galliano et al. (2009) for functions, and we extended the definition of named entities to some expressions which are not composed of proper names (e.g., phrases built around substantives).

In this work, we decided to extend the coverage of the named entities rather than sub-dividing the existing classes as it has been done in previous work. As we aimed to build a fact database from news data, we chose to support new kinds of entities (time, function, etc.) in order to extract a maximum of information from the corpus we processed. Compared to existing named entity structuration, our approach is more general than the extensions that have been done for specific domains, and is simpler than the complete hierarchy defined by Sekine (2004). This structure allows us to cover a large amount of named entities with a basic categorization so as to be quickly suitable for all further annotation work. The extended named entities we defined are both hierarchical and compositional (Grouin et al., 2011). This hierarchical and compositional nature of the extended named entities imply a specific method when evaluating system outputs (see Section 3).

2.3 Hierarchy

We used two kinds of elements: types and components. The types with their subtypes categorize a named entity. While types and subtypes were used previously, we consider that structuring the contents of an entity (its components) is important too. Components categorize the elements inside a named entity.

Types and subtypes refer to the general category of a named entity. They give general information about the annotated expression. The taxonomy is composed of 7 types and 32 sub-types:

- Person: *pers.ind* (invidual person), *pers.coll* (collectivity of persons);
- Location: administrative (*loc.adm.town, loc.adm.reg, loc.adm.nat, loc.adm.sup*) and physical (*loc.phys.geo, loc.phys.hydro, loc.phys.astro*);
- Organization: *org.ent* (services), *org.adm* (administration);
- Amount: quantity (with unit or general object), duration;
- Time: date *time.date.abs* (absolute date: "November 8, 2011"), *time.date.rel* (date relative to the discourse: "yesterday"), and hour

time.hour.abs (absolute hour), *time.hour.rel* (hour relative to the discourse);

- Production: *prod.object* (manufactury object), *prod.art* (artistic products), *prod.media* (media products), *prod.fin* (financial products), *prod.soft* (software), *prod.award, prod.serv* (transportation route), *prod.doctr* (doctrine), *prod.rule* (law);
- Functions: *func.ind* (individual function), *func.coll* (collectivity of functions).

Types and subtypes constitute the first level of annotation. They refer to a general segmentation of the world into major categories. Within these categories, we defined a second level of annotation we call *components*.

Components can be considered as clues that help the annotator (human or system) to produce an annotation: either to determine the named entity type (e.g. a first name is a clue for the *pers.ind* named entity subtype), or to set the named entity boundaries (e.g. a given token is a clue for the named entity, and is within its scope, while the next token is not a clue and is outside its scope). Components are second-level elements, and can never be used outside the scope of a type or subtype element.

An entity is thus composed of components that are of two kinds: transverse components that can fit each type of entity, and specific components only used for a reduce set of components:

1. Transverse components
   - *name* (the entity name),
   - *kind* (hypernym of the entity),
   - *qualifier* (a qualifying adjective),
   - *demonym* (inhabitant or ethnic group name),
   - *val* (a number),
   - *unit* (a unit),
   - *object* (an object),
   - *range-mark* (a range between two values).
2. Specific components
   - *name.last, name.first, name.middle, title* for “pers.ind" (Figure 1),
   - *address.number, po-box, zip-code, other-address-component* for “loc.add.phys",
   - and *week, day, month, year, century, millenium, reference-era, time-modifier* for “time.date" (Figure 3).

2.4 Composition

During the Ester II evaluation campaign, there was an attempt to use compositionality in named entities for two categories (persons and functions) where a person entity could contain a function entity.[1] Nevertheless, the evaluation did not take into account this inclusion and only focused on the encompassing annotation.[2]

In the present work, we also considered the compositional nature of those extended named entities. Entities can be compositional for three reasons:

1. a type contains a component: the *pers.ind* type is composed of several components such as *name.first* and *name.last* (Figure 1);

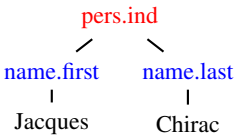

Figure 1: Basic type and component inclusion.

2. a type includes another type, used as a component. Cases of inclusion can be found in the *function* type (Figure 2), where type *func.ind*, which spans the whole expression, includes type *org.adm*, which spans the single word *Budget*:

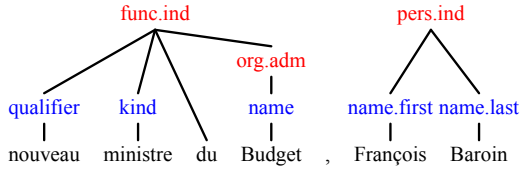

Figure 2: Multi-level annotation of entity types (red tags) and components (blue tags): *new minister of budget , François Baroin*.

[1] Example of compositionality in Ester II campaign: *<pers.hum> <func.pol> président </func.pol> <pers.hum> Chirac </pers.hum> </pers.hum>*

[2] Final annotation: *<pers.hum> président Chirac </pers.hum>*

3. in cases of metonymy (a term is substituted for another one in a relation of contiguity) and antonomasia (a proper name is used as a substantive and vice versa), where a type of entity is used to refer to another entity type (Figure 3). The type to which the entity intrinsically belongs is annotated. This entity is over-annotated with the type to which the expression belongs in the considered context:

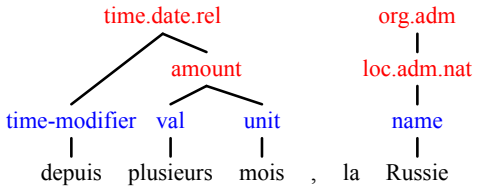

Figure 3: Annotation with types (red tags) and components (blue tags) including metonymy: *since several months , Russia. . .*

2.5 Discussion

Due to its non-flat structure, the representation of compositionality in extended named entities is richer than that used so far in spoken language understanding, compared with Bonneau-Maynard et al. (2006) and Mori et al. (2008); due to its extended definition, it is also richer than that used in named entity detection, in contrast with Galliano et al. (2009) or Nadeau and Sekine (2007). This calls for novel ways to evaluate named entity detection systems.

A consequence of the representation's richer structure is an increased complexity in the evaluation methodology. The 1:1 comparisons applied to traditional, flat named entities must give way to the mapping-based approaches we will present in the next section.

Moreover, when working on speech, evaluating the results of systems applied to automatic speech transcriptions is central to real-world use cases. This leads us to the issue of evaluating named entity detection systems applied to noisy inputs (produced by automatic speech recognition systems) using references built on clean data (manual transcriptions). The reference projection approach we propose will be described in the second half of the next section.

3 Evaluation methodology

We now come to the issues raised by the evaluation of automatically annotated extended named entities in speech transcripts. We first lay out the basic evaluation metrics (Section 3.1), then address the issues raised by compositionality (Section 3.2) and by ASR output errors (Section 3.3).

3.1 Metrics

The metrics used in Named Entity extraction evaluation are precision (P), recall (R), and their weighted mean F-measure (F) (van Rijsbergen, 1979). They are easy to use, since they only require to determine whether a hypothesized entity element is correct or not.

Let Ref = total number of elements in the reference, Hyp = total number of elements in the hypothesis, and C = number of correct elements in the hypothesis. Precision is defined as the observed probability for a hypothesized element to be correct:

$$P = \frac{C}{Hyp}$$

In the same way, recall is the observed probability for a reference element to have been found:

$$R = \frac{C}{Ref}$$

F-measure is the weighted harmonic mean of P and R, generally balanced with $\beta = 1$:

$$F = \frac{(1+\beta^2)RP}{\beta^2 P + R}$$

The main issue in these metrics lies in their binary decision process: either an entity element is correct, or it is not, whereas we generally want finer control.

Errors in named entities are in fact bidimensional: their span or their type can be incorrect. It is interesting to count only "half an error" if one of the two is correct. Within each category, some errors can be considered as less severe than others (e.g., presence of a determiner in span errors, entity types with fuzzy boundaries in the annotation guide).

A popular alternative is to proceed with an *error enumeration* approach, such as the Slot Error Rate (SER) defined by Makhoul et al. (1999): collect the individual errors, sum a cost for each one and divide the total by the number of elements in the reference (the slots). In our case, we went

for a simple weighting scheme where insertions (I), deletions (D) and elements with errors both in span and in type (S_{ST}) cost 1, while elements with errors only in either span (S_S) or type (S_T) cost 0.5. Span or type errors are substitutions (S_S, S_T, and S_{ST}).

We chose our final score as:

$$\text{SER} = \frac{D + I + S_{ST} + 0.5 \times (S_S + S_T)}{Ref}$$

Dividing by Ref normalizes the result, allowing us to compare results more easily across different files. This value is traditionally expressed as a percentage.

3.2 Evaluation on manual transcriptions

For simple annotation guides with no compositionality, enumerating all errors is easy: a word can only be associated with at most one entity in the reference, and likewise in the hypothesis, so entities can be directly compared when they have common words without any ambiguity.

In our case, the annotation compositionality makes things harder. Entity elements (entities or components) can be nested, and words are usually associated to at least two elements: one entity and one component, and sometimes more. The enumeration phase needs to establish explicitly which hypothesis element should be compared with each reference element.

Building on methodologies used in speech diarization evaluation (Diarization Error Rate), we defined a *mapping* as a set of 1–1 associations between reference and hypothesis elements. Each element from one side can be associated to at most one from the other side, and a number of elements can remain unassociated on both sides. From a given mapping, an error list can be built, where associated elements result in either correct matches or substitutions, and unassociated elements result in insertions and deletions. Hence given a mapping, a score can be computed. The final score of a system is then defined as the minimal error rate attainable over all possible mappings.

Enumerating all possible mappings is unthinkable. Since the score is additive, and restricting the acceptable associations to elements with at least one common word, it becomes possible to apply a dynamic programming approach. We thus use a variant of the Viterbi algorithm where "time" is the word stream, "probability" the score and "hidden state" the associations.

The text is split into a series of segments cut where reference or hypothesis entities start or end. An empty association hypothesis is first created, then segments are handled in the text order.

Two phases are applied for each segment: the first one, *opening*, expands the association hypothesis set by combining each one with every possible association choice for each of the entities beginning at the segment start. Two constraints are applied at this level: an entity can only have zero or one association, and associations must not cross one another (i.e. parent-descendant links between entities must not be inverted when projected through the association set).

Once all hypotheses are built, the *closure* phase follows where ending entities are taken into account. The post-segment state of each association hypothesis is computed, including its score, and for every set of equivalent hypotheses in a dynamic programming sense, only the best score is kept.

Two association hypotheses are considered equivalent if, for every entity present in both closing and following segments, the specific hypothesized associations are identical. We underline that where no entity is present in the text (reference or hypothesis), only one association hypothesis is left. The same happens at the end of the text where the remaining association is the optimal one.

3.3 Generalization to automatic transcriptions

The main issue when evaluating a Named Entity extraction system over Automatic Speech Recognition (ASR) systems output is: what must be evaluated first? We can either evaluate *what is there* (the system annotation) or *what should have been there*.

A system should not be penalized for missing things that have been lost earlier in the pipeline, or extracting entities that were not actually said but are present in ASR output. This leads us to an evaluation methodology equivalent to that of manual transcriptions.

The ASR output is just considered as a distinct, independent document, to be annotated by humans and by systems, and the results are compared. The human annotation part becomes way more difficult. It is quite hard to annotate documents in which parts make no sense, where adjudication discussions can become endless. More sig-

nificantly for an application, ASR is a step in the document handling pipeline where the end user is only interested in the final result.

We thus decided to evaluate system performance compared to *what should have been there*, expecting the systems to find the entities present in the manual transcriptions whatever the quality of the ASR output. There is room thus for developers to try methodologies to cope with ASR errors using a higher-level understanding of annotations.

Reference projection. To evaluate system output from noisy text with a reference built from a clean text, we followed Burger et al. (1998) and Hirschman et al. (1999) who proposed to *project* the clean reference on the noisy text in order to build a new reference. That new reference then allows us to apply the clean text methodology.

This projection method consists in finding new positions for the frontiers through either a dynamic programming alignment (standard sclite-type ASR evaluation alignment) or a phone-level dynamic programming alignment using canonical phonetizations. They noticed the result was too strict frontier-wise and required reducing the weight of frontier errors to obtain significant results.

In Question Answering from speech transcripts evaluation, Moreau et al. (2010) required that QA systems extract answers to natural language questions from ASR outputs of broadcast news shows. The inherent application was to replay the sound segment containing the answer, with a time interval as an answer; it tolerated a time interval around the boundaries. The results were satisfactory.

We thus decided to project the clean reference on the noisy text following five steps:

1. Build a forced alignment of the reference text to the speech signal;

2. Extract the start and end times from the reference annotations using the alignment;

3. Select a tolerance time interval;

4. Find the ASR word frontiers within the tolerance intervals placed around the frontiers of reference entity elements;

5. Build a *fuzzy* reference when multiple frontiers are possible.

A fuzzy reference means that each reference element can have multiple frontiers, which is equivalent to having multiple references, and choosing the one that gives the best score for the system. The number of possible references is way too large and the enumeration has to be done locally and coupled with the Viterbi alignment to reduce the search space to tolerable limits.

Apart from the alignment algorithm, the main difficulty is that a structurally correct reference post-projection does not always exist. Indeed, the ASR system may not output words where an entity element is supposed to be, or may merge small words into a larger one, preventing from fitting all reference elements to the available words. Such colliding elements have to be handled and we decided when encountered to remove one arbitrarily. They are rare enough for that decision to have a minor impact on the scores.

A more satisfactory method would be to merge the colliding elements into one when possible, creating reference elements with multiple acceptable types. Figure 4 illustrates the results of building a fuzzy reference.

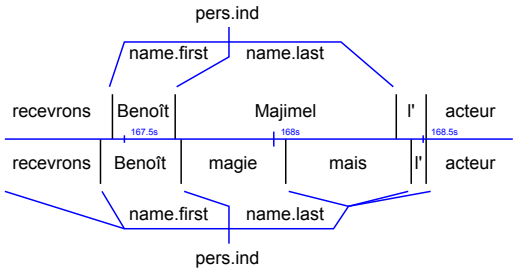

Figure 4: Example of a fuzzy reference built by temporal alignment of clean reference and noisy transcript

The top part of the figure shows the manual reference (clean reference), with a *pers.ind* entity "Benoît Magimel" which is decomposed into two components *name.first* "Benoît" and *name.last* "Magimel". In the middle, the temporal line shows the results of the forced alignment of these words on the audio signal.

In the lower part of the figure is the ASR result, "recevrons Benoît magie mais l' acteur", with its own temporal positions as given by the ASR system itself. Accepting any frontier within an interval then gives us the final fuzzy reference at the bottom, where the *name.first* component and the associated *pers.ind* can either start before "re-

cevrons" or just after, the *name.first—name.last* transition still happens after "Benoït", and the *name.last* and complete entity can stop either after "magie", "mais" or "l"'.

In our case, all systems gave the same hypothesis with "Benoït" as both *pers.ind* and *name.first*, which gave them one correct (the *name.first*), one bad frontier (the *pers.ind*) and one miss (the *name.last*). A more advanced system could have used "Benoït" as a trigger to search for "Magimel", and other last names associated with that specific first name, in a phonetic representation of the following words, or in the signal itself. Then, it may have output "magie mais" or "magie mais l"' as the last name. It is interesting to note that either hypothesis would have ended with a perfect score for the system. That example shows how the fuzzy projection methodology opens the door to the evaluation of more advanced systems that try to use higher-level knowledge to see through the ASR system errors.

An interesting and useful side effect of the mapping methodology we used is that the chosen mapping is human-readable. One can check what associations were chosen and in the ASR case what frontiers were selected among the possible ones. This is useful for both error analysis and convincing oneself of the quality of the evaluation measure. It also makes it possible to merge all of the systems outputs in an evaluation and collate the errors in order to help correct the references more efficiently where needed.

4 Quaero evaluation results

As an illustration of the use of the extended named entities and of the evaluation methods introduced above, we present here an evaluation of extended named entity recognition from speech transcripts, which we organized in the context of the project Quaero. The task consisted in extracting and categorizing a large number of named entities in transcriptions of broadcast spoken data in French. Three teams participated, each with one NER system.

The training data were those of the Ester II evaluation campaign: 188 shows from various sources have been manually transcribed and annotated given this new definition of extended named entities (Table 1, Training). The test data were composed of test and development data from the Quaero 2010 ASR evaluation (Table 1, Test) (Lamel, 2010). Several test data versions were provided:

- a manual transcription prepared by a human expert,
- three different ASR outputs (ASR1, ASR2, ASR3) with a word error rate (WER) ranging from 20.96% to 27.44% (Table 1, last three rows), and
- an improved version of the ASR1 output, where punctuation and capitalization have been automatically added (ASR1+).

The training data consisted of Broadcast News data (BN) while the test data included Broadcast News data and more varied data including talk shows and debates (Broadcast Conversations, BC; see Table 1, last two columns). One of the objectives of this work was to measure the robustness of the NER systems against different types of data and unknown types of data.

Inf. \ Data	Training	Test	Test BN	Test BC
# shows	188	18	8	10
# lines	43289	5637	1704	3933
# distinct words	39639	10139	5591	6836
# words	1251586	97871	32951	64920
# types	113885	5523	2762	2761
# distinct types	41	32	28	29
# compon.	146405	8902	4541	4361
# distinct compon.	29	22	22	21
WER ASR1	–	20.96%	16.32%	23.34%
WER ASR2	–	21.56%	18.77%	22.99%
WER ASR3	–	27.44%	24.06%	29.18%

Table 1: Data description.

Table 2 shows the results of the three participating NER systems, with a breakdown into broadcast news and broadcast conversations.

On the manual transcriptions, values of slot error rate (SER) ranged from 33.3% to 48.9% for the NER systems on the whole data. Similarly to the ASR systems, NER systems obtained better SER (from 29.7% to 42.7%) on broadcast news than on broadcast conversations (37% to 55.3%).

	Whole data				
	Man.	ASR1	ASR1+	ASR2	ASR3
P1	48.9%	71.4%	71.1%	68.3%	75.2%
P2	33.3%	61.1%	66.3%	59.3%	63.2%
P3	41.0%	72.2%	68.7%	70.7%	72.9%
	Broadcast News data				
P1	42.7%	55.3%	52.7%	58.5%	61.4%
P2	29.7%	48.5%	53.8%	52.2%	53.5%
P3	39.1%	55.6%	54.5%	60.3%	61.8%
	Broadcast Conversations data				
P1	55.3%	87.9%	89.9%	78.3%	89.2%
P2	37.0%	73.9%	79.0%	66.6%	73.0%
P3	43.0%	89.3%	83.3%	81.2%	84.1%

Table 2: SER results for the overall data, broadcast news data and broadcast conversations data. The ASR1+ column is a version of the ASR1 with automatically added punctuation and capitalization.

Obviously, the SER worsened when dealing with ASR outputs, which are all true case (*i.e.*, upper and lower case are those expected in normal text). The loss ranged from 19.4% (P1 on ASR2 with a 21.56% WER) to 33% (P2 on ASR1+ with 20.96% WER). It is interesting to note that the ASR1+ system, which is ASR1 with automatically added punctuation and capitalization at the beginning of sentences, hindered system P2.

Another interesting point is that the ASR2 output with a higher WER than the ASR1 system on the whole data allowed better performance for entity detection than the ASR1 output.

5 Conclusion and perspectives

In this paper, we presented a representation of structured named entities, and methods to evaluate the recognition of such structured named entities. We contributed a mapping between reference and hypothesis elements which allows us to enumerate errors and compute the value of the slot error rate. We also provided a projection of extended named entities from a clean reference to noisy texts produced by automatic speech transcription systems, which allows us to compute the slot error rate against what was actually said rather than against what was recognized by the ASR systems.

These extended named entities and evaluation algorithms have been used in the Quaero Named Entities on Spoken Data evaluation. Evaluation results are consistent with expectations, which is a first test of the validity of the method. Indeed, further work is planned to study more closely and more systematically the obtained alignments.

Compared to the recognition of standard named entities, this new task is harder for systems, but this new structuring will be useful to make information extraction more precise. Moreover, the evaluation methodology we proposed is very flexible and should be usable for other tasks such as syntactic analysis on spoken data. An interesting and useful side-effect of this mapping methodology is its human readability. This makes it easier to check the chosen associations, as well as the selected frontiers in the ASR case.

This work is useful for both error analysis and convincing oneself of the evaluation measure quality. It also makes it possible to merge all systems outputs in an evaluation and collate the errors to help correct the reference more efficiently where needed.

Due to the scarcity of annotated corpora in named entities, we plan to provide both guidelines and annotated corpora for free to the scientific community.

Acknowledgments

This work was partly realized as part of the Quaero Programme, funded by OSEO, French State agency for innovation and by the French ANR ETAPE project.

Normalising Audio Transcriptions for Unwritten Languages

Adel Foda* and **Steven Bird†**

Abstract

The task of documenting the world's languages is a mainstream activity in linguistics which is yet to spill over into computational linguistics. We propose a new task of transcription normalisation as an algorithmic method for speeding up the process of transcribing audio sources, leading to text collections of usable quality. We report on the application of sentence and word alignment algorithms to this task, before describing a new algorithm. All of the algorithms are evaluated over synthetic datasets. Although the results are nuanced, the transcription normalisation task is suggested as an NLP contribution to the grand challenge of documenting the world's languages.

1 Introduction

The majority of the world's 6800 languages are relatively unstudied. Although some of the world's languages have been carefully described and analysed, most of them have not yet even been documented. Such documentation consists of 'comprehensive and transparent records supporting wide ranging scientific investigations of the language' (Woodbury, 2010). In this context then, it is striking that 50 years of research in computational linguistics have so far only touched about 1% of the world's languages. In 100 years, 90% will be extinct or on the way out (Krauss, 2007). Accordingly, we set ourselves the following question: what can computational linguistics offer to support the urgent task of documenting and analyzing the world's endangered languages? There have been other recent efforts to address this question, focussing on interlinear text (Xia and Lewis, 2007; Baldridge and Palmer, 2009). Our focus is different, being concerned with creating the unannotated text that is presupposed by this earlier work. We also differentiate our work from more general computational support for documentary and descriptive linguistics, such as tools for transcribing audio or editing lexicons.

Recently, Abney and Bird (2010) have proposed to incorporate *machine translation* (MT) into the workflow of language documentation. However, a significant challenge for this program is posed by the fact that the majority of the world's languages are not written. How can NLP techniques be applied to improve the speed and efficiency of audio transcription for unwritten languages?

The task of transcription differs from transliteration (Knight and Graehl, 1998) in several ways. Transliteration is required in the context of machine translation for dealing with proper names, which are a common source of out-of-vocabulary items. The goal is to make the words pronounceable in a target language having a different inventory of sounds and syllables, and having different grapheme-to-phoneme rules. Since the source and target languages have established orthographies, the correct placement of word boundaries is never in question.

Transcription, on the other hand, involves representing spoken utterances in written form. In the absence of a standard orthography or lexicon, two transcribers will usually represent sounds using different symbols, and will often disagree on the placement of word boundaries. Transcribers may use a mixture of conventions from other languages, e.g. "vowels as in Italian, consonants as in English", and may invent their own system of diacritics. The goal is to faithfully capture all of the significant aspects of pronunciation. By obtaining many independent transcriptions of the same utterance, we can hope that the most consistent practices will come to dominate, giving rise to a collectively-defined system of normalized transcriptions.

This paper reports on an investigation into algorithmic methods for normalising sets of transcriptions of an audio recording. We begin by describing the role that MT could yet play in language documentation efforts, and discuss the initial challenge of audio transcription (section 2). Next, we observe that the problem of aligning the words of two audio transcriptions is analogous to sentence-by-sentence alignment of two documents: there is no-reordering, and only contiguous material needs

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 527–535,
Chiang Mai, Thailand, November 8 – 13, 2011.

to be split or merged. In section 3, we perform transcription alignment and evaluate its effectiveness by adapting two existing algorithms. In section 4 we describe a novel method using an extension of Hidden Markov Models in order to infer the hidden 'sound' sequence heard by transcribers. This permits each transcription to be normalised into a sequence of 'sounds'. Each of the methods is evaluated using synthetic data (section 5), data that has been generated in order to have known ground truths on which to evaluate the methods.

2 MT for unwritten languages

Recently, Abney and Bird (2010) have proposed to incorporate MT into the workflow of language documentation. MT supports the task of ensuring interpretability of the language records. It is not feasible to construct richly annotated resources, such as treebanks, for low-density languages. Instead, as argued by Abney and Bird (2010), we should take translation into English (or some other reference language) to be an adequate representation of the meaning of source language texts. Furthermore, also following (Abney and Bird, 2010), we assume that a language documentation is only complete if an adult who is already proficient in one of the world's major languages is able to acquire fluency in the language using only the archived bilingual resources. Obviously, such a test would take years to perform, and would need to be done again, each time the resources for a language are updated. However, a statistical machine translation (SMT) system can attempt this acquisition automatically, and its mistakes highlight any shortcomings in the documentation while there is still time to collect more. All that is required then, is substantial quantities of bilingual text, or n-lingual text in the general case, in machine-readable format. A structure that has been proposed to accommodate this data is the *Universal Corpus*.

A significant challenge for this program is posed by the fact that the majority of the world's languages are not written. Amongst the remaining languages that have a writing system, the majority do not have widespread literacy. Even where literacy is widespread, the majority of languages do not have a substantial community of writers. Finally, the presence of an orthography and users of the orthography does not ensure consistent spelling. How then, could we hope to obtain significant quantities of text in such languages?

Substantial efforts are already underway to record the oral literature of endangered languages while there is still time. This is painstaking work, and transcription is usually a slow process given the issues with orthography just identified. However, such transcriptions are an essential step to the creation of other language resources such as lexicons and grammars. This leads to a more narrowly focussed question: how can NLP techniques be applied to improve the speed and efficiency of audio transcription for unwritten languages?

Let us suppose that, for a given language, several native speakers were available to transcribe large quantities of audio recordings. We can be sure that no two speakers will transcribe the same source recording the same way. There will be variations in spelling, word segmentation, capitalisation, punctuation, and so forth. These variations will stem from varying levels of education, and varying experience of literacy in other languages. With enough resources, we could arrange for each source to be transcribed by more than one speaker. What would it take to automatically combine and normalise these transcriptions to produce a single transcription per source, of sufficient quality to be useful for downstream language technologies? These normalised transcriptions could then be aligned with manually supplied translations, leading to a bitext collection.

3 Existing methods

3.1 The Gale-Church Algorithm

The Gale-Church Algorithm (GCA) aligns the sentences of a document with those of its translation in a foreign language (Gale and Church, 1993). The algorithm exploits the fact that longer sentences in one language tend to correspond to longer sentences in the other. A pair of documents is aligned into cliques of zero, one or two consecutive sentences from each language.

Model Description. The model assumes that for a sentence of length L_1, the length of the corresponding clique of sentences in the foreign language is distributed as:

$$L_2 \sim N(cL_1, s^2 L_1) \tag{3.1}$$

where c represents the mean number of characters emitted in the foreign language for each character in the source language, and s^2 is the variance per translated character. Empirical studies on European languages determined the optimal parameters to be $c = 1, s^2 = 6.8$ (Gale and Church, 1993).

The best alignment between paragraphs is determined by minimising a cost metric for alignments, based on the distribution given in Equation 3.1, and prior probabilities for different alignment types. Specifically, the cost of an alignment between a set of sentences E (of total length L_1) and a foreign set F (of total length L_2) is defined by

$$D(F, E) = -\log P(\#F|\#E)P(L_2|L_1) \tag{3.2}$$

$P(L_2|L_1)$ is calculated by integrating the normal distribution given in Equation (3.1) over all values more extreme (further from the mean) than

Alignment	0-1	1-1	2-1	2-2
Prior	0.010	0.890	0.089	0.011

Table 1: Original prior probabilities for alignment types in the GCA (Gale and Church, 1993).

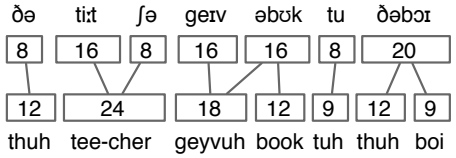

Figure 1: Aligning words from non-standard orthographic transcriptions with the Gale-Church Algorithm, using normalised word lengths.

L_2. $P(\#F|\#E)$ is the prior probability of alignment between sentence sets of sizes $|F|$ and $|E|$. The priors for alignment types used in the original algorithm are given in Table 1.

Then, for two paragraphs with numbers of sentences L_1 and L_2, their highest-probability alignment is derived using the following procedure. Denote the probability of the best alignment between the sentences 1 ... $i \leq I$ and 1 ... $j \leq J$ by $P(i,j)$, and the alignment itself by $B(i,j)$. Then $B(i,j)$ is determined by:

$$\arg\max_{b \in \{0,1,2\}^2} \big[P(i-b_1, j-b_2) \times D(\{i-b_1+1, ..., i\}, \{j-b_2+1, ..., j\})\big]$$

Application to transcription normalisation. The GCA can be applied to align transcriptions at the level of words, rather than sentences, without violating the assumptions of the model (see Figure 1). In this way, the algorithm may be used to pre-process documents by splitting them into smaller pieces – aligned words – for further character-level processing such as alignment and transliteration.

The algorithm as defined is only applicable to aligning two sentences at a time. However, it has a simple extension to allow alignments of N transcriptions simultaneously. The best alignment between sentences $\{1, ..., i_1\}$, ..., $\{1, ..., i_N\}$ is determined by:

$$\arg\max_{b \in \{0,1,2\}^N} \big[P(i_1 - b_1, ..., i_N - b_N) \times D(\{i_1 - b_1 + 1, ..., i_1\}, \ldots, \{i_N - b_N + 1, ..., i_N\})\big]$$

where the distance function D is defined as an N-dimensional generalisation of the original GCA distance function.

Limitations. The GCA only uses the information about the lengths of the word fragments. Hence it ignores other useful information such as the characters used in the word fragments. A tightly coupled character pair, e.g. characters corresponding to a rare sound, may strongly indicate the true fragment alignment. In determining the most likely alignment between sentences, the algorithm uses predefined prior probabilities of alignment types, based on European languages. In order to apply the algorithm to word fragment alignments, these prior probabilities should be re-estimated. Since the GCA is only applied to synthetic data in this work, we will retain the original priors and generate data according to them.

3.2 Moses

In order to perform a system-level evaluation of the GCA as a transcription pre-processor for character-based aligners, we require an established alignment system. For this purpose we use Moses, which is an SMT system designed to extend the IBM Models for unsupervised phrase-based translation (Koehn, 2010).

Model description. Moses uses a mathematical model to determine a probability distribution over possible translations of a sentence. Given a source language sentence e, a foreign language sentence f, and a division of the sentences into I phrases (blocks of consecutive words), the probability of the foreign sentence given the source sentence is defined as follows (Koehn, 2010):

$$p(f^I|e^I) = \prod_{i=1}^{I} \phi(f_i|e_i) d(\text{start}_i - \text{end}_{i-1} - 1) \quad (3.3)$$

where e_i and f_i are the ith phrases in the source and foreign languages, $\phi(f|e)$ is the probability of translating the phrase e into f, start_i is the position of the first word in the ith phrase, end_i is the position of the last word in the ith phrase, and d is a function that penalises re-ordering (when $\text{start}_i - \text{end}_{i-1} - 1 \neq 0$).

Application to transcription problem. To apply Moses to the transcription normalisation problem, we adopt the basic unit of characters instead of words. In this context, a "phrase" corresponds to a word fragment, or sequence of characters.

The first step of Moses training uses GIZA++ (Och and Ney, 2003) to establish likely word alignments. We use the HMM model for word alignment (Vogel et al., 1996), since the IBM models encompass reorderings which are not relevant for transcription alignment. An example of training Moses to detect regular sound correspondences between Portuguese and Spanish from a comparative wordlist (Wagner, 2010) is shown in Table 2.

4 HMM method

In this section a new method for transcription normalisation based on Hidden Markov Models is in-

ES	PT	ϕ(ES|PT)	N
ie	e	0.72	50
rse	r se	0.93	28
rs	r se	0.81	32
ón	ão	0.71	24

Table 2: Sample of results from training Moses on a Spanish-Portuguese comparative wordlist. ϕ is the proportion of instances of the ES fragment aligning with the PT fragment. N is the number of samples of the ES fragment.

troduced. This method aims to address the problem of N-way transcription normalisation.

4.1 Model description

The leading idea in the new model is that whatever orthography is used, the sequence of characters in a transcription corresponds closely to the sequence of sounds heard by the transcriber. This suggests a model in which the characters are treated as emissions and the sounds are treated as hidden states in a modified version of a Hidden Markov Model. Our goal is to infer the most likely hidden state (sound) sequence given a set of N transcriptions of the same audio, and to use this as a normalised form.

Each hidden state (sound) is associated with a probability distribution over all possible emissions. Emissions are character sequences ranging in length from 0 up to some maximum, denoted LE. Hence, denoting the emission probability distribution for hidden state element s by ϕ_s,

$$\phi_s(e) : \bigcup_{i=0}^{LE} \{c_1, c_2, ..., c_N\}^i \rightarrow [0, 1] \tag{4.1}$$

where the $\{c_i\}$ is an inventory of all the characters used in the orthography.

This setup would be sufficient if character emissions occur in a strict linear order with respect to the hidden states emitting them, but that is not always true. A counter-example is given by the English word *date*. In Figure 2, the last three sounds together cause the emission *ate*: the emission of the character *e* is unique to the *combination* of the sounds. This phenomenon is not modelled sufficiently by, say, adding some probability of emitting the characters *te* from the *t* sound; the extra letter is only emitted when the sounds occur together.

To address this problem, we allow emissions from *blocks* of hidden states acting in unison, referred to as **source blocks** or just **sources**. A source block, s, is defined by:

$$s \in \bigcup_{i=1}^{LB} \{h_1, h_2, ..., h_M\}^i \tag{4.2}$$

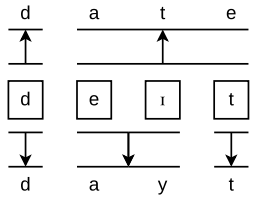

Figure 2: Transcriptions of the word *date* using English orthography and a hypothetical phonetic orthography. The true sequence of sounds is shown in IPA in the center. The correspondence between sounds and orthographic representation is indicated using arrows. Note that the last three sounds together are responsible for the emission of the characters *ate* in English orthography.

where LB is the length of the longest source block allowed by the model, and the h_i are the hidden states of the model, of which there are M in total. Each block has its own emission probability distribution which treated as being independent from the emission distributions of its components. In Figure 2, the last three sounds act as a block in the top transcription language. Apart from block emissions, no other provisions are made for out-of-order emissions.

Given a set of N transcriptions assumed to be of the same audio, we can compute its probability with respect to a given hidden state sequence using the ideas of source blocks and emissions. A **model** is a pair composed of a hidden state sequence $S = \left(h_1, h_2, ..., h_{|S|}\right)$ and an **alignment** ψ of the state sequence to the characters in the transcriptions. The alignment is constructed by splitting each transcription into emissions, and splitting the hidden state sequence into source blocks, which are assigned to the emissions in order (hence, for each transcription, there must be an equal number of source blocks and emissions). Note that the hidden state sequence may be split into source blocks differently for each transcription. Hence, the complete alignment is a vector of independent per-transcription alignments, $\psi = (\psi_i)$. An alignment ψ_i of a hidden state sequence of length $|S|$ to a particular transcription of length L_i is defined as a vector of pairs (see Figure 3):

$$\psi_i = [([s_1, s_2), [t_1, t_2)), ([s_2, s_3), [t_2, t_3)), \ldots, ([s_J, |S|), [t_J, L_i + 1))] \tag{4.3}$$

where $s_1 = t_1 = 1$, $J = |\psi_i|$ is the number of source blocks, and t_i may equal t_{i+1} in the case of a zero-length emission. Then, the probability of an observed set of M transcriptions given a state

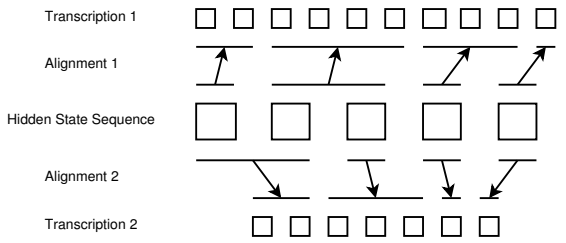

Figure 3: Sample alignment of a hidden state sequence of length 5 to two transcriptions. In transcription 1, sounds $[2,3]$ emit characters $[3,6]$ as a block, and in transcription 2, sounds $[1,2]$ emit characters $[1,2]$ as a block. The alignment for Transcription 1 as defined in (4.3) is: $\psi_1 = (([1,2),[1,3)),([2,4),[3,7)),([4,5),[7,10)),([5,6),[10,11)))$.

sequence and alignment is given by:

$$P(T_1, T_2, ..., T_M | S, \psi) = \prod_{i=1}^{M} \prod_{j=1}^{J} \phi^i([t_j, t_{j+1})|[s_j, s_{j+1})) \quad (4.4)$$

where we have defined $\phi^i(e|s)$ to be the probability of emitting the emission e from the source block s in the ith transcription language. For the purpose of inferring the most likely hidden state sequence, we use Bayes' Theorem: the probability of a model given a set of transcriptions is proportional to:

$$P(S, \psi | T_1, T_2, ..., T_M) \propto P(S, \psi) P(T_1, T_2, ..., T_M | S, \psi) \quad (4.5)$$

where to calculate $P(S, \psi)$, we use a first order Markov Model on the hidden state sequence, and make no relative penalties for different alignments:

$$P(S, \psi) = P(S) = \prod_{(S_i, S_{i+1})} P(S_{i+1} | S_i) \quad (4.6)$$

4.2 Model Implementation

The model and an EM training procedure were implemented in C++.

Training. Training follows a modified Expectation Maximisation format. The emission distributions and bigram model for the hidden states are initialised randomly, then the following process is looped over a fixed number of iterations:

1. Model fitting:
   (a) State sequences are sampled randomly for each sentence group in the corpus.
   (b) Random alignments to the transcriptions are generated for each state sequence.
   (c) Probability of the random fits calculated.
2. Model re-estimation:
   (a) Count for each emission event and state sequence event are weighted by probability of the sample in which they occur and added to running totals.
   (b) Weighted counts for each event are normalised and smoothing is applied.
   (c) Pairs of sources with low information radii are merged.

Sampling Strategy. We use a greedy sampling strategy to ensure that some high likelihood models are included in the sample. Specifically, the process is as follows:

1. Choose a random number of sounds for the state sequence.
2. Choose a (uniformly) random alignment to the transcriptions.
3. For each state sequence position, randomly select sounds and evaluate the probability of the partial model.
4. Choose the sound that had the highest probability.

The number of times random sounds are drawn in step 3 is equal to the number of hidden states used by the model. This ensures a good chance of a higher-probability sound being chosen, while preventing lower probability samples from being unrepresented.

Clustering. The last part of the E-step in the main training procedure is a form of clustering. The two most similar source blocks (defined by similarity of their emission distributions) are combined. One source block takes on the average distribution of the two, while the other is re-initialised with a uniform distribution. This leaves one source block free to acquire a new emission probability distribution, which may lead to a better overall modelling of the data. Hence, the clustering step provides a way for the training to jump out of local maxima. Clustering may be repeated a variable number of times, to merge multiple similar source pairs in a single training iteration. The similarity measure over emission distributions used to determine which source pairs to merge is the *information radius* (Manning and Schütze, 1999).

Length normalisation. Longer sentences naturally correspond to longer state sequences. Hence there are more possible models for a longer sentence, and therefore the probability of any given model is lower. This reduces the weight associated with a longer sentence when training. In fact, given two sentences, one twice as long as the other, the weight of the longer sentence will be roughly the square of the weight of the shorter one. Since the event counts are weighted by the probability of the sample containing them (and hence weights are < 1), longer sentences will contribute less data

when training. This bias can be prevented using length normalisation. Length normalisation scales the weight of a sample according to its length. The length normalised weight for a sample is given by $w^* = \sqrt[|S|]{w}$ where $|S|$ is the length of the state sequence and w is the model probability computed using Equation (4.4).

4.3 Limitations

While the hidden state sequence is a natural normalised form for transcriptions, it is not enlightening when inspected. Hidden states are labelled only by integers, hence there is no immediate indication of what sound a particular hidden state may represent. Thus, a further decoding procedure may be needed to convert the true normalised form to a human-readable form.

Another limitation of the method is that it does not consider previously-known correspondences between transcription styles. For example, transcribers using similar character sets would be likely to use the same characters to mean the same sounds. The algorithm converts each data set into a list of integers, where each unique character has a single entry in a map. The maps for each transcription language are independent. Taking this type of information into account in advance may speed up the training process and improve its accuracy.

A further limitation is that the emission distribution associated with a source block is treated as being independent from the emission distributions of its constituent sounds. This is unrealistic; for example, if a source block in English contains the sound t, it is very likely that the emission produced by that source block will contain the letter t, but this is not captured in the model.

5 Evaluation

In the first sections we outline two synthetic data generation methods. These are designed to allow evaluation of character-based aligners based on the ground truth emission correspondences in the generated corpora. A metric quantifying the difference between the emission distributions learned by the character aligner and the ground-truth distributions is also defined. The evaluation is limited to the case of two parallel transcriptions. Evaluation of a character-based aligner involves an 18 part test performed for each data generation method: combinations of 3 sentence lengths (5, 10, and 15 words), and 3 corpus sizes (10, 25, 50 sentences), with and without GCA pre-processing of the corpus. Each test was performed 3 times with different randomly generated corpora and the results were averaged to give the presented value.

The next section involves an evaluation of GCA for the purpose of pre-processing transcriptions for normalisation. For this purpose, we outline a simple data generation scheme to produce parallel corpora with known ground truth alignments. Furthermore, the efficacy of the GCA as a preprocessor for character-based alignment tools is examined by studying the effect of GCA pre-processing on alignments learnt by the well-known Moses SMT system.

5.1 Synthetic method 1

This method is intended to produce corpora with character-aligned text in two randomly generated 'languages'. First, a set E of random possible emissions are generated in the first language. For each emission $e \in E$, a probability distribution over emissions in the second language, $\phi_e(f)$, is randomly generated. The support of each $\phi_e(f)$ distribution includes a small number of emissions, uniformly chosen between 1 and 5.

To generate words, a random integer is chosen from a gamma distribution, and that number of emissions are drawn uniformly from the set E of possible emissions in the first language. For each emission e included in the word, a corresponding emission f is drawn from the $\phi_e(f)$ distribution. The emissions are concatenated to form the words. An alignment type is then drawn from the GCA priors (Table 1). The corresponding words are split according to the alignment type, where split points are chosen uniformly along the length of the words. Sentences are generated by stringing together series of words generated in this way. Hence the true emission correspondence distributions ϕ_e are known and can be compared to those learnt by an aligner.

5.2 Synthetic method 2: Block-based HMM

The second synthetic method involves generation of parallel corpora under the assumptions of the HMM method. This method may be used to generate any number of transcriptions simultaneously, but for this application we limit generation to two languages at a time. The data generation process is as follows:

1. A random language model for hidden states is generated, a random set of valid source blocks is generated, and random emission distributions for all valid source blocks are generated as in Synthetic Method 1.
2. For each individual word, a state sequence length is drawn from a gamma distribution.
3. For each word, a random sequence of sounds of that length is generated according to the language model, with initial probabilities equal to the stationary probabilities of the chain.
4. Starting with the longest block length, LE, and working back to blocks of length 1, emissions are chosen for any valid blocks appearing

in the state sequence.
5. The resulting emissions are concatenated to form the words for each transcription.
6. An alignment type is chosen from the GCA priors and the words are split according to that alignment, uniformly along their length.
7. Words formed this way are strung together to form sentences.

To calculate the true correspondence distributions between emissions we use Bayes' Theorem. Let f be an emission in the second language, and e an emission in the first language. Then the probability of an instance of e corresponding to f in the corpus is:

$$P(f|e) = \sum_{s \in S} P(f, s|e) \propto \sum_{s \in S} P(s)P(e|s)P(f|s) \tag{5.1}$$

Where S is the set of possible source blocks. Note that emissions selected for the different transcriptions from a common source are independent, so that $P(f|s, e) = P(f|s)$. Note also that the division of the hidden state sequence into blocks is common to both transcription languages. To calculate Equation (5.1), $P(e|s)$ and $P(f|s)$ are taken directly from the emission distributions. $P(s)$ is calculated using the stationary properties of the Markov chain used in sequence generation. Writing $s = s_1, s_2, ..., s_N$, we have the approximation:

$$P(s) = \alpha(s_1)P(s_1|s_2) ... P(s_{N-1}|s_N) \tag{5.2}$$

where $\alpha(s_1)$ is the stationary probability of the first sound of the source block. Equation (5.2) is only correct if word boundaries are treated as states in the HMM, which they are not; state sequence lengths are pre-drawn from a gamma distribution. However, the assumption becomes more accurate as the mean word length increases, and the average source block length decreases. Keeping block lengths short (maximum of 2-sound blocks) mitigates the effects of this inaccuracy, and the assumption will be kept.

5.3 Evaluation metric

For each of the data generation methods explained above, we have access to ground truth distributions for regular emission correspondences between the two languages. We define an accuracy metric based on the information radii between the true correspondence distributions (produced during corpus generation) and those produced by the aligners. Moses automatically produces emission correspondence distributions, and for the HMM method they are calculated using Equation (5.1).

Although information radius is only defined for two distributions, we can define a new metric quantifying the distance between a set of paired distributions. Let the paired distribution sets be $\{P_i\}$ and $\{Q_i\}$, $i \in E$, (E is the set of all emissions observed in the first language). Then we will use the metric:

$$D = \sum_{i \in I} w_i \text{IRad}(P_i, Q_i) \tag{5.3}$$

where IRad is the information radius (Manning and Schütze, 1999), and the weight w_i is the proportion of occurrences of the ith emission in the corpus, relative to all other emissions.

Align	P	R	F-score	N
0 - 1	0.00	0.00	0.00	104
1 - 1	0.90	0.95	0.93	8886
1 - 2	0.82	0.67	0.74	893
2 - 2	0.00	0.00	0.00	117

Table 3: Results of running GCA on a corpus

5.4 Gale-Church evaluation

For evaluation of the GCA, parallel corpora were generated using the following procedure:

1. A random sequence of alignments (0-1,1-1, etc.) was drawn with probabilities equal to the priors in the GCA (Table 1).
2. For each alignment, a random word length was drawn from a gamma distribution to form the first corpus. The parameters of the gamma distribution were chosen to be similar to those in the distribution of lengths of English words (West, 2008).
3. Each such word was randomly 'translated' under the assumptions of the GCA; the corresponding word length was drawn from a normal distribution according to the assumptions of the GCA (Gale and Church, 1993).
4. Each word pair in both corpora was then split according to their associated alignment type. Word splitting was distributed uniformly along the length of the word.

The parallel corpora generated were aligned using the unmodified GCA, and the accuracy of the resulting alignment was quantified using an F-score.

Results of running the GCA on a corpus generated using the above method are presented in Table 3. The algorithm did not correctly identify any 0-1 or 2-2 alignments. This effect occurs when aligning short (word size of less than 10 characters) fragments; increasing the word lengths to sentence size (∼100 characters) causes the alignments to be picked up by the algorithm. The effect likely relates to the very low priors assigned to those alignment types (see Table 1). On the other alignment categories, the algorithm performs well.

The results of running Moses on corpora generated using synthetic methods 1 and 2 are shown in Tables 4 and 5 respectively. For both data generation methods it is clear that pre-processing using

M/+G		#Sentences 10	25	50
#Words	5	0.33/0.27	0.28/0.16	0.31/0.15
	10	0.46/0.29	0.46/0.16	0.30/0.10
	15	- /0.31	- /0.22	- /0.16

Table 4: Moses accuracy scores calculated using (5.3) (lower is better), for Synthetic Method 1. M: Moses alone, M+G: corpus pre-processed using the GCA. A dash represents failure of Moses to train (common with long sentences).

M/+G		#Sentences 10	25	50
#Words	5	0.18/0.06	0.05/0.03	0.03/0.03
	10	0.29/0.04	0.18/0.01	0.32/0.05
	15	0.28/0.03	0.33/0.04	0.21/0.02

Table 5: Moses accuracy scores calculated using (5.3) (lower is better), for Synthetic Method 2. M: Moses alone, M+G: corpus pre-processed using the GCA.

GCA improves the ability of Moses to learn emission correspondences. The effect of using GCA as a pre-processor is especially pronounced in the case of synthetic method 2, where dramatic decreases in the evaluation metric are observed. In addition to improving the accuracy of the training, the GCA also makes training possible on corpora which include longer sentences.

5.5 HMM Method

The results of running the HMM Method on corpora generated using synthetic methods 1 and 2 are shown in Tables 6 and 7 respectively. GCA preprocessing appears to have little effect on accuracy for this method. The method performs extremely well on corpora generated using synthetic method 2, which uses the assumptions of the HMM model. Comparing the results of training across the two data generation methods, it is clear that while the HMM method performs exceptionally on corpora generated using its assumptions, the implementation cannot yet achieve similar results on corpora which are generated differently.

H/+G		#Sentences 10	25	50
#Words	5	0.18/0.18	0.42/0.43	
	10	0.12/0.12	0.22/0.22	
	15	0.21/0.22	0.25/0.25	

Table 6: HMM Method accuracy scores calculated using (5.3) (lower is better), for Synthetic Method 1. H: HMM Method alone, H+G: corpus pre-processed using the GCA. Not all evaluations were completed due to prohibitive running times on large corpora.

H/+G		#Sentences 10	25	50
#Words	5	0.00/0.00	0.00/0.00	
	10	0.00/0.00	0.00/0.00	
	15	0.00/0.00	0.01/0.01	

Table 7: HMM Method accuracy scores calculated using (5.3) (lower is better), for Synthetic Method 2. H: HMM Method alone, H+G: corpus pre-processed using the GCA. Not all evaluations were completed due to prohibitive running times on large corpora.

6 Conclusion

We have introduced the transcription normalisation problem, and have tested the application of new and existing computational methods to it, with mixed results.

The evaluation of the Gale-Church Algorithm showed that it has a significant positive impact on subsequent training of character aligners. Hence the GCA will be useful in preparing texts so that they may be subject to character level processing, such as alignment and transliteration.

Regrettably, the implementation of the HMM method could not be fully developed in the available time. Features such as greedy sampling of the alignment space remain to be implemented. The method displayed promising results on corpora generated under HMM assumptions, however it is not yet versatile enough to achieve similar results when modelling corpora generated under different assumptions.

The results of the evaluation, while illustrating some interesting comparisons, are difficult to interpret. For instance, it is unclear what value of the accuracy metric a system would have to produce before it could be declared accurate enough to be useful in the transcription normalisation problem. Such investigations would require human evaluators.

Abstract

This paper describes a novel method of constructing a language model for speech recognition of inputs with a particular style, using a large-scale Web archive. Our target is an open domain voice-activated QA system and our speech recognition module must recognize relatively short, domain independent questions. The central issue is how to prepare a large scale training corpus with low cost, and we tackled this problem by combining an existing domain adaptation method and distributional word similarity. From 500 seed sentences and 600 million Web pages we constructed a language model covering 413,000 words. We achieved an average improvement of 3.25 points in word error rate over a baseline model constructed from randomly sampled Web sentences.

1 Introduction

This paper presents a novel language model construction method for speech recognition, which is to be utilized by *Ikkyu*, an open-domain voice-activated Japanese QA system. Ikkyu takes relatively short spoken questions concerning a broad range of topics as input through a smartphone and provides the answers retrieved from a large scale Web archive. The challenge we tackle here is to provide a language model for a large-vocabulary speech recognition module to recognize such questions.

The widespread practice in language model construction is to train the model with a corpus that matches the domain and style of the target application. "Domain" usually refers to a set of utterances that are strongly related to a particular topic

Figure 1: Screenshot of our QA system (*Ikkyu*) with the answers for *"What causes deflation?"*.

(e.g., travel). Ikkyu does not have any domain in this sense. The final QA system is expected to answer all the questions concerning every possible topic as far as our QA module can find the answers from the Web.

Since current state-of-the-art speech recognition systems cannot recognize long sentences through a smartphone with a high sentence accuracy, we decided to focus on relatively short questions, roughly consisting of a noun, an interrogative pronoun, and a predicate. Also, our current QA module can deal with only relatively short questions and this restricts the answerable questions. We call the restrictions on possible questions due to these factors *style* hereafter. (See Section 2 for a detailed description of style.) Our challenge is to prepare a large number of questions over various topics that match this style. Manual construction of such a corpus is impossible considering the necessary vocabulary coverage, thus an automatic method for collecting questions is needed.

Our method starts from an extremely small seed

Table 1: Correctly recognized question examples from the test data. (May contain questions that can not be answered by our QA module.)

corpus consisting of hundreds of sentences that are manually tailored so that they match the style while also covering a wide range of topics. Next it selects sentences similar to ones in the seed corpus from a large Web archive (Shinzato et al., 2008). The selection is done by a combination of distributional similarity for nouns (Kazama et al., 2010) and an existing automatic *domain* adaptation method, intended to construct a relatively large *in-domain* training corpus (Misu and Kawahara, 2006). We show that this adaptation technique can be useful even in constructing an open-domain but style restricted corpus.

The major problem we tackle is the following: since constructing a large seed corpus is not affordable, we need to deal with the inevitable sparsity of a smaller seed corpus. Since this seed corpus needs to cover as many topics as possible, the number of questions for each topic is too scarce. Although the domain adaptation method is designed to deal with a similar problem, i.e., data sparseness caused by small seed corpora, it is questionable whether it would be equally efficient in domain independent, style restricted settings with a seed corpus of the same size. Our basic idea to overcome this difficulty is to expand the seed corpus by replacing nouns with distributionally similar nouns in the seed corpus, adding the resulting new sentences to the seed corpus. As a result, the domain adaptation method can pick up sentences referring to a wider range of topics from the Web more efficiently.

Table 2: Answerable questions of the QA module.

In the experiments using an existing speech recognition engine, ATRASR (Matsuda et al., 2006), our proposal's best model covering 413,000 words achieved an average word error rate of 15.49% and an average sentence error rate of 54.73%. The obtained improvement by our method over a baseline language model constructed from randomly sampled Web sentences was 3.25 points in word error rate and 4.28 points in sentence error rate.

Table 1 shows some questions correctly recognized by our best model. These suggest that our speech recognition module can actually recognize questions concerning a wide range of topics.

2 Our Open-Domain QA System *(Ikkyu)*

Before presenting the proposed method, we explain about Ikkyu, our open domain QA system, to clarify the motivation behind the task settings and the requirements for our speech recognition module. Figure 1 is a screenshot of Ikkyu, answering the question *"What causes deflation?"*. The answers are extracted from a large Web archive (6.0×10^8 Web pages) (Shinzato et al., 2008) in just a few seconds and each answer is linked to the original Web page from which it is extracted. Users can check more information regarding the answers just by following these links. Table 2 lists some examples of the questions the current prototype can actually answer.

For the example question of Figure 1 (*"What causes deflation?"*), the system unexpectedly presented a major Japanese automobile manufacturer as an answer. The blog entry, from which the system extracted the answer, claimed that the company kept its huge profit (more than tens of billion US dollars) and this shrinked public demand and

worsened the deflation. The same story was reported in an authoritative economic magazine after we found this answer.

The ultimate objective in this speech driven QA project is to offer a platform with which users can easily broaden their viewpoint by discovering valuable information including unexpected ones, like the example above, at any time, any place, which may result in more efficient decision making in all circumstances. In achieving this goal, we believe flexible speech recognition can be a great help since it can allow users to ask anytime, anywhere, any questions that come to mind.

The QA module is an extension of a pattern-based relation extraction method (De Saeger et al., 2009). It converts the input question, such as *"What causes deflation?"*, into the lexico-syntactic binary pattern "X causes Y" and automatically computes its paraphrases as well, such as "X triggers Y" and "Y is a cause of X". X and Y are variables, corresponding to the topic and interrogative pronoun of the question. These patterns are then matched against the Web archive after one of the variables is filled with the corresponding noun in the original question (Y = "deflation" in the above example). The nouns matching the unfilled variable (X) are provided as answers.

An important point here is that the form of the answerable questions are restricted by the patterns utilized by the QA module. These were automatically extracted beforehand from frequently observed dependency paths of a Web archive, amounting to 70 million in number, thus covering virtually all topics found in the archive. Because of this pattern extraction scheme, most patterns consist of a predicate, two variables (to be filled with nouns) and some postpositions connecting the predicate and the variables. Due to this tendency in the patterns, most answerable questions consist of a predicate, a noun, an interrogative pronoun and some additional function words. This is the *style* we assumed for our QA system.

Further elaboration of this notion of *style* may lead to the idea that the language model may be derived by converting all possible patterns into questions. We attempted this approach, but found that it was extremely difficult, as will be discussed in Section 5.3.

Instead, we start from a small corpus prepared in a relatively independent way from the architecture of our QA module. A positive side-effect of this approach is that it can be applied to speech recognition for other QA systems as far as the style of the questions match that of our QA module.

3 Background

This section describes the statistical domain adaptation method and the distributional word similarity to be used in the proposed method.

3.1 Statistical adaptation method

We combine our similarity based expansion method with an existing statistical adaptation method proposed by Misu and Kawahara (2006). In their method a seed corpus S is used to generate search queries for retrieving similar, relevant text from the Web. The search queries are generated by automatically extracting keywords with large TF-IDF values. Next, for each sentence from the retrieved text a $score$ is calculated, i.e. the word perplexity relative to the seed language model.

$$score = 2^{-\frac{1}{n}\sum_{i=1}^{n}\log_2 p(w_i|w_{i-1},w_{i-2})}$$

Here w_i represents the i-th word in a sentence with n words. For trigrams that contain unknown words, the minimum trigram probability of the seed language model is assigned as a penalty. The sentences whose $score$ is smaller than a threshold θ are selected to form the training corpus T, together with the seed corpus.

Note that this method selects sentences from Web search results using the keyword queries determined according to TF-IDF. However, our main goal is to efficiently identify questions covering a wide range of topics while matching a certain style, often represented by colloquial textual fragments and therefore consisting of frequent words. We judged that Web search using TF-IDF score is harmful because it is likely to filter out such frequent words, therefore we skipped it. Instead, $score$ was computed for all the sentences of the Web archive and sentences were selected solely based on the $score$ values. We fixed the unknown trigram probability at 10^{-10}. Compound nouns (or noun sequences) are treated as single noun.

We call our implementation of this statistical adaptation method "Misu's method" hereafter.

3.2 Distributional word similarity

Distributional word similarity measures the semantic similarity between words based on the distributional hypothesis (Harris, 1954), which states that words that occur in the same contexts tend to have similar meanings. Based on this hypothesis, many similarity measures have been proposed. We adopt a recent method of Kazama et al. (2010).

Kazama et al. (2010) applied the Bayesian approach for the similarity calculation to alleviate the problem of data sparseness. The method starts from the base similarity measure, the Bhattacharyya coefficient, which is defined over probability distributions p_1 and p_2 as follows:

$$BC(p_1, p_2) = \sum_{k=1}^{K} \sqrt{p_{1k} \times p_{2k}}$$

p_1 and p_2 are the conditional context distributions for two given words, $p(f_k|w_1)$ and $p(f_k|w_2)$. The contexts, f_k, used in (Kazama et al., 2010) are dependency relations such as "subj-of-swim" for the word "tuna". Instead of using $p(f_k|w_1)$ directly, their method estimates the distribution of $p(f_k|w_1)$ itself using the Bayesian method to capture the unreliability of data and calculates the expectation of the above base similarity under those distributions. They showed that this method outperforms many existing similarity measures through the experiments using large-scale Japanese Web data.

4 Proposed Method

The proposed method can be described as follows. The inputs are the seed corpus S and a Web archive W.

Step 1 For each sentence s in S, pick up every noun w that is not in a stop-word list L and replace w in s with the most similar k words according to Kazama's distributional similarity (Kazama et al., 2010). The resulting sentences are added to S.

Step 2 Apply Misu's method (Misu and Kawahara, 2006) to S and W and construct a training corpus T.

Step 3 Construct a language model from T using existing tools for speech recognition.

Assume the question *"What are the symptoms of gout?"* is in S, "gout" and "symptom" are not in L, "osteoporosis" and "cause" are among the k most similar words to "gout" and "symptom" respectively. Then, in Step 1 the new sentences *"What are the symptoms of osteoporosis?"* and *"What are the causes of gout?"* are added to the seed corpus S. In Step 2, we can expect that Misu's method picks up sentences such as *"What are the treatments of osteoporosis?"* in the Web archive and adds it to the training corpus T. This is because the new question shares two trigrams ("What are the" and "of osteoporosis ?") with the newly added seed sentence *"What are the causes of osteoporosis?"*, and is likely to have a relatively low (thus better) $score$ value. Note that the question is less likely to be added to the training corpus if the noun replacement of "gout" with "osteoporosis" was not conducted since it has less common trigrams with the original seed question. This is a benefit obtained by our method.

In our experiments, we used approximately 500 questions as seed corpus S. These were manually crafted according to the instructions described in Section 5.1.2. The Web archive W consists of 6.0×10^8 Japanese Web pages (Shinzato et al., 2008). The distributional similarity between nouns was computed from another Web archive consisting of 1.0×10^8 Japanese Web pages. The stop-word list L contains about 2,000 nouns whose frequency exceed 10^7 in our Web archive. This list was devised because highly frequent nouns often behave as function words, and replacing such nouns often yield ill-formed sentences.

While the style of the initial seed corpus necessarily reflects the underlying task (i.e. recognizing question sentences), the various steps of our proposed method do not rely on any explicit or implicit stylistic elements of the input seed corpus, so we consider our method to be task-independent.

5 Evaluation

5.1 Evaluation settings

5.1.1 Corpora

We prepared two Web archives as the starting point of language modeling: the first (`www`) is unfiltered in regards of style, while the second (`wwwq`) is a subset of the first, attempting to follow the style requirements of the QA system.

- **www** The first archive consists of 6.0×10^8 Web pages (Shinzato et al., 2008). We use this Web archive as training data for language modeling. After sanity check, we retained a corpus of 1.79×10^{10} words in 1.35×10^9 sentences. We call this corpus `www`.

- **wwwq** While the `www` corpus preserves the open-domain characteristics of the Web archive, it completely ignores the requirements of Ikkyu regarding style, containing various sentence types besides questions. Using simple heuristics, we selected questions

from www. Since Japanese doesn't necessarily use question marks with questions, we identified questions as sentences that end with question marks or question markers (ka, kai, kashira, kana). We also extracted requests, which end with kudasai (≈*please*) or continuative verb + gerund te (≈Japanese colloquial request). This filtering retained a question corpus of 1.23×10^9 words in 1.01×10^8 sentences. We call this corpus wwwq.

Note that these regular expressions allow many sentences that don't match the style of Ikkyu, such as *why*, *how* or polar questions. Removing such problematic sentences from the corpus is not a trivial task in Japanese. For instance, interrogative pronouns can be omitted in Japanese.

The benefit of our proposed method is that we can rely on statistics and a small seed corpus without dealing with such numerous minor problems.

5.1.2 Evaluation sets

We recorded the questions uttered by 50 people (25 female and 25 male). Each subject was presented with 100 questions that Ikkyu can accept as input, after which each subject uttered approximately 50 of her/his own spontaneous questions which were recorded using smartphones. They were instructed to formulate simple questions, consisting of a noun, a predicate and an interrogative pronoun ("what", "who", "where" or "when") for a wide range of topics as far as possible, with the interrogative pronoun possibly being replaced by an expression to formulate a request, or being omitted altogether. Note that in spite of these instructions the recorded data contains some questions which do not conform.

The group was randomly split into three, with g0 containing 10 speakers, g1 and g2 containing 20 speakers each. Table 3 shows their details. The corpus of g0 was used as seed corpus, whereas g1 and g2 were used for two-fold cross validation.

Group	**g0** (S)	**g1**	**g2**
# of sentences	498	1000	999
# of words	4043	7671	8322
average sentence length	8.118	7.671	8.330

Table 3: Seed corpus and evaluation data.

5.2 Results

5.2.1 Best distributional similarity rank (k)

Firstly, we tried to find the best similarity rank k and training data size combination in terms of word-error-rate (WER), using the following values: k=1, 2, 3, 4, 5, 10, 15, 20, 100. After the seed corpus expansion, we incrementally increased the size of the training data, starting from a 10 million word corpus, gradually changing the threshold θ on Misu's score. We determined the best setting by two-fold cross validation, that is, we used the g1 set as development set with g2 as evaluation set, and vice versa. Figure 2 presents the WER curves for each parameter k, trained on the www corpus. Training on the www corpus provided with the best absolute performances, with $k = 10$ being the best setting in terms of WER consistently in both evaluation data, when the corpus size was approximately 160 million words (Figure 2). The vocabulary of this model has 413,000 entries. Note that $k = 10$ achieved best or 2nd best WER at most data points. This consistency suggests the effectiveness of our noun replacement. An interesting point is that the performance is saturated when k is relatively small, suggesting that the noun replacement is a relatively sensitive operation.

Note that when $k = 0$, the method is equivalent to Misu's method. The difference in WER between the best performance of Misu's method and our method when $k = 10$ is 0.19 points in g1 and 0.72 points in g2. Using McNemar's test (McNemar, 1947), we found that these differences are statistically significant ($p < 0.05$). Although the difference in g1 is quite small, (1) the best performance of our method is achieved using a smaller training corpus (50% of Misu's method); (2) if we use the same corpus size achieving the best performance in all the settings, i.e., 160 million words, the difference between Misu's method and $k = 10$ is even larger: 0.66 points in g1 and 0.95 points in g2; (3) there is also a large difference between the peak performances regarding sentence error rate (SER) in both of g1 and g2 (0.90 and 1.90 points). These observations suggest that our method is more effective than Misu's original method.

When we used the question archive wwwq instead of www, the same tendency was observed. The best performance was obtained when $k = 10$ for both g1 and g2. The peak performance was obtained when the corpus size had 80 million words consistently in both test data. However, the best

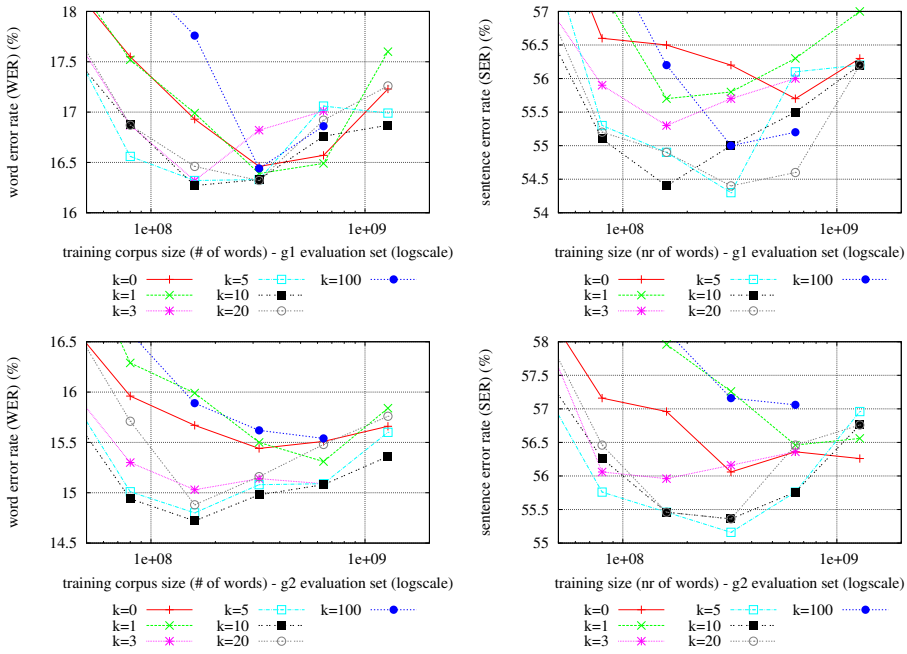

Figure 2: WER curves with various distributional similarity rank k, trained on the www corpus.

performance was worse than when we trained on www (16.35% in g1 and 15.28% in g2).

5.2.2 Comparison with the baselines

Next, we confirm that our method with the best setting ($k = 10$, 160 million words, trained on www) outperforms other baseline methods by comparing the following methods:

- **www.X** Our method applied to www.
- **wwwq.X** Our method applied to wwwq.
- **www.R** Random sampling from www.
- **wwwq.R** Random sampling from wwwq.

The results are presented in Figure 4.

Here we must mention that due to memory constraints, our language model training module (ATRASR) could not handle the entire www corpus. (We used machines with 72 GB memory.) The largest training data we could experiment on was 3.10×10^9 words. In case of the wwwq corpus such limitations don't apply, since 1.23×10^9 words can be handled by the module.

The peak performance of the baselines were achieved when the training data was largest, with wwwq showing lower WERs. Our method outperformed both baselines: regarding WER, we achieved 16.27% and 14.72% on g1 and g2, with an average improvement of 3.25 points, over the best baseline (www). These differences are also statistically significant ($p < 0.01$). Regarding SER, we achieved 54.30% and 55.16% on g1 and g2, respectively, with an average improvement of 4.28 points over the best baseline (wwwq), with the difference being statistically significant ($p < 0.01$). The performances of the baseline methods are not saturated and it may show much lower WER and SER if we can avoid the memory limitation problem somehow. However, the corpus size becomes so large (about 8 times the size of our best method), that would cause a significant slowdown of speech recognition. Figure 3 shows the real time factor[1] measured in our experiments. The best baseline method (trained on www) is already 2.8 times slower than the proposed method with the best setting. These observations suggest that our method is most suitable for our purpose.

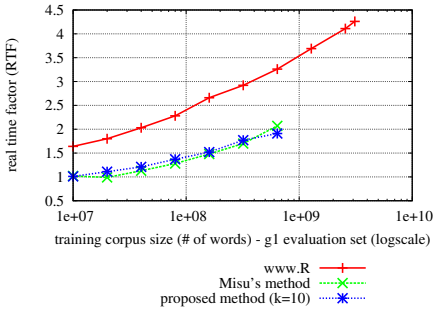

Figure 3: RTF in function of training corpus size.

[1]RTF ("real time factor"): defined as the processing time of the input divided by the duration of the input.

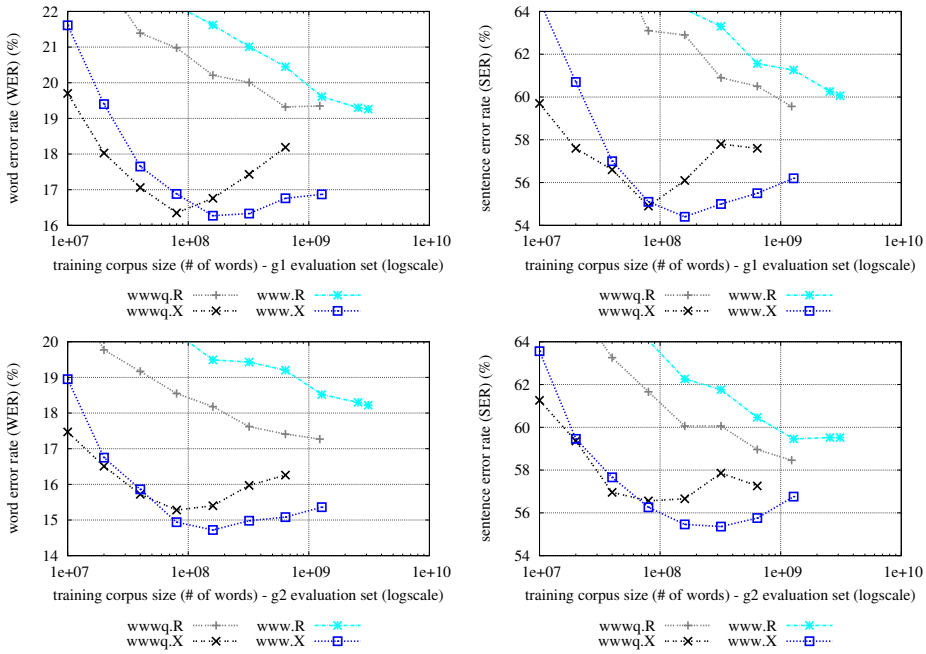

Figure 4: Our proposal versus the baselines.

5.2.3 N-best evaluation

The user interface of our QA system on smartphones has a user-friendly editing environment for word lattices provided by the speech recognition module. The user can correct the recognition results just by selecting some alternative words if the correct ones are included in the best N recognition results. The chance of a correct recognition is estimated as the probability of the correct question being in the N-best recognition results. We calculated SER over the top 100 recognition results. We found that between 59% and 62% (on g2 and g1, respectively) of speech inputs can be easily retrieved either by the top speech recognition result, or utilizing the error-recovery interface. This is important for the QA module in order to properly interpret and answer the questions.

5.3 Discussions

A concern is whether noun replacement really works as we intended. The improvement may have been achieved only for the words other than nouns, particularly the ones frequently observed in questions, such as verb suffixes indicating interrogative mood. This would not lead to topic expansion, as we intended. We conducted another series of experiments to investigate this supposition. Figure 5 shows the WER and SER of only nouns in the test data. Regarding noun-SER, a sentence is correct if all its nouns are correctly recognized. Interrogative pronouns were not considered. Using two-fold cross validation, on both g1 and g2 our method consistently achieved a lower noun-WER and noun-SER than Misu's method (without noun replacement), resulting in more accurate noun recognition. The difference between the best performances was 0.70 and 0.56 points in terms of noun-WER (on g1 and g2, respectively); 1.20 and 1.80 points in terms of noun-SER. These differences are statistically significant ($p < 0.05$). This implies that our concern was unfounded. Another observation is that the performance of the noun recognition does not saturate as the corpus size grows as far as we have tested. Analyzing this phenomenon more deeply and further improving the performance is our future work.

Another point is whether the noun replacement must be done before applying Misu's method. We may be able to achieve the same effect by performing noun replacement on the corpus obtained by Misu's method only using the original seed corpus. We experimentally confirmed this is not the case, although we don't present the experimental results for the sake of space. A possible explanation is that noun replacement generates many semantically ill-formed questions. If these are used as training corpus, they may be harmful. However, as seeds they only derive trigram probabilities for sentence selection, the selected sentences being natural, real life sentences from the Web.

We also attempted to build a language model by converting the patterns used by the QA module

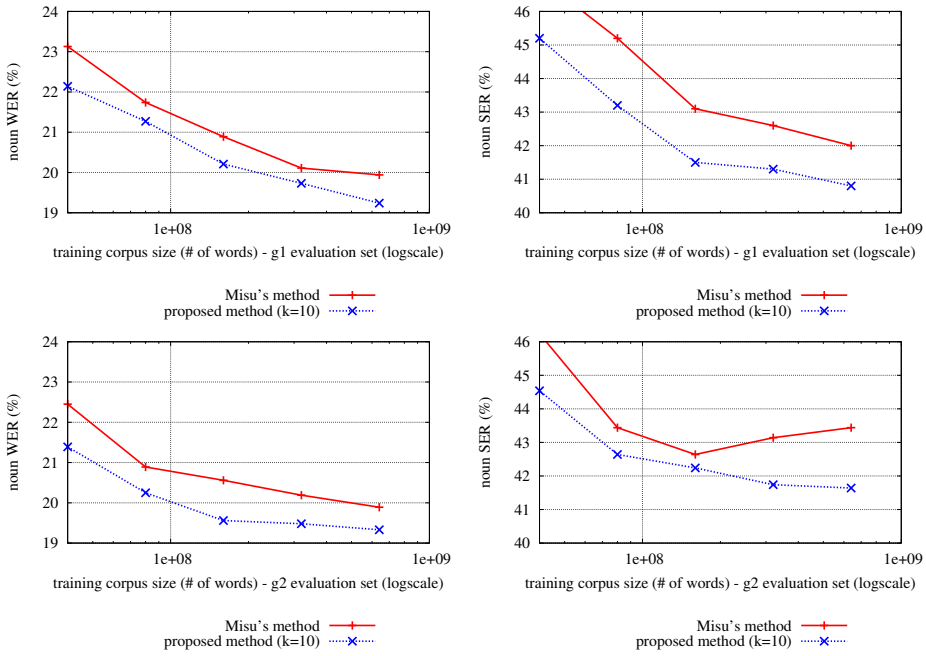

Figure 5: Noun evaluation on www.

to questions by replacing one of its variables with interrogative pronouns and attach some words indicating the interrogative mood. For instance, we could generate *"What causes deflation?"* from the pattern "X causes Y", but also less natural questions, such as *"What causes destruction?"*, which is extremely vague and is unlikely to be asked without a specific context. The conversion procedures generated a large number of such unnatural questions, and the resulting speech recognition performance was worse than that obtained by a corpus randomly sampled from our Web archive. To achieve the performance compatible to our method, thorough research must be conducted on generating only natural questions.

6 Related Work

The Web has been used as a relatively inexpensive source of large-scale data. "Just-in-time" language modeling (Berger et al., 1998) submits content words from previous user sentences as queries to a web search engine, Zhu et al. (2001) use a search engine to update the probabilities of already existing n-grams. More recently Bulyko et al. (2003) use frequent n-grams of the seed corpus as queries to retrieve similar text from the Web. Sarikaya et al. (2005) retrieves relevant text based on the BLEU score. Word perplexity is another frequently used similarity measure (Misu and Kawahara, 2006; Creutz et al., 2009). Some of these frameworks can be substituted for Misu's method in our framework, such replacement being a primary candidate of our future work.

Another category of related work relevant to our method is class-based language modeling (Brown et al., 1992). Many attempts refine this framework (Yamamoto et al., 2001; Chen and Chu, 2010; Emami et al., 2010). By replacing word trigrams in Misu's method by class trigrams, we may be able to achieve an effect similar to that obtained by our method without conducting noun replacement as additional procedure. However, the granularity of word classes may be a problem, considering that, in our framework, the optimal number of similar nouns replacing a noun in the seed corpus is relatively small (just 10). The comparison of class-based language models and our framework would be an interesting future work.

7 Conclusions

We have proposed a similarity based language model construction method for Ikkyu, a voice driven open-domain QA system. We used the combination of a distributional similarity based noun replacement method and a statistical domain adaptation method. Our best language model outperformed the baseline model constructed from random sampling of a Web archive by 3.25 points in word error rate and 4.28 points in sentence error rate, while using 8 times less training data.

The application of chordal graphs to inferring phylogenetic trees of languages

Abstract

Phylogenetic methods are used to build evolutionary trees of languages given character data that may include lexical, phonological, and morphological information. Such data rarely admits a perfect phylogeny. We explore the use of the more permissive conservative Dollo phylogeny as an alternative or complementary approach. We propose a heuristic search algorithm based on the notion of chordal graphs. We test this approach by generating phylogenetic trees from three datasets, and comparing them to those produced by other researchers.

1 Introduction

Reconstructing the histories of language families is one of the principal tasks of historical linguistics. A linguistic phylogenetic tree conveys the evolution of a language family. The family tree can be constructed on the basis of characteristics that are common to sets of languages. which include lexical, phonological, and morphological affinities. Of particular importance are cognates — words that originate from the same ancestral word, and are distinct from words that are "borrowed", i.e. transferred between languages at some point in history. For example, English *brother* is cognate with German *bruder* and Russian *brat*, all of which come from a Proto-Indo-European word reconstructed as *bhrāter*, while *cousin* is a borrowing from French.

The task of inferring phylogenetic trees of languages is complicated by the pervasiveness of borrowings, which frequently occur when languages are in close contact. For example, English is a Germanic language but the majority of its vocabulary is borrowed from other branches of Indo-European. Several approaches have been proposed to incorporate borrowings into the tree building process (Minett and Wang, 2003). In particular, Nakhleh et al. (2005a) introduce the concept of a phylogenetic *network*, which is obtained by augmenting a putative tree with edges representing contact between languages. They present a method to calculate the minimum number of borrowings required to admit that tree. However, the method does not actually construct a tree from the data, and it may be computationally intractable when the number of borrowings is large.

In this paper, we propose to apply a conservative Dollo phylogeny (CDP) as a model of linguistic phylogenetics. The approach was originally developed by Przytycka et al. (2006) in computational biology. Since it is NP-Hard to compute the minimum number of deletions required for a dataset to conform to a CDP (Lewis and Yannakakis, 1980), we propose a heuristic search algorithm based on the notion of chordal graphs. Our algorithm produces an output tree that minimizes the number of borrowings directly from the data. In addition, it has the potential of being significantly faster to compute than the more commonly known perfect phylogeny. Our approach produces plausible phylogenetic trees on three different datasets.

This paper is structured as follows. In Section 2, we outline the required background, including several graph theoretic notions and alternative phylogenies. In Section 3, we describe our heuristic search algorithm to compute the minimum set of data entries that are inconsistent with a CDP. We also describe a number of preprocessing steps that we take in order to make our problem more computationally feasible. In Section 4, we describe the experiments on three datasets, and compare the resulting phylogenetic trees to those produced by other researchers. In Section 5, we describe an extension to our heuristic search. We conclude with future work and a summary in Sections 6 and 7.

Chiang Mai, Thailand, November 8 – 13, 2011.

2 Background

In this section, we outline the notions of perfect and Dollo phylogenies, and several graph-theoretic notions, including intersection graphs and chordal graphs.

2.1 Perfect phylogeny

A *character* represents a property of languages. In this paper, we consider only binary characters, which have two possible states: 1 and 0. For example, a presence or absence of a particular cognate can be considered a character. The information encoded by a set of characters is used for constructing phylogenetic trees. We say that a character *back evolved* if after evolving from 0 state to 1 state, it subsequently is lost and switches back on the tree from 1 state to 0 state. We say that a character has *parallel evolution* if it evolves twice on the tree from state 0 to state 1 independently. We say that a character is *borrowed* if it has been transferred from one branch to another by contact between linguistic groups.

Given a set of binary characters, we say that a rooted tree with languages as the leaf nodes is a *perfect phylogeny* if for each character there exists a binary labeling such that the root node is labeled with a zero, and all nodes sharing the same label are connected. This implies that each character evolves exactly once, and that there is no back-mutation or borrowing. For example, the tree in Figure 1 is not a perfect phylogeny because characters one and two back-evolve. It is possible to recognize whether a set of characters admits a perfect phylogeny in polynomial time (Felsenstein, 2004).

The character data representing actual languages rarely admit a perfect phylogeny because back mutation, parallel evolution, and borrowing often occur in the course of linguistic evolution. Instead, we are usually interested in establishing for a given character data how far away it is from admitting a perfect phylogeny. *Maximum parsimony* attempts to minimize the overall number of evolutionary events required on a tree to explain the character data, where an evolutionary event is a switch of a character from one state to another (Felsenstein, 2004). Because maximum parsimony is NP-Hard (Day et al., 1986), many approximate approaches have been proposed for this task. Nakhleh et al. (2005b) provide an excellent survey of linguistic phylogenetic methods.

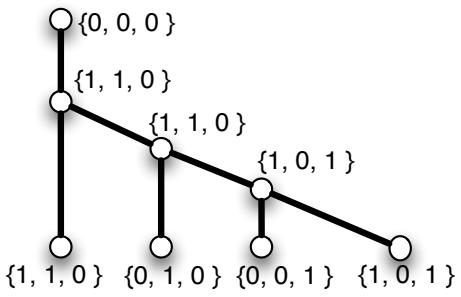

Figure 1: An example of a tree with three characters that is a conservative Dollo phylogeny (CDP), but not a perfect phylogeny.

Nakhleh et al. (2005a) propose perfect *phylogeny networks* as a way of simplifying the phylogeny problem. A perfect phylogeny network is a graph (not necessarily a tree) such that every character exhibits a perfect phylogeny on at least one of the subtrees of that graph. This approach is particularly powerful in modeling borrowing; however, it requires the underlying genetic tree to be defined beforehand. The edges added to the tree represent contact between languages. Unfortunately, even given a phylogenetic tree and character data, determining the minimum number of edges one must add to produce a perfect phylogeny network is NP-Hard (Day et al., 1986). Nakhleh et al. (2005a) mention that applying the perfect phylogeny network approach to their Indo-European language dataset is tractable only because very few edges need to be added to their tree to produce a perfect phylogeny network.

2.2 Dollo phylogenies

Given a set of binary characters, we say that a rooted tree with languages as the leaf nodes is a *Dollo phylogeny* if for each character there exists a binary labeling such that the root node is labeled with a zero, and all nodes sharing the label 1 are connected (Farris, 1977). In essence, each character evolves exactly once, but, in contrast to a perfect phylogeny, an arbitrary number of back-mutations are allowed. Unfortunately, every set of character data admits a Dollo phylogeny. Clearly, the notion of Dollo phylogeny is too permissive to be useful in linguistic phylogenetics.

Przytycka et al. (2006) propose the notion of a *conservative Dollo phylogeny* (CDP), which is a Dollo phylogeny satisfying an additional con-

dition: any two characters that occur together in their 1 states at an internal node must also occur together in their 1 states at some leaf node. For example, the tree in Figure 1 is a CDP.

In the context of language evolution, the CDP condition implies that for any two characters in some ancestral language, there exist corresponding evidence in the form of a known language possessing both of those characters. This is a very strong requirement for which numerous linguistic counter-examples can be found, but it is much less strong, and therefore more more likely to be satisfied, than the requirement for a perfect phylogeny. We expect the CDP condition to guide our heuristic search algorithm towards more realistic phylogenetic reconstructions, especially in cases where a number of diverse languages share a relatively small set of reliable characters.

Few non-trivial datasets representing language families admit a CDP. This may be attributed either to borrowing or to the violation of the CDP condition. Since we have no way distinguish between the two explanations, in the remainder of this paper we will simply refer to such events as borrowings. In most cases, our objective is to establish the minimum number of those instances.

2.3 Chordal graphs

In this section we define the notions of chordal and intersection graphs that underlie our heuristic search algorithm.

Graph $G = (V, E)$, where E is the set of edges, and V is the set of vertices, is an *intersection graph* of a family of sets $\mathcal{R}$ if there is a one-to-one and onto function (*bijection*) $\mathcal{F}$ between V and $\mathcal{R}$ such that

$$\forall s, t \in R : (F(s), F(t)) \in E \text{ iff } s \cap t \neq \emptyset \quad (1)$$

Informally, each vertex in the intersection graph represents a set, and two vertices are connected by an edge if and only if the two corresponding sets intersect. Figure 2 shows an example of an intersection graph. Given sets, we can compute their intersection graph in linear time.

A *chord* of a cycle is an edge between two non-consecutive vertices of a cycle. A *chordless cycle* is a cycle with no chords. A *chordal graph* is a graph with no chordless cycles of length greater than three. Figure 3 shows an example of a chordal graph. Rose et al. (1976) provide a linear-time recognition algorithm for chordal graphs.

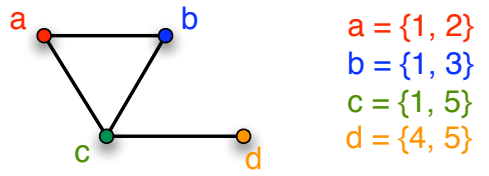

Figure 2: An example of a family of sets on the right and an intersection graph of those sets on the left.

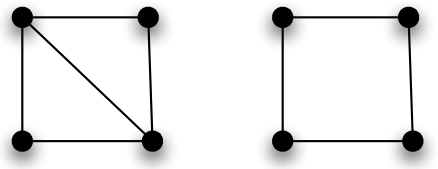

Figure 3: An example chordal graph on the left, and a graph that is not chordal on the right.

We can consider a character in phylogeny data as a set composed of the individuals or languages that possess that character. For example, the set for a cognate is the set of languages that contain that cognate. Przytycka et al. (2006) prove that a set of characters admits a CDP if and only if their intersection graph is chordal. Therefore, it is possible to determine whether a set of characters admits a CDP in linear time. We employ this result in order to infer phylogenetic trees of languages.

3 Heuristic search

Our search algorithm takes the intersection graph of the character data as input, and finds the minimum number of vertices (characters, in this case) that must be removed to produce a chordal graph. We take advantage of the fact that a character dataset admits a CDP if and only if the intersection graph of the character data is chordal. Our heuristic breadth-first search is guaranteed to find the minimum number of the inconsistent vertices.

One key observation allows this search to execute in reasonable time:

Observation 1. *Let $G = (V, E)$ be a graph. Let C be a chordless cycle of G. Let V' be a set of vertices such that removing V' from G results in a chordal graph. Then V' must include at least one vertex on C.*

Algorithm 1 Our main heuristic search algorithm.
search(Graph $G = (V, E)$, List *currentSolution*)

```
1: Vertex v ← isChordal(G);
2: if v = null then
3:    Print currentSolution
4:    return
5: end if
6: Vector candidates ← getCandidates(G, v)
7: for all Vertex u in candidates do
8:    Add u to currentSolution
9:    Graph G' ← G[V\{u}]
10:   search(G', currentSolution)
11:   Remove u from currentSolution
12: end for
```

Algorithm 2 Candidate generator.
getCandidates(Graph $G = (V, E)$, Vertex v)

```
1: Cycle C ← the vertices of the shortest chordless cycle of length ≥ 4 containing v
2: if |C| > 4 then
3:    Cycle C_4 ← a chordless cycle of length 4 if one exists in G
4:    if C_4 is not null then
5:       return C_4
6:    end if
7: end if
8: return C
```

Proof. Assume that V' contains none of the vertices in C. Then all vertices of C are in $V \backslash V'$. Therefore C is present in the graph obtained by removing V' from G, which is chordal by definition of V', a contradiction. □

By applying the above observation inductively, at each stage of our search, we need only consider as successor states the states produced by removing a vertex in a chordless cycle of our graph.

The pseudo-code of our heuristic search is shown in Algorithm 1. Subroutine *isChordal* takes a graph as a parameter, and returns a vertex that belongs to a chordless cycle, or $null$ if G is chordal. The subroutine implements the algorithm based on lexicographic breadth-first search proposed by Rose et al. (1976). The subroutine *getCandidates* for selecting the candidate nodes to be considered in the search is formalized in Algorithm 2. It gets all vertices on a chordless cycle, and identifies them as candidates for removal. In order to guarantee optimality, we need to recursively consider removing each of these vertices. Observation 1 makes this search computationally feasible in experimental data. In the worst case, the algorithm has exponential running time in the size of the input data, which is what we expect in the case of an exact algorithm applied to an NP-complete problem.

3.1 Language grouping

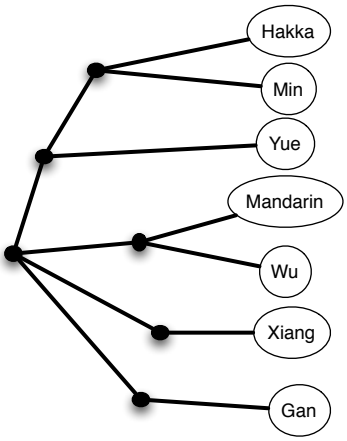
In order to make our experiments computationally tractable, we follow Nakhleh et al. (2005a) in combining sets of languages into single units. For example, we consider the Germanic languages as a single group because we are confident that their most recent common ancestor is not an ancestor of any other language. The operation of language grouping is performed as a preprocessing step to the construction of the intersection graph of the characters.

Beyond achieving the goal of decreasing computation time, we expect that the application of language grouping will actually make our data closer to admitting a CDP in a way consistent with true evolutionary history. Consider two characters s and t that intersect in the context of language grouping L, but not without. Then s and t are not present in any of the same languages, but there are two languages $l_i, l_j \in L$ such that l_i has character s but not t, and language l_j has character t but not s. If s and t are only present within the language grouping, they are not informative when language family grouping is used. However, if both s and t are present at an internal node ancestral to language grouping L, then this will make the data closer to admitting a CDP by decreasing the number of borrowings that we need to posit.

3.2 Tree extraction

Once our search has found a minimum set of vertices to remove from our graph in order to make it chordal, we extract a phylogenetic tree from the resulting graph. Gavril (1974) shows that chordal graphs are the intersection graphs of subtrees of a tree, and gives a polynomial-time algorithm to build a corresponding family of subtrees. Following Przytycka et al. (2006), we use the union of those subtrees as a phylogenetic tree for our languages.

Figure 4: The tree given by our algorithm for Chinese dialect cognate data.



4 Experiments

In order to assess the suitability of the CDP approach to linguistic phylogeny we performed experiments on three datasets.

4.1 Chinese dialects

The data consist of 15 cognates across seven Chinese dialects compiled by Minett and Wang (2003). The set can be characterized as relatively small and clean.

The tree produced by our algorithm (Figure 4, which is non-binary, is completely consistent with one of the five binary trees (Type III) of Minett and Wang (2003). Also, our tree shares the grouping of Hakka and Min with all five of their proposed trees.

Minett and Wang (2003) show that in order to explain their data, at least seven borrowings must have occurred. Our algorithm gives the same number.

The experiment confirms that our method is sound, and produces results that are open to further elucidation.

4.2 CPHL subset

The dataset consists of 22 phonological characters and 13 morphological characters for 24 Indo-European languages from the Computational Phylogenetics in Historical Linguistics (CPHL) project[1]. We decided to exclude the lexical characters which are the most likely to be borrowed.

For example, one phonological character identifies languages that underwent the loss of initial y when it was followed by e. Three languages (Hittite, Luvian, and Lycian) which exhibit that sound change are encoded as character 1, while the remaining Indo-European languages are encoded as character 2.

Figure 5 shows the tree produced by our method on the CPHL subset. No characters needed to be removed from the intersection graph of the characters to yield a chordal graph, which can be interpreted that our CDP assumption is reasonable.

There are several differences between the tree in Figure 5 and the tree presented on the website of the CPHL project. First, Albanian is grouped with the Armenian and Greek languages rather than with the Germanic languages. Second, there is a node of high degree linking four language subfamilies. This result implies that the character set is not sufficiently large to establish a more detailed relationship between those subfamilies.

Nakhleh et al. (2005a) use the CPHL dataset to build perfect phylogenetic networks. However, their approach requires a phylogenetic tree as input, and minimizes borrowing events over only that tree. In contrast, our approach minimizes borrowing events over all possible phylogenetic trees without enumerating them.

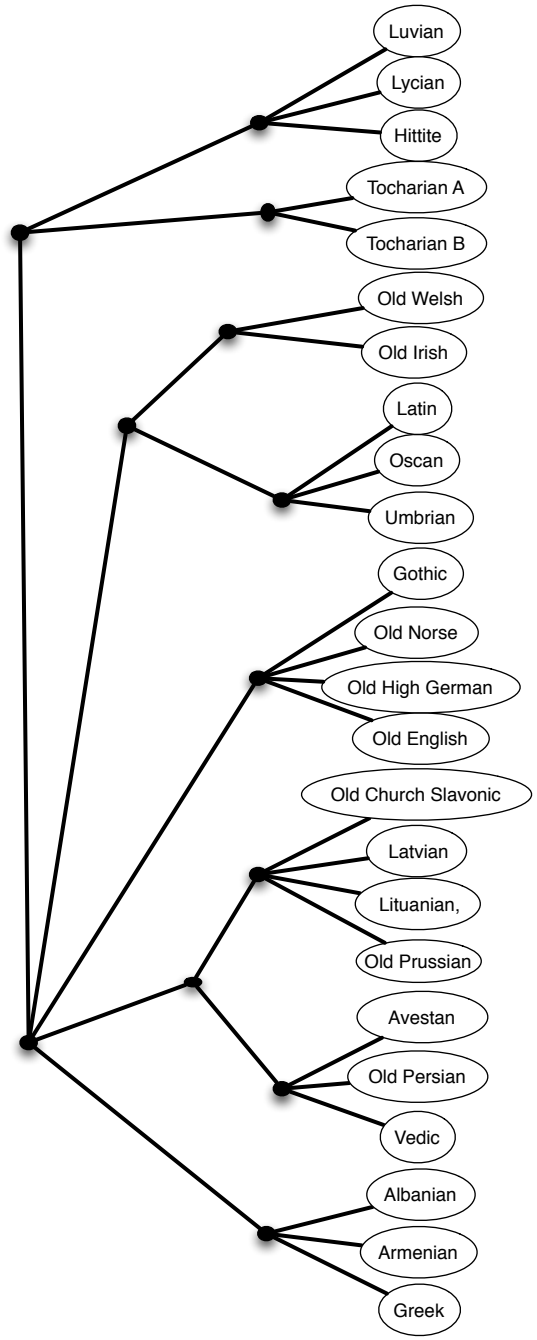
4.3 Comparative Indo-European Data Corpus

The dataset consists of 84 Swadesh 200-word lists representing contemporary Indo-European languages (Dyen et al., 1992). We used only the most reliable cognate sets numbered between 002 and 099, which contain forms that are cognate with each other and not cognate with the forms belonging to other sets. Each cognate set is treated as a separate character. For grouping purposes, we divided the languages into the following ten groups: Celtic, Romance, Germanic, Baltic, Slavic, Indic, Greek, Armenian, Iranian, and Albanian.

As a further simplifying step, we identified all cases where the same language group contains multiple cognate sets representing the same Swadesh meaning. For example, consider the words for 'neck': Nepali *manto* is cognate with Irish *muineal*, while Gujarati *gerden* is cognate with Macedonian *vrat*. In such cases, we removed all but one of the cognate sets involved, provided they are found in only two language families. In our example, we therefore remove the cognate set

[1] http://www.cs.rice.edu/~nakhleh/CPHL/

Figure 5: The tree given by our algorithm for the CPHL dataset, morphological and phonological characters only, with no language grouping.



shared between the Celtic and Indic families. This does not affect the total number of required borrowings.

Figure 6 shows the tree obtained when we ran our search on the Comparative Indo-European Data Corpus with language grouping. To construct this tree, our search found a minimum set of eight inconsistent cognates. We have analyzed these cognates, and while a few are inherited, most are either borrowings or annotation errors (e.g., Slovenian *jagat* 'to hunt' or Albanian *tuti* 'all').

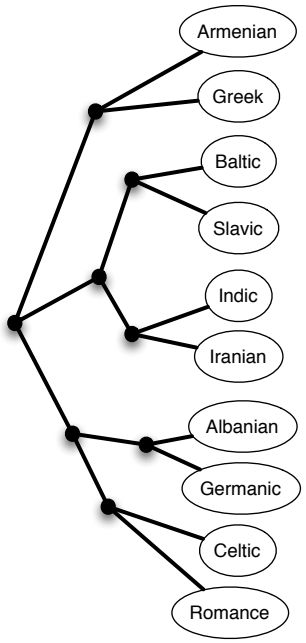
Although the consensus about the exact form of the Indo-European language phylogeny is yet to be reached in spite of many decades of research, our tree conforms to several well-established facts, including the affinity betwen Baltic and Slavic, Indic and Iranian, and the *Satem core*. However, there are some differences in comparison with the tree proposed by the CPHL project.

In Figure 6, the Albanian and Germanic languages are more closely grouped with the Celtic and Romance languages than the Baltic, Slavic, Indic, Greek and Armenian Languages. The opposite is true in the tree proposed by Nakhleh et al. (2005a). However, they note that the Germanic languages seem to have exhibited a large amount of borrowing compared to the other languages they considered, and mention that on their trees the position of Albanian is uncertain. If Germanic has undergone a substantial amount of non-tree-like evolution, then it is unsurprising that it is the major source of disagreement between our and their trees.

Our tree in Figure 6 also differs from our tree in Figure 5, in which a single vertex branches to many groups of languages. Another difference is the placement of Albanian.

Gray and Atkinson (2003) also built a phylogenetic tree for the Indo-European languages using the Comparative Indo-European Data Corpus. Their tree differs significantly from that proposed by Nakhleh et al. (2005a). The tree produced by Gray and Atkinson (2003) does not group Balto-Slavic with Indo-Iranian, while both our tree and the tree in (Nakhleh et al., 2005a) do. Gray and Atkinson (2003) instead groups Balto-Slavic with the Germanic, Romance, and Celtic language families. The placement of Albanian is different in all three trees. All three trees group Baltic with Slavic, Armenian with Greek, and Indic with Iranian.

Figure 6: The tree given by our algorithm for the Comparative Indo-European Data Corpus with language grouping.



5 Tiered search

We noticed when running experiments that characters that are thought in the literature to be borrowed are often present in few language families, whereas characters that are thought to be ancestrally inherited are often present in a larger number of language families. We therefore devised a tiered version of our heuristic search. In this version, we first run the search on only the characters that are present at more than two language families. We find the minimum number of these characters that must be removed to result in a chordal graph, remove that minimum set from the overall dataset, and run a subsequent search on this set in which the only vertices that are allowed to be removed are present at exactly two language families. We finally concatenate the minimum set of vertices that this search finds with the minimum set found in the earlier search to produce our overall minimal set of borrowing events.

We tested tiered search on the Comparative Indo-European Data Corpus. Our results were negative. In particular, the resulting tree fails to group Baltic and Slavic together, which is universally accepted in historical linguistics. This suggests that the observation is not sufficiently general to improve the proposed method.

6 Future work

We plan to extend our research on several directions.

First, our heuristic search could likely be made more efficient, though not asymptotically. Apart from the careful selection of nodes to evaluate as noted in Observation 1, we perform no search tree pruning. There are likely choices of nodes to be evaluated that are strictly dominated by other nodes. For example, consider two vertices u, v in a chordless cycle C of length greater than three such that the only neighbors of u are in C, but v is also in other chordless cycles, and has neighbors outside C. Then the choice to remove v strictly dominates the choice to remove u.

Second, we plan to modify our search procedure to minimize the total number of borrowings. rather than the total number of borrowed characters. We have found that in our experiments that minimizing the later has always minimized the former, but this may not be the case in all datasets.

Finally, we intend to improve the speed of the heuristic search, which would enable us to run tests on larger and more inconsistent datasets.

7 Conclusion

We have proposed conservative Dollo-phylogeny as a model for linguistic phylogenetics. We devised and tested an algorithm for calculating the minimum number of inconsistent characters within a dataset over all possible phylogenetic trees without enumerating those trees. We tested this approach on three datasets with positive results.

The main advantage of this approach is its speed. All computations took very little time - on the order of seconds. Previous approaches have been much slower. The trees produced by our method are therefore useful not only in their own right, but also as a very rapid initial stage of a computation. One possible approach would be to quickly generate trees with our method, and then use them as input to a more exhaustive algorithm.

Our approach calculates the minimum number of characters that are inconsistent with CDP across all possible phylogenetic trees without actually considering these trees individually. The CDP model and our heuristic algorithm may be particularly useful in cases where the number of languages is large, or where not even a partial tree is known.

Abstract

We show that transductive (cross-domain) learning is an important consideration in building a general-purpose language identification system, and develop a feature selection method that generalizes across domains. Our results demonstrate that our method provides improvements in transductive transfer learning for language identification. We provide an implementation of the method and show that our system is faster than popular standalone language identification systems, while maintaining competitive accuracy.

1 Introduction

Language identification (LangID) is the task of determining the language(s) that a text is written in. It is considered by some researchers to be a solved task, because previous research has reported near-perfect accuracy (Cavnar and Trenkle, 1994). Hughes et al. (2006) elaborated a number of simplifying assumptions that have made this the case, and Baldwin and Lui (2010a) showed that when some of these assumptions are relaxed to make the task closer to the actuality of open-web LangID, it becomes considerably harder. In this paper, we demonstrate that the style of evaluation used by Baldwin and Lui (2010a) performs well in-domain but badly cross-domain, and develop a novel method for preserving high in-domain accuracy, while significantly boosting cross-domain accuracy. Similarly to Baldwin and Lui (2010a), we make the simplifying assumption that all documents are monolingual, despite recent work on multilingual LangID (Baldwin and Lui, 2010b).

LangID is usually formulated as a supervised machine learning problem and evaluated in an offline setting (Cavnar and Trenkle, 1994; Baldwin and Lui, 2010a). However, its primary use is online without any additional configuration, optimized for maximal cross-domain accuracy. A number of such standalone LangID systems are available, notable among which is `TextCat` (van Noord, 1997). `TextCat` has been the LangID solution of choice in research, and is the basis of language identification/filtering in the ClueWeb09 Dataset (Callan and Hoy, 2009) and CorpusBuilder (Ghani et al., 2004). Elsewhere, Google provides LangID as a web service via its Google Language Detect API (`GoogleAPI`). While it has much higher accuracy than `TextCat` (as we show in Section 6.1), research applications contravene the service's terms of use, and moreover the service is rate-limited.

Our ideal system should offer the same advantages as `TextCat` in terms of licensing and run-time speed, while matching the open-domain accuracy and ease-of-use of an API such as `GoogleAPI`. To this end, we release the optimized final LangID system described in this paper, and benchmark it against `TextCat` and `GoogleAPI`. Our major contributions are: (1) we show that negative transfer occurs when training a classifier over a combined set of LangID datasets; (2) we show that language models learned in a particular domain do not always generalize to other domains; (3) we develop a method for extracting features for LangID that are not tied to a particular domain, and show that our method mitigates negative transfer and provides improvements in cross-domain LangID; (4) we show that our method can incorporate additional languages without a penalty in performance on existing languages; and (5) we provide an implementation of our method that is faster than state-of-the-art LangID systems while maintaining competitive accuracy.

2 Background

LangID as a computational task is usually attributed to Gold (1967), who sought to investigate

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 553–561,
Chiang Mai, Thailand, November 8 – 13, 2011.

language learnability from a language theory perspective. However, its current form is much more recognizable in the work of Cavnar and Trenkle (1994), where the authors classified documents according to rank order statistics over byte n-grams between a document and a global language profile. Since the 1990s, LangID has been formulated as a supervised machine learning task, and has been greatly influenced by text categorization in general. Monolingual LangID of a test document D_i takes the form of a mapping onto a unique language from a closed set of languages C, i.e. $\mathcal{I} : D_i \rightarrow c_i \in C$.

Statistical approaches applied to LangID include the use of Markov models over n-gram frequencies (Dunning, 1994) and dot products of word frequency vectors (Darnashek, 1995). Kernel methods have also been applied to the task of LangID (Kruengkrai et al., 2005). Linguistically motivated models for LangID have also been proposed, such as stop word list overlap (Johnson, 1993), where a document is classified according to its overlap with lists for different languages. There has also been work on word and part of speech correlation (Grefenstette, 1995), cross-language tokenisation (Giguet, 1995) and grammatical-class models (Dueire Lins and Gonçalves, 2004).

LangID has been applied in a variety of domains, including USENET messages (Cavnar and Trenkle, 1994), web pages (Kikui, 1996; Martins and Silva, 2005; Liu and Liang, 2008), and web search queries (Hammarstrom, 2007; Ceylan and Kim, 2009). It has been shown to improve performance of other tasks such as parsing (Alex et al., 2007) and multilingual text retrieval (McNamee and Mayfield, 2004). It has also been used for gathering data for linguistic corpus creation (Ghani et al., 2004; Baldwin et al., 2006; Xia et al., 2009; Xia and Lewis, 2009), and is an important area of research for supporting low-density languages (Hughes et al., 2006; Abney and Bird, 2010).

Transfer learning refers to the use of data from external domains to improve task performance on a target domain. Pan and Yang (2010) provide a survey, in which they define *transductive* transfer learning, where labels are available in source domain(s) but not in the target domain. This corresponds exactly to our task, where we wish to train a classifier using language-labelled data from a variety of sources, and apply this classifier to target data without making any assumptions about its domain. Pan and Yang (2010) also discuss the phenomenon of *negative transfer*, whereby including data from the source domain(s) results in reduced performance in the target domain.

Table 1: Summary of the LangID datasets

Other work has used the term *domain adaptation* to refer to *inductive* transfer learning, where labels are available in both the source and target domains, and the goal is to improve the performance in the target domain (Daumé III and Marcu, 2006; Daumé III, 2007). Daumé III and Marcu (2006) tackle this problem by using a mixture model, where data in a specific domain is modelled as coming from a mixture of domain-specific and general components, and the linkage between domains is achieved by sharing a single general component. In our task, we have no labels in the target domain, and thus know nothing about the domain-specific component. Thus, our challenge is to build a suitable model of the general component, which we do by eliminating features that make minimal contribution to the general component. This approach makes the conversion of documents to a standardized representation much simpler than a model that decomposes individual features into general and domain-specific components.

3 Data Sources

For this work, we collected language-labelled development data from five sources of diverse origin, and use these as the basis of our examination of in-domain, inductive (all-domain) and transductive (cross-domain) learning. We additionally use three independent test data sets to validate the effectiveness of the final methodology. Statistics of all datasets are provided in Table 1.

3.1 Development data sets

JRC-ACQUIS: JRC-ACQUIS is an aligned multilingual parallel corpus (Steinberger et al., 2006) totalling 463792 documents in 22 lan-

guages. From the corpus, we randomly selected 20000 documents without replacement, maintaing the relative skew of languages. For each document, only the text enclosed in the <body> tags was retained.

CLUEWEB09: The ClueWeb09 dataset (Callan and Hoy, 2009) consists of about 1 billion web pages in 10 languages.[1] The language of each document was automatically detected using TextCat, an implementation of the algorithm of Cavnar and Trenkle (1994). We sampled 20000 instances from the dataset by selecting the first instance in each of 20000 files selected without replacement. Because the language labels are automatically assigned, they do not constitute a true gold-standard, and we thus use CLUEWEB09 exclusively as a training dataset in Section 6.

WIKIPEDIA: Wikimedia provides dumps of the complete contents of all Wikipedia wikis.[2] Individual languages have their own wiki, usually under the corresponding ISO 639-1 code. We obtained XML dumps of the wikis with valid ISO 639-1 codes. From these dumps, we selected 20000 pages in a skew-preserving fashion. In order to ensure that each language contained at least 20 documents, we limited selection to the 68 largest wikis by page count. The data we used was obtained from July–August 2010.

RCV2: Reuters RCV2[3] consists of over 487000 Reuters News stories in 13 languages. We randomly selected 20000 documents in a skew-preserving fashion.

DEBIAN: The Debian Project maintains manual translations of the content strings of a large number of software packages.[4] We obtained all translations with codes corresponding to valid ISO 639-1 codes. This resulted in 21735 language-package pairs in 89 languages.

For each dataset, we randomly divided the documents into two equal-sized partitions. One partition was used for selecting language features and for training, and the other was used for testing. To distinguish between them, we label the partitions A and B, respectively. For example, DEBIAN$_{\mathrm{A}}$ is the partition of the DEBIAN dataset used to compute feature weights and language models, and DEBIAN$_{\mathrm{B}}$ is the partition used for testing. We also make frequent use of the union of the A partitions across all datasets, and will refer to this as UNION$_{\mathrm{A}}$.

3.2 Test data sets

In order to evaluate accuracy in the transductive learning setting, we make use of N-EUROGOV, N-TCL and N-WIKIPEDIA, the three datasets described in detail by Baldwin and Lui (2010a). N-EUROGOV was sourced from the EuroGOV collection used in the 2005 Web-CLEF task, N-TCL was manually sourced by the Thai Computational Linguistics Laboratory (TCL) in 2005 from online news sources, and N-WIKIPEDIA is drawn from a 2008 dump of Wikipedia, with normalization.

4 Learning Algorithms

In this work, we use a multinomial naive Bayes learner. For brevity, we only give a short sketch of the technique; it is described in much more detail by McCallum and Nigam (1998). The crux of the method is to compute the probability that an instance belongs to a class C_i from a given closed set C, and hence assign the most probable class to a document D, consisting of a vector of n features $x_1 ... x_n$:

$$c = argmax_{C_i \in C} P(C_i|D)$$

Bayes' theorem allows us to re-express this as:

$$c = argmax_{C_i \in C} \frac{P(D|C_i)P(C_i)}{P(D)}$$

where $P(D)$ is a normalizing constant independent of C_i. Thus for classification, we only need to estimate $P(D|C_i)$ and $P(C_i)$. C is modelled as a categorical distribution over classes, and so $P(C_i)$ is obtained via a maximum likelihood estimate. In order to estimate $P(D|C_i)$, we make the naive assumption that each term is conditionally independent, hence:

$$P(D|C_j) = \prod_{i=1}^{n} \frac{P(t_i|C_j)^{N_{D,t_i}}}{N_{D,t_i}!}$$

where N_{D,t_i} is the frequency with which term t_i occurs in D.

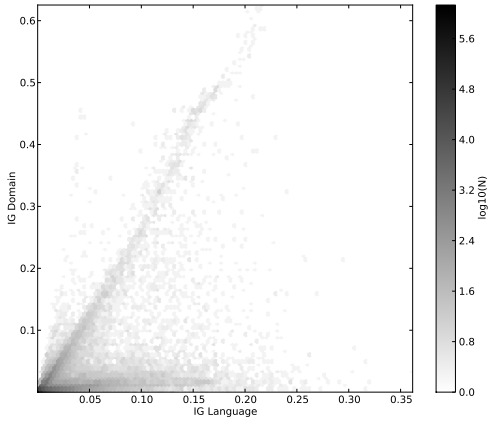

Figure 1: Scatter plot of IG for language vs. IG for domain (byte trigrams)

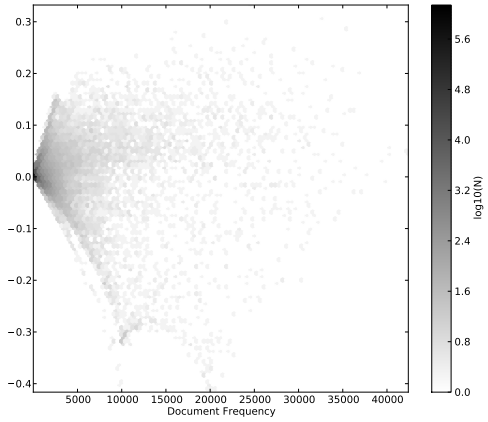

Figure 2: Scatter plot of DF vs. $\mathcal{LD}$ (byte trigrams)

The reason we select multinomial naive Bayes is that it is relatively lightweight and has been shown to be highly accurate when combined with feature selection (McCallum and Nigam, 1998; Manning et al., 2008). To establish the generalizability of our results, we also experimented with a nearest prototype classifier based on skew divergence (Lee, 2001), based on the findings of Baldwin and Lui (2010a). However, when combined with feature selection, we found it was consistently outperformed by the naive Bayes classifier, and thus omit results from this paper. We also experimented with a linear-kernel SVM learner, but once again omit results as we found it to be comparable in accuracy to naive Bayes when combined with feature selection, but much slower to retrain.

5 Feature Selection

The document representation that we use is a mixture of byte n-grams (Cavnar and Trenkle, 1994; Baldwin and Lui, 2010a), as it is language-neutral in that it does not make any assumptions about the language or language type of each document. In particular, we make no assumptions about word delimitation (e.g. via white space) in each language. Results from Baldwin and Lui (2010a) additionally suggest that explicit encoding detection is not necessary in LangID, and that the simple byte tokenization strategy also used in this work is superior to encoding-aware codepoint-based tokenization. Where we have data in more than one encoding, we do not transcode it; instead we simply extract byte features across all the encodings. In practice this is not an issue as the data that we use is mostly UTF8-encoded, with small quantities of other encodings (esp. in N-TCL). We make no further mention of encoding as it is not the focus of this work.

Cavnar and Trenkle (1994) perform feature selection over such a mixture of n-grams, where $1 \leq n \leq 5$. Their feature selection method is based on the frequency of terms, where the N most frequent terms for each language are retained in the global feature set. Related to term frequency is document frequency, where rather than counting individual terms in a class, we count the number of documents that a particular term appears in. Feature selection based on document frequency has been shown to be inferior to other methods. Generally it has been found that Information Gain ($\mathcal{IG}$: Quinlan (1986)) is particularly suited to feature selection in multiclass problem settings such as LangID (Yang and Pedersen, 1997; Forman, 2003).

The novel aspect of our research is that we consider $\mathcal{IG}$ of particular n-gram features along multiple dimensions: (1) with respect to the set of all languages; (2) with respect to a given language; and (3) with respect to the domain the data was obtained from. We are interested in identifying features that have high $\mathcal{IG}$ with respect to language but low $\mathcal{IG}$ with respect to domain.

For each of 1-grams, 2-grams and 3-grams we computed the $\mathcal{IG}$ of each feature with respect to the set of all languages in our development datasets (97 languages), as well as with respect to the set of 5 domains. A scatter plot of $\mathcal{IG}$ for language vs. domain for 3-grams is presented in Figure 1. From this analysis, it is clearly visible

that there are two distinct groups of features: one where the $\mathcal{IG}$ for language is strongly correlated with that for domain, and one where the $\mathcal{IG}$ for language is largely independent of that for domain. We are interested in identifying features in the second group, and so for each feature we compute a $\mathcal{LD}$ ($\mathcal{L}$anguage-$\mathcal{D}$omain) score, defined as:

$$\mathcal{LD}^{all}(t) = \mathcal{IG}^{all}_{lang}(t) - \mathcal{IG}_{domain}(t)$$

The number of features to consider grows exponentially with n-gram order. This makes calculating the $\mathcal{IG}$ for higher token n-gram orders computationally infeasible. Yang and Pedersen (1997) found that document frequency ($\mathcal{DF}$) and $\mathcal{IG}$ were strongly correlated. Thus, we studied the relationship between $\mathcal{LD}$ and $\mathcal{DF}$ in our data, and found that low $\mathcal{DF}$ is a good predictor of low $\mathcal{LD}$ score, but not vice versa, as seen in Figure 2. As $\mathcal{DF}$ is much cheaper to compute than $\mathcal{IG}$, we first identify the 15000 features with highest $\mathcal{DF}$ for a given n-gram order, and assign a $\mathcal{LD}$ score of 0 to all features outside this set.

We also consider an alternative formulation of $\mathcal{LD}$. Due to skews between the quantities of data for each language, the highest-ranked features by $\mathcal{LD}$ tend to be biased towards the more common languages. In order to mitigate this, we also consider a formulation whereby we compute a $\mathcal{LD}^{bin}$ score for each feature conditioned on each language l:

$$\mathcal{LD}^{bin}(t|l) = \mathcal{IG}^{bin}_{language}(t|l) - \mathcal{IG}_{domain}(t)$$

In order to give better representaiton to less-frequent languages, we then select the top-scoring features from each language, and define the $\mathcal{LD}^{bin}$ feature set as the union of these features.

The number of features N is a parameter in both methods that we will investigate empirically in Section 6.

6 Experimental Setup and Results

The results presented in Baldwin and Lui (2010a) are based on cross-validation within datasets, without considering the applicabiliy of a model learned in one domain to LangID in another domain. Baldwin and Lui (2010a) also presented preliminary results with regards to feature selection, based on the Cavnar and Trenkle (1994) method. We first compare results with and without feature selection using our $\mathcal{LD}^{bin}$ and $\mathcal{LD}^{all}$ metrics, as well as $\mathcal{IG}^{all}_{lang}$—where we select the top features according to their information gain with the set of all languages—and finally $\mathcal{IG}^{bin}_{lang}$—where we select a fixed number of features per language, according to their information gain with the language.

Baldwin and Lui (2010a) found that byte bigrams performed well as a feature set for LangID, so we use them for this initial experiment. Tokenizing across all of our datasets results in 57160 unique bigrams. For $\mathcal{IG}^{all}_{lang}$ and $\mathcal{LD}^{all}$, we consider the top 2000 to 10000 features, in increments of 1000. For the per-language metrics, we experiment with selecting 100 to 800 features per langauge, in increments of 100.

We perform this experiment in two settings: (1) the supervised learning setting, where we use training and test data from the same domain; and (2) the inductive transfer learning setting, where we train a single classifier on UNION_A—the union of the A partitions across the five domains—and use this to classify partition B from each of the five domains in turn. We found that for $\mathcal{IG}^{all}_{lang}$, 10000 features produced the best results; for $\mathcal{IG}^{bin}_{lang}$, it was 100 features per class, corresponding to 4078 features; for $\mathcal{LD}^{all}$, it was 3000 features; and for $\mathcal{LD}^{bin}$ it was 200 features per class, corresponding to 3086 features. We report the results for the best parametrization of each feature selection metric in Tables 2 and 3. In each case, we present the classification accuracy for the full feature set ("Full"), followed by the classification accuracy for feature selection over the same combination of training and test dataset, as the Δ over Full. In all our experiments, the language skew present in each domain is preserved in both the training and the test partitions.

In the supervised case, the accuracy attained is similar when using the full feature set as for the respective reduced feature sets. This shows that utilizing the reduced feature sets does not harm in-domain classification accuracy, implying that we are able to preserve the key features required for classifying the data.

In the case of inductive transfer learning, we observe negative transfer: the greater amount of training data causes the accuracy to drop. This is particularly evident over RCV2, where adding in data from the other four domains results in a drop in accuracy from 0.973 to 0.576. We find that the $\mathcal{LD}$ features are generally able to better mitigate this than the $\mathcal{IG}_{lang}$ features. $\mathcal{LD}^{bin}$ features pro-

Table 3: Inductive Transfer Learning (all-domain) accuracy, relative to all features ("Full")

vide the best accuracy over each dataset in the inductive transfer learning setting, increasing accuracy over RCV2 to 0.986, exceeding the accuracy of the in-domain classification on the full feature set. We find that $\mathcal{LD}^{bin}$ features can also improve accuracy for in-domain classification, increasing accuracy on RCV2 to a near-perfect 0.999. These results validate the choice of $\mathcal{LD}^{bin}$ as a suitable metric for selecting general features for LangID.

Since our aim is to build a classifier in a transductive transfer learning setting, we examined the behaviour of the $\mathcal{LD}^{bin}$ features in such a setting over our 5 datasets. For each dataset, we trained a classifier on the A partitions, and evaluated the classifier on the B partition of each of the other datasets. Since each dataset covers a different set of languages, there may be languages in the evaluation dataset that are not present in the training dataset. It makes no sense to attempt to classify documents in these languages since we will by definition misclassify them, so the results resported in Table 4 are only over languages in the evaluation set that are also present in the training set. As a result, caution must be exercised in naively comparing accuracy figures across different combinations of training and test datasets.

In Table 4, we see several examples of language models not generalizing to other domains. For example, we see that when using all features, the language models learned from RCV2 classify data from the RCV2 domain with accuracy 0.973, but this drops to 0.838, 0.889 and 0.796 in other domains. We also find that language models from other domains have reduced accuracy when classifying RCV2 data. We find that in all these cases, using the $\mathcal{LD}^{bin}$ features mitigates this loss in accuracy. On RCV2 in particular, use of the $\mathcal{LD}^{bin}$ features results in over 0.95 accuracy when training with any of the 5 domains.

There is a number of domains where the use of the $\mathcal{LD}^{bin}$ features results in a loss in accuracy relative to the full feature set. This contrasts with our results in the inductive learning setting. We hypothesize that this is due to the $\mathcal{LD}^{bin}$ features having been selected from the union of all 5 datasets. While this feature set represents a general model across these 5 domains, for a specific pair of domains there will be some additional features that are strong predictors of language.

Preliminary work by Baldwin and Lui (2010a) suggested that feature selection over a mixture of n-grams yielded promising results. This is also supported by Cavnar and Trenkle (1994), who use a mixture of 1- to 5-grams. We thus investigated the interaction between the range of n-gram orders used for feature selection, the number of features selected per language and classification accuracy. Based on the results in Tables 2, 3 and 4, we used the $\mathcal{LD}^{bin}$ metric exclusively.

We conducted a parameter search for maximum token order M (e.g. $M = 3$ would mean all 1-, 2- and 3-grams) and number of features per language N. We considered $1 \leq M \leq 9$ and $100 \leq N \leq 800$ in increments of 100 features. We tested all combinations exhaustively in a supervised learning task across the union of all 5 datasets. We found that the best results are obtained for $M \geq 4$ and $N \geq 300$. In order to maximize classification rate we need to minimize the number of features used, so we chose $M = 4$ and $N = 300$, producing a feature set consisting of 7480 features.

In building a universal LangID tool, we need to quantify the effect of training on languages extraneous to the target domain. To investigate this, we perform experiments over the datasets of Baldwin and Lui (2010a) using two different classifiers: a reference classifier trained on all languages

Table 5: Comparison of standalone classification tools, in terms of accuracy and speed (documents/second), relative to `langid.py`

present in the training set, and a domain-specific classifier trained only on languages in the test set. The reference classifier is trained on 1–4-grams, selecting 300 features per language on the full 97 languages, whereas each domain-specific classifier is trained only on the subset of languages present in the target domain.

Figure 3 shows a scatter plot of the per-language accuracy over the different datasets. Rather than harming performance, we find that adding languges extraneous to the target domain generally has no impact on accuracy over the languages in the dataset. In fact, it occasionally positively impacts on accuracy (points to the left of the diagonal), and for the rare instances where it hurts accuracy (points to the right of the diagonal), the difference is relatively modest.

6.1 Comparison to existing tools

Our ultimate interest is in building a standalone classifier that is fast and accurate. For comparison to existing tools, we implemented our method as a Python module (`langid.py`), in the form of a single Python file with pre-trained models for 97 languages. It can act as a standalone LangID system, an embedded Python module, or a web service with an AJAX API.[5]

We compared the speed and accuracy of our system to `TextCat`, as well as `GoogleAPI`. `GoogleAPI` is constrained to: (1) limit the classification rate to 10 documents/second, and (2) base the classification only on the first 500 bytes of the document. These constraints are imposed by the service's terms of use. For `TextCat`, we test it: (1) off-the-shelf using the pre-trained language models, and (2) after retraining it over the same training data as `langid.py`.

Table 5 shows the accuracy of each system across 7 test datasets, as well as the speed in documents per second. We present absolute accuracy and speed for `langid.py`, and relative accuracy and slowdown for the other classifiers. The machine used to perform this experiment was a commodity desktop-class machine, with an Intel Q9400 4-Core CPU, 4GB of RAM and a 7200RPM SATA II hard drive. The slowdown for `GoogleAPI` is reported based on a classification rate of 10 documents per second.

We find that in general, `langid.py` is faster and more accurate than `TextCat` (both off-the-shelf and re-trained). The difference is smallest over a "traditional" LangID dataset like N-EUROGOV which contains only 10 languages, and is much more pronounced over a dataset like N-TCL which has a much larger variety of languages. Comparing `langid.py` and `GoogleAPI`, the two systems are evenly matched in accuracy, but again, `langid.py` is significantly faster. All differences in accuracy are statistically significant (McNemar's test, $p < 0.01$).

We note that the accuracy of `langid.py` is slightly lower on N-TCL than on other datasets. N-TCL has a high proportion of non-UTF8 doc-

[5] The code is available for public download from `http://www.csse.unimelb.edu.au/research/lt/resources/langid/`

Test dataset	Feature selection		
	TextCat	$\mathcal{CT}$	$\mathcal{LD}^{bin}$
N-EUROGOV	0.904	+0.067	+0.083
N-TCL	0.672	+0.016	+0.227
N-WIKIPEDIA	0.686	+0.084	+0.223

Table 6: Comparison of TextCat to a NB classifier using $\mathcal{CT}$ and $\mathcal{LD}^{bin}$ for feature selection, using UNION_A as the training data

uments (57%). To quantify the effect of this, we transcoded all the documents in N-TCL to UTF8 and repeated the experiment. We found that after transcoding, the accuracy of langid.py increased from 0.904 to 0.947. This indicates that unsupported encodings have a small impact on accuracy, though it is relatively minor considering that the majority of the data is not UTF8-encoded.

The are two key conceptual differences between TextCat and langid.py: feature selection and learning algorithm. TextCat ($\mathcal{CT}$) selects features per language by term frequency, whereas langid.py uses $\mathcal{LD}^{bin}$ (the focus of this work). On the other hand, the learning algorithm used by TextCat is a nearest-prototype method using the token rank difference metric of Cavnar and Trenkle (1994), whereas langid.py uses multinomial naive Bayes. In order to consider these differences independently, we combine the $\mathcal{CT}$ feature selection with the multinomial naive Bayes learner, selecting the union of the top-300 features per language by document frequency over 1- to 5-grams, yielding 10846 features. For comparison, we also selected the top 300 features by $\mathcal{LD}^{bin}$ over 1- to 5-grams, yielding 8166 features. We then trained a naive Bayes classifier over UNION_A using the respective feature sets, and used it to classify each of N-EUROGOV, N-TCL and N-WIKIPEDIA. In Table 6, we compare the accuracy of these two classifiers to (retrained) TextCat. Across all datasets, $\mathcal{LD}^{bin}$ is superior to $\mathcal{CT}$. Additionally, NB with $\mathcal{CT}$ is superior to TextCat (which uses the same feature selection strategy, with the nearest prototype learner), although the difference here is much smaller. This suggests that the bulk of the improvement of langid.py over TextCat is due to the use of $\mathcal{LD}^{bin}$, as developed in this research.

7 Conclusion

We demonstrated the problem of negative transfer in training a LangID system using language-labelled data from a variety of domains. We developed a method for identifying features that are strongly predictive of language across multiple domains by examining the difference in information gain of each feature with language and with the source domain. We used this method to compile a feature set from 50,000 documents in 97 languages across 5 datasets, and implemented this as a standalone LangID system using a naive Bayes classifier. We empirically compared our system to state-of-the-art LangID systems, and found our system to be faster whilst maintaining competitive accuracy.

Abstract

Entity linking maps name mentions in context to entries in a knowledge base through resolving the name variations and ambiguities. In this paper, we propose two advancements for entity linking. First, a Wikipedia-LDA method is proposed to model the contexts as the probability distributions over Wikipedia categories, which allows the context similarity being measured in a semantic space instead of literal term space used by other studies for the disambiguation. Furthermore, to automate the training instance annotation without compromising the accuracy, an instance selection strategy is proposed to select an informative, representative and diverse subset from an auto-generated dataset. During the iterative selection process, the batch sizes at each iteration change according to the variance of classifier's confidence or accuracy between batches in sequence, which not only makes the selection insensitive to the initial batch size, but also leads to a better performance. The above two advancements give significant improvements to entity linking individually. Collectively they lead the highest performance on *KBP-10* task. Being a generic approach, the batch size changing method can also benefit active learning for other tasks.

1 Introduction

Knowledge base population (KBP)[1] involves gathering information scattered among the documents of a large collection to populate a knowledge base (KB) (e.g. Wikipedia). This requires either linking entity mentions in the documents with entries in the KB or highlighting these mentions as new entries to current KB.

Entity linking (McNamee and Dang, 2009) involves both finding name variants (e.g. both *"George H. W. Bush"* and *"George Bush Senior"* refer to the 41st U.S. president) and name disambiguation (e.g. given *"George Bush"* and its context, we should be able to disambiguate which president it is referring to).

Compared with Cross-Document Coreference (Bagga and Baldwin, 1998) which clusters the articles according to the entity mentioned, entity linking has a given entity list (i.e. the reference KB) to which we disambiguate the entity mentions. Moreover, in the articles, there are new entities not present in KB.

For name disambiguation in entity linking, there has been much previous work which demonstrates modeling context is an important part of measuring document similarity. However, the traditional approach for entity linking treats the context as a bag of words, n-grams, noun phrases or/and co-occurring named entities, and measures context similarity by the comparison of the weighted literal term vectors (Varma *et al*., 2009; Li *et al*., 2009; McNamee *et al*., 2009; Zhang *et al*., 2010; Zheng *et al*., 2010; Dredze *et al*., 2010). Such literal matching suffers from sparseness issue. For example, consider the following four observations of *Michael Jordan* without term match:

1) Michael Jordan is a leading researcher in machine learning and artificial intelligence.

2) Michael Jordan is currently a full professor at the University of California, Berkeley.

3) Michael Jordan (born February, 1963) is a former American professional basketball player.

4) Michael Jordan wins NBA MVP of 91-92 season.

To measure the similarity of these contexts, the semantic knowledge underlying the words is needed.

Furthermore, current state-of-the-art entity linking systems (Dredze *et al*., 2010; Zheng *et al*., 2010) are based on supervised learning approach requiring lots of annotated training instances to achieve good performance. However, entity linking annotation is highly dependent on the KB. When a new KB comes, the annotating process needs to be repeated. We have tried to automate this annotating process (Zhang *et al.* 2010). However, as discussed in that paper, the distribution of the auto-generated data is not con-

[1] http://nlp.cs.qc.cuny.edu/kbp/2010/

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 562–570,
Chiang Mai, Thailand, November 8 – 13, 2011.

sistent with the real dataset, because only some types of instances can be generated.

In this paper, we propose two approaches: (1) a Wikipedia-LDA model to effectively mine the semantic knowledge from the contexts of the mentions. Such topic model allows us to measure the similarity between articles and KB entries in the semantic space of Wikipedia category. (2) An instance selection strategy to effectively utilize the auto-generated annotation through an iterative process of selecting a representative, informative and diverse batch of instances at each iteration. The batch sizes at each iteration change according to the variance of classifier's confidence or accuracy between batches in sequence, which makes selection insensitive to the initial batch size and performs better than fixed size.

We conduct evaluation on *KBP-10* data (Ji *et al.*, 2010). Experiments show that the Wikipedia-LDA model is able to effectively capture the underlying semantic information and produce statistically significant improvement over literal matching alone. Correspondingly, instance selection can make the dataset more balanced and it also produces a significant gain in entity linking performance. Collectively, the two advancements lead the highest performance on *KBP-10* task. Being a generic approach, the batch size changing method proposed in this paper can also benefit active learning for other tasks.

The remainder of this paper is organized as follows. Section 2 introduces the framework for entity linking. We present our Wikipedia-LDA model in Section 3, and the instance selection in Section 4. Section 5 shows the experiments and discussions. Section 6 concludes our work.

2 Entity Linking Framework

Entity linking is done through two steps: name variation resolution and name disambiguation. Name variation resolution finds variants for each entry in KB and then generates the possible KB candidates for the given name mention by string matching. Name disambiguation is to map a mention to the correct entry in the candidate set.

2.1 Name Variation Resolution

Wikipedia contains many name variants of entities like confusable names, spelling variations, nick names, etc. We extract the name variants of an entry in KB by leveraging the knowledge sources in Wikipedia: "titles of entity pages", "disambiguation pages"[2], "redirect pages"[3] and "anchor texts". With the acquired name variants for entries in KB, the possible KB candidates for a given name mention can be retrieved by string matching. If the given mention is an acronym, we will expand it from the given article, and then use entity linking process.

2.2 Name Disambiguation

First, using a learning to rank method, we rank all the retrieved KB candidates to identify the most likely candidate. In this learning to rank method, each name mention and the associated candidates are formed by a list of feature vectors. During linking, the score for each candidate entry is given by the ranker. The learning algorithm we used is ranking SVM (Herbrich *et al.*, 2000).

Next, the preferred KB candidate is presented to a binary classifier (Vapnik, 1995) to determine if it is believed as the target entry for a name mention. From here, we can decide whether the mention and top candidate are linked. If not, the mention has no corresponding entry in KB (*NIL*). The base features adopted for both learning to rank and classification include 15 feature groups divided to 3 categories. A summary of the features is listed in Table 1. Due to the space limit, we only show the feature name, leaving out the feature details which can be found in (Dredze *et al*., 2010; Zheng *et al*., 2010).

Categories	Feature Names
Surface	Exact Equal Surface, Start With String of Query, End With String of Query, Equal Word Num, Miss Word Num
Contextual	TF-IDF Similarity, Similarity Rank, All Words in Text, NE Number Match, Country in Text Match, Country in Text Miss, Country in Title Match, Country in Title Miss, City in Title Match
Others	NE Type

Table 1: Base Feature Set

3 Wikipedia-LDA Model

In the similar task cross-document coreference (Han and Zhao 2009) and other tasks (e.g. text classification) (Wang and Domeniconi, 2008), Wikipedia concepts are used to model the text. Wikipedia concept is a kind of entity-level topic. In our approach, we use the cross-entity topic Wikipedia Categories to represent the semantic knowledge.

[2] http://en.wikipedia.org/wiki/Wikipedia:Disambiguation
[3] http://en.wikipedia.org/wiki/Wikipedia:Redirect

Thus, we model the contexts as the distributions over Wikipedia categories. Then, the similarity between the contexts can be measured in a semantically meaningful space. Finally, such semantic similarity, together with other base features, is incorporated in the trainable models to learn the ranker and classifier.

3.1 Modeling the Contexts as Distributions over Wikipedia Categories

Wikipedia requires contributors to assign categories to each article, which are defined as "major topics that are likely to be useful to someone reading the article". Thus, Wikipedia can serve as a document collection with multiple topical labels, where we can learn the posterior distribution over words for each topical label (i.e. Wikipedia category). Then, from the observed words in the mention's context and KB entry, we can estimate the distribution of the contexts over the Wikipedia categories. To obtain this distribution, we use a supervised Latent Dirichlet Allocation (LDA) model – labeled LDA defined by Ramage *et al*. (2009), which represents state-of-the-art method for multi-labeled text classification. It performs better on collections with more semantically diverse labels, which we need in order to leverage on the large semantically diverse categories from Wikipedia as the topical labels.

Figure 1 shows us a graphical representation of the labeled LDA for the multi-labeled document collection. Labeled LDA is a three level hierarchical Bayesian model. β is the multinomial distribution over words for a Wikipedia category, which has a Dirichlet prior with hyperparameter η. Both the category set Λ as well as the topic prior α influence the topic mixture θ. These distributions can be used to generate documents in the form of a collection of words (w). D is the number of documents, N is the document length and K is the number of categories.

After the model is trained by Wikipedia data, the distributions of KB entry and the article over K categories are estimated by calculating the topic proportions θ. θ is given by an EM procedure that treats θ as a parameter with Z missing.

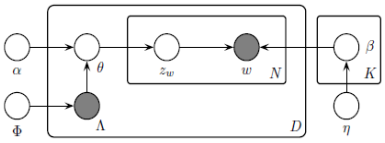

Figure 1: Graphical model of Labeled LDA

3.2 Context Similarity

We have mapped the contexts to a K-dimensional semantic space. Thus, we can calculate the context similarity by their distance in this space. To measure the context similarity in the K-dimensional topical space, we calculate the Cosine value as below:

$$Similarity_{d,e} = \frac{\sum_{k=1}^{K} \theta_{d,k} \times \theta_{e,k}}{\sqrt{\sum_{k=1}^{K} (\theta_{d,k})^2} \times \sqrt{\sum_{k=1}^{K} (\theta_{e,k})^2}} \quad (1)$$

Where d means the document with the name mention and e means the KB entry.

Such semantic similarity can be further combined with other term matching features for SVM ranker and classifier of entity linking.

3.3 Wikipedia Category Selection

Each article in Wikipedia is assigned several categories by the contributors as requested. However, from our observation some categories in Wikipedia may not be suitable to model the topics of a document. Thus, we shall consider selecting an appropriate subset from the Wikipedia categories to effectively model the contexts. We examined five possible category subsets: **All**, **All-admin**, **isa_all**, **isa_class**, and **isa_instance**.

Wikipedia contains 165,744 categories. This is the set **All.**

There are some meta-categories used for encyclopedia management in Wikipedia, e.g. "*Wikipedia editing guidelines*", which are unsuitable to describe the topics of a document. Thus, we remove the categories which contain any of the following strings: *wikipedia*, *wikiprojects*, *lists*, *mediawiki*, *template*, *user*, *portal*, *categories*, *articles* and *pages*. This leaves 127,325 categories (**All-admin**).

However, some categories such as "*people by status*" and "*Geography by place*" in the **All-admin** set cannot serve as the topics of a document properly. Thus, we need to remove them from the category set. From our observation, the topical categories are usually in *is-a* relation. For example, the relation between the two topical categories "*Olympic basketball players*" and "*Olympic competitors*" is an *is-a* relation, while the categories to be removed "*people by status*" and "*Geography by place*" are not in any *is-a* relation. We thus only select the categories connected by *is-a* relation to **isa_all** subset.

Since the categories are connected by unlabeled links in Wikipedia, we need to identify *is-a* relation links. We use the four methods as below

proposed by Ponzetto and Strube (2007) to distinguish *is-a* and *not-is-a* relation links.

We first use a syntax-based method: assign *is-a* to the link between two categories if they share the same lexical head lemma (e.g. "*British Computer Scientists*" and "*Computer Scientists*").

Then, we use structural information from the category network: (1) for a category *c*, look for a Wikipedia article *P* with the same name. Take all *P*'s categories whose lexical heads are plural nouns $CP = \{cp_1, cp_2, \ldots, cp_n\}$. Take all supercategories of *c*, $SC = \{sc_1, sc_2, \ldots, sc_k\}$. If the head lemma of one of cp_i matches the head lemma of sc_j, label the relation between *c* and sc_j as *is-a*. (2) assign *is-a* label to the link between two categories if a Wikipedia article is redundantly categorized under both of them. For example, "*Internet*" is categorized under both "*Computer networks*" and "*Computing*" and there is a link between "*Computer networks*" and "*Computing*". Then this link is assigned *is-a*.

Next, we use lexical-syntactic patterns in a corpus. This method uses two sets of patterns. One set is used to identify *is-a* relations (Caraballo, 1999; Hearst, 1992), for example "*such* NP_1 *as* NP_2", NP_1 and NP_2 are the values of categories and their subcategories respectively. The second set is used to identify *not-is-a* relations. For example "NP_1 *has* NP_2", where the link between NP_1 and NP_2 will be assigned *not-is-a*. These patterns are used with a corpus built from Wikipedia articles, and separately with the Tipster corpus (Harman and Liberman, 1993). The label is assigned by majority voting between the frequency counts for the two types of patterns.

Finally, we assign *is-a* labels to links based on transitive closures - all categories along an *is-a* chain are connected to each other by *is-a* links.

Another fact is that the categories defined by Wikipedia are not all classes. For example, "*Microsoft*" is an instance of the class "*Computer and Video Game Companies*", and it appears both as an article page and as a category in Wikipedia. We would like to further examine the two different subsets: **isa_class**, and **isa_instance** in **isa_all** set for entity linking**.** To distinguish instance and class in **isa_all** set, we use a structure-based method (Zirn *et al*., 2008). The categories which have other subcategories or Wikipedia articles connected to them by *is-a* relation are assigned *class* label. In our problem, the remaining categories are approximately regarded as instances.

4 Instance Selection Strategy

In this section, we explore a method to effectively utilize a large-scale auto-generated data for entity linking.

In our pervious work (Zhang *et al*. 2010), we proposed automatically gathering large-scale training instances for entity linking. The basic idea is to take a document with an unambiguous mention referring to an entity *e1* in KB and replace it with its variation which may refer to *e1*, *e2* or others. For example, a mention "*Abbott Laboratories*" in a document only refers to one KB entry "*Abbott Laboratories*". "*Abbott Laboratories*" in the document is replaced with its ambiguous synonyms, including *"Abbott" "ABT"*, etc. Following this approach, from the 1.7 million documents in *KBP-10* text collection, we generate 45,000 instances.

However, the distribution of the auto-generated data is not consistent with the real dataset, since the data generation process can only create some types of training instances. In the case of *"Abbott Laboratories"*, more than ten "*Abbott*" mentions are linked to "*Abbott Laboratories*" entry in KB, but no "*Abbott*" example is linked to other entries like "*Bud Abbott*" "*Abbott Texas*", etc. Thus, we need an instance selection approach to reduce the effect of this distribution problem. However, the traditional instance selection approaches (Brighton and Mellish, 2002; Liu and Motoda, 2002) only can solve two problems: 1) a large dataset causes response-time to become slow 2) the noisy instances affect accuracy, which are different from our needs here. We thus propose an instance selection approach to select a more balanced subset from the auto-annotated instances. This instance selection strategy is similar to active learning (Shen *et al*., 2004; Brinker, 2003) for reducing the manual annotation effort on training instances through proposing only the useful candidates to annotators. As we already have a large set of auto-generated training instances, the selection here is a fully automatic process to get a useful and more balanced subset instead.

We use the SVM classifier mentioned in Section 2.2 to select the instances from the large dataset. The initial classifier can be trained on a set of initial training instances, which can be a small part of the whole auto-generated data, or the limited manual annotated training instances available, e.g. those provided by *KBP-10*.

Our instance selection method is an iterative process. We select an informative, representative

and diverse batch of instances based on current hyperplane and add them to the current training instance set at each iteration to further adjust the hyperplane for more accurate classification.

We use the distance as the measure to select informative instances. The distance of an instance's feature vector to the hyperplane is computed as follows:

$$Dist(w) = \left|\sum_{i=1}^{N} \alpha_i y_i k(s_i, w) + b\right| \quad (2)$$

Where w is the feature vector of the instance, α_i, y_i and s_i correspond to the weight, class and feature vector of the i^{th} support vector respectively. $\boldsymbol{N}$ is the number of the support vectors.

Next, we quantify the representativeness of an instance by its density. Such density is defined as the average similarity between this instance and all other instances in the dataset. If an instance has the largest density among all the instances in the dataset, it can be regarded as the centroid of this set and also the most representative instance.

$$Density(w_i) = \frac{\sum_{j \neq i} Sim(w_i, w_j)}{N-1} \quad (3)$$

Where w is the instance in the dataset and N is the size of dataset. *Sim* is cosine similarity.

We combine the informativeness and representativeness by the function $\lambda(1 - Dist(w)) + (1 - \lambda)Density(w)$, in which *Dist* and *Density* are normalized first. The individual importance of each part in this function is adjusted by a tradeoff parameter λ (set to 0.5 in our experiment). The instance with the maximum value of this function will be selected first to the batch. This instance will be compared individually with the selected instances in current batch to make sure their similarity is less than a threshold β. This is to diversify the training instance in the batch to maximize the contribution of each instance. We set β to the average similarity between the instances in the original dataset. When a batch of α instances is selected, we add them to the training instance set and retrain the classifier.

Such a batch learning process will stop at the peak confidence of the SVM classifier, since Vlachos (2008) shows that the confidence of the SVM classifier is consistent with its performance. The confidence can be estimated as the sum of the distances to hyperplane for the instances of an un-annotated development set. The development set guides the selection process to solve the distribution problem mentioned above. Alternatively, we can also leverage on some annotated development data and use accuracy instead to guide the selection process. We explore both approaches for different application scenarios in our experiments.

We now need to decide how to set the batch size α at each iteration. It is straightforward to set a fixed batch size α (**Fixed Number**), which never changes during the process. However, there are some limitations as demonstrated in our experiment in this paper. First, the performance is sensitive to the batch size. Second, if we set the batch size too big, it will impede further improvement allowed by small batch size. But if we set the batch size too small from the beginning, it will dramatically increase the number of iterations needed which will make the selection too slow. To resolve the above issues, we change the batch size according to the variance of classifier's confidence on an un-annotated set. Thus, we assign an integer to α_1 and α_2 in the first two iterations, and α_i $(i > 2)$ in the i^{th} iteration is computed as below (**Flexible Number)**:

$$\alpha_i = \frac{\alpha_{i-1} * (con_{i-1} - con_{i-2})}{con_{i-2} - con_{i-3}} \quad (4)$$

where con_i is the confidence of the classifier on the un-annotated dataset at i^{th} iteration.

Figure 2 summarizes the selection procedure.

Given: Initial Training Set $T=\{T_1,T_2...T_m\}$,
Original Set to be selected $A= \{A_1,A_2...A_n\}$,
Batch Set with the maximal size α.
Initialization: *Batch Set* = ∅
Loop until the confidence/accuracy of the classifier on a development set does not increase
Train a Classifier on T
Batch Set=∅
Update α according to Equation 4
Loop until *Batch Set* is full
- Select A_i with the maximal value P from A $P = \lambda(1 - Dist(w)) + (1 - \lambda)Density(w)$
- RepeatFlag=false;
- **Loop** for each A_k in *Batch Set*
  If $Sim(A_i,A_k) > \beta$ **Then**
  RepeatFlag=true
  Stop the Loop
- **If** RepeatFlag==false **Then**
  Add A_i to *Batch Set*
- Remove A_i from A

$T = T \cup Batch\ Set$

5 Experiments and Discussions

5.1 Experimental Setup

In our study, we use *KBP-10* knowledge base and document collection to evaluate our approach for entity linking. The KB is auto-generated from Wikipedia. The KB contains

Features	ALL	NIL	Non-NIL	ORG	GPE	PER
Base Features	83.2	88.2	77.2	82.1	75.1	92.5
Base + All	84.0	88.6	78.5	84.0	76.0	92.1
Base + All - admin	84.9	88.9	80.0	84.9	76.9	92.8
Base + isa_all	**85.9**	89.1	82.0	85.2	78.6	93.8
Base + isa_class	85.5	88.8	81.3	84.9	78.0	93.2
Base+isa_instance	83.9	88.9	77.8	82.9	76.6	92.1

Table 2: Results of Entity Linking for Semantic Features

818,741 different entries and the document collection contains 1.7 million documents. Each KB entry consists of the Wikipedia Infobox[4] and the corresponding Wikipedia page text. The test data has 2,250 mentions across three named entity types: Person (PER), Geo-Political Entity (GPE) and Organization (ORG). The documents containing these mentions are from newswire and blog text. The training set consists of 3,904 newswire mentions and 1,500 web mentions. In order to leverage name variant information mentioned in Section 2.1 and category network mentioned in Section 3.3, we further get Wikipedia data directly from Wikipedia website[5]. The version we use is released on Oct. 08, 2008.

For pre-processing, we perform sentence boundary detection derived from Stanford parser (Klein and Manning, 2003), named entity recognition using a SVM based system trained and tested on ACE 2005 with 92.5(P) 84.3(R) 88.2(F), and co-reference resolution using a SVM based resolver trained and tested on ACE 2005 with 79.5%(P), 66.7%(R) and 72.5%(F). In our implementation, we use the binary SVM^{Light} developed by Joachims (1999) and SVM^{Rank} developed by Joachims (2006). The classifier and ranker are trained with default parameters. The Stanford Topic Model Toolbox[6] is used for Labeled-LDA with default learning parameters.

We adopt micro-averaged accuracy used in *KBP-10* to evaluate our Entity Linker, i.e. the number of correct links divided by the total number of mentions.

5.2 System with Wikipedia-LDA

Table 2 lists the performance of entity linking with overall accuracy (*ALL*) as well as accuracy on subsets (*Nil, Non-Nil, ORG,GPE* and *PER*) of the data. In the first row, only base features described in Section 2.2 are used. This baseline system models the contexts with literal terms. The second to sixth rows report the results combining base features with semantic knowledge (i.e. the context similarity is computed by the five different subsets of Wikipedia categories mentioned in Section 3.3).

American novels	American film actors	Members of the National Academy of Sciences	American basketball players
novel	role	prize	**nba**
book	actor	**researcher**	**basketball**
story	films	**professor**	points
paperback	appeared	science	rebounds
plot	actress	nobel	games
print	television	institute	draft
edition	hollywood	theory	guard
isbn	california	physics	overall
hardback	roles	received	coach
characters	movie	sciences	**professional**
published	acting	medal	assists
man	married	chemistry	play
father	death	academy	**season**
love	character	award	forward
written	starred	ph. d	ncaa

Table 3: Sample Wikipedia Categories and Corresponding Top 15 Words

We see that all the five systems with semantic features perform better than the baseline system, which models the context similarity as literal term matching. Especially, the **isa_all** and **isa_class** can achieve significantly better result than the baseline ($\rho < 0.05$, χ^2 test). These results prove that the semantic knowledge underlying the contexts has good disambiguation power for entity linking. Table 3 tells the reason of the improvements. Table 3 shows us four sample Wikipedia categories and top 15 highly probable words identified by the topic model for these categories. The topic model successfully assigns a high probability to the words *"researcher"* and *"professor"* in the category *"Members of the National Academy of Sciences"*, and assign a high probability to the words "*nba*" "*basketball*" "*professional*" and "*season*" in the category *"American basketball players"*. Such semantic

KBP+Auto_Gen+IS	**85.5**	87.7	82.9	84.7	78.9	92.8

Table 4: Results of Entity Linking for Instance Selection

knowledge learned from Wikipedia data is helpful in the example of *"Michael Jordan"* mentioned in Section 1. This shows that entity linking can benefit from the semantic information underlying the words and overcome the shortcomings of literal matching.

We further compare the performances of the five different category subsets. From the last five rows of Table 2, we can see that **isa_all** subset performs best among the five subsets for disambiguation. This should be because **isa_all** includes more categories than **isa_class** and **isa_instance**, and thus can capture more semantic information. However, although **All** and **All-admin** include even more categories, they introduce many categories which are unsuitable to model the topics of a news article or blog text, such as the two categories mentioned in Section 3.3, "*people by status*" which is not in an *is-a relation* and "*Wikipedia editing guidelines*" which is used for encyclopedia management.

5.3 System with Instance Selection

Table 4 shows the results for evaluating our instance selection strategy. These experiments use the base features (Section 2.2).

5.3.1 With and Without Manual Annotated Data

We want to find out the effectiveness of our instance selection strategy if no manually annotated data is available. In the first block of Table 4, we compare the performances of the systems with and without instance selection. "*Auto_Gen*" uses the auto-generated dataset described at the beginning of Section 4 as the training set directly, and "*Auto_Gen+IS*" applies our instance selection to the auto-generated data for training. In the instance selection process, we use the KB entries with more than 15 linked documents in the auto-generated data as our Initial Training Set (1,800 instances) to train a classifier, and then use this classifier to select instance from the auto-generated dataset. The first block of Table 4 shows that our instance selection gives significant improvements ($\rho < 0.05$, χ^2 test). These improvements show our selection strategy makes the training set more balanced and it can effectively reduce the effect of distribution problem in the large scale dataset.

We further evaluate our instance selection strategy when a large manually annotated data is available in the second block of Table 4. *"KBP"* is trained on the manually annotated *KBP-10* training set. "*KBP+Auto_Gen*" is trained on *KBP-10* set and the auto-generated set. *"KBP+Auto_Gen+IS"* uses *KBP-10* training set as the Initial Training Set, and applies instance selection process to the auto-generated data. Comparing "*KBP+ Auto_Gen*" with "*KBP*", we can see that the unbalanced distribution caused serious problem which even pull down the performance achieved by the large manual annotation alone. The experiment results of "*KBP*" and "*KBP+Auto_Gen+IS*" show that our instance selection strategy appears very necessary to bring further improvements over the large manually annotated dataset (5,404 instances). These significant ($\rho < 0.05$, χ^2 test) improvements are achieved by incorporating more training instances in a reasonable way.

Comparing the performance of *"Auto_Gen+IS"* with *"KBP"* in Table 4, we can find that our method performs better without hard intensive work on annotating 5,404 articles. This proves that using our instance selection can save labor without compromise of entity linking accuracy. The pretty much same performance of *"Auto_Gen+IS"* with *"KBP +Auto_Gen+IS"* also confirms the above conclusion.

5.3.2 Fixed Size Vs. Changing Size

We are also interested in the effectiveness of the two schemes (i.e. Fixed Number and Flexible Number) of setting the batch size α mentioned in Section 4. In Figure 3, we set the batch size α in Fixed Number scheme and α_1 α_2 in Flexible Number scheme, to different numbers from 50 to 140 increasing 10 each time. We conduct instance selection to the auto-generated data. Figure 3 shows that flexible batch size outperforms the fixed size for entity linking. Especially, the

improvement at α=50, 60 and 70 is significant ($\rho < 0.05$, χ^2 test). This proves that batch size should be in line with the variance of the classifier's confidence at each iteration of instance selection. Furthermore, in this Figure, the performance of flexible batch size is more stable than the Fixed Number scheme. This shows that Flexible Number scheme makes the entity linking system insensitive to the initial batch size during instance selection process. Thus the initial batch size of the experiments in Table 4 is set to 80, which we believe that very similar performance can be achieved even with a different initial size. Another fact is that the selection process is similar to active learning, which needs to manually annotate the selected instances in each batch. Thus, being a generic approach, the batch size changing method proposed in this paper can also benefit active learning for other tasks.

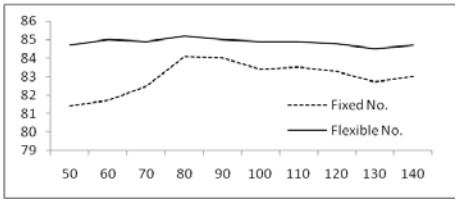

Figure 3: Performance Curves for Two Batch Size Schemes

5.3.3 (Un-)Annotated Development Set

In the above study, we directly use the test set without annotations as the development set for instance selection to optimize our solution to the application data. Such an approach will be useful when the application set is available in advance as in the case with *KBP* benchmarks.

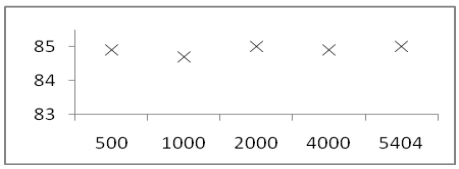

Figure 4: Annotated Development data

When the application set is unavailable beforehand, in other words, the articles to be linked only arrive one after the other in linking stage, we leverage on the accuracy on annotated development set for the instance selection. Figure 4 shows the performances on different sizes of annotated development set. The results show that the different sizes contribute more or less same performances. We only need to use a small amount of annotated development data, 500 articles in our study to guide the instance selection to achieve similar performance as with unannotated test set being development data.

5.4 Overall Result Combining Two Approaches

We also evaluate our model which combines the Wikipedia- LDA and Instance Selection together on *KBP-10* data, and compare our method with the top 7 systems in *KBP-10* shared task (Ji *et al*., 2010). As shown in Figure 5, the first column is the performance of our system for entity linking, which outperforms the best solution[7] in *KBP-10* shared task.

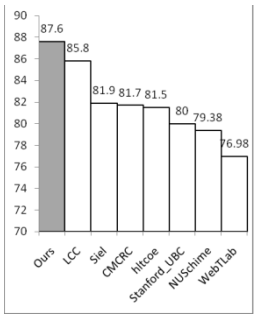

Figure 5: A Comparison with *KBP-10* Systems

6 Conclusion

In our paper, we explored using two innovative approaches for entity linking. We proposed a Wikipedia-LDA to entity linking, which can discover the semantic knowledge underlying the contexts. We also investigated the effectiveness of five subsets of Wikipedia categories to model the contexts. Furthermore, we proposed a batch size changing instance selection strategy to reduce the effect of distribution problem in the auto-generated data. It makes entity linking system achieve state-of-the-art performance without hard labor. Meanwhile, the flexible batch size not only makes the selection insensitive to the initial batch size, but also leads to a better performance than the fixed batch size. The above two advancements significantly improve entity linking system individually, and collectively they lead the highest performance on *KBP-10* task.

Acknowledgment

This work is partially supported by Microsoft Research Asia eHealth Theme Program.

[7] Another system submission shows 86.8%. However, it accesses web which is not allowed in *KBP* benchmark as the purpose to develop a standalone system, which is our focus here as well.

Discovering Latent Concepts and Exploiting Ontological Features for Semantic Text Search

Vuong M. Ngo[1,2,3] and **Tru H. Cao**[1,2]

[1]HCMC University of Technology and [2]John von Neumann Institute, VNU-HCM, and [3]VNG Corporation

{vuong,tru}@cse.hcmut.edu.vn

Abstract

Named entities and WordNet words are important in defining the content of a text in which they occur. Named entities have ontological features, namely, their aliases, classes, and identifiers. WordNet words also have ontological features, namely, their synonyms, hypernyms, hyponyms, and senses. Those features of concepts may be hidden from their textual appearance. Besides, there are related concepts that do not appear in a query, but can bring out the meaning of the query if they are added. The traditional constrained spreading activation algorithms use all relations of a node in the network that will add unsuitable information into the query. Meanwhile, we only use relations represented in the query. We propose an ontology-based generalized Vector Space Model to semantic text search. It discovers relevant latent concepts in a query by relation constrained spreading activation. Besides, to represent a word having more than one possible direct sense, it combines the most specific common hypernym of the remaining undisambiguated multi-senses with the form of the word. Experiments on a benchmark dataset in terms of the MAP measure for the retrieval performance show that our model is 41.9% and 29.3% better than the purely keyword-based model and the traditional constrained spreading activation model, respectively.

1. Introduction

With rapid development of the World Wide Web and e-societies, Information Retrieval (IR) has many challenges in discovering and exploiting those rich and huge information resources. Semantic search improves search precision and recall by understanding user's intent and the contextual meaning of concepts in documents and queries (Huston and Croft, 2010; Losada, et al, 2010; Egozi, et al, 2011).

Concepts are named entities or WordNet words (unnamed entities). Named entities are those that are referred to by names such as people, organizations, and locations (Sekine, 2004) and could be described in ontologies. Each fully recognized named entity (NE) has three features, namely, name, class, and identifier. WordNet words are words in a lexical database (e.g. WordNet database). Each fully recognized WordNet word (WW) has three features, namely, form, direct hypernym, and sense.

Lexical search is not adequate to represent the semantics of queries referring to NEs or WWs. Some examples of NE-based queries are: (1) Search for documents about "*football clubs*"; (2) Search for documents about "*Barcelona*"; (3) Search for documents about "*Paris City*"; (4) Search for documents about "*Paris City, Texas, USA*". In fact, the first query searches for documents containing NEs of the class *Football Club*, e.g. *Chelsea* or *Barcelona*, rather than those containing the keywords "*football club*". For the second query, target documents may mention *Football Club Barcelona* under other names, i.e., the football club's aliases, such as *Football Club Barca*. Besides, documents containing *Barcelona City* or *Barcelona University* are also suitable. In the third query, users do not expect to receive answer documents about entities that are also named "*Paris*", e.g. the actress *Paris Hilton* or *University of Paris* but are not cities. Meanwhile, the fourth query requests documents about a precisely identified named entity, i.e., the *Paris City in Texas, USA*, not the one in France. That are, entity aliases, classes, and identifiers have to be taken into account.

Some examples about WW-based queries are: (1) Search for documents about "*movement"*; (2) Search for documents about "*movement belonging to change"*; and (3) Search for documents about "*movement belonging to the act of changing location from one place to another"*. That is because the word *movement* has many different senses. In fact, the first query searches for documents containing not only the word *movement* but also its synonyms, e.g. *motion*, *front*, *cam-*

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 571–579,
Chiang Mai, Thailand, November 8 – 13, 2011.

paign, and *trend*, or its hypernyms, e.g. *change*, *occurrence*, *social group*, *venture*, and *disposition*. For the second query, users do not expect to receive answer documents about words that are also labelled "*movement"*, e.g. *movement belonging to a natural event* and *movement belonging to a venture*, but do not express changes. Meanwhile, the third query requests documents about a precisely identified word sense. The word *movement* means not only the action of changing something but also the act of changing location from one place to another, e.g. *the movement of people from the farms to the cities*.

Moreover, queries may contain both named entities and WordNet words. Some examples of NE-WW based queries are "*temblor in USA"* or *"natural calamity in USA"*, for which documents about "*earthquake in United States of America*" are truly relevant answers.

Besides, there are latent concepts that do not appear in queries but present user's intent. Intuitively, adding correct related concepts to a query will increase the recall and the precision of searching. In contrast, adding incorrect related concepts will decrease performance of IR system. For examples, consider the following queries: (1) Search for documents about "*cities that are tourist destinations of Thailand*"; (2) Search for documents about "*tsunami in Southeast Asia*"; (3) Search for documents about "*settlements are built in west of Jerusalem*"; and (4) Search for documents about "*Barack Obama uses high-tech defences*". For the first query, Chiang Mai and Phuket should be added into the query, because they belong to class *City* and are *tourist destinations of Thailand*. For the second query, countries having relation "*is part of*" with *Southeast Asia* in the exploited ontology should be added into the query, e.g. *Indonesia* or *Philippine*. However, added countries should be those that were actually hit by at least one tsunami, according to the given ontology. So, *Laos* should not be added into the query. For the third query, if there are facts that *settlements are built in* the locations in the *west of Jerusalem*, e.g. *Givat Zeev* and *Pisgat Zeev*, then those locations should add into the query. For the fourth query, bullet-resistant suit should be added into the query; because it *is hyponym of high-tech defences* and the President *Barack Obama have used* a bullet-resistant suit.

In this paper, we propose a new ontology-based text search model with two key ideas as our two contributions. First, it exploits different ontological features of NE and WW existing in documents and queries. Until now, there is no other text search model that formally exploits and presents in documents and queries all above-mentioned NE features or all above-mentioned WW features. Specifically, in a context, after a disambiguation process, if a WordNet word has more than one sense with the equally highest rank, then the most specific common hypernym (msc_hypernym) of those senses will be chosen and the word will be represented by the pair of that hypernym and the form of the word. Meanwhile, other WordNet-based text search models choose one of those senses randomly or all of the senses (Vooheres, 1994; Liu, et al., 2004; Zaihrayeu, et al., 2007; Hsu, et al., 2008; Giunchiglia, et al., 2009). Second, our model expands a query by latent concepts relating to concepts and relations in the original query as asserted in employed ontologies. Our proposal is more general than Fu, et al. (2005), which considered only spatial relations.

In the next section, we discuss related works. Section 3 describes the proposed system architecture and detailed model. Section 4 presents evaluation of the proposed model and discussion on experiment results in comparison to other models. Finally, section 5 gives some concluding remarks.

2 Related Works

2.1 Exploiting Named Entities

There are works exploiting NEs but not for document search. The Falcons system described in Cheng, et al. (2008) is assisted by users to determine clearly the meaning of queries. In Cheng, et al. (2007), the authors use classes of NEs associated with keywords in a query. However, they are for entity search.

Vallet and Zaragoza (2008), Santos, et al. (2010), Demartini, et al. (2010), and Kaptein, et al. (2010) use only names and classes of NEs, and they are for entity ranking (Balog, et al. 2009).

Gupta and Ratinov (2008), Chang, et al. (2008), Wang, et al. (2009), and Jing, et al. (2010) use only labels of concepts (NE names or WW forms) to represent documents and queries. Moreover, they are for document classification, not document search.

There are some papers using named entity for document search. Bast et al. (2007) considers only entity classes in combination with keywords. In Ahn, et al. (2010), the NameSieve system uses only names and classes of NEs, and limits in four entity class: who, where, when and

what. Beside, the system is helped by users to determine clearly the meaning of queries. In Egozi, et al. (2011), the authors use only names of concepts to present documents and queries.

2.2 Exploting WordNet

Voorhees (1994), Liu, et al. (2004) and Hsu, et al. (2008) use all forms of a sense and all forms of every hyponym of a sense in a query. Meanwhile, Zaihrayeu, et al. (2007) uses all forms of a sense to expand a document, and Wang, et. al. (2004) and Giunchiglia, et al. (2009) additionally use all forms of every hypernym of a sense in a document. Mihalcea and Moldovan (2000) use senses in both queries and documents, and all forms of every hypernym of a sense in a document.

Moreover, since the above-surveyed papers, except for Mihalcea and Moldovan (2000), use word forms to represent word senses, it may reduce the precision of system. Indeed, a query containing a word having form *f* and sense *x* could also match to documents containing a word having the same form *f* but different sense *y*. The drawback is similar with using only word forms of hypernyms and hyponyms of senses.

Especially, in case a word has more than one sense determined by a Word Sense Diambiguation (WSD) algorithm, the above works choose randomly one sense from those senses, which may decrease the retrieval performance if that is a wrong choice. In contrast, in our system, such a word is represented by the combination of its form and the most specific common hypernym of the senses.

2.3 Exploiting Latent Concepts

Some systems improve document retrieval performance by expanding queries with user's participation, such as Sanderson (2004), Balog, et al. (2008), Castellani, et al. (2009), Meij, et al. (2009) and Ahn, et al. (2010). Whereas, Bendersky and Croft (2008), and Huston and Croft (2010) identify key concepts in queries to remove unimportant words.

In Wang and Zhai (2008), the authors exploit synonyms or co-occurring relations in search engine logs for repairing or expanding queries. In Losada, et al. (2010), the system uses pseudo-relevance feedback to expand queries. However, the two systems do not take account relations in a query.

In Tran, et al. (2007), the authors map concepts of a query to an ontology to find suitable related concepts. In Cheng, et al. (2007), the target problem is to search for named entities of specified classes associated with keywords in a query. Different from our model, the two systems do not take account relations in queries and they are for question-and-answering but not document search.

In Castells, et al. (2007), the system finds identified named entities belonging to a class of NE in a query, after the query's vector is constructed by the NEs. This step is unnecessarily time consuming. In our proposed models, the query and document vectors having the entity class can be constructed and matched right away. Beside, its queries must be specified by RDQL. Similarity, in Kasneci, et al. (2008), queries must be written by SPARQL. Concepts and relations must be clearly specified by users. Whereas, this need not in our system. Moreover, the work is for question-and-answering, not document retrieval.

Spreading Activation (SA) is a popular algorithm for query expansion. But pure-SA would return most results irrelevant to queries (Berthold, et al., 2009). So, SA algorithms have been constrained by some methods to improve retrieval performance.

In Rocha, et al. (2004), the authors propose a hybrid spread activation algorithm that combined SA algorithm together with ontology based information retrieval. In Aswath, et al. (2005), the system uses a two-level SA network to activate strongly positive and strongly negative matches based on keyword search results.

In Schumacher, et al. (2008), the system finds answers of given query and added into the query before using an SA algorithm. Besides, Hsu, et al (2008) expands query by using SA on all relations in WordNet and only selecting kernel words that are activated and represent the content of a query by some rules.

In Jiang and Tan (2009), the authors map the original query to a keyword set and searches for documents relating to the keyword set. After that, the documents are pre-annotated with information of an ontology and the initial concepts are extracted from the retrieved documents. An SA algorithm is used to find concepts semantically relating to the concepts in the ontology. Finally, the activated concepts are used to re-rank the documents to present for user. In Lee, et al. (2010), the system sets up an associative network with nodes being web pages and links between the nodes being relations between the web pages. Initial nodes of SA algorithm are web pages that are strongly associated to given query.

Next, other nodes (web pages) of their network are activated.

However, the above Constrained-SA (CSA) models do not use relations in a given query to constrain spreading. Meanwhile, our relation-CSA method activates concepts relating to concepts and relations in queries. In Fu, et al. (2005), the authors use the relations in a query to expand the query. However, the work only exploits spatial relations (e.g. near, inside, north of). In contrast, in this paper, we propose more general rules for query expansion.

3 Ontology-based Text Search

3.1 System Architecture

Our proposed system architecture of semantic text search is shown in Figure 1. It has two main parts. Part 1 presents document and query annotation and expansion. Part 2 presents the query expansion module using a relation-CSA (RCSA) method.

Our proposed model needs an ontology having: (1) a comprehensive class catalog with a large concept population for expressing clearly information of documents and queries; and (2) a comprehensive set of relations between concepts and facts for expanding queries with latently related concepts. Since no single ontology is rich enough for every domain and application, merging or combining multiple ontologies are reasonable solutions (Choi, et al. 2006). So we have combined 3 ontologies, namely, KIM, WordNet, and YAGO to have a rich ontology for our model.

In this work we employ KIM (Kiryakov, et al. 2005) for automatic NE recognition and semantic annotation of documents and queries. The KIM PROTON ontology contains about 300 classes and 100 attributes and relations. KIM World Knowledge Base (KB) contains about 77,500 entities with more than 110,000 aliases. NE descriptions are stored in an RDF(S) repository. Each NE has information about its specific class, aliases, and attributes (i.e., its own properties or relations with other NEs). The average precision and recall of the NE recognition engine are about 90% and 86%, respectively[1].

WordNet (Fellbaum, 1998) is a lexical database for English organized in synonym sets (synsets). There are various semantic relations between these synonym sets, such as hypernym, hyponym, holonym, meronym, and similarity. WordNet version 3.0 contains about 155,000 words organized in over 117,000 synsets.

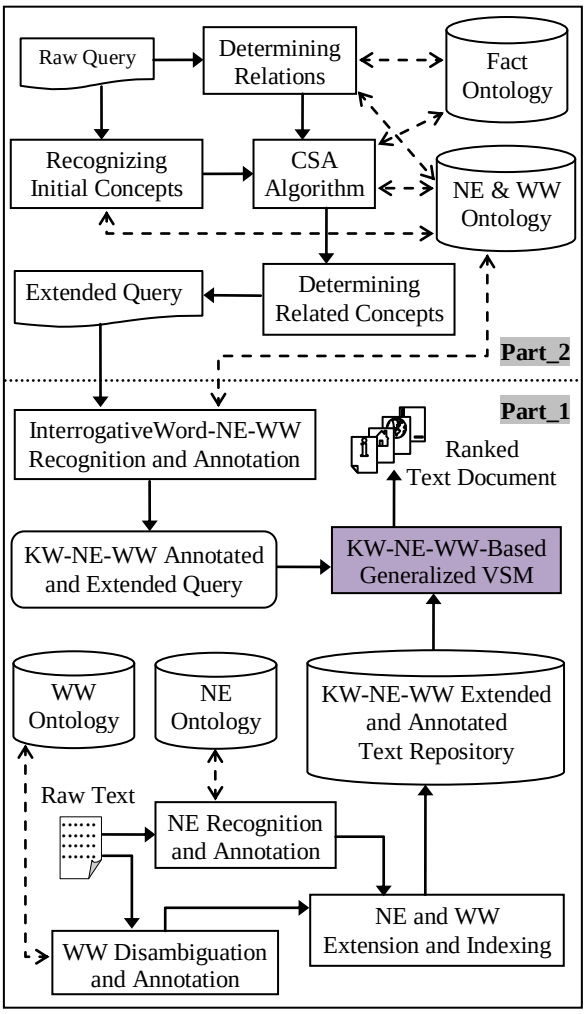

Figure 1. System architecture for semantic search

Since KIM ontology and WordNet define only a small number of relations, and KIM KB contains a limited number of facts, we employ YAGO (Yet Another Great Ontology) (Suchanek, et al. 2007; Suchanek, et al. 2008) for an ontology of relations in the system. It contains about 1.95 millions entities, 93 different relation types, and 19 millions facts about specific relations between entities. The correctness of the facts is about 95%. In addition, with logical extraction techniques and a flexible architecture, YAGO can be further extended in future. Note that, to have more relation types and facts for experiments, we can manually combine it with Wikipedia. We use KIM, WordNet, YAGO as the NE, WW, and Fact ontologies in our system, respectively.

The NE Recognition-and-Annotation module and WW Disambiguation-and-Annotation module extract and embed NE features and WW features in a raw text, respectively. The text is then indexed by contained NE features, WW features,

[1] It is reported at http://www.ontotext.com/kim/performance.html.

and keywords, and stored in the Extended KW-NE-WW Annotated Text Repository. Meanwhile, the InterrogativeWord-NE-WW Recognition-and-Annotation module extracts and embeds the most specific NE features and WW features in the extended query, and replaces the interrogative word if existing by a suitable class. Semantic document search is performed via the KW-NE-WW-Based Generalized Vector Space Model (VSM) module.

3.2 Word Sense Disambiguation

To choose the intended sense of a word in a context, a WSD algorithm is employed. Supervised WSD systems have high accuracy (Pradhan, et al. 2007) but need manually sense-tagged corpora for training. In IR, training corpora of a supervised WSD algorithm need to be large which are usually laborious and expensive to construct. Knowledge-based WSD systems (Liu, et al. 2005; Sinha and Mihalcea, 2007; Navigli and Lapata, 2007; Agirre and Soroa, 2009a) are developed to overcome the knowledge acquisition bottleneck and avoid manual effort. Besides, for specific domains, knowledge-based WSD systems have better performance than generic supervised WSD systems trained on balanced corpora (Agirre, et al. 2009b). We use Personalizing PageRank algorithm of Agirre and Soroa (2009a) having 56.8% accuracy for our WordNet based WSD. Moreover, we enhance it by using Pos-Tagger and Lemmatization in Toutanova, et al. (2003) having 97.24% accuracy. However, if a word has two or more probable senses, then our WSD algorithm will choose the most specific common hypernym of the senses in hypernym hierarchy of WordNet. We use WordNet version 3.0 for the WSD algorithm. Figure 2 describes the difference between the traditional KB-based WSDs and our KB-based WSD.

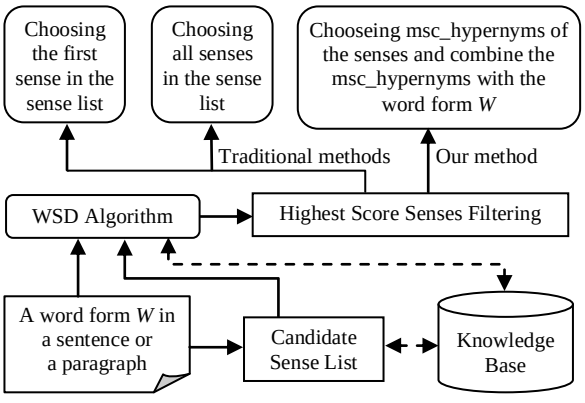

Figure 2. Difference between the traditional KB-based WSDs and our KB-based WSD

3.3 Annotating and Expanding in Queries and Documents

We propose a generalized VSM in which a document or a query is represented by a vector over a space of generalized terms. Each term is a NE feature, a WW feature, or a keyword. As usual, similarity of a document and a query is defined by the cosine of the angle between their representing vectors. Our work has implemented the model by developing a platform modified from Lucene[2]. The system automatically processes documents for KW-NE-WW-based searching in the following steps:

1. Removing stop-words in the documents.
2. Recognizing and annotating NEs in the documents using KIM[3].
3. Disambiguating and annotating WWs that are not NEs in the document using the WSD algorithm mentioned in section 3.2.
4. Words not defined in KIM and WordNet are treated as plain keywords.
5. Extending the documents with implied NE features. That is, for each entity named *n* possibly with class *c* and identifier *id* in a document, the triples (*n*/*/*), (*/*c*/*), (*n*/*c*/*), (*alias*(*n*)/*/*), (*/*super*(*c*)/*), (*n*/*super*(*c*)/*), (*alias*(*n*)/*c*/*), (*alias*(*n*)/ *super*(*c*)/*), and (*/*/*id*) are virtually added to the document. Here *alias*(*n*), *super*(*c*), *syn(w)* and *super(h)* respectively denote any alias of *n*, any super class of *c*, any synonym of *w*, and any super hypernym of *h* in the ontology and knowledge base of discourse.
6. Extending the document with implied WW features:
   - If the sense *s* of the word is determined, then *s* and its expanded features *form*(*s*), *hypernym*(*s*), *form*(*hypernym*(*s*)), *form*(*s*)/*hypernym*(*s*) are added into the document.
   - If the word has more than one sense with *f* and *msc_hypernym*(*possible_senses*(*f*)) as its apparent form and the most specific common hypernym, respectively, then *f and f/msc_hypernym*(*possible_senses*(*f*)) and their expanded features:

     form(*msc_hypernym*(*possible_senses*(*f*))),

     msc_hypernym(*possible_senses*(*f*)),

     form(*hypernym*(*msc_hypernym*(*possible_senses*(*f*)))),

     hypernym(*msc_hypernym*(*possible_senses*(*f*))),

[2] http://lucene.apache.org/

[3] http://www.ontotext.com/kim/

f/hypernym(*msc_hypernym*(*possible_senses*(*f*))) are virtually added to the document.

7. Original and implied features of NE and WW, and plain keywords are indexed by S-Lucene.

A query is also automatically processed in the following steps:

1. Removing stop-words in the query.
2. Recognizing and annotating NEs in the query.
3. Disambiguating and annotating WWs that are not NEs in the query.
4. Words not defined in KIM and WordNet are treated as plain keywords.
5. Representing each recognized entity named *n* possibly with class *c* and identifier *id* by the most specific and available triple among (*n*/*/*), (*/*c*/*), (*n*/*c*/*), and (*/*/*id*).
6. Representing each recognized WordNet word:
   - If the sense *s* of the word is determined, then the word is represented by *s*.
   - If the word has more than one sense with *f* and *msc_hypernym*(*possible_senses*(*f*)) as its apparent form and the most specific common hypernym, respectively, then the word is represented by *f/msc_hypernym* (*possible_senses*(*f*)).

Besides, there is latent information of the interrogative words *Who*, *What*, *Which*, *When*, *Where*, or *How* in a query. For example, given the query "*Where was George Washington born?*", the important terms are not only the NE *George Washington* and the WW "*born*", but also the interrogative word *Where*, which is to search for locations or documents mentioning them. For instance, *Where* in this example should be mapped to the class *Location* of NE. The mapping could be automatically done with high accuracy using the method proposed in (Cao, et al. 2008).

3.4 Discovering Latent Concepts in Queries

The followings are the six main steps of our RCSA method to determine relevant latent related concepts for a query:

1. Recognizing relation phrases: Relation phrases are prepositions, verbs, and other phrases representing relations, such as *in*, *on*, *is*, *near*, *north of*, *live in*, *located near*, *was actress in*, *is author of*, and *was born*. We have implemented a relation phrase recognition using the ANNIE tool of GATE (Cunningham, et al. 2006).
2. Determining relations: Each relation phrase recognized in step 1 is mapped to the corresponding relation in fact ontology or NE ontology by a manually built dictionary. For example, "*was actress in*" is mapped to *actedIn*, "*is author of*" is mapped to *wrote*, and "*nationality is*" is mapped to *isCitizenOf*.
3. Recognizing initial concepts: we find concepts in the query by mapping the words expressed in the query to entity names or word forms in the exploited ontologies. These are original concepts in the query and initial concepts of the method.
4. Presenting each relation in the query in the form C_1RC_2, where R is a relation found in step 2, and C_1 and C_2 are initial concepts found in step 3.
5. Determining related concepts. Let C_4 be a latent concept derived from a relation C_1RC_2.
   - If C_2 is a NE having identifier and belonging to class *Location*:
     - If R is described by a verb and a spatial relation phrase, e.g. "born in the north of", find C_4 that satisfies $C_4R_SC_2$ in the employed NE ontology and $C_1R_FC_4$ in the Fact ontology, where R_S is the relation expressed by the verb and R_F is the relation expressed by the spatial relation phrase.
     - Otherwise, find C_4 that satisfies C_4 *is_part_of* C_2 in the NE ontology and C_1RC_4 in the Fact ontology.
   - If C_2 is a NE class only, find C_4 that satisfies C_4 *is_subClass_of* C_2 in the NE ontology and C_1RC_4 in the Fact ontology.
   - If C_2 is a WW, find C_4 that satisfies C_4 *is_hyponym_of* C_2 in the WW ontology and C_1RC_4 in the Fact ontology.
6. Before being added into the query, the latent concepts are represented by their main entity aliases or word forms.

Comparing with pure-SA algorithm, the RCSA algorithm has two constraints as follows: (1) distance constraint: only concepts having direct relations, in accordance to the exploited ontology, with original nodes in queries are activated; and (2) relation constraint: relations used for spreading in the Fact ontology must appear in the query.

For the computational cost, we note that document annotation is performed offline, while queries are typically short and thus query annotation and expansion could be done quickly. Therefore, the query answering time is not a problem.

4 Experiments

Evaluation of a retrieval method requires two components being a test dataset and quality measures (Baeza-Yates and Ribeiro-Neto, 1999; Manning, et al. 2008). The L.A. Times document collection is employed, which was used by 15 papers among the 33 full-papers of SIGIR-2007 and SIGIR-2008 about text IR using TREC dataset. The L.A. Times consists of more than 130,000 documents in nearly 500MB. Next, queries in the QA Track-1999, which have answer documents in this document collection, are used. So, there are 124 queries of 200 queries in this Track chosen.

Table 1. MAPs and two-sided p-values of the Lexical, NE+KW, WW+KW and NE+WW+KW models.

Model A and **MAP**	**Model B** and **MAP**	**Improvement**	**Two-Sided P-Value**
NE+WW +KW **0.6024**	Lexical **0.5099**	18.1%	0.02004
	NE+KW **0.5652**	6.6%	0.03359
	WW+KW **0.5391**	11.7%	0.04118

Table 2. MAPs and two-sided p-values of the Lexical, CSA and RCSA models.

Model A and **MAP**	**Model B** and **MAP**	**Improvement**	**Two-Sided P-Value**
RCSA **0.6594**	Lexical **0.5099**	29.3%	0.02952
	CSA **0.5592**	17.9%	0.04987

We have evaluated and compared the IR models in average Precision-Recall (P-R) curves, average F-measure-Recall (F-R) curves, and mean average precision (MAP) values (Baeza-Yates and Ribeiro-Neto, 1999; Manning, et al. 2008). Because, average P-R curves and average F-R curves represent commonly the retrieval performance and allow comparison of those of different systems. The closer the curve is to the right top corner, the better performance it represents (Manning, et al. 2008). Whereas, MAP is a single measure of retrieval quality across recall levels and considered as a standard measure in the TREC community (Voorhees and Harman, 2005). Obtained values of the measures presented above might occur by chance. Therefore, a statistical significance test is required (Hull, 1993). We use Fisher's randomization (permutation) test for evaluating the significance of the observed difference between two systems, as recommendation of Smucker, et al. (2007). As shown Smucker, et al. (2007), 100,000 permutations were acceptable for a randomization test and the threshold 0.05 of the two-sided significance level, or two-sided p-value, could detect significance.

We conduct experiments to compare the results obtained by the following seven different search models:

1. Lexical: This is the Lucene text search engine as a tweak of the traditional keyword-based VSM.
2. NE+KW: This is the model only exploiting features of NEs to annotate and expand documents and queries.
3. WW+KW: This is the model only exploiting features of WW to annotate and expand documents and queries.
4. NE+WW+KW: This is the model combining NE+KW and WW+KW, as presented in section 3.3.
5. CSA: This is the model using the traditional constrained SA algorithm. It expands queries by broadcasting all direct-links to original concepts in the Fact ontology to find related concepts. The expanded queries and documents of the CSA model are represented by keywords.
6. RCSA (6): This is the model improving the above CSA model. The RCSA model only uses links presented in a query to find related concepts, as presented in section 3.4.
7. Semantic Search: This is the model combining RCSA and NE+WW+KW, as presented in section 3.

The MAP values of the models and two-sided p-values of randomization tests between them in Table 1 show that taking into account ontological features in queries and documents does enhance text retrieval performance; NE+WW+KW performs about 18.1%, 6.6%, and 11.7% better than the Lexical, NE+KW and WW+KW models in terms of the MAP measure, respectively.

In Table 2, we see that RCSA model really performs about 29.3% and 17.9% better than the Lexical and CSA models in terms of the MAP measure, respectively. So, discovering latent concepts in a query does enhance text retrieval performance.

Finally, Table 3 and Figure 3 show that text retrieval performance is improved by the combination of discovering latent concepts and exploiting logical feature in documents and queries. In terms of the MAP measure, Semantic Search performs about 41.9% and 29.3% better than the Lexical and CSA models, respectively. Beside, Semantic Search also performs about 28%, 34.2%, 20.1%, and 9.7% better than the NE+KW, WW+KW, NE+WW+KW and RCSA models, respectively.

Table 3. MAPs and two-sided p-values of the Semantic Search model and the other six models.

Model A and **MAP**	**Model B** and **MAP**	**Improvement**	**Two-Sided P-Value**
Semantic Search 0.7233	Lexical **0.5099**	41.9%	0.01071
	NE+KW **0.5652**	28.0%	0.00313
	WW+KW **0.5391**	34.2%	0.00845
	NE+WW+KW **0.6024**	20.1%	0.01791
	CSA **0.5592**	29.3%	0.01255
	RCSA **0.6594**	9.7%	0.04516

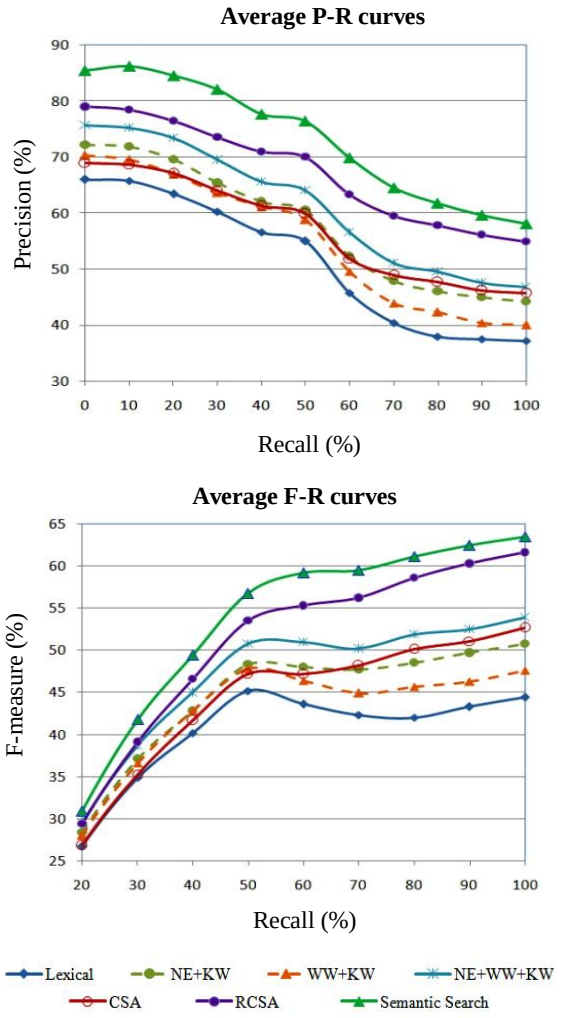

Figure 3. Average P-R and F-R curves of the seven search models on 124 queries of TREC

5 Conclusion

We have presented the generalized VSM that exploits and annotates ontological features of named entities and WordNet words in documents and queries for semantic text search. In case a word has more than one sense determined by a WSD algorithm, the word is represented by the combination of its form and the most specific common hypernym of those senses. Besides, our model expands a query by discovering relevant latent concepts in the query by constrained spreading activation using relations in the query.

The conducted experiments on a TREC dataset have showed that our semantic search improves the search quality in terms of the precision, recall, F, and MAP measures. Although this work uses VSM for proving the advantage of exploiting the proposed ontological features and discovering latent concepts in text search, it could be adapted for other information retrieval models as well.

Abstract

Cross-lingual document clustering (CLDC) is the task to automatically organize a large collection of cross-lingual documents into groups considering content or topic. Different from the traditional hard matching strategy, this paper extends traditional generalized vector space model (GVSM) to handle cross-lingual cases, referred to as CLGVSM, by incorporating cross-lingual word similarity measures. With this model, we further compare different word similarity measures in cross-lingual document clustering. To select cross-lingual features effectively, we also propose a *soft-matching* based feature selection method in CLGVSM. Experimental results on benchmarking data set show that (1) the proposed CLGVSM is very effective for cross-document clustering, outperforming the two strong baselines vector space model (VSM) and latent semantic analysis (LSA) significantly; and (2) the new feature selection method can further improve CLGVSM.

1 Introduction

The globalization of business environment urges organizations to maintain documents in different language. Obviously, organizations and research communities nowadays encounter the challenge of cross-lingual document clustering (CLDC). Document clustering seeks to automatically organize a large collection of documents into groups of similar documents. Various document clustering technologies have been proposed to deal with monolingual documents.

The classical solution to monolingual document clustering is vector space model (VSM), which explores bag of words (BOW) to construct feature space. Each document is converted to a VSM vector. Serious problem occurs when words are matched to the features using the hard matching strategy. For example, when the word *coast* is selected as a feature, word *seashore* will not contribute to hard matching unless it is also selected as a feature.

Different semantic document representation models have been proposed to address the shortcoming of VSM. Some semantic document representing models such as Latent Semantic Analysis (LSA) (Landauer et al., 1998) and Latent Dirichlet Allocation (Blei et al., 2003) implicitly capture statistical semantics by mapping documents to a lower dimension space. Other models such as Generalized Vector Space Model (GVSM) (Wang et al., 1985) extract statistical semantics in an explicit way by directly estimating measures of correlations between words.

The above models are designed for monolingual document sets and cannot be applied to cross-lingual scenario unless a bridge is created to connect cross-lingual features. Carbonell et al. (1997) use semantic models in parallel corpus. As features are selected from a common parallel/comparable corpus, which is usually different from the test cross-lingual document, over-fitting problem inevitably happens.

Other researchers propose to translate features or documents with bilingual dictionary or machine translation tools (Mathieu et al., 2004).However, ambiguity happens constantly and it is difficult to determine translation of a word. Meanwhile, if one translation of a word is selected as feature, the hard matching problem still occurs and becomes more serious.

In this paper, we extend the monolingual GVSM to handle cross-lingual cases, referred to as Cross-lingual GVSM (CLGVSM). Besides term correlation, we make use of word similarity in CLGVSM. For the cross-lingual we use statistical word similarity measure with the parallel corpus. We further improve cross-lingual word

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 580–588,
Chiang Mai, Thailand, November 8 – 13, 2011.

similarity by incorporating dictionary or translation probability. Experimental results show that the best result is achieved when combining the Second Order Co-occurrence Pointwise Mutual Information (SOCPMI) measure on the test dataset and translation probability in development dataset.

Selecting cross-lingual features is a key issue in cross-lingual document clustering. In this work, we propose a *soft-matching* based feature selection method in CLGVSM. In the new feature selection method, most representative terms are selected in semantic space according to Soft Term Frequency and Soft Document Frequency. In this way, a non-feature word can improve weight of the semantically similar features and make contribution to document clustering. Experimental results show that CLGVSM outperforms both LSA and VSM significantly with the help of proper word similarity measure.

The rest of this paper is organized as follows. In section 2, related work is surveyed. In section 3, the CLGVSM model is discussed. Experimental results as well as discussion are presented in Section 4. We conclude this paper in Section 5.

2 Related work

2.1 Monolingual Document Representation Models

The most commonly used model for document representation is the vector space model (VSM). It is assumed in VSM that terms are independent of each other and thus any semantic relations between them are ignored. Proposed by Landauer et al. (1998), LSA seeks to decompose the term-document matrix using singular value decomposition, in which each feature is a linear combination of all words.

Proposed by Wang et al. (1985) and further improved by Farahat and Kamel (2010), GVSM is proved an effective document representation model to address limitation of VSM. The model estimates similarity between documents based on how much their terms are related. Wang et al. (1985) pointed out orthonormal basis in VSM and proposed a new model to remove the assumption. Farahat and Kamel (2010) improved GVSM by developing better estimation of term correlation and applying dimension reduction techniques in a semantic space. Results show that the improved GVSM is advantageous over other representation models such as LSA.

Other document representation models are based on lexical ontologies such as WordNet, to represent documents in the concept space (Hotho et al., 2003). Similar representation models are seeks to exploit knowledge within an encyclopedia. Explicit Semantic Analysis (Cimiano et al., 2009) is a famous model that represents words as vectors in a space of concepts represented by articles from Wikipedia.

Most of those semantic models are designed for monolingual document sets, and cannot be used in cross-lingual scenario directly.

2.2 Cross-lingual Document Clustering

The difficulty of CLDC is how to deal with cross-language issue. The straightforward solution is document translation. In TDT3[1], four systems attempted to used Machine Translation systems (Leek et al., 1999). The results show that using a machine translation tool leads to around 50% performance loss, compared with monolingual topic tracking. This ascribed mainly to the poor accuracy of machine translation systems.

Dictionary and corpus are two popular ways to get cross-language information. Some researches (Evans and Klavans, 2003) use dictionary to translate documents. Others (Mathieu et al., 2004) use dictionary to translate features or keywords. But it is hard to select proper translation of ambiguous words. Mathieu et al. (2004) use bilingual dictionaries to translate named entities and keywords and modify the cosine similarity formula to calculate similarity between bilingual documents. Pouliquen et.al (2004) rely on a multilingual thesaurus called Eurovoc to create cross-lingual article vectors.

Wei et al. (2008) use LSA to construct a multilingual semantic space onto which words and document in either language can be mapped and dimensions are reduced again according to documents to be cluster. Yogatama and Tanaka-Ishii (2009) use propagation algorithm to merge multilingual spaces from comparable corpus and spectral method to cluster documents. Li et al. (2007) use Kernel Canonical Correlation Analysis, a method of finding the maximally correlated projections of documents in two languages for cross-language Japanese-English patent retrieval and document classification. Unlike document classification, document clustering lacks training data. So semantic space is constructed from the parallel/comparable corpus, and the dimensions are selected on the basis of their importance in parallel/comparable corpus, which is usually different from the target multilingual documents.

[1]http://www.itl.nist.gov/iad/mig//tests/tdt/1999/index.html

In this work, our proposed CLGVSM use semantic similarity to solve word matching problem caused by different languages. Semantic space is constructed based on word similarity and in our feature selection method, features are select on the basis of their importance in documents to be clustered.

2.3 Cross-lingual Word Similarity

In both monolingual GVSM (Wang et al, 1985) and improved GVSM (Farahat and Kamel, 2010), correlation, correlation between words is computed in documents to be clustered and correlation of the best performance in document clustering is calculate as covariance of words with the assumption that words are random variables with Gaussian distributions. In this work we use word similarity which is calculated as cosine similarity of term vector covariance. This measure can be called as COV measure.

But this similarities method is estimated in test documents which lacks cross-lingual information.

Various measures for cross-lingual word semantic similarity have been proposed to explore statistical techniques and semantic network.

Research works propose to use *WordNet* by Resnik (1999) to measure similarity between English words. Liu and Li (2002) adopt HowNet calculate word similarity in machine translation. Xia et al. (2011) propose to explore cross-lingual word similarity by observing concept definition provided by HowNet.

Corpus-based measures for semantic similarity are found more interesting. The classical method is Pointwise Mutual Information (PMI) (Church and Hanks, 1990). Many researches are based on PMI, such as PMI-IR (Turney, 2001) and Second Order Co-occurrence PMI (SOCPMI) (Islam and Inkpen, 2006). SOCPMI is proved better than PMI-IR and some other similarity measures (Islam and Inkpen, 2006).

In this work, we implement three representative measures: HowNet-based measure (Xia et al., 2011), SOCPMI measure (Islam and Inkpen, 2006) and COV measure (Farahat and Kamel, 2010).

3 Cross-Lingual Generalized VSM

3.1 Generalized VSM

Let $D = \{d_j; j = 1, ...N\}$ be a set of N documents which contain *M* terms, X be a $M \times N$ matrix whose element x_{ij} represents the weight of term t_i in document d_j. GVSM (Wang et al, 1985) estimates correlation between documents based on how their terms are related. The GVSM model presents document in a non-orthogonal space and similarity between two documents is calculated as follows.

$$Sim^{\mathrm{GVSM}}(d_1, d_2) = \frac{d_1^T G d_2}{\sqrt{d_1^T G d_1}\sqrt{d_2^T G d_2}}, \quad (1)$$

where G is an $M \times M$ association matrix which represents correlations between terms and is usually computed as inner-products of term vectors in some space. An example of 3×3 association matrix is given as follows.

$$\begin{array}{c} \\ t_1 \\ t_2 \\ t_3 \end{array} \begin{array}{c} \begin{array}{ccc} t_1 & t_2 & t_3 \end{array} \\ \begin{pmatrix} 0.1 & 0.2 & 0.3 \\ 0.4 & 0.5 & 0.3 \\ 0.4 & 0.2 & 1 \end{pmatrix}_{3\times 3}, \end{array}$$

where every row and column represents a term, respectively.

In tradition GVSM (Wang et al, 1985), terms are represented as vectors in the dual space of documents and the association measures between terms are calculated as the cosine of the angle between their vectors in the dual space. Accordingly,G can be calculated as:

$$G = L^{-1/2} X X^T L^{-1/2} \quad (2)$$

where L is a diagonal matrix whose elements are the lengths of term vectors in the dual space.

And in improved GVSM (Farahat and Kamel, 2010), the best G which is covariance matrix of terms is calculated as

$$G_{\mathrm{COV}} = \frac{1}{n_c - 1} Q H Q^T \quad (4)$$

where Q is random sample of $X$and

$$H = 1 - \frac{1}{n_c} e e^T \quad (5)$$

G_{COV} maps uncorrelated terms to near-orthogonal directions and negatively correlated terms to opposite directions in the semantic space, while traditional G maps both uncorrelated terms and negatively correlated terms to near-orthogonal directions. Thus we use cosine similarities between term vectors in case of G_{COV} as one of our similarity measures. As the GVSM models proposed, G is estimated from documents to be clustered; they cannot acquire cross-lingual information and cannot deal with cross-lingual issues directly. So we extend GVSM to cross-lingual GVSM by using cross-lingual word similarity measures in section 3.2

3.2 Cross-Lingual GVSM

Note that before (Farahat and Kamel, 2010); term correlation was used in GVSM to construct association matrixes G with the inner-product of term vectors in some semantic space. Length of term vectors quantifies how important of the term in the documents. Thus correlation of terms is not totally the same with similarity of terms. But it is difficult for term correlation to adapt into cross-lingual case. Term vectors generated from test data lack cross-lingual information. Carbonell et.al (1997), generate term vectors from development data. Noise occurs because term importance differs in two dataset.

For those reasons mentioned above, we choose word similarity instead of term correlation to construct word association matrix. And the other advantage of using word similarity is that we can ignore noisy similarity values which contribute little to document similarity calculation. In that case, the associate matrix becomes sparse and computational time can be saved. Therefore in this work, we explore the following several word similarity measures in constructing word association and setup a similarity threshold.

Knowledge-based Similarity Measures

We choose to use cross-lingual word similarity based on HowNet (Xia et al., 2011) which makes use of concept graph in HowNet. HowNet is concept based and the atom unit is sememe, so similarity between words is actually reflected by the sememes they carry. The key idea of cross-lingual word similarity calculation is to locate bilingually definitions for given words so that the language barrier is overcome. For details please refer to Xia et al. (2011).

Statistical Similarity Measures

Statistical similarity actually reflects conceptual relevance between words as it considers merely word co-occurrences within a corpus. We evaluate two statistical similarity measures: SOCPMI and COV in this work.

SOCPMI was proposed by Islam and Inkpen (2006), in which PMI is applied to rank the neighboring words with in a corpus. The measure is proved accurate because it calculates relevance between two words that do not co-occur frequently. Note that the original SOCPMI measure is designed to deal with monolingual word similarity. We extend this measure in this work to calculate similarity between cross-lingual words. The goal is achieved by counting neighboring words with the same language in the corpus and computing the cross-lingual PMI in a parallel corpus.

As we mentioned above， associate matrix G constructed by covariance of term vectors achieve the best performance in monolingual document clustering. In this paper we use the cosine similarity instead of inner-product in COV similarity measure.

The two above word similarity measures both need to be calculated in a cross-lingual parallel/comparable corpus.

Combining Similarity with Dictionary or Translation probability

The statistical word similarity measures are developed with general development corpus. However, we believe word co-occurrence in the test documents is also very useful. Thus we improve cross-lingual word similarity in the following way: statistical monolingual word similarity is computed from test documents first and a dictionary or translation probability as a bridge is used to get cross-lingual word similarity.

When using dictionary as bridge, assuming word w_i which has a translation list T_i^{T}={ $t_{i_k}^{\mathrm{T}}$; $k = 1...N_i^{\mathrm{T}}$} and word $w_j$which has a translation list T_j^{T}={$t_{j_k}^{\mathrm{T}}$;$k = 1...N_j^{\mathrm{T}}$}, we choose the highest value between similarities of $w_i$and each words in $T_j^{\mathrm{T}}$and similarities of w_j and each words in T_i^{T}as similarity between w_i and w_j.

When using translation probability as bridge, assuming word w_i which has a translation probability list P_i^{T}={$t_{i_k}^{\mathrm{T}}$: p_{i_k};$k = 1...N_i^{\mathrm{W}}$} and word w_j which has a translation list P_j^{T} ={ $t_{i_k}^{\mathrm{T}}$: p_{j_k} ; $k = 1...N_j^{\mathrm{W}}$}, the similarity of $w_i$and w_j can be calculated as follows:

$$Sim^{\mathrm{PR}}(w_i \to w_j) = \sum_k p_{i_k} \times Sim^{\mathrm{Mono}}(w_j, t_{i_k}^{\mathrm{W}}) \quad (6)$$

$$Sim^{\mathrm{PR}}(w_j \to w_i) = \sum_k p_{j_k} \times Sim^{\mathrm{Mono}}(w_j, t_{i_k}^{\mathrm{W}}) \quad (7)$$

$$Sim^{\mathrm{PR}}(w_i, w_j) = \max\{Sim^{\mathrm{PR}}(w_i \to w_j), Sim^{\mathrm{PR}}(w_i \leftarrow w_j)\} \quad (8)$$

where Sim^{Mono}returns monolingual word similarity.

3.3 Feature selection for GVSM

Term Importance based on GVSM

In the VSM model, importance of a term is proportional to Term Frequency (*TF*) in a single document, and inversed proportional to Document Frequency (*DF*) in a document set. We argue that the theory can be improved.

Consider a document that contains term *criminal* for 3 times and term *imprisonment* for 10 time. We find that term *criminal* is still very important though its *TF* is low. This is because term *imprisonment* is semantically similar to *criminal* and it appears many times. If the classical term matching method is named *hard matching*, we can call our method *soft matching*. We incorporate the *soft-matching* idea to the GVSM model.

In the GVSM model, importance of a term can be reflected by the following statistics.

(1) Soft Term Frequency

The soft term frequency (TF^s) considers the term and the semantically similar terms. Given term t and document d, we first retrieve the semantically similar terms $T=\{t_i\}_{i=1...M^T}$ from document d. We define the soft term frequency (TF^s) as follows.

$$TF^s(t,d) = \sum_i TF_i \times Sim(t,t_i) \quad (9)$$

where TF_i denotes term frequency of term t_i within document d.

Note that the soft term frequency is calculated within a single document.

(2) Soft Document Frequency

The soft document frequency (DF^s) considers not only number of documents that contain the term, but also the number of documents that contains the semantically similar terms. Given term t and document set $D = \{d_j\}_{j=1...N}$. Let $d_j = \{t_{i,j}\}_{i=1...M^D}$ denote terms within document d_j. We define the soft document frequency (DF^s) as follows.

$$DF^s(t) = \sum_{d_j \in D} \max_i \{Sim(t,t_{i,j}))\} \quad (10)$$

Note that the soft document frequency is calculated within a document set. We use maximum instead of summation in order to reduce the effects of word pairs with low similarities.

Feature Selection in GVSM

With GVSM-based term importance, features can be selected appropriately. Following the idea of TF-IDF, we refine inverse document frequency as follows.

$$IDF^s(t) = log\Big(\frac{N}{DF^s(t)}\Big), \quad (11)$$

where N denotes number of documents.

The soft weighting equation of term t in document d is as follows.

$$w^s(t,d) = TF^s(t,d) IDF^s(t) \quad (12)$$

If we select features for a document based solely on term weight, some semantically similar terms might be selected because they hold close weights. This results in fewer representatives feature set. Before feature selection we update term TF^s as follows:

1) Setup an initial term list.
2) Sort terms in the list according to their TF^s in descending order.
3) Move the first term t_0 into the tentative feature list.
4) For each remaining term in the list, update its TF^x using the following equation.

$$TF^s_{g+1}(t,d) = TF^s_g(t,d) - \sum_{t_k \in d} (Sim(t,t_k) Sim(t_0,t_k) TF^s(t_k,d), \quad (13)$$

where t_k denotes a term in document d, and g the iteration round number.

5) Delete terms a weight less than 0 in the list.
6) Repeat step 2) ~ 5) until the term list becomes empty.

Once the tentative feature list is obtained, we then calculate weight for each candidate features using Eq (12). The features of each document are then ranked according to the weight and joined together to represent document set.

Document representation in GVSM

With the feature set available, we describe how a document is represented with the features. Let $F = \{f_i\}_{i=1...M^F}$ denote the feature set, and $T = \{t_j\}_{j=1...M^D}$ denote terms within document d. We now try to map d to the feature space.

For each feature, it should be mapped no matter whether it appears in the document set. But in order to avoid redundant information, we map only one term with each feature.

So for feature list F sort by TF^s in document d, the actually weight of feature f_i in document d is as follows:

First, retrieve the most similar term t^* which is not included in T^M, which stores terms that have been matched.

$$t^* = argmax_{t_i \in d, t_i \notin T_M} Sim(t, f_i) \quad (14)$$

Then we re-calculate weight w^a of term f_i as follows.

$$w^a(f_i,d) = TF(t^*) IDF^s(f_i) \quad (15)$$

Finally, put t^* into T^M and repeat until all features are matched once.

3.4 Document Clustering based on GVSM

With document similarity, we employ certain clustering algorithm to manage the cross-lingual documents with a few clusters. As clustering algorithm is not core of this work, we simply choose the classic document clustering algorithm, i.e., HAC (Hierarchical Agglomerative Clustering) algorithm (Voorhees, 1986). To measure cluster-cluster similarity, we adopt the group-average link algorithm (Voorhees, 1986). The merging procedure repeats until a desired number of clusters are obtained.

4 Evaluation

4.1 Setup

Development dataset: We randomly extract 1M parallel sentence pairs from LDC corpora (i.e., LDC2004E12, LDC2004T08, LDC2005T10, LDC2003E14, LDC2002E18m LDC2005T06, LDC2003E07 and LDC2004T07) as our development data to train the bilingual corpus-based term similarity and get translation probability.
Dictionary: Translation pairs are extracted from HowNet.
Translation Probability: We compute translation probability by Giza++ (Och and Ney, 2000) in development data.
Test dataset: Four datasets are tested in this paper.

Corpus	TDT41 (2002) (Topic#/Story#)	TDT42 (2003) (Topic#/Story#)

We first extract two datasets from the TDT4 evaluation dataset (see statistics in Table 1).

CLTC datasets

The second dataset is extracted from our own cross-lingual topic corpus (CLTC). The news articles are retrieved from Gigaword (English and Chinese), and the topics are labeled by human (see statistics in Table 2).

Evaluation criteria

We adopt the evaluation criteria proposed by Steinbach et al. (2000). The calculation starts from maximum F-measure of each cluster. Let A_i represent the set of articles managed in a system-generated cluster c_i, A_j the set of articles managed in a human-generated cluster c_j. F-measure of the system-generated cluster c_i is calculated as follows.

$$\begin{aligned} p_{i,j} &= \frac{|A_i \cap A_j|}{|A_j|} \quad p_i = \max_j\{p_{i,j}\} \\ r_{i,j} &= \frac{|A_i \cap A_j|}{|A_i|} \quad r_i = \max_j\{r_{i,j}\} \\ f_{i,j} &= \frac{2 \cdot p_{i,j} \cdot r_{i,j}}{p_{i,j} + r_{i,j}} \quad f_i = \max_j\{f_{i,j}\} \end{aligned} \tag{16}$$

where $p_{i,j}$, $r_{i,j}$ and $f_{i,j}$represent precision, recall and measure of cluster when compared with clusterc_j , respectively.

We also use relative F-measure to compare systems over all dataset which is used by Farahat and Kamel (2010).In this approach, the F measure for a particular data set are normalized relative to the best value obtained using different representation models when applying the same clustering algorithm to the same data set:

$$F_r = \frac{F}{\max_i\{F_i\}}, \tag{17}$$

where F_i denotes F-measure values obtained using different representation models.

The relative F measures are then averaged for different data sets.

4.2 Evaluation

Experiment 1: Different word similarity calculation measures

This experiment seeks to compare different cross-lingual word similarity (CLWS) measures. Seven CLWS measures are implemented:
HN: HowNet-based cross-lingual word similarity measure.
SOCPMI^DEV: SOCPMI similarity measure learned from development data.
SOCPMI&DIC: SOCPMI similarity measure calculated in test documents and dictionary as cross-lingual bridge.
SOCPMI&TranPro: SOCPMI similarity measure directly computed in test documents and translation probability on development set as cross-lingual bridge.
COV^DEV: COV similarity measure learned from development data.
COV&DIC: COV similarity measure computed in test documents and dictionary as cross-lingual bridge.

System / Dataset	HN	SOCPMI ^DEV	SOCPMI &DIC	SOCPMI &TranPro	COV ^DEV	COV &DIC	COV &TranPro
TDT41	0.783	0.880	0.854	0.892	0.824	0.868	0.907
TDT42	0.797	0.880	0.835	0.880	0.860	0.840	0.851
CLTC1	0.764	0.818	0.834	0.877	0.782	0.854	0.874
CLTC2	0.667	0.856	0.804	0.839	0.805	0.833	0.840

Table 3. Highest F-measure of CLDC systems with different CLWS measures.

System	HN	SOCPMI ^DEV	SOCPMI &DIC	SOCPMI &TranPro	COV ^DEV	COV &DIC	COV &TranPro
ARF	0.855	0.976	0.945	**0.991**	0.929	0.965	0.986

Table 4. Average of relative F-measure (ARF) of CLDC systems with different CLWS measures.

COV&TranPro: COV similarity measure in test documents and translation probability as cross-lingual bridge.

All the CLDC systems use HAC algorithm to do clustering documents. The thresholds of similarity measures in this paper is all set 0.4 based on our empirical study. Experiment results on four datasets are as Table 3. Table 4 computed from Table 3 shows the average of relative F-measure (ARF) over all data sets for different CLWS measures.

We can observe from Table 3 and Table 4 that the performance of HowNet is much worse than other systems in all dataset. We look into the intermediate results to check the reasons. We find semantic similarities between words computed based on HowNet are too high. For example, word similarity between *Federal Reserve* and *bank* is assigned 1 by HowNet. Error analysis shows that HowNet-based CLWS measure puts much emphasis upon the semantic property of given word rather than semantic itself. So it tends to assign bigger CLWS values to semantically similar word pairs, no matter how semantically relevant they are. This would obviously jeopardize document clustering. With such an observation, we conclude that HowNet-based CLWS measure is not suitable for document clustering.

We can also observe that systems with translation probability outperform those with dictionary when the same monolingual word similarity measures are used. For instance, SOCPMI&TranPro outperforms SOCPMI&DIC by 4.5% on average on relative F-measure and COV&TranPro outperforms COV&DIC by 1.9%. Two reasons are worth noting. First, dictionary extracted from HowNet have more OOV than translation probability computed from development corpus. Translation probability is more discriminative than dictionary when word is ambiguous. It tries to get word similarity from the most frequency translation.

Seen from Table 4 that SOCPMI&TranPro outperforms SOCPMI^DEV by 1.5% on average relative F-measure and COV&TranPro outperforms COV^DEV by 5.5% on average relative F-measure. As both systems use the same development data to get cross-lingual information and the different is that systems computed word similarity in test dataset take use of word occurrence information in test dataset so we can conclude that with combining word similarity in test dataset and translation probability can is useful in cross-lingual document clustering.

And over all seven systems, SOCPMI&TRAN achieves the best result on average, so we select SOCPMI&TRAN as our word similarity measures and next experiments both use this word similarity measure.

Experiment 2: Different feature selection vs. dimension reduction methods

This experiment aims to compare the proposed feature selection method and the existing ones**.** Three CLDC systems are implemented.

SFS: feature selection we proposed by TF^s-$IDF^s$and soft matching is used in GVSM.

HFS: feature selection by TF-IDF and hard matching is used in GVSM.

NFS: feature selection is not used, which equals to system SOCPMI&TranPro in Experiment 1.

System / Dataset	SFS	HFS	NFS
TDT41	0.900	0.903	0.892
TDT42	0.899	0.881	0.880
CLTC1	0.876	0.869	0.877
CLTC2	0.891	0.847	0.839

Table5. Highest F-measure of CLDC systems with/without feature selection.

System	SFS	HFS	NFS
F-measure	**0.998**	0.980	0.976

Table6. Average of relative F-measure of CLGVSM systems with/without feature selection.

Experiment results on four test datasets are given in Table 5. Table 6 computed from Table 5 shows the ARF over all data sets for different feature selection methods.

Seen from Table 6, system with feature selection we proposed using soft matching outperforms system with feature selection using hard matching by 1.8% on average relative F-measure It also outperforms system without feature selection by 2.2% on average relative F-measure.

This reveals that feature selection does improve GVSM. The reason why it works is that with TF^s and DF^s, it can select the most representative terms as feature set and with proper document representation method, documents are properly matched into feature space.

Experiment 3: Different document representation models

This experiment aims to compare CLGVSM with VSM and LSA. Three CLDC systems are implemented:

CLGVSM: Our system, which equals FS system in Experiment 2.

VSM: A baseline system that uses VSM to represent documents and cosine similarity to compute document systems. HowNet dictionary is used to match terms in different languages.

LSA: LSA uses dictionary to match terms in different languages and make use of LSA in test dataset. The number of LSA dimensions is set to 200,

Experiment results on two data sets are given in Table 7. Table 8 computed from Table 7 shows the ARF over all data sets for different document representation models.

System	CLGVSM	VSM	LSA
TDT41	0.900	0.877	0.885
TDT42	0.899	0.835	0.881
CLTC1	0.876	0.792	0.867
CLTC2	0.891	0.776	0.841

Table7. Highest F-measure of CLDCsystems with different document representation models.

System	CLGVSM	VSM	LSA
F-measure	**1**	0.920	0.974

Table8. Average of relative F-measure of CLDCsystems with different document representation models.

We can observe from Table 8 that CLGVSM outperforms VSM by 8.0% on average relative F-measure. It means CLGVSM improve cross-lingual document clustering by using SOCPMI^TRAN similarity measure. Observation shows that the word similarity measure makes significant contribution to document clustering. Using second order co-occurrence information of words, SOCPMI assigns word pair with higher PMI a higher similarity. This coincides perfectly with the real demand in word similarity measuring. For example, word similarity between 犯罪分子 (*criminal*) and *imprisonment* is assigned 0.49 by SOCPMI. When 犯罪分子 is chosen as a feature, document containing *imprisonment* holds a reasonable similarity with document containing 犯罪分子 even though they do not contain common word.

Results also show that CLGVSM outperforms LSA by 2.6% on average relative F-measure. It means CLGVSM is better than LSA in cross-lingual document clustering by using SOCPMI^TRAN similarity measure. The follow reason is worth noting. When dictionary is used to match words in LSA, the semantic relation between different translations of one term in one document is added and this brings much noise. While in CLGVSM, cross-lingual terms are soft matched by SOCPMI^TRAN term similarity.

5 Conclusion

In this paper, we extend monolingual generalized VSM (GVSM) to handle cross-lingual cases, referred to as CLGVSM, by incorporating cross-lingual word similarity measures.Under GVSM, we compare different word similarity measures in cross-lingual document clustering. We propose new feature selection method for CLGVSM and experiments show it improves document clustering. We also compare CLGVSM and other well-known document representation models such as VSM and LSA and experiments show it outperform both VSM and LSA significantly.

Three conclusions can be drawn in this paper. Firstly, HowNet-based word similarity method is less suitable for document clustering. Secondly, translation probability computed from a development dataset as a cross-lingual bridge performs better than HowNet dictionary. At last, combining word similarity in test dataset and translation probability in development dataset can help cross-lingual document clustering.

In the future, we will apply CLGVSM in more languages pairs and extend it in more than two languages. As GVSM represents document with semantic space, we can utilize GVSM to handle sparse data problem in short text clustering.

Abstract

As a classic natural language processing technology, topic detection recently attracts more research interests due largely to the rapid development of microblog. The most challenging issue in microblog topic detection is sparse data problem. In this paper, the temporal-author-topic (TAT) model is designed to accomplish microblog topic detection in two phases. In the first phase, the TAT model is applied to clean the thread, namely, to filter noisy microblog texts out of each thread. In the second phase, microblog texts within each thread are merged to form the thread text so that the TAT model is applied to find global topics. The new approach differs from the Hierarchical Agglomerative Clustering (HAC) algorithm by making use of microblog threads to overcome the sparse data problem. Experimental results justify our claims.

1 Introduction

Topic detection is the technique that discovers the latent topics from the given collection of text. Originated from the famous TDT evaluation workshop[1], topic detection research has attracted intensive and persistent interests from governments with security purpose. With the rapid advance of the Internet, the Web content becomes so plentiful that people start to explore how to make good use of the content with commercial purpose. Very recently, microblog becomes surprisingly popular. According to the recent Twitter statistics, 155 million tweets are created per day on average[2]. This leads to huge research passion on the microblog content.

Theoretically, topic detection from microblog text is similar to that from news articles. However, the microblog text is rather different from news articles. According to Ellen et al. (2011), microblog text is a typical microtext. Compared to regular long text such as news article, the microblog text exhibits the following characteristics.

- **Short**. Every microblog text finishes in less than 140. In fact, most texts are only a sentence or even a phrase.
- **Informal**. Spoken language is typically used, usually containing abbreviations and misspellings.
- **Semi-structured**. Each microblog text contains text as well as author and time.
- **Highly contextual**. Most microblog texts are created by replying or evaluating the existing texts. Meanwhile, they are replied or evaluated by others.
- **Conversational.** The microblog texts are usually naturally organized by thousands of conversation threads. In the thread, we name the top text by *head posting*, and the remaining texts by *followup postings*.

The following challenges in microblog text processing are worth noting. Firstly, microblog texts, especially the *followup postings*, contain very few characters. This inevitably leads to serious sparse data problem when machine learning algorithms are adopted to handle the microblog texts. Secondly, grammar is usually informal in microblog texts. Abbreviations and misspellings are constant. This makes standard language processing tools inapplicable on microblog texts. Thirdly, in the *followup postings*, anaphora and ellipsis are constantly used. This makes topic analysis rather difficult.

Some related work has been reported on microtext such as chat language and short messages (Dyke et al., 1999; Zhou et al., 2005; Shen et al., 2006; Peng et al., 2007). An earlier attempt on microblog text processing is Shen et al. (2009), which adopts TFIDF algorithm to analyze the Chinese microblog texts. Ramage et al. (2010) maps Twitter texts to four potential

Chiang Mai, Thailand, November 8 – 13, 2011.

dimensions by labeled LDA, then sorts and recommends Twitter based on the result of LDA. However, the common drawback of the related work is sparse data problem because each posting is viewed as an individual text.

We argue that each microblog thread maintains a dominating topic, and that the thread structure plays an important role in microblog topic detection. In this work, the temporal-author-topic (TAT) model is designed to accomplish microblog topic detection in two phases. In the first phase, the TAT model is applied on each thread to organize the intra-thread postings into a few clusters, in which the cluster containing the head posting should dominate. The intention is to exclude the *followup postings* that are irrelevant to the head *posting* from the thread. In this way, the thread is made cleaner. In the second phase, postings within each cleaned thread are merged to form a bigger text, referred to as thread text. The TAT model is then applied on the thread texts to find global topics.

The new approach makes use of microblog threads to address the sparse data problem, which makes the approach different from any hierarchical text clustering approaches, e.g., Hierarchical Agglomerative Clustering (HAC). As it contains all relevant postings in the thread, the thread text is longer that any individual posting. In this manner, the sparse data problem can be relieved to great extent. Contributions of this work are summarized as follows.

(1) The thread structure in microblog is investigated in this work to address the sparse data problem in microblog topic detection. We argue cleaning and merging are crucial.

(2) A benchmark dataset is developed, which can be used by researchers to evaluate microblog topic detection approaches.

(3) The temporal-author-topic (TAT) model is proposed to model microblog text.

(4) A two-phase approach is designed to accomplish microblog topic detection. In the first phase, the thread structure is used to clean every thread. In the second phase, each cleaned thread is merged to form a bigger text so that microblog topic detection is made more accurate.

The rest of this paper is organized as follows. In Section 2, related work is summarized. In Section 3, the principle of our approach is given. In section 4, the temporal-author-topic model is described. Section 5 presents the two-phase topic detection approach. Section 6 presents experimental results as well as discussions. We conclude this paper in Section 7.

2 Related Work

2.1 Topic Detection

Topic detection (TD) appeared as a subtask in TDT (topic detection and tracking) evaluation workshops. Since 1998, many research efforts have been made. The earlier work is carried out under TDT evaluation. Many famous universities and companies such as IBM Watson, BBN, CMU and CUHK, have participated in TDT workshop. TDT has been more and more important.

Two subtasks are included in TD evaluation, i.e., online topic detection and hierarchical topic detection. Online topic detection (OTD) is to detect new topic and collect the subsequent relevant news. The OTD systems usually focus on selection and combination of the clustering methods. Generally, k-means clustering algorithm is adopted by researchers. Yang et al. (1998) first adopted the hierarchy clustering to detect topics, but the results can be further enhanced. Therefore, Xu et al. (1999) and Wartena et al. (2008) used k-means to cluster the news streams to realize the topic detection, and the results are better than previous work. Papka et al. (1999) compared different clustering algorithms and attempted to combine the advantage of each algorithm. The results show the combination is efficient.

TDT 2004 defines a new TD task: hierarchical topic detection (HTD)[3]. HTD presents that the theme and topic of the news reports usually distribute in different levels. For example, *Financial Crisis in Wall Street* and *Rise of Gold Price* both belong to the topic *The 10 Financial Events in 2009*, but the emphasis of the theme makes two reports in different levels. Cutting et al. (1992) proposed a hybrid clustering algorithm to improve traditional HAC (Hierarchical Agglomerative Clustering). Trieschnigg et al. (2004) adopted incremental hierarchical clustering to implement HTD. Complexity of TD is decreased in this approach, on condition that remaining efficiency of clustering. All proposed TD approaches can achieve good performance in regular texts. However, it is not known whether the clustering algorithms are effective in microblog TD.

[3] http://ciir.cs.umass.edu/pubfiles/ir-389.pdf

Our approach is similar to HAC in nature. However, two differences are worth noting. First, each microblog thread is viewed as a priori cluster in our approach. The intra-thread topic detection helps to clean the thread. In contrast, the HAC approach does not use the thread structure. Second, the irrelevant postings are excluded in forming the thread text, which is used in higher level topic clustering. Differently, the HAC approach excludes no text.

2.2 Mircoblog Text Processing

Microblog is a user-relationship based platform to assist user sharing and gaining information. As microblog booms, microtext is made large scale. Microblog text processing has thus become an important topic. In this paper, we mainly summarize the related work on microblog topic detection. Microblog topic detection exhibits profound significance. Two functions are interesting. Firstly, it is able to remind users of the important events that has happened or is happening in a period. Sharifi et al. (2010) proposed a method to summarize the topic in microblog. Microblog texts were detected if they contain the same maximum common substring, and the substring is regarded as the title of microblog topic. Nevertheless, there exists much noise in the microblog postings. Thus, the maximum common substring might be a meaningless phrase or sentence. O'Connor et al. (2010) used document clustering and text summarization techniques to induce topics that are relevant to the query[4]. The main idea of the method is still to match the microblog texts that contain the key words or phrases, making the results less accurate.

Secondly, irrelevant texts can be filtered out with topic detection approach. Wang et al. (2010) proposed a TwitterRank algorithm, which sorts the returned microblog texts by relevance score. In Liu et al. (2010), a feature selection method based on part-of-speech and HowNet is proposed, which can improve the performance of microblog classification. Similarly, Sriram et al. (2010) classified tweets into five categories, i.e. News, Events, Opinions, Deals and Private Messages by making use of author information within the tweets. With such a system, user can choose to view tweets based on their interest. Unfortunately, every posting is regarded as an individual text in previous methods, suffering the serious sparse data problem.

[4] http://tweetmotif.com/

3 The Principle

3.1 The Idea

To illustrate our idea, we take a *head posting* and its *followup postings* as a Twitter example in Figure 1.

With thousands of samples like Figure 1, we make observations and come up with the corresponding arguments as follows.

Figure 1. A Twitter head posting and its *followup* postings

Observation 1: The *followup postings* are created to reply the head posting directly or indirectly.

Argument 1: Postings in one thread are usually topic-relevant.

For example, the three *followup postings* in Figure 1 are all topic-relevant.

Observation 2: There exist a few irrelevant postings, e.g., spam and meaningless postings.

Argument 2: The irrelevant postings can be distinguished from the relevant ones considering content similarity.

Observation 3: The individual postings are very short, i.e., up to 140 characters, while a thread usually contains more than 20 postings, which add up to more than 200 words.

Argument 3: The topic-relevant postings in a thread can be merged to form a bigger text so as to relieve sparse data problem.

With above arguments, we propose a two-phase microblog topic detection approach,

in which irrelevant postings are filtered out of the threads in the first phase and relevant postings in each thread are merged to form a bigger thread text.

3.2 Definitions

For description convenience, we first give some definitions being related to microblog text.

***Definition* 1: Posting**. A *posting* is a piece of semi-structured microblog text that covers author, time and textual content, denoted with d.

***Definition* 2: Head Posting**. A *head posting* is a piece of microblog text that is spontaneously delivered, denoted with d^H.

***Definition* 3: Followup Posting**. A *followup posting* is a piece of microblog text that replies to another piece of microblog text, denoted with d^F.

***Definition* 4: Thread**. A *thread* is a set of microblog texts that contains the head posting and the *followup postings*, denoted with $T = (V, E)$. The thread complies with the tree structure.

***Definition* 5: Forest**. A *forest* is a set of microblog threads, denoted with $F = (V^{\cup}, E^{\cup})$.

An example microblog forest is given in Figure 2, in which three threads maintains three head postings and fourteen *followup postings*.

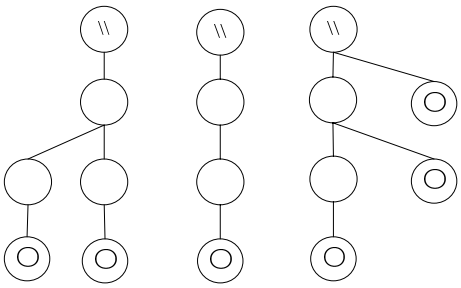

Figure 2. The example microblog forest contains three threads, where ⦶ represents the *head posting*, ○ the non-leaf *followup postings*, and ◎ the leaf *followup postings*.

The forest structure discloses some important information. As shown in Figure 2, every thread begins with a head posting and contains a few *followup postings*.

3.3 The Workflow

The workflow of our two-phase topic detection approach is given in Figure 3. In the first phase, intra-thread topic detection is run locally to find irrelevant *followup postings* within each thread. In the second phase, the relevant postings in each thread are merged to form a thread text so that the global topic detection is achieved with the thread texts. As thread texts are bigger in size, global topic detection can thus yield better results. In this way, sparse data problem in microblog topic detection can be alleviated to great extent.

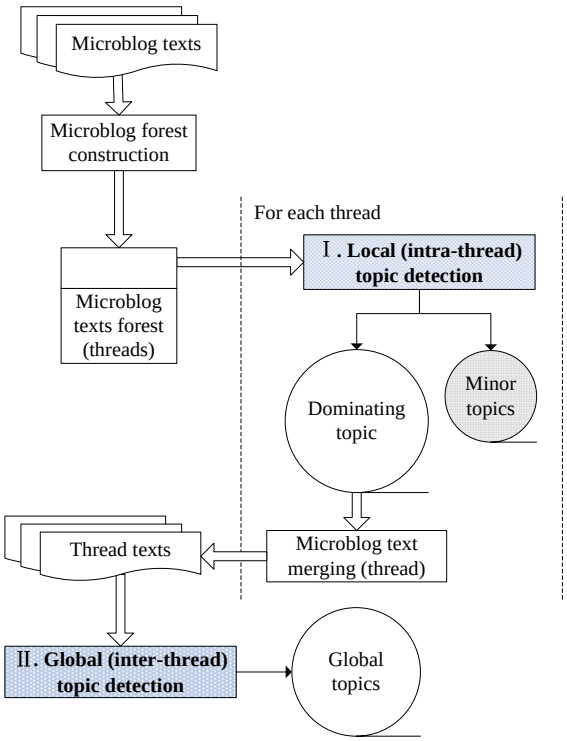

Figure 3. The workflow of our approach.

4 The Approach

Topic detection relies on a topic models. In this work, the temporal-author-topic model (TAT) is proposed to handle microblog texts. For description convenience, we first give the probabilistic topic model.

4.1 Probabilistic Topic Model

The common topic model used in topic detection is probabilistic topic model. Three distributions are given as follows:

(1) Word-topic distribution: $P(w, z) = \varphi(z)$;

(2) Word-topic dispatch: $P(w|z) = \delta(w)$

(3) Word-document distribution: $P(w, d) = \psi(d)$;

where z represents a topic, and w a word. The topic analysis actually judges the topic distribution $\theta(d)$ of document d.

4.2 Temporal-Author-Topic Model

As a kind of Internet microtext, the microblog text is intentional, conversational and

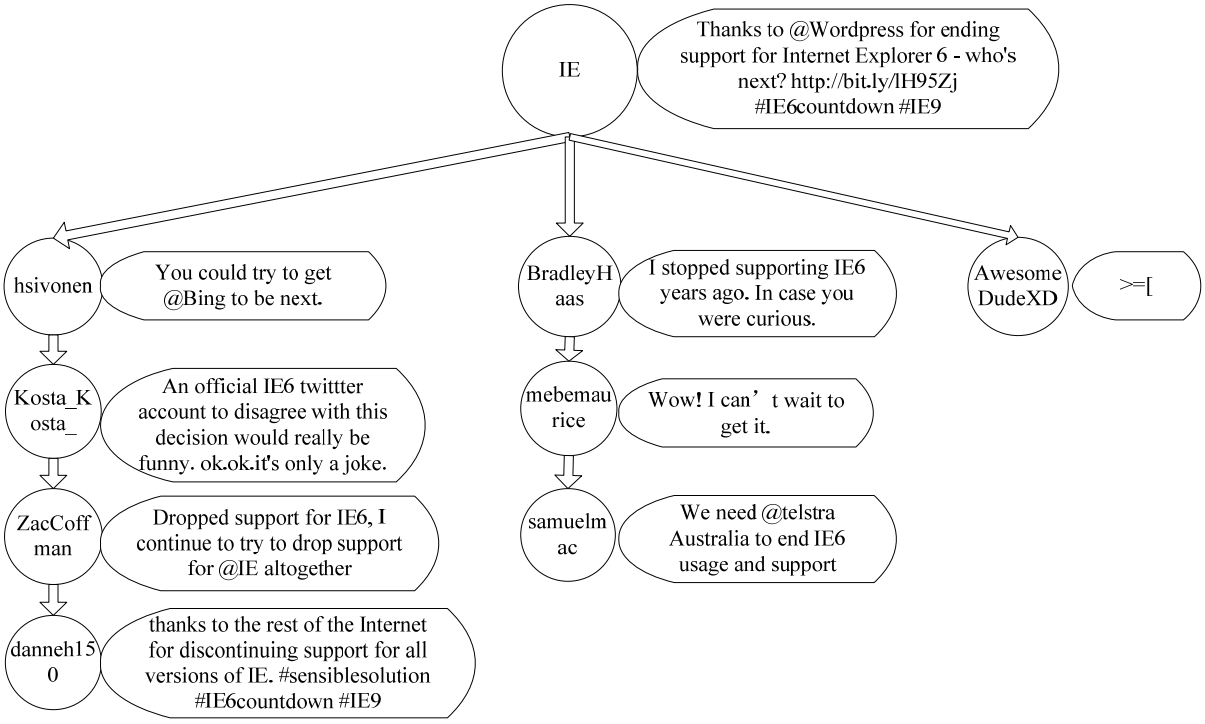

Figure 4. Tree structure of the microblog thread T^O

personalized. The topic model for the microblog texts should reflect above characteristics. We consider the following information as the features in microblog topic detection.

- **Author**: In the microblog texts, author is a prominent feature. Observations show that one author usually participates in a limited number of topics. In this work, the author information is added in the common topic model, and the author-topic (AT) model is formed.
- **Timestamp**: We also find out that, if an author delivers several statements within a short period, these statements probably focus on a limited number of topics. Thus we define the interval as one hour, which means two posts are probably related to the same topic if they are delivered within one hour. Considering the temporal information, the AT model then evolves to the temporal-author-topic (TAT) model.
- **Thread**: Thread information is very important to microblog topic detection. Suppose a set of postings belong to the same conversation thread, they are assumed to talk about the same topic, which is initiated by the *head posting*. In this work, thread information is viewed as a key feature.

Finally, based on the common topic model, TAT adds in the following distributions:

(4) Temporal-Author-Topic distribution: $P(t, a, w, z) = \rho(z)$;

(5) Temporal-Author-Topic dispatch: $P(t, a, w|z) = \sigma(w)$;

where t is timestamp, a the author.

The distribution can be obtained from microblog text development dataset.

4.3 Local Topic Detection

Local topic detection, also called intra-thread topic detection, is the first phase in microblog topic detection. In this phase, the topic analysis is one-cluster based, which means that a dominating topic will be detected while the texts in the other topics are deemed irrelevant to the dominating topic.

Figure 4 gives a tree structure of the microblog thread T^O in Figure 1. The thread tree has three sub-trees, namely, there are three subtopics within thread T^O. However, seen from Figure 4, the right sub-tree is obviously not relevant to the dominating topic. Thus in this thread, the posting in the right sub-tree is deemed a spam posting. We adopt topic detection to filter such spam postings in every microblog thread.

The TAT model is used in thread topic detection in this work. We further consider more heuristics. In microblog threads, there exist many *followup postings*.

Given a pair of postings, in which one posting replies the other, the two postings P_1 and P_2 hold *A-reply-B* relation. They are assumed to talk about the same topic. The *A-reply-B* relation

plays an important role in thread topic detection. We define that, if two postings hold the *A-reply-B* relation, in clustering, the similarity of two postings is increased by a parameter λ. The similarity formula is given as follows.

$$Sim(P_1, P_2) = \lambda + Sim(P_1, P_2),$$
$$\lambda = \frac{1}{|N|} \quad , \quad (1)$$

where $Sim(P_1, P_2)$ represents the posting similarity calculated with VSM model, and $|N|$ is the number of postings in the thread.

Due to the quantity of spam postings is small, after calculating the similarity, the cluster which has the least postings may be filtered as the spam. As a result, a clean and topic-related thread T^R is obtained from thread T^O.

4.4 Global Topic Detection

Global topic detection, also referred to as inter-thread topic detection, is conducted on forest level. Microblog texts are usually very short, i.e., less than 140 characters. We propose to make use of thread structure to address the sparse data problem. We merge microblog texts in every clean thread to form a bigger thread text. Then the global topic detection is achieved with thread texts. Once a thread text is assigned a topic label, microblog texts in this thread are all assign the label. In this way, the ultimate goal of microblog topic detection is achieved.

Denote thread text being generated with thread T^R by X_i, which is combination of all the posts in thread T^R. Now we convert the microblog text into a set of thread texts $X_{i=1,\ldots,N}$. The global topic detection is executed on $X_{i=1,\ldots,N}$ to find microblog topics.

4.5 LDA-based Feature Weighting

TFIDF (term frequency and inverse document frequency) is widely used to calculate feature weights. In this paper, we also evaluate the Latent Dirichlet Allocation (LDA) in feature selection. LDA is proven better than TFIDF in regular texts (Madsen et al., 2005; Krestel et al., 2009). In this work, we evaluate how it works on microblog texts.

LDA is an unsupervised model proposed by Blei et al. (2003). It views every text as the combination of topics, and transfers the dimension of words into topics.

To be specific, LDA models document as a mixture of *K* latent topics, each of which is a multinomial distribution over a word vocabulary *W*. For document j, we first draw a mixed proportion $\theta_{k|j}$ from a Dirichlet with parameter a. For the i^{th} word in the document, a topic z_{ij} is drawn with topic k chosen with probability $\theta_{k|j}$. Then word x_{ij} is drawn from the z_{ij}^{th} topic by taking on value *w* with probability $\phi_{w|k}$. Finally, a Dirichlet prior with parameter β is placed on the topics $\phi_{w|k}$. Thus, the generative process is given as follows.

$$\phi_{k|j} \sim D[\alpha] \quad \phi_{w|k} \sim D[\beta]$$
$$z_{ij} \sim \theta_{k|j} \quad x_{ij} \sim \phi_{w|z_{ij}} \quad (2)$$

Given the observed words $X = \{x_{ij}\}$, Bayesian inference seeks to compute the posterior distribution over the latent topic indices $Z = \{z_{ij}\}$, the mixed proportion $\theta_{k|j}$, and the topics $\phi_{w|k}$. An efficient procedure is to use collapsed Gibbs sampling, where θ and ϕ are marginalized out, and the latent variables Z are sampled. Given the current state of all but one variable z_{ij}, the conditional probability of z_{ij} is given below.

$$p(z_{ij} = k | z^{\neg ij}), x, \alpha, \beta) \propto$$
$$(\alpha + n_{k|j}^{\neg ij})(\beta + n_{x_{ij}|k}^{\neg ij})(w\beta + n_k^{\neg ij}) \quad , \quad (3)$$

where the superscript $\neg ij$ means that the corresponding data-item is excluded in the count values, and $n_{jkw} = \#\{i : x_{ij} = w, z_{ij} = k\}$. We use the convention that missing indices are summed out: $\sum_w n_{jkw}$ and $n_{w|k} = \sum_j n_{jkw}$.

4.6 VSM-based Document Similarity

Vector Space Model (VSM) is a widely used document representation model. Let *d* represent a document and $\{t_i\}_{i=1,\ldots,K}$ feature terms appearing in document *d*. Then document *d* can be represented by the following text vector V_d according to the TFIDF or LDA.

$$V_d = (t_1 : w_1^s; \ldots; t_K^s),$$

where w_i^s is weight of feature term t_i.

In VSM, document similarity is usually measured using the cosine function, which is given as follows.

$$Sim(d_1, d_2) = \frac{D_1^T, D_2}{\sqrt{D_1^T, D_1}\sqrt{D_2^T, D_2}}, \quad (4)$$

where D_1 and D_2 denote the two document vectors.

4.7 Text Clustering

Any clustering algorithms can be used in our algorithm. In this work, but we choose K-means (Duda et al., 1973) and HAC (Voorhees, 1986).

HAC is similar to our approach due to the hierarchical nature. So we intend to compare our approach against HAC. We select K-means because it is a classical clustering algorithm.

5 Experiment

5.1 Data Preparation

There is no benchmark dataset that fits into our scenario. We have to compile the gold standard by ourselves.

We use SINA microblog API[5] to extract Chinese microblog texts. Then the gold standard is compiled by six human annotators. The annotation scheme complies with the TDT4 annotation guideline.

Finally, we constructed a microblog dataset containing 1,100 threads and 16,500 postings (i.e., 15 postings in each thread on average). The postings are managed in 100 topics.

5.2 Evaluation Metrics

We adopted the evaluation metrics proposed by Steinbach et al. (2000). The calculation starts from the maximum *F*-measure in each cluster. Let A_i represent the set of articles that are managed in a system-generated cluster c_i, A_j is the set of articles managed in a human-generated cluster c_j. *F* measure of the system-generated cluster c_i is calculated as follows.

$$\begin{aligned} p_{i,j} &= \frac{|A_i \cap A_j|}{|A_j|} \quad p_i = \max_j\{p_{i,j}\} \\ r_{i,j} &= \frac{|A_i \cap A_j|}{|A_i|} \quad r_i = \max_j\{r_{i,j}\}, \\ f_{i,j} &= \frac{2 \cdot p_{i,j} \cdot r_{i,j}}{p_{i,j} + r_{i,j}} \quad f_i = \max_j\{f_{i,j}\} \end{aligned} \tag{5}$$

where $p_{i,j}$, $r_{i,j}$ and $f_{i,j}$ represent precision, recall and *F* measure of cluster c_i when compared with cluster c_j, respectively.

5.3 The Approaches

Three baseline approaches are developed in this work. The intention is to evaluate the influence of author, timestamp and thread information on topic analysis, respectively.

Baseline B1: Only posting text is used in topic detection. All postings are used equally in topic detection.

Baseline B2: Author information is added to the baseline system B1 and the author-topic (AT) model is formed. All postings are used equally in topic detection.

Baseline B3: Timestamp is added to baseline system B2 and the temporal-author-topic (TAT) model is formed. All postings are used equally in topic detection.

Our approach OUR: The TAT model is used in topic modeling. The thread information is considered, and topics within microblog texts are detected in two phases.

Note that TFIDF or LDA are adopted for feature selection and HAC or K-means for text clustering in all systems. To evaluate how topic number influences the approach, six predefined class numbers are defined in this experiment, ranging from 50 to 100.

5.4 Results and Discussions

Table 1 reports the experimental results of our approach and the baselines on gold-standard dataset of predefined cluster number of 100, which use TFIDF or LDA feature selection and HAC or K-means clustering algorithm.

	K-means + TFIDF (%)	K-means + LDA (%)	HAC + TFIDF (%)	HAC + LDA (%)
B1	21.1	23.2	17.2	21.7
B2	25.5	26.4	22.2	25
B3	25.2	27	21.8	25.4
OUR	26.6	31.2	24.7	27.5

Table 1. F measure values of approaches with predefined topic number 100.

Three observations are made on the experiment results. Firstly, according to Table 1, system B2 outperforms B1 by 4.6%, system B3 outperforms B2 by 1.1%, and our system outperforms B3 by 2.8% on average. It is thus proven that author, timestamp and thread information are important in microblog topic detection.

The significant outperformance can be explained by two types of errors that constantly happen in baseline systems but not in our system. Errors of the first type come from the conversation threads. In the baseline systems, each posting is considered as an individual text. The contextual information is ignored in the clustering process. For example, one posting reads: *It's really cute*! It is difficult for the baseline systems to figure out which topic it belongs to. In contrast, our approach can merge the posting to the head posting reads: *Beijing Kennel Club adopts six stray dogs.* It is no longer for our system to detect what is really cute.

[5] http://open.weibo.com/wiki/index.php/SDK

The second typical error comes from the sparse data problem. As aforementioned, a posting is considered as an individual text in baseline systems. When we use TFIDF or LDA in feature selection and adopt VSM to represent the posting, the data sparseness is serious. For instance, a text vector V_i looks like

$$V_i = (t_1 : 0; t_2 : 0; ...; t_{k-1} : 1, t_k : 0),$$

where only the feature t_{k-1} appears in the posting. We even find some extreme postings that contain no feature at all. It is difficult to calculate the similarity between two such postings.

In our approach, thread is viewed as a whole, and thread text is used to find global topics. The sparse data problem is alleviated to great extent. This is the major reason that leads to significant outperformance.

Secondly, we compare feature selection algorithms, i.e. TFIDF and LDA, in all experiments. LDA is demonstrated to be better than TFIDF in regular texts. In this work, we try to prove this conclusion with microblog texts. As shown in Table 1, the system using LDA outperforms that uses TFIDF. We thus conclude that the conclusion made by Madsen, et al. (2005) and Krestel et al. (2009) is also true on microblog texts.

Thirdly, we compare different clustering algorithms, i.e. HAC and K-means, in our experiments. Seen from Table 1, the system using K-means outperforms that uses HAC. We can conclude that K-means algorithm fits into our approach better than HAC.

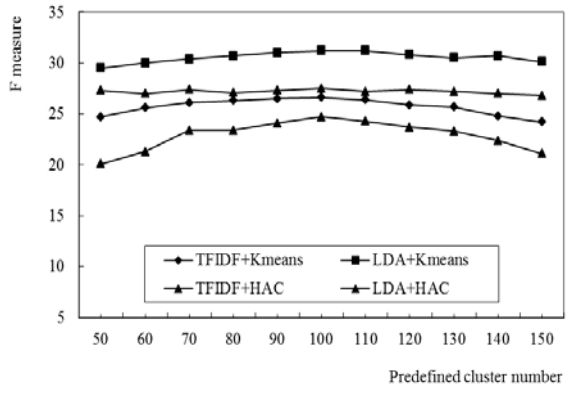

Figure 4. F measure curves of our approach with various topic numbers.

Finally, we evaluate how the predefined topic number influences the clustering algorithm. Seen from Figure 4, the approaches with LDA perform stably with different topic number. But for the approaches with TFIDF, different trend is disclosed. Performance of the approaches climbs gradually. Shown in Figure 4, our approach improves less when topic number is closer to 100. When the topic number is bigger than 100, F measure of our approach starts to drop. It can thus be concluded that TFIDF is sensitive to topic number than LDA. Note that the topic number in the gold standard dataset is 100. We thus conclude that the approach fits to the datasets well.

6 Conclusion and Future Work

In this paper, the Temporal-Author-Topic (TAT) model is proposed for microblog topic detection. Experimental results show that, the new model fits specially into microblog when information about timestamp and author is incorporated. We further make use of the thread information and propose a two-phase approach. Intra-thread topic detection is first executed to clean every thread, and then inter-thread topic detection is run to find global topics more precisely with bigger thread texts. The notable contribution lies in that the serious sparse data problem in microblog processing is alleviated to great extent.

However, the reported work is still preliminary. In the future, we will conduct full evaluation with microblog text in multiple languages. Meanwhile, we are aware that the maximum F measure (i.e., 31.2%) of the approach is rather low. We will incorporate various word similarity measures to achieve feature selection and document similarity in concept level.

Abstract

The design of a Spoken Dialogue System (SDS) is a long, iterative and costly process. Especially, it requires test phases on actual users either for assessment of performance or optimization. The number of test phases should be minimized, yet without degrading the final performance of the system. For these reasons, there has been an increasing interest for dialogue simulation during the last decade. Dialogue simulation requires simulating the behavior of users and therefore requires user modeling. User simulation is often done by statistical systems that have to be tuned or trained on data. Yet data are generally incomplete with regard to the necessary information for simulating the user decision making process. For example, the internal knowledge the user builds along the conversation about the information exchanged while interacting is difficult to annotate.

In this contribution, we propose the use of a previously developed user simulation system based on Bayesian Networks (BN) and the training of this model using algorithms dealing with missing data. Experiments show that this training method increases the simulation performance in terms of similarity with real dialogues.

1 Introduction

The design of a Spoken Dialogue System (SDS) is a long, iterative and costly process. Although several attempts exist to simplify this design such as the VoiceXML language (W3C, 2008), graphical interfaces (McTear, 1998) or machine-learning-based methods (Pietquin and Dutoit, 2003), it remains an expert job. Especially, it requires test phases on actual users either for assessment of performance (Eckert et al., 1997; López-Cózar et al., 2006) or strategy optimization by means of reinforcement learning (Levin et al., 1997; Pietquin and Dutoit, 2006a). The number of test phases should be minimized, yet without degrading the final performance of the system. One solution to this problem is the use of Wizard-of-Oz methods (Kelley, 1984; Rieser, 2008). Although this doesn't require a real implementation of the dialogue system to be tested, this is still time and money consuming. For these reasons, there has been an increasing interest for dialogue simulation during the last decade (Eckert et al., 1997; Pietquin and Dutoit, 2006a; Schatzmann et al., 2006; López-Cózar et al., 2006). Dialogue simulation requires simulating the behavior of users and therefore requires user modeling as well as error modelling (Pietquin and Dutoit, 2006b; Schatzmann et al., 2007b). Most often, dialogue simulation takes place at the intention level (Eckert et al., 1997; Pietquin and Dutoit, 2006a; Schatzmann et al., 2007c) but can take place at the speech signal level (López-Cózar et al., 2006). This paper focuses on the former solution and more specifically on statistical user simulation (Eckert et al., 1997; Cuayáhuitl et al., 2005; Pietquin and Dutoit, 2006a; Schatzmann et al., 2007c). Statistical models are generally parametric generative models where parameters are conditional probabilities that can either be hand-tuned (estimated by experts) because of the complexity of the model (Pietquin, 2006; Schatzmann et al., 2007a), trained on actual man-machine dialogue data (Eckert et al., 1997; Cuayáhuitl et al., 2005; Pietquin et al., 2009; Syed and Williams, 2008) or a mix of both (Scheffler and Young, 2001; Keizer et al., 2010) so as to deal with parameters which are not directly accessible in a database. Indeed, data are often incomplete with regard to the necessary information for simulating the user decision making process. For

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 598–604,
Chiang Mai, Thailand, November 8 – 13, 2011.

example, the internal knowledge the user builds along the conversation about the dialogue context is difficult to annotate.

In this contribution, we propose the use of a previously developed user simulation system based on Bayesian Networks (BN) described in Section 2 and the training of this model using algorithms dealing with missing data. As said before, in the case of man-machine dialogues data, some information is often missing in the annotations. This paper focuses on the user's internal representation of the dialogue context which is referred to as the *knowledge* of the user. This is a major difference with other papers of the literature such as (Syed and Williams, 2008) where transition probabilities are estimated according to the history of system and user acts. Taking into account the incremental knowledge of the user about previous exchanges is important to ensure the consistency of the dialogue during the interaction (Pietquin, 2006). Although it is a difficult task, the knowledge of the user could be inferred from the data itself, by a human expert, a set of rules, or a trained classification algorithm dedicated to this task. In Section 4, this approach is followed, the knowledge (or an accurate estimate) is supposed to be known and the derived training methods for learning the BN parameters are explained. Alternatively, the knowledge of the user can be treated as hidden and the BN parameters can be learned using corresponding Expectation-Maximization algorithms. This approach is described in Section 5, both within a statistical framework (expected-likelihood maximization) and within a Bayesian framework (starting from some prior distribution over parameters). The experiments described in Section 6 show that this training method increases the simulation performance in terms of similarity with real dialogues.

2 BN-based user simulation

The user simulation method studied in this paper is based on the probabilistic model of a man-machine dialog proposed in (Pietquin, 2005; Pietquin and Dutoit, 2006a). The interaction between the user and the dialog manager is seen as a sequential transfer of intentions thanks to dialog acts organized in turns noted t. At each turn t the dialog manager selects a system act a_t conditionally to its internal state s_t and according to its strategy. The user answers by a user act u_t which is conditioned by the goal g_t s/he is pursuing and the knowledge k_t s/he has about the dialog (what has been exchanged before reaching turn t). So, at a given turn, the information exchange can be modeled thanks to the joint probability $p(a, s, u, g, k)$ of all these variables. This joint probability can be factored as:

$$p(a, s, u, g, k) = p(u|g, k, a, s)p(g|k, a, s)p(k|s, a)p(a|s)p(s)$$

Given that :

- since the user doesn't have access to the SDS state, u, g and k cannot depend on s,
- the user's goal can only be modified according to his/her knowledge of the dialog,

this expression can be simplified:

$$p(a, s, u, g, k) = \underbrace{p(u|g, k, a)}_{\text{User act}} \overbrace{p(g|k)}^{\text{Goal Modif.}} \underbrace{p(k|a)}_{\text{Know. update}} \overbrace{p(a|s)}^{\text{DM Policy}} p(s)$$

This can be expressed by the Bayesian network depicted on Fig. 1.

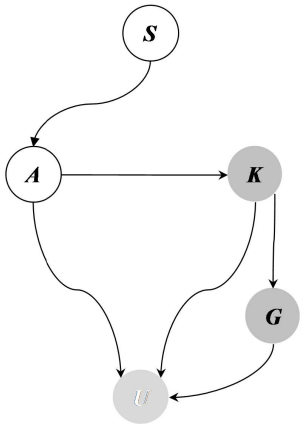

Figure 1: Bayesian Network-based Simulated User

As explained in (Pietquin and Dutoit, 2006a), the practical use of this kind of BN requires a tractable representation of the stochastic variables $\{a, s, u, g, k\}$. Variables are therefore considered as vectors of either boolean either symbolic values which makes them discrete in any case and limits the number of conditional probabilities which are the parameters Θ of this model (see (Pietquin, 2005; Pietquin and Dutoit, 2006a) for more details).

In this BN, nodes represented as empty circles ○ are input variables of the simulator (actually the outputs of the SDS), the light-gray circle ● is the output variable (user's utterance) and the dark-gray circles ● are internal variables (knowledge and goal). The parameters linked to these internal variables are generally hard to obtain from data collection since it is hard to infer what are the user knowledge and goal from the transcripts of interactions. The most difficult is probably to infer the knowledge of the user since in data collection settings or Wizard-of-Oz experiments, the user goal can be imposed on test users while the knowledge is built during the interaction and depends on it.

3 Dialogue example within the TownInfo domain

A dialogue example between the simulated user and the HIS dialogue manager (Young et al., 2009) is shown below. The user has the goal to get the name, phone number and address of a restaurant that serves Italian food and beer. The dialogue shows both system (SYS) and user (USR) acts. At the start of the dialogue, the simulator is initialised with a (randomly generated) user goal. Some of the slots are constrained by the user (G_C) and other are requested by him (G_R).

```
G_R> name, phone, addr
G_C> type=restaurant, food=italian, drinks=beer

Sys> hello() [Greet]
Usr> hello() {1.00}
     .
Sys> repeat() [Repeat]
Usr> hello(type=restaurant) {1.00}
     --
Sys> request(near) [Request]
Usr> inform(food=italian,drinks=beer) {1.00}
     --
Sys> inform(name=none,type=restaurant,
       food=italian) [Offer]
Usr> reqalts(food=indian) {1.00}
     --
Sys> inform(name="Carnaby Street",type=restaurant,
       drinks=beer,food=indian) [Offer]
Usr> deny(drinks=wine,drinks=beer) {1.00}
     --
Sys> inform(name="The Parrot",type=bar,drinks=beer,
        food=indian) [Offer]
Usr> request(phone) {1.00}
     --
Sys> inform(name="The Parrot",
        phone="728-66-32") [Inform]
Usr> request(addr) {1.00}
     --
Sys> inform(name="The Parrot",
        addr="Art Square") [Inform]
Usr> bye()
     --

End> --
```

In the next sections, the training methods used for estimating the parameters of the BN-based user simulation described in Section 2 are described.

4 Training methods with complete data

4.1 Maximum likelihood

When all variables in a dataset are observed, a statistical framework can be used, in which the frequencies of events appearing in the database are computed. This is known as the *maximum likelihood* approach:

$$\Theta^{ML}_{i,j,k} = \hat{p}\left(X_i = x_k \mid pa(X_i) = x_j\right) = \frac{N_{i,j,k}}{\sum_k N_{i,j,k}}$$

where the set of $\Theta^{ML}_{i,j,k}$ are the BN parameters that need to be learned, $N_{i,j,k}$ is the number of events in the database for which the variable X_i is in the state x_k and its parents in the network (pa) in the configuration x_j.

4.2 Bayesian training

Bayesian estimation of the parameters is slightly different. It actually aims at estimating the probability distribution over parameters and estimates the parameters using either a *maximum a posteriori* (MAP) approach or the parameters' expectation given this distribution. This is done knowing that the variables have been observed and requires some prior on the parameters. Using a Dirichlet distribution prior (standard choice for multivariate distributions), it is possible to derive an analytical formula for the expected parameters which is similar to the one obtained in the previous section. Using the MAP approach:

$$\Theta^{MAP}_{i,j,k} = \hat{p}\left(X_i = x_k \mid pa(X_i) = x_j\right) = \frac{N_{i,j,k} + \alpha_{i,j,k} - 1}{\sum_k N_{i,j,k} + \alpha_{i,j,k} - 1}$$

where the $\alpha_{i,j,k}$ are the coefficients of the Dirichlet distribution.

Using the *a priori* expectation approach (AEP) instead of the MAP, one gets:

$$\Theta^{AEP}_{i,j,k} = \hat{p}\left(X_i = x_k \mid pa(X_i) = x_j\right) = \frac{N_{i,j,k} + \alpha_{i,j,k}}{\sum_k N_{i,j,k} + \alpha_{i,j,k}}$$

4.3 Priors on parameters

The $\alpha_{i,j,k}$ are priors on parameters' distribution (Dirichlet distribution coefficients), as they are set by an expert. It is thus possible to give to these coefficients more or less importance, given the confidence of the expert. This will result in different trained BN/retrained BN user simulators. Fine-tuning the $\alpha_{i,j,k}$ will allow us to get simulators behaving more or less like the human users which produced the database, as shown in Section 6. Of course, if nothing is known (no expert available), a uniform distribution over parameters (all coefficient being equal) can be taken as a prior and the method can still be used.

5 Training methods with missing data

5.1 Expectation-Maximization algorithm

The *Expectation-Maximization* (EM) algorithm (Dempster et al., 1977) allows estimating the BN parameters even when the data corresponding to some of the parameters is missing.

EM is a recursive algorithm applied until convergence as explained hereafter.

Let us assume that:

- $X_\nu = \left\{X_\nu^{(l)}\right\}_{l=1\ldots N}$ is the set of the N observable data.
- $\Theta^{(t)} = \left\{\Theta_{i,j,k}^{(t)}\right\}$ are the estimations of the parameters of the BN at iteration t.

EM is a recursive algorithm, initialized with arbitrary $\Theta^{(0)}$ values, consisting of two steps:

- **Expectation (E)** step: the missing data $N_{i,j,k}$ are estimated, by computing their expectation conditionally to the data and to the current parameter estimates (i.e., to the current distribution estimate):

$$N_{i,j,k}^* = E[N_{i,j,k}] = \sum_{l=1}^{N} \hat{p}\left(X_i = x_k \mid pa(X_i) = x_j, X_\nu^{(l)}, \Theta^{(t)}\right)$$

  This consists in doing inference using the current parameter values, and in replacing the missing values by the probabilities obtained by inference.

- **Maximization (M)** step: replacing the missing $N_{i,j,k}$ by their expected value computed in the previous step, it is possible to compute the new parameter values $\Theta^{(t+1)}$, using maximum likelihood:

$$\Theta_{i,j,k}^{(t+1)} = \frac{N_{i,j,k}^*}{\sum_k N_{i,j,k}^*}$$

5.2 Expectation-Maximization algorithm and Bayesian training

The EM algorithm can be used within the Bayesian framework as well. In that case, the maximum likelihood estimation used in the **M** step must be replaced by an *a posteriori* maximum. Using the *a posteriori* expectation, one gets:

$$\Theta^{(EM)} = \Theta_{i,j,k}^{(t+1)} = \frac{N_{i,j,k}^* + \alpha_{i,j,k}}{\sum_k N_{i,j,k}^* + \alpha_{i,j,k}}$$

6 Experiment

6.1 Dialogue task and data

To test the different training algorithms, the user simulator parameters have been learnt on a database containing 1234 actual man-machine dialogues in the domain of tourist information. The dialogue system is a large-scale application aiming at retrieving information about user's interests in a city (about restaurants, hotels, *etc*.) so as to provide relevant propositions of venues as described in (Keizer et al., 2010). The venues can be of different types such as bar, restaurants and hotels. Each venue is described by a set of features (type of cuisine, location in the city *etc*.). The hierarchical structure of the task makes it relatively complex as well as the high number of slots (13). The data contains transcripts and semantic annotations in terms of dialogue act. The BN-based user simulator has been tested against the HIS Dialogue Manager developed at Cambridge University (Young et al., 2009).

6.2 Training methods

Six training setups for the BN-based user simulator were tested. 1000 dialogues were generated for each configuration after training. The six setups are described below:

- "ori-T-BN": the knowledge parameters were estimated on the database and the BN parameters were learned using the results by a Maximum Likelihood method ($\Theta_{i,j,k}^{ML}$) (see Section 4).

- "mod-T-BN": the knowledge parameters were estimated on the database and the BN parameters were learned with a Bayesian learning method (AEP method) and using priors fixed by an expert, reasonably taken into account ($\Theta_{i,j,k}^{AEP}$) (see Section 4).
- "H-BN": the BN parameters were hand-coded by an expert (Heuristics).
- "mod-T1-BN": the knowledge was supposed missing and the BN parameters were learned using the database by Bayesian EM and priors fixed by an expert; first version: expert almost not taken into account ($\Theta^{(EM)}$) (see Section 5).
- "mod-T2-BN": the knowledge was supposed missing and the BN parameters were learned using the database by Bayesian EM and priors fixed by an expert; second version: expert reasonnably taken into account ($\Theta^{(EM)}$).
- "mod-T3-BN": the knowledge was supposed missing and the BN parameters were learned using the database by Bayesian EM and priors fixed by an expert; third version: expert much taken into account ($\Theta^{(EM)}$).

The last three configurations are the most realistic ones.

6.3 Evaluation methods

Four dissimilarity measures have been computed: the Precision, the Recall, the symmetric Kullback-Leibler dissimilarity DS and the average number of turns per dialog (Pietquin and Hastie, 2011).

Precision:

$$P = 100 \times \frac{\text{Correctly predicted actions}}{\text{All actions in simulated response}}$$

Recall:

$$R = 100 \times \frac{\text{Correctly predicted actions}}{\text{All actions in real response}}$$

$$DS(P||Q) = \frac{D_{KL}(P||Q) + D_{KL}(Q||P)}{2}$$

where

$$D_{KL}(P||Q) = \sum_{i=1}^{M} p_i log(\frac{p_i}{q_i}),$$

and where p_i (resp. q_i) is the frequency of dialogue act a_i in the histogram of distribution P (resp. Q) obtained on the database (resp. on the generated data). The simulated dialogues are compared to the dialogues from the database on this basis. Notice that the Precision and the Recall must be as high as possible, the Kullback-Leibler as low as possible and the average number of turns per dialogue as close to the average number of turns per dialogue in the database (which is 8.185).

	ori-T-BN	mod-T-BN	H-BN
Precision:	47.11	50.62	63.63
Recall:	57.89	60.68	53.20
DS:	0.7292	0.6712	0.8803
Nturns/diag:	18.19	15.15	5.283

Table 1: Dissimilarities using the first three BN configurations

	mod-T1-BN	mod-T2-BN	mod-T3-BN
Precision:	63.71	64.60	67.13
Recall:	61.84	63.83	69.27
DS:	0.6674	0.7864	0.5288
Nturns/diag:	7.690	7.980	8.703

Table 2: Dissimilarities using the last three BN configurations

6.4 Results

The results are provided in Tables 1 and 2. Table 1 clearly indicates that the first configurations do not provide realistic dialogues. Considering the Recall, the DS and the number of turns, the mod-T-BN gives the best results. The fact that ori-T-BN gives bad results indicates that the database is not large enough, and/or that the inferred knowledge is not very accurate. The H-BN was designed to give as short as possible dialogues: this can be seen in the dissimilarity measures.

Table 2 indicates that the training techniques with missing data are efficient, allowing not to use the error-prone (automatic or manual) knowledge inference. Taking the expert information into account allows to improve the performance to some extent, considering the Precison, the Recall and the number of turns per dialogue dissimilarity measures. The DS dissimilarity measure gives more uncertain results.

7 Conclusions

In this paper, the problem of user simulation in spoken dialogue systems is addressed and particularly the training of statistical user simulation systems on actual data. Most often, actual man-machine dialogue corpora annotations do not contain all the required information for simulating the user's decision-making process. For instance, the knowledge of the dialogue context which is incrementally built by the user during the interaction is very difficult to annotate. To tackle this problem, this contribution proposes the use of expectation-maximization algorithms (in a Maximum Likelihood setting or a Bayesian setting) to learn parameters of a BN-based user model. Experimental results show that this method improves significantly the similarity of automatically generated dialogues.

In the future, this user model will be used to train a reinforcement-learning-based dialogue manager so as to optimize the dialogue strategy. Also, the extension of this user simulation technique to other tasks is envisioned. The simulation of the grounding process which is possible thanks to this kind of model (Rossignol et al., 2010) should also benefit from this training method to generate more realistic dialogues. Finally, we want to compare the performance of this user model to newly proposed models such as in (Chandramohan et al., 2011) according to several metrics (Pietquin and Hastie, 2011).

Abstract

In this paper, we introduce the task of identifying general and specific sentences in news articles. Given the novelty of the task, we explore the feasibility of using existing annotations of discourse relations as training data for a general/specific classifier. The classifier relies on several classes of features that capture lexical and syntactic information, as well as word specificity and polarity. We also validate our results on sentences that were directly judged by multiple annotators to be general or specific. We analyze the annotator agreement on specificity judgements and study the strengths and robustness of features. We also provide a task-based evaluation of our classifier on general and specific summaries written by people. Here we show that the specificity levels predicted by our classifier correlates with the intuitive judgement of specificity employed by people for creating these summaries.

1 Introduction

Sentences in written text differ in how much specific content they have. Consider the sentences in Table 1 from a news article about the Booker prize. The first one is specific and details the issues surrounding the books chosen for the award. The second sentence is general, it states that the prize is controversial but provides no details. In this work, we present the first analysis of properties associated with general and specific sentences and introduce an approach to automatically identify the two types.

The distinction between general and specific sentences would be beneficial for several applications. Prescriptive books on writing advise that sentences that make use of vague and abstract words should be avoided or else immediately followed by specific clarifications (Alred et al., 2003). So our classifier could be useful for the prediction of writing quality. Other applications include text generation systems which should control the type of content produced and information extraction systems can use the distinction to extract different types of information.

The novel, a story of Scottish low-life narrated largely in Glaswegian dialect, is unlikely to prove a popular choice with booksellers who have damned all six books shortlisted for the prize as boring, elitist and - worst of all - unsaleable.
...
The Booker prize has, in its 26-year history, always provoked controversy.

Table 1: General (in italics) and specific sentences

Our definition of general/specific is based on the level of detail present in a sentence. This definition contrasts our work from some other recent studies around the idea of generic/specific distinctions in text. Reiter and Frank (2010) present an automatic approach to distinguish between noun phrases which describe a class of individuals (generic) versus those which refer to a specific individual(s). In Mathew and Katz (2009), the aim is to distinguish sentences which relate to a specific event (called episodic) from those which describe a general fact (habitual sentences). Our focus is on a different and broader notion of general/specific which is motivated by potential applications in summarization and writing feedback. The task of identifying these types of sentences has not been addressed in prior work.

We present a supervised classifier for detecting general and specific sentences. We obtain our training data from the Penn Discourse Treebank (PDTB), where relevant distinctions have been annotated in the larger context of discourse relation analysis. We show that classification accuracies as high as 75% can be obtained for distinguishing sentences of the two types compared with a ran-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 605–613,
Chiang Mai, Thailand, November 8 – 13, 2011.

dom baseline of 50%. We also perform an annotation study to obtain direct judgements from people about general/specific sentences in news articles from two corpora and use this dataset to validate the accuracy of our features and their robustness across genre. Finally, we train a classifier on the combined set of all annotated data.

We also present a task-based evaluation of our classifier using a large corpus of summaries written by people. For some of the topics, people were instructed to write specific summaries that focus on details, for others they were asked to include only general content. We find that our classifier successfully predicts the difference in specificity between these two types of summaries.

2 A general vs. specific sentence classifier based on discourse relations

The task of differentiating general and specific content has not been addressed in prior work, so there is no existing corpus annotated for specificity. For this reason, we first exploit indirect annotations of these distinctions in the form of certain types of discourse relations annotated in the Penn Discourse Treebank (PDTB) (Prasad et al., 2008). The discourse relations we consider are Specification and Instantiation. They are defined to hold between adjacent sentences. The definitions of the relations do not talk directly about the specificity of sentences, but they seem to indirectly indicate that the first one is general and the second is specific. The exact definitions of these two relations in the PDTB are given in (Prasad et al., 2007). Some examples are shown in Table 2.

The PDTB annotations cover 1 million words from Wall Street Journal (WSJ) articles. Instantiations and Specifications are fairly frequent (1403 and 2370 respectively). In contrast to efforts in automatic discourse processing (Marcu and Echihabi, 2001; Sporleder and Lascarides, 2008), in our work we are not interested in identifying adjacent sentences between which this relation holds. Our idea is to use the *first* sentences in these relations as general sentences and the *second* as specific sentences.[1] Although the definitions of these relations describe the specificity of one sentence relative to the other, we do not focus on this pairwise difference in specificity. We believe that the realization of a general sentence should have some unique properties regardless of the particular sentence that precedes or follows it.

We use these relations to study the properties of general and specific sentences and to test the feasibility of differentiating these two types. We obtain good success on this task and equipped with the knowledge from our study, we collect direct judgements of general/specific notion from annotators on a smaller set of sentences. Using these annotations, we confirm that our classifier learnt on the discourse relations generalizes without noticeable compromise in accuracy. We describe our classifier based on discourse relations here, the annotation study is detailed in the next section.

2.1 Features

Based on a small development set of 10 examples each of Instantiation and Specification, we came up with several features that distinguished between the specific and general sentences in the sample. Some of our features require syntax information. We compute these using the manual parse annotations for the articles from the Penn Treebank corpus (Marcus et al., 1994).

Sentence length. We expected general sentences to be shorter than the specific ones. So we introduced two features—the number of words in the sentence and the number of nouns.

Polarity. Sentences with strong opinion are typical in the general category in our examples in Table 2. For instance, the phrases "publishing sensation", and "very slowly–if at all" are evaluative while the specific sentences in these relations present evidence which justify the general statements. So, we record for each sentence the number of positive, negative and polar (not neutral) words using two lexicons—The General Inquirer (Stone et al., 1966) and the MPQA Subjectivity Lexicon (Wilson et al., 2005). We also add another set of features where each of these counts is normalized by the sentence length.

Specificity. Specific sentences are more likely to contain specific words and details. We use two sets of features to capture specificity of words in the sentence. The first of these is based on WordNet (Miller et al., 1990) and is motivated by prior work by Resnik (1995) where hypernym relations from WordNet were used to compute specificity. For each noun and verb in a sentence, we record the length of the path from the word to the root of

[1] We use only the *implicit* relations from the PDTB; ie, the sentences are not linked by an explicit discourse connective such as 'because' or 'but' that signals the relation.

Instantiations

[1] *The 40-year-old Mr. Murakami is a publishing sensation in Japan.* A more recent novel, " Norwegian Wood " (every Japanese under 40 seems to be fluent in Beatles lyrics), has sold more than four million copies since Kodansha published it in 1987.

[2] *Sales figures of the test-prep materials aren't known, but their reach into schools is significant.* In Arizona, California, Florida, Louisiana, Maryland, New Jersey, South Carolina and Texas, educators say they are common classroom tools.

[3] *Despite recent declines in yields, investors continue to pour cash into money funds.* Assets of the 400 taxable funds grew by $ 1.5 billion during the last week, to $ 352.7 billion.

Specifications

[4] *By most measures, the nation's industrial sector is now growing very slowly—if at all.* Factory payrolls fell in September.

[5] *Mrs. Hills said that the U.S. is still concerned about 'disturbing developments in Turkey and continuing slow progress in Malaysia.'* She didn't elaborate, although earlier U.S. trade reports have complained of videocassette piracy in Malaysia and disregard for U.S. pharmaceutical patents in Turkey.

[6] *Alan Spoon, recently named Newsweek president said Newsweek's ad rates would increase 5% in January.* A full, four-color page in Newsweek will cost $100,980

Table 2: Examples of general (in italics) and specific sentences from the PDTB

the WordNet hierarchy through the hypernym relations. The longer this path, we would expect the words to be more specific. The average, min and max values of these distances are computed separately for nouns and verbs and are used as features.

Another measure of word specificity is the inverse document frequency (idf) for a word w (Joho and Sanderson, 2007), defined as $\log \frac{N}{n}$. Here N is the number of documents in a large collection, and n is the number of documents that contain the word w. We use articles from one year (87,052 documents) of the New York Times (NYT) corpus (Sandhaus, 2008) to compute idf. Words not seen in the NYT corpus were treated as if they were seen once. The features for a sentence are the average, min and max idfs for words in the sentence.

NE+CD. In news articles, especially the WSJ, specific sentences often contain numbers and dollar amounts. So we add as features the count of numbers (identified using the part of speech), proper names and dollar signs. The performance of these features, however, is likely to be genre-dependent. We also introduce another entity-related feature—the number of plural nouns. From our example sentences, we notice that plural quantities or sets are a property of general sentences.

Language models. General sentences often contain unexpected, catchy words or phrases. Consider the phrase "pour cash" in example [3] (Table 2); it is figurative and informal in the context of finance reports. When one reads the second sentence in the relation and observes the actual rise in funds investments, we understand why such a figurative phrase was used to introduce this fact. We expected that language models would capture this aspect by assigning a lower likelihood to unexpected content in the general sentences. We build unigram, bigram and trigram language models using one year of news articles from the NYT corpus. Using each model, we obtain the log probability and perplexity of the sentences to use as features. The unigram language model captures the familiarity of individual words. On the other hand, we expect the perplexity computed using higher order models to distinguish between common word transitions in the domain, and those that are unexpected and evoke surprise.

Syntax. We also noted frequent usage of qualitative words such as adjectives and adverbs in general sentences. So we include some syntax based features: counts of adjectives, adverbs, adjective phrases and adverbial phrases. We also record the number of verb phrases and their average length in words and the number of prepositional phrases. We expect that longer verb phrases would be associated with more specific sentences.

Words. We also add the count of each word in the sentence as a feature. Numbers and punctuations were removed but all other words were included. Only words seen in the training set are valid features. New words in the test sentences are ignored.

2.2 Results

We build two classifiers for distinguishing general and specific sentences: one trained on sentences from Instantiation relations, and one on sentences from Specification. The first sentence in the relation was considered an example of general sentence, and the second of specific one. No pairing information was preserved or exploited. We train a logistic regression classifier[2] with each set of features described above and evaluate the predictions

[2] http://www.csie.ntu.edu.tw/ cjlin/liblinear/

Features	Instantiations	Specifications
NE+CD	68.6	56.1
language models	65.8	55.7
specificity	63.6	57.2
syntax	63.3	57.3
polarity	63.0	53.4
sentence length	54.0	57.2
all non-lexical	75.0	62.0
lexical (words)	74.8	59.1
all features	75.9	59.5

Table 3: Classifier accuracy (baseline 50%)

using 10-fold cross validation.

We choose logistic regression for our task because we expected that a probability measure would be more appropriate to associate with each sentence rather than hard classification into the two classes. We provide further analysis of the classifier confidence in the next section. Here for reporting results, we use a threshold value of 0.5 on the confidence score. There are equal number of positive and negative examples, so the baseline random accuracy is 50%. Table 3 shows the accuracy of our features.

The classifiers trained on Instantiation examples are promising and better than those trained on Specifications. The highest accuracy on Instantiations-based classifier comes from combining all features, reaching 75.9% which is more than 25% absolute improvement over the baseline. The individually best class of features are the words with 74.8% accuracy showing that there are strong lexical indicators of the distinction.

Among the non-lexical features, the NE+CD class is the strongest with an accuracy of 68%. Language models, syntax, polarity and specificity features are also good predictors, each outperforming the baseline by over 10% accuracy. The sentence length features are the least indicative. These non-lexical feature classes though not that strong individually, combine to give the same performance as the word features. Moreover, one would expect that non-lexical features would be more robust across different types of news and topics compared to the lexical ones and would have fewer issues related to data sparsity. We analyse this aspect in the next section.

For the Specifications-based classifier, the highest performance is barely 10% above baseline. The best accuracy (62%) is obtained with a combination of all non-lexical features. In contrast to the Instantiations case, language models and entities features sets are less accurate in making the general-specific distinction on the Specification examples. Polarity is the worst set of features with only 53% accuracy.

A possible explanation of the difference in results from the two types of training data is that in Specification relations, the specificity of the second sentence is only relative to that of the first. On the other hand, for Instantiations, there are individual characteristics related to the generality or specificity of sentences. We confirm this hypothesis in Section 3.2.

2.3 Feature analysis

In this section, we take a closer look at the features that most successfully distinguished specific and general sentences on the *Instantiation* dataset. Given that words were the most predictive feature class, we identified those with highest weight in the logistic regression model. Here we list the top word features for the two types of sentences and which appear in at least 25 training examples.

General number, but, also, however, officials, some, what, prices, made, lot, business, were

Specific one, a, to, co, i, called, we, could, get, and, first, inc

Discourse connectives such as 'but', 'also' and 'however', and vague words such as 'some' and 'lot' are top indicators for general sentences. Words indicative of specific sentences are 'a', 'one' and pronouns. However, a large number of other words appear to be domain specific indicators—'officials', 'number', 'prices' and 'business' for general sentences, and 'co.', 'inc' for the specific category.

The weights associated with non-lexical features conformed to our intuitions. Mentions of numbers and names are predictive of specific sentences. Plural nouns are a property of general sentences. However, the dollar sign, which we expected is more likely with specific sentences turned out to be more frequent in the other category. As for the language model features, general sentences tended to have lower probability and higher perplexity than specific ones. General sentences also have greater counts of polarity words (normalized by length) and higher number of adjectives and adverbs and their phrases. At the same time, these sentences have fewer and shorter verb phrases and fewer prepositional phrases.

3 Testing the classifier on new sentences

So far, we have used discourse relations as sources of general and specific sentences. Here we present

an annotation study where we asked people to directly judge a sentence as general or specific. We use these annotations to validate our classifier based on discourse relations and to ascertain whether these distinctions can be performed intuitively by people. So we only elicit annotations on a small set of examples rather than build a large corpus for training.

We also use sentences from articles from different news sources, enabling us to study the robustness of the classifier for news in general, beyond the more domain specific materials from the Wall Street Journal. Further we highlight a useful aspect of our predictions. We find that the confidence (probability from logistic regression) with which our classifier predicts the class for a sentence is correlated with the level of annotator agreement on the sentence. This finding suggests that the confidence scores can be used successfully to assign a graded level of specificity.

3.1 Annotations for general/specific

For our initial study outlined above, we have used the Instantiation and Specification sentences from Wall Street Journal texts in the PDTB. So we chose three WSJ articles from the PDTB corpus for further annotation, each around 100 sentences long. These articles were the ones with maximum number of Instantiations because we wanted to test whether people would judge the two sentences in Instantiations in the same manner as we have used them (the first general and the second specific).

We also chose articles from another corpus, AQUAINT (Graff, 2002), to compare the effect of corpus specifics on the classifier performance. These are a set of 8 news articles, six published by the Associated Press (AP) and two by Financial Times and are around 30 sentences each. Overall, there were 294 sentences from the WSJ and 292 from AP. Both sets of articles are about news, but the WSJ contains mainly financial reports.

We used Amazon's Mechanical Turk (MTURK)[3] to obtain annotations. We presented a user with one sentence at random and three options for classifying it: general/ specific/ can't decide. We provided minimal instructions[4] and annotators were encouraged to use their intuition to choose a judgement.

	WSJ articles			AP articles		
Agree	**total**	**gen**	**spec**	**total**	**gen**	**spec**
5	96	51	45	108	33	75
4	102	57	45	91	35	56
3	95	52	43	88	49	39
undecided	1			5		
Total	294	160	133	292	117	170

Table 4: Annotator agreement

We obtained judgements from 5 unique users for each sentence. However, it is not the case that all sentences were judged by the *same* 5 annotators. So we do not compute the standardly reported Kappa measures for annotator agreement. Rather, we present statistics on the number of sentences split by how many annotators agreed on the sentence class. We also indicate the number of sentences where the majority decision was general or specific (Table 4).

As we can see from the table, there were only very few cases (6 out of $\sim$600) where no majority decision was reached by the 5 annotators. For about two-thirds of the examples ($\sim$400) in both the WSJ and AP, there was either full agreement among the five annotators or one disagreement. These results are high for a new task where annotators mainly relied on intuition. Some examples of sentences with different agreement levels are shown in Table 5.

Here we can notice why the examples with low agreement could be confusing. Sentence [S2] judged as specific (by three annotators) contains details such as the exact quantities of rainfall. At the same time, it contains the vague phrase "still had only". The remaining two annotators could have seen these general properties as more relevant for their judgement. Sentence [G2] which also had low agreement, has some general properties but also specific information, such as the phrase describing the word "companies".

In terms of the distribution of general and specific sentences, the two sets of articles differ. In the WSJ, there are more general (55% of total) than specific sentences. In the AP articles, specific sentences form the majority (60%) and there is a wider gap between the two types. One reason for this difference could be the length of the ar-

[3] http://sites.google.com/site/amtworkshop2010/

[4] "Sentences could vary in how much detail they contain. One distinction we might make is whether a sentence is general or specific. General sentences are broad statements made about a topic. Specific sentences contain details and can be used to support or explain the general sentences further. In other words, general sentences create expectations in the minds of a reader who would definitely need evidence or examples from the author. Specific sentences can stand by themselves. For example, one can think of the first sentence of an article or a paragraph as a general sentence compared to one which appears in the middle. In this task, use your intuition to rate the given sentence as general or specific."

General	Agree = 5	[G1] The conditions necessary for a dollar crisis had been building up in currency markets for some time.
	Agree = 3	[G2] The flip side of the hurricane's coin was a strong showing from the stocks of home construction companies expected to benefit from demand for rebuilding damaged or destroyed homes.
Specific	Agree = 5	[S1] By midnight, 119 mph winds were reported in Charleston.
	Agree = 3	[S2] But the weather service said all Mississippi farm communities still had only 30 percent to 50 percent of normal moisture.

Table 5: Example general and specific sentences with agreement 5 and 3

	General	**Specific**
Sent1	29 L5(14), L4(9), L3(6)	3 L5(1), L4(1), L3(1)
Sent2	6 L5(1), L4(3), L3(2)	26 L5(13), L4(9), L3(4)

Table 6: Annotator judgements on instantiation sentences

	General	**Specific**
Sent1	10 L5(4), L4(3), L3(3)	6 L5(1), L4(1), L3(4)
Sent2	8 L5(5), L4(3), L3(0)	8 L5(5), L4(2), L3(1)

Table 7: Annotator judgements on specification sentences

ticles. Those from WSJ are much longer than the AP articles and probably longer articles have more topics and corresponding general statements.

3.2 Results on Instantiation examples

We have assumed from the definitions of Instantiation and Specification relations, that their first sentences (*Sent1*) are general and their second (*Sent2*) specific. Further, we used these two sentences independently in two different classes. Now we test this intuition directly. Would people given only one of these sentences in isolation, give it the same judgement of generality as we have assumed?

There were 32 Instantiations and 16 Specification relations in the three WSJ articles we annotated and each of these relations is associated with two sentences, *Sent1* and *Sent2*. In Tables 6 and 7, we provide the annotator judgements and agreement levels on these sentences. The number of sentences x in each category with a certain level of agreement y is indicated as Ly(x). So L5(3) means that three sentences had full agreement 5.

For Instantiations, we find that the majority of *Sent1* are judged as general and the majority of *Sent2* are specific, 80% in each case. But for both *Sent1* and *Sent2*, there is one sentence which all the annotators agreed should be in the opposite class than assumed. So there are some cases where without context, the judgement can be rather different. But such examples are infrequent in the Instantiation sentences.

On the other hand, Specifications show a weaker pattern. For *Sent1*, still a majority (62.5%) of the sentences are called as general. However, for *Sent2*, the examples are equally split between general and specific categories. Hence it is not surprising that the Instantiation sentences have more detectable properties associated with the first general sentence and the second specific sentence and the classifier trained with these examples obtains better performance compared with training on Specifications.

3.3 Classifier accuracy and confidence

Now we test our classifier trained on Instantiation relations on the new annotations we have obtained on WSJ and AP articles. The parse trees for sentences in the test set were obtained using the Stanford Parser (Klein and Manning, 2003). Since our classifier was trained on Instantiations sentences from the WSJ, when testing on the new WSJ annotations, we retrained the classifier after excluding sentences that overlapped with the test set.

Our goal here is to a) understand the performance and genre independence of our features on the new test set b) explore the accuracy on examples with different levels of annotator agreement c) build a combined classifier using both discourse relations and direct annotations.

In each line of Table 8, we report the performance on examples from the specified agreement levels. A '+' sign indicates that examples from multiple agreement levels were combined.

Non-lexical features give the best performance on both sets of articles. The word features trained on WSJ Instantiations give more than 10% lower accuracy than non-lexical features, even on the WSJ articles. So lexical features probably do not cover all example types but non-lexical features provide better abstraction and portability across corpora. The accuracy of the non-lexical features on all directly annotated examples (*Agreement 3+4+5*) is 76% on WSJ and 81% on AP, similar to results on the Instantiation sentences.

But the accuracy increases on examples with

Examples	WSJ sentences Size	All features	Nonlexical	Words	AP sentences Size	All features	Nonlexical	Words
Agreement 5	96	90.6	96.8	84.3	108	69.4	94.4	78.7
Agreement $4+5$	198	80.8	88.8	77.7	199	65.8	89.9	74.8
Agreement $3+4+5$	293	73.7	76.7	71.6	287	59.2	81.1	67.5

Table 8: Accuracy of classifier on annotated examples

higher agreement and is over 90% for sentences with full agreement. The sentences with more agreement appear to have easily detectable properties for the respective class and so the classifier produces accurate predictions for them. As we saw, examples with low annotator agreement (Table 5) probably have a mix of properties from both classes. We further analyze the relationship between agreement and classifier performance by studying the classifier confidence scores.

In Table 9, we report the mean value of the classifier confidence for predicting the *correct class* for sentences having different agreement levels. A correct prediction occurs when the confidence is above 0.5 for the target class, so all the values we consider here are above 0.5. We now want to study when the correct prediction is made, how large is the confidence on examples with different annotator agreement levels. When the mean value of confidence scores at a particular agreement level was significantly better than another (determined by a two-sided t-test), those levels with lower confidence are indicated within parentheses.

As expected, the confidence of the classifier is significantly higher at greater levels of agreement again proving that the examples with higher annotator agreement are easier to classify automatically. So, the probability value produced by the classifier could be a better metric to use than the hard classification into classes. Further, since humans do have a low agreement on one-third of the sentences, a graded value is probably more suitable for the prediction of generality of a sentence.

We now have a larger set of annotated examples, so we combine the sentences from these two corpora with the Instantiation examples and build a combined classifier. Here the total general sentences is 1648 and there are 1674 specific sentences. So the distribution is almost equal and the baseline random performance would be 50% accuracy. The 10-fold cross validation accuracies from non-lexical, word and 'all features' on this full set are shown below.

Nonlexical : 72.36
Words : 72.36
All features: 74.68

Agreement	WSJ	AP
5	0.77 (4, 3)	0.78 (4,3)
4	0.70	0.70 (3)
3	0.67	0.66

Table 9: Mean value of confidence score on correct predictions

Here, after combining the examples, the classifier learns the lexical features indicative of both types of articles. So we end up with a similar trend as on the Instantiations based classifer. Both non-lexical and word features individually obtain 72% accuracy. Their combination is slightly better with 75% accuracy. So word features only when trained on both types of data again end up becoming good predictors and complementary with non-lexical features. So for new domains, the non-lexical features would be more robust.

Overall, we have provided a classifier that has high accuracy on a diverse set of examples.

4 Task based evaluation

So far we have tested our classifier on individual sentences which were judged as general or specific. Now we provide a task-based evaluation on news summaries. Here people were asked to write general or specific summaries for a set of articles, in the first type conveying only the general ideas and in the second providing specific details about the topic. We show that our classifier successfully distinguishes these two types of summaries.

Summarization is one task where the distinction between general and specific content is relevant. The space available for summary content is limited. So authors include some specific detail but at the same time have to generalize other content to stay within the space limit. Early work in Jing and McKeown (2000) report that when people create summaries, they generalize some of the sentences from the source text, others are made more specific. From the point of view of automatic systems, Haghighi and Vanderwende (2009) developed a topic model-based summarization system which learns the topics of the input at both overall document level as well as specific subtopics. Sentences are assumed to be generated by a combination of the general and specific topics in the input

texts. However, since the preference of such sentences is not known, only heuristics were applied to choose the proportions. We expect our classifier to be useful in such cases.

4.1 Data

We use summaries and source texts from the Document Understanding Conference (DUC) organized by NIST in 2005.[5] The task in 2005 was to create summaries that are either general or specific. Each input consists of 25 to 50 news articles on a common topic. A topic statement is provided for *each input* which states the user's information need. Gold standard summaries for evaluation are created by human assessors for all these inputs. A length limit of 250 words is enforced.

During the creation of input sets, the annotators were asked to specify for each input, the type of summary that would be appropriate. So annotators provided a desired *summary granularity* for each input: either *general* or *specific*. There were a total of 50 inputs, 24 of them were marked for general summaries, the remaining for specific.

Next these input texts and topic statements were given to trained NIST assessors for writing summaries.[6] For some inputs (20), 9 summaries each were provided by the assessors, other inputs had 4 summaries. Considering the granularity of inputs, there is a roughly equal distribution of general (146) and specific (154) summaries. We now test if our classifier predictions can distinguish between these general and specific summaries where people relied on an intuitive idea of general and specific content overall in the summary.

4.2 Difference in specificity

For this analysis, we use the combined classifier from the Instantiation relations and extra annotations. We used the combination of all features since it gave the best performance for this setup.

Next we assigned a specificity level for each summary in the following way. For each sentence in the summary, we obtained the classifier confidence for predicting the sentence to be "specific". Each token in the summary was assigned the confidence of the sentence in which it appeared. Then the *average specificity of words* in the summary was computed as the average value of this confidence measure over all the tokens in the summary.

[5] http://duc.nist.gov/duc2005/

[6] The guidelines and example summaries can be found at http://duc.nist.gov/duc2005/.

Text	General category	Specific category
Summaries	0.55 (0.15)	0.63 (0.14)
Inputs	0.63 (0.06)	0.65 (0.04)

Table 10: Mean value (and standard deviation) of specificity levels for inputs and summaries

The statistics for this score in the general and specific categories are shown in Table 10.

For specific summaries, the mean specificity is 0.63, while for general ones it is only 0.55. The difference is also statistically significant under a two sided t-test (p-value of 1.5e-06). This result shows that our predictions are able to distinguish the two types of summaries.

We also computed the specificity scores for inputs in the same manner. Here the mean value is around 0.63 and does not vary significantly between the two classes (pvalue = 0.275). So while the inputs do not vary in specificity for the two categories, the summary authors have injected the required granularity during summary creation. To emulate the human summaries, systems would need to optimize for a measure of general/specific rather than use a generic strategy. Our classifier's predictions could be combined with other content selection features for such purposes.

5 Conclusion

We have introduced a new task—identification of general and specific sentences. We have shown how certain discourse relations involve these two types of sentences and can be used as training data for the task. We introduced features such as polarity, word specificity, language models, entity-related and lexical features which resulted in high classification performance, 25% absolute increase over the baseline. Our classifier also provides a graded score for specificity and can distinguish general and specific summaries written by people.

With this success, for future work, we plan to investigate the use of our classifier in applications which can use the general/specific notion. One task is providing feedback during writing. By learning patterns of use of general and specific sentences, we can use our predictions to annotate sentences which need more support from the writer. We also plan to explore pairs of general and specific sentences for the task of question generation. Specific sentences with important content can be treated as a potential answer, while a general sentence on the same subtopic can be used to generate the question.

A POS-based Ensemble Model for Cross-domain Sentiment Classification

Rui Xia and **Chengqing Zong**

National Laboratory of Pattern Recognition
Institute of Automation, Chinese Academy of Sciences
rxia.cn@gmail.com, cqzong@nlpr.ia.ac.cn

Abstract

In this paper, we focus on the tasks of cross-domain sentiment classification. We find across different domains, features with some types of part-of-speech (POS) tags are domain-dependent, while some others are domain-free. Based on this finding, we proposed a POS-based ensemble model to efficiently integrate features with different types of POS tags to improve the classification performance. Weights are trained by stochastic gradient descent (SGD) to optimize the perceptron and minimal classification error (MCE) criteria. Experimental results show that the proposed ensemble model is quite effective for the task of cross-domain sentiment classification.

1 Introduction

In recent years, transfer learning and domain adaptation, the task aiming to utilize labeled data from the other domains (source domain) to help learning for current domain (target domain), has attracted more and more attention in the fields of both machine learning and natural language processing, including sentiment classification. The task of sentiment classification is supposed to be domain-specific. Classifiers trained on the source domain usually perform poorly in the target domain. This is quite reasonable since the word distribution changes from one domain to another, and some words that are positive in one domain may express an opposite meaning in another one. Therefore, it is challenging to transfer a classifier trained on the source domain to the target domain.

Methodology to solve this problem can be divided into three major categories (Pan and Yang, 2009): the instance-based transfer, the feature-based transfer and the parameter-based transfer. The instance-based transfer learns the importance of labeled data in the source domain by instance re-weighting and importance sampling. These re-weighed instances are then used for learning in the target domain. Feature-based transfer aims to learn a good feature representation for the target domain using labeled data in the source domain with the help of a large number of unlabeled data in the target domain. The parameter-based transfer mostly assumes that individual models for related tasks share some parameters or prior distribution of hyper-parameters. The shared part is then added to the cost function for transfer learning.

In this paper, we propose a POS-based ensemble model for cross-domain sentiment classification. Other than the above-mentioned methodology, the transfer procedure in our approach is neither instance re-weighting nor feature representation. Broadly speaking, our approach belongs to the parameter-based transfer, but different from the traditional ways, the transfer procedure is embodied in an ensemble manner.

By observing the K-L distance of multi-domain datasets, we find that cross different domains, the distribution of features with some types of POS tags, such as adjectives and adverbs, has little

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 614–622,
Chiang Mai, Thailand, November 8 – 13, 2011.

change; while some other parts, for example, nouns, vary sharply. Furthermore, we investigate the most significant features ranked by information gain (IG). We find that the significance of adjectives and adverbs increases from in-domain to cross-domain tasks, while nouns become less important.

Based on these findings, we infer that an efficient ensemble of features according to their POS tags, may benefit more from the domain-free parts and overcome the drawbacks of domain-dependent parts, and finally enhance the overall cross-domain sentiment classification performance. We proposed two methods, namely the average perceptron (Perc) and the minimal classification error (MCE) criterion, to learn the weights of base-classifiers.

The remainder of this paper is organized as follows. Section 2 reviews related work. In Section 3, we introduce our motivation with detailed investigation. In Section 4, we propose our ensemble model for cross-domain sentiment classification. Experimental results are reported and discussed in Section 5 and 6 respectively. Section 7 draws conclusions and outlines directions for future work.

2 Related Work

2.1 Domain Adaptation

Existing approaches for cross-domain sentiment classification mostly belong to the feature-based transfer. Among them, the structural correspondence learning (SCL) algorithm proposed by (Blitzer et al., 2007) is the representative one. SCL tries to get the mapping matrix from non-pivot feature space to pivot feature space. Non-pivot features are then transferred though a projection over the principle components of the mapping matrix. (Li et al., 2009b) proposed to transfer lexical prior knowledge across domains via matrix factorization techniques. (Pan et al., 2010) proposed cross-domain sentiment classification via spectral feature alignment and compared their method with SCL.

Another work (Aue and Gamon, 2005) combined small amounts of labeled data with large amounts of labeled data in target domain to learn the model parameters for a generative naïve Bayes classifier using the Expectation Maximization (EM) algorithm.

The above work all need a large amount of unlabeled data in the target domain to help building the transfer procedure. Our approach does not need those unlabeled data. Nevertheless, we do need a small amount of labeled data from target domain, say, 50-200 instances, to help transfer learning.

2.2 Ensemble Techniques

Several researchers have achieved improvements in sentiment classification accuracy via the ensemble techniques. The work (Whitehead and Yaeger, 2008) conducted four ensemble algorithms (bagging, boosting, random subspace and bagging random subspaces) for sentiment classification. In the work by (Li et al., 2007), different classifiers were generated with different sets of features according to their POS tags. Those component classifiers are then selected and combined using several fixed rules. Experimental results showed that sum rule achieves the best performance.

We made a comparative study (Xia et al., 2011) about the effectiveness of ensemble techniques for sentiment classification. Two schemes of feature set were designed at first. Three well-known classification algorithms were then employed as base-classifiers for each of the feature sets. Three types of ensemble models were finally conducted for three ensemble strategies, with the emphasis on the evaluation of the effectiveness of ensemble techniques for sentiment classification.

Different from above methods, our focus in this paper is cross-domain sentiment classification. Compared to our former reports, we prove that the ensemble model is more effective for cross-domain tasks than for the in-domain ones.

3 Problem Investigation

3.1 POS Tag Groups

The POS information is supposed to be a significant indicator of sentiment expression. The work on subjectivity detection (Hatzivassiloglou and Wiebe, 2000) revealed a high correlation between the presence of adjectives and sentence subjectivity, yet this may not be taken to mean that other POS tags do not contribute. Indeed, it was resulted in (Pang et al., 2002; Benamara et al., 2007) that using only adjectives as features actually results in much worse performance than using the same number of most frequent unigrams. Other re-

searchers (Riloff et al., 2003) pointed out that certain verbs and nouns are also strong indicators of sentiment. According to their significance to sentiment classification, we categorize the POS tags into four groups, as shown in Table 1.

Group	Contained POS tags
J	adjectives, adverbs
V	verbs
N	nouns
O	the other POS tags

Table 1. Four groups of POS tags

3.2 Cross-domain K-L Distances

When conducting transfer learning, it is crucial to find that from one domain to another, which part of knowledge changes and which part of knowledge remains similar. Then the "unchanged" part of knowledge should be kept during the learning process, while the "changed" part should be transferred. Our intuition is that from one domain to another, nouns change the most, because domains (or topics) are mostly denoted by nouns; while adjectives and adverbs change less, for example, "*great*" and "*love*" always express the meaning that something is good, no matter the domain is Book or Movie.

Holding this belief, we observe the cross-domain K-L distance (also called relative entropy) of the class-conditional distribution of each type of POS tags. We use the Multi-Domain Sentiment Dataset[1] for statistics. This dataset was introduced by (Blitzer et al., 2007) and then widely used in the field of cross-domain sentiment classification. It contains product reviews taken from Amazon.com from four product types (domains) – Book (B), DVD (D), Electronics (E) and Kitchen (K). Each of these contains 1000 positive and 1000 negative reviews.

We use the term "X-Y" to denote the task computing K-L distance of domain X and Y. For example, "B-D" denotes the K-L distance between the Book domain and DVD domain. We compute the K-L distance of two domains for each class based on the assumption that the class-conditional distribution is the multinomial distribution. The results are presented in Table 2.

We focus on the comparison between different types of POS tags. The K-L distance of N is the largest in all cross-domain tasks, significantly larger than the other POS types and Uni (unigrams). It indicates that from one domain to another, the change of N is the biggest part. On the contrary, the distribution of O changes the least. It is reasonable that the POS tags contained in O, such as prepositions, pronouns, etc., are mostly domain-free. The K-L distance of J is larger than that of O, but significantly smaller than that of N. The value is also smaller compared to that of all unigrams. V gives the comparable K-L distance. We may conclude that most features in J and V are partially domain-free. It also coincides with our intuition that "*great*" and "*love*" always express a positive meaning in whatever domains.

Generally, the cross-domain K-L distances of different types of POS tags can be ranked as: N>>Uni>V>J>O.

Task	Class	J	V	N	O	Uni
B-D	**Pos**	0.1608	0.2022	0.5420	0.0197	0.1968
	Neg	0.1427	0.1632	0.5149	0.0144	0.1779
B-E	**Pos**	0.4353	0.3752	1.2125	0.1329	0.4738
	Neg	0.3585	0.3414	1.1787	0.1221	0.4416
B-K	**Pos**	0.4487	0.4255	1.2059	0.1146	0.4752
	Neg	0.3348	0.3770	1.2620	0.1298	0.4690
D-E	**Pos**	0.3983	0.3614	1.1751	0.1281	0.4579
	Neg	0.3430	0.3429	1.1850	0.0905	0.4279
D-K	**Pos**	0.4028	0.4125	1.2587	0.1168	0.4820
	Neg	0.3372	0.3687	1.3352	0.0921	0.4686

Table 2: Cross-domain K-L distance

3.3 Most Significant Cross-domain Features

Furthermore, we investigate the most significant cross-domain features. We choose the top-N features that are ranked by information gain (IG) which was proved to be an effective feature selection method for sentiment classification (Li et al.,

[1] http://www.cs.jhu.edu/~mdredze/datasets/sentiment/

2009a). In table 3, we report the number of different POS tags from top-50, 100, 200, 500 and 1000 features respectively. "In" denotes the average result of four individual domains. "Share" denotes the number of features shared by all of the four groups of top-*N* features.

We first observe the average results of four individual top-100 features. The number of J, V, N and O cover the percentage of 42.0, 24.0, 24.0 and 9.0 respectively. Among the four groups of top-100 features, only 11 words appear in all of them. These features are "*great*", "*love*", "*unfortunately*", "*money*", "*highly*", "*bad*", "*worst*", "*excellent*", "*not*", "*waste*" and "*best*", where adjectives, verbs and nouns cover 81.8%, 9.1% and 9.1% respectively. In the case of individual top-200 features, the number of shared words by four domains is 19, 63.2% of which are adjectives.

As *N* increases, the percentage of four groups of POS tags in shared features can be generally ranked as: J>V>N>O. This has confirmed our intuition that nouns are the most domain-specific, while adjectives and adverbs are especially good cross-domain features.

Top-*N*	In/Share	Num	J (%)	V (%)	N (%)	O (%)
100	**In**	100	42.0	24.0	24.0	9.0
	Share	11	81.8	9.1	9.1	0.0
200	**In**	200	35.0	27.5	28.0	19.5
	Share	19	63.2	15.8	10.5	10.5
500	**In**	500	30.4	26.6	33.6	9.4
	Share	35	54.3	20.0	14.3	11.4
1000	**In**	1000	27.4	26.8	37.8	8.0
	Share	67	44.8	22.4	20.9	11.9

Table 3: Top-features by feature selection

4 The Ensemble Model

4.1 A POS-based Weighted Combination

The pursuit of POS-based weighted combination is motivated by the intuition that an appropriate integration of different participants might leverage distinct strengths. For example, the weights assigned to adjectives and adverbs are supposed to be higher than that of nouns.

We first build a new meta-feature vector $\hat{\mathbf{x}} = [o_{11},\ldots,o_{kj},\ldots,o_{DC}]$, where $o_{kj}(\mathbf{x})$ denotes the predicted score of the *k*th base-classifier for the *j*th class, C is the number of classes and D is the number of base-classifiers (in our approach C equals 2 and D equals 4). Then, the weighted combination could be represented by

$$O_j = \sum_{k=1}^{D} \omega_k o_{kj} = \sum_{k=1}^{D} \omega_k \hat{\mathbf{x}}_{k\times D+j}, \qquad (1)$$

where $\hat{\mathbf{x}}_{k\times D+j}$ denotes the score for the *j*th class of the *k*th base-classifier.

4.2 Weight Optimization

To learn the weights in Equation (1) , we propose to use stochastic gradient descent (SGD) to optimize some criteria. We consider two criteria in our approach, namely the perceptron (Perc) model, and minimal classification error (MCE) criterion.

The cost function of Perc in multi-class case is given by

$$J_p = \frac{1}{N}\sum_{i=1}^{N}\left[\max_{j=1,\ldots,C} g_j(\hat{\mathbf{x}}_i) - g_{y_i}(\hat{\mathbf{x}}_i)\right]. \qquad (2)$$

Note that in implementation, we utilize the average perceptron, a variation of perceptron that averages weights of all iterations, to improve the robustness.

The MCE criterion proposed by (Juang and Katagiri, 1992) is supposed to be more relevant to the classification error. In their approach, a simple version of misclassification measure of the instance $\hat{\mathbf{x}}_i$ from the *j*th class is defined by

$$d_j(\hat{\mathbf{x}}_i) = -g_{y_i}(\hat{\mathbf{x}}_i) + \max_{h\neq j}\{g_h(\hat{\mathbf{x}}_i)\}. \qquad (3)$$

Based on this measure, the cost function of MCE is given by

$$J_{mce} = \frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C} I(y_i = j)\delta(d_j(\hat{\mathbf{x}}_i) + \alpha), \qquad (4)$$

where $\delta(\bullet)$ is the sigmoid function, and α is the hyper-parameter.

SGD uses approximate gradients estimated from subsets of the training data and updates the parameters in an online manner:

$$w_k(t+1) = w_k(t) - \eta(t)\frac{\partial J}{\partial w_k}, \quad (5)$$

where t denotes the iteration step and $\eta(t)$ denotes the learning rate. Compared to standard gradient descent, SGD is much faster and more efficient, especially for large datasets.

5 Experiments

5.1 Experimental Settings

We use the Multi-domain dataset for experiments, which was already introduced in Section 3.2. The term "source→target" is used to denote the cross-domain tasks. For example, "D→B" represents the task that is trained in the DVD domain but the tested in the Book domain.

In our experiments, each dataset is split into a training set of 1600 instances, and a test set of 400 instances. The NLTK toolkit[2] is used for word tokenization. The MXPOST[3] tool is chosen as our POS tagger. Features with the term frequency no less than four are selected for classification.

Since it was reported that Naïve Bayes performs the best among three classifiers (Naïve Bayes, MaxEnt and SVM) on Multi-Domain Sentiment Dataset (Xia et al., 2011), we choose it as the base classification algorithm. We use the tool OpenPR-NB[4] in our experiments, with the settings of multinomial event model and Laplace smoothing.

After base-classification, the predicted score of the test set is randomly split to a meta-development set and meta-test set. The ensemble systems are trained on the meta-development set to classify the meta-test set to get the final prediction. The learning rate of SGD is set to be one and the maximal iteration number is set to be 100.

The process of meta-learning and test is randomly repeated for 100 times. All of the following results are in terms of an average of the 100 repeats.[5]

[2] http://www.nltk.org/
[3] http://www.inf.ed.ac.uk/resources/nlp/local_doc/MXPOST.html
[4] http://www.openpr.org.cn/
[5] The leave-one-out cross validation procedure was used in some previous work. In our experiments, since the size of development set is required to be comparatively small, cross validation is not quite suitable.

5.2 Results of Uni-based Ensemble

Table 4 reports the performance of Uni-based ensemble. Unigrams are categorized into four groups according to Table 1, denoted by Uni-J, Uni-V, Uni-N and Uni-O respectively. The perforamce of using all unigrams without transfer (denoted by Uni) is taken as the baseline. In ensemble approaches, we report results of three rules, i.e., the Sum rule, Perc and MCE criteria. Perc and MCE are trained by 200 labeled data in the target domain.

At first, we focus on the comparison of Uni and Uni-J. Uni-J performs consistently better than Uni in most of the cross-domain tasks (71.40% vs. 70.54%). This is opposite to the conclusion in in-domain tasks that using only adjectives as features results in much worse performance than using the same number of most frequent unigrams (Pang et al., 2002; Benamara et al., 2007). It also confirms our intuition that adjectives and adverbs are more effective feature for cross-domain tasks, and an efficient ensemble of these POS tags may be more effective.

Secondly, we observe the performance of Sum rule. We have drawn the conclusion in (Xia et al., 2011) that Sum rule is a low-cost yet effective approach for sentiment classification. However, this conclusion may not hold in the cross-domain tasks. Sum rule performs significantly worse than the best base-classifier (Uni-J). This is quite reasonable that assigning equal weights to unbalanced component base-classifiers will reduce the effect of ensemble.

Finally, we observe the results of weighted combination. Their performance is consistently higher than Uni and Uni-J, except for the task E→K (a slight decline). In average of 12 tasks, Perc and MCE outperform the Uni baseline by 3.01% and 3.94% respectively. Comparing Perc and MCE, the performance of MCE is more attractive, 0.93% higher than Perc in average.

Tasks	Uni-J	Uni-V	Uni-N	Uni-O	Uni	Ensemble		
						Sum	Perc	MCE
D→B	75.50	62.00	62.00	56.00	73.25	74.75	77.87	**78.88**
E→B	72.75	59.50	59.75	57.00	69.75	71.25	**72.35**	**72.35**
K→B	68.75	59.50	57.75	54.50	67.75	66.75	69.59	**70.47**
B→D	74.75	64.00	65.00	66.75	74.50	75.00	77.46	**77.81**
E→D	70.25	57.25	52.50	56.50	67.50	66.75	71.47	**72.66**

E→K	75.25	68.25	67.50	57.00	**80.25**	77.50	79.39	79.65
Average	71.40	61.15	59.96	56.38	70.54	70.71	73.55	**74.48**

Table 4. Performance (%) of Uni-based Ensemble

5.3 Results of UB-based Ensemble

We still consider using unigrams and bigrams together as candidate features for ensemble. Unigrams and bigrams are divided into four subsets (UB-J, UB-V, UB-N and UB-O), according to the POS tags of its headword. The performance of unigrams and bigrams without transfer is used as the baseline (denoted by UB). The reported ensemble results are also with the help of 200 labeled data from the target domain. Detailed results are presented in Table 5.

We still first compare UB-J and UB. This time, UB-J beats UB in some tasks, but it does not show general superiority. It is probably due to that some adjective information has coupled with other POS tags, such as J-N. Nevertheless, its performance is still comparative higher compared with the other three types of POS tags.

With regard to the ensemble methods, the performance of sum rule is not so sound, the same as before. The weighted combination still gains significant improvements over the UB baseline. In average, Prec and MCE outperform the UB baseline by 3.01% and 3.94% respectively. Overall, the ensemble model is quite effective for cross-domain sentiment classification. Among them, MCE is the most effective.

6 Discussion

6.1 Ensemble Model Revisited

In this section, we try to give some explanations about why the ensemble model is effective for cross-domain sentiment classification.

In traditional linear classifiers, the weights assigned to each feature are trained on the source-domain labeled data. Each weight thus embodies the significance of its responding feature to the source-domain classification. Transferring from one domain to another, those weights need to be adapted to the target domain.

Based on the observation that some parts of the feature are domain-dependent and some parts are domain-free, an efficient ensemble may be an effective way to adapt those weights to the target-domain. The behind transferring procedure can be interpreted as:

$$\begin{aligned} &\log P(c_j \mid d) \\ &\propto \log P(c_j) + \sum_i \log P(t_i \mid c_j) \\ &= \log P(c_j) + \omega_1 \sum_{i_1 \in J} \log P(t_{i_1} \mid c_j) + \omega_2 \sum_{i_2 \in V} \log P(t_{i_2} \mid c_j) \\ &\quad + \omega_3 \sum_{i_3 \in N} \log P(t_{i_3} \mid c_j) + \omega_4 \sum_{i_4 \in O} \log P(t_{i_4} \mid c_j), \end{aligned} \tag{6}$$

Tasks	UB-J	UB-V	UB-N	UB-O	UB	Ensemble		
						Sum	Perc	MCE
D→B	78.00	64.25	65.75	59.00	76.25	77.00	79.51	**81.01**
E→B	72.50	64.75	64.75	62.75	77.75	76.50	77.09	**77.80**

Average	72.79	65.08	63.13	58.29	74.48	74.79	75.93	**77.01**

Table 5. Performance (%) of UB-based Ensemble

where the conditional word probability is transferred from $P(t_i \mid c_j)$ to $P(t_i \mid c_j)^{\omega_j}$, which encodes information of both the sentiment significance and cross-domain ability.

In table 6, we present the average weights trained by MCE across all tasks. We can see that the weight of J is the largest in four parts, generally a half percentage. Thereby, the conditional probability of features in J will get a comparatively larger value. Such re-assignments of parameters will be good for cross-domain tasks.

Ensemble Tasks	J	V	N	O
Uni-based	0.52	0.20	0.16	0.12
UB-based	0.45	0.21	0.16	0.18

Table 6. Average weights trained by MCE

6.2 Sensitivity on Parameter Tuning

In this section, we test the sensitivity on parameter tuning. For simplicity, we fix the weights of V and O to be 0.20 and 0.15 respectively. We use ω to denote the weight of J, and the weight of N is thus $(0.65-\omega)$. We tune the value of ω from 0 to 0.65, and observe the average accuracy of ensemble. The curve is displayed in Fig. 1.

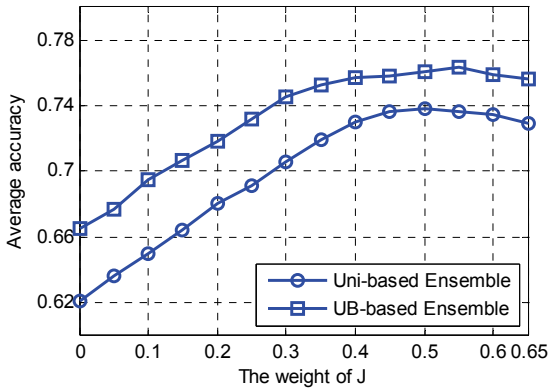

Fig. 1. Parameter sensitivity test

We can conclude from Fig. 1 that the ensemble performance is quite sensitive to the weights assigned to base-classifiers. When ω is close to 0, the weight of N is comparatively larger, and the ensemble performance drops sharply. The best result was obtained when ω locates at the area close to 0.5. The golden weights are quite similar to the results trained by MCE (Table 6). This shows that MCE is effective at parameter tuning.

Moreover, these weights can also be regarded as the empirical values when performing POS-based ensemble, in case that there is no or very few labeled data available in the target domain.

6.3 Dependency on the Size of Labeled Data in the Target Domain

Finally, we discuss the dependency of our approach on the size of labeled data in the target domain. In Fig. 2, we observe the performance of our ensemble model as the size of labeled data from the target domain increases from 50 to 300. "In-domain" denotes the accuracy trained on those labeled data for in-domain classification. "No transfer" denotes the result trained on 1600 labeled data in the source domain without transfer. Two ensemble approaches are also displayed for comparison. The reported accuracy is the average of 12 cross-domain tasks.

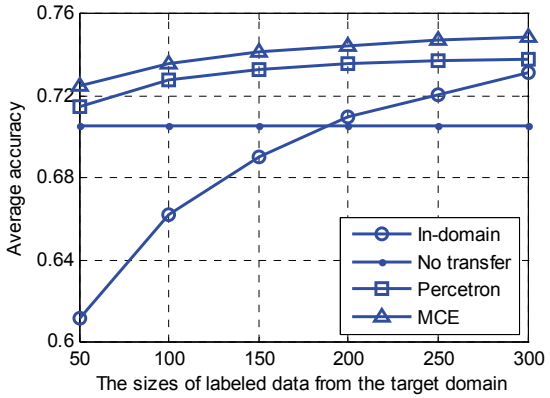

Fig. 2. Performance as labeled data in target domain increase

From Fig. 2, we can see that when the size of labeled data is small, the in-domain performance is fairly poor. At this time, the ensemble model could substantially improve the performance. As the size of labeled data increases, all of the systems yield higher performance. When the size increases to 300, the ensemble model shows limited superiority. It is reasonable that the in-domain learning is always the best if labeled data is enough.

Although the improvements of the ensemble model gained over the in-domain system become less as the size of labeled data increases, we could still conclude that in the case that there is only few labeled data in the target domain, the ensemble model is quite effective, to take the advantage of a large number of labeled data from the source domains, to help improving sentiment classification performance in the target domain.

7 Conclusion

In this paper, we propose a POS-based ensemble model for cross-domain sentiment classification. The motivation is based on the observation that some types of POS tags are domain-free, while some others are domain-dependent. Therefore, an efficient ensemble of them would leverage distinct strengths and improve the classification performance. Experimental results show that when the labeled data in the target is few, the proposed ensemble model is quite effective to make use of the labeled data from the source domain to improve the classification performance in the target domain.

We also update our previous conclusion drawn regarding the effectiveness of ensemble for in-domain sentiment classification (Xia and Zong, 2010; Xia et al., 2011). We conclude that the POS-based ensemble model is more effective for cross-domain sentiment classification than in-domain tasks.

In the future, we plan to extend the ensemble model to the tasks of cross-domain sentiment classification with multiple source domains. We also wish to make use of a large amount of unlabeled data in the target domain to help assist the ensemble performance for cross-domain sentiment classification in the framework of ensemble learning.

Ensemble-style Self-training on Citation Classification

Cailing Dong **Ulrich Schäfer**
German Research Center for Artificial Intelligence (DFKI) GmbH
Language Technology Lab, Campus D 3 1, D-66123 Saarbrücken, Germany
cherinedong@gmail.com ulrich.schaefer@dfki.de

Abstract

Classification of citations into categories such as use, refutation, comparison etc. may have several relevant applications for digital libraries such as paper browsing aids, reading recommendations, qualified citation indexing, or fine-grained impact factor calculation. Most citation classification approaches described so far heavily rely on rule systems and patterns tailored to specific science domains. We focus on a less manual approach by learning domain-insensitive features from textual, physical, and syntactic aspects. Our experiments show the effectiveness of this feature set with various machine learning algorithms on datasets of different sizes. Furthermore, we build an ensemble-style self-training classification model and get better classification performance using only few training data, which largely reduces the manual annotation work in this task.

1 Introduction

Still in the current age of Semantic Web, structured repositories, ontologies and huge databases, scientific knowledge is preserved and transported in rather unstructured pieces of information, vulgo scientific papers or other similar, textual representations. Except bibliographical metadata, (manually) assigned keywords or coarse-grained classifications, there is no further, general method to unlock the written treasures without tedious reading, while full-text search is generally considered too imprecise and may be misleading.

Citations, spread over scientific text, are important anchors that help to structure the broad publication space. They are of invaluable importance to beginners in a scientific field as they ultimately point to seminal, original work and knowledge not explicitly available or repeated in every publication. Citations are also the primary discourse links in scientific discussion which typically span over years or even decades. Furthermore, citations are helpful to understand and reproduce findings. Thus, they form a predominant text feature for every reader. Wan et al. (2009), e.g., present a study on user needs for browsing scientific publications and show that citations play an important role, Schäfer and Kasterka (2010) suggest a novel user interface for navigating in typed citation graphs.

Garfield (1965) is probably the first to discuss an automatic computation of a citation classification. Many studies on citation classification are generally derived from the four-dimensional citation schema proposed by Moravcsik and Murugesan (1975). They distinguish between confirmative vs. negational; conceptual (theory) vs. operational (method); evolutionary (build on cited work) vs. juxtapositional (alternative to cited work); and organic (necessary to understand, reproduce) vs. perfunctory (citation out of politeness, policy, piety). The number of different proposed classes (also called citation *functions*) varies from 3 to 35 (Garfield, 1965; Garzone, 1996; Mercer and DiMarco, 2004; Teufel et al., 2006; Harwood, 2009). Most approaches try to identify more detailed dimensions and mutually exclusive classes by making use of many different features, such as the location of the *citation sentence*[1], surrounding POS tags, and the Boolean information indicating self-citation. In (Teufel et al., 2006), POS tags were employed to find grammatical subjects and further classified as specific agent types, while Mercer and DiMarco (2004) proved the efficiency of rhetoric cues in citation classification. Both studies suggest the potential capability of syntactic features in classifying citations.

Differently from previous work that mainly focuses on cue words and depends on large training sets, our work has the following contributions:

1. *Small but comprehensive feature set:* we only use a small set of features to describe a cita-

[1] We call the exact single sentence which contains the citation the *citation sentence*. There may be several citation sentences for each *reference* listed at the end of a paper.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 623–631,
Chiang Mai, Thailand, November 8 – 13, 2011.

tion sentence. It covers textual, physical and syntactic aspects and is domain-independent, which could help to make the adaptation to different science domains minimal.

2. *Robust supervised classification model:* we compare the performance of different machine learning algorithms with various sizes of training data. The results show the robustness of the classifiers on our feature set even with a small training set.
3. *Ensemble-style self-training classification model:* we design a semi-supervised learning algorithm to make use of unlabeled data. Differently from standard self-training algorithms, we use an ensemble learning model to choose more reliable new labeled data and achieve good performance. This approach helps to reduce the manual annotation effort.

The paper is structured as follows. We describe our corpus and annotation schema in Section 2, the definition of features will be elaborated in Section 3. We explain the classification experiments in Section 4 and finally conclude in Section 5.

2 Corpus and Annotation

2.1 Definition of Citation Functions

In this paper, we focus on the dimension of "organic or perfunctory" citations in Moravcsik and Murugesan (1975)'s schema and divide the citations into the following four general categories:

- **Background** ***(class0)***: citations which describe background of the main topic on the whole, or provide recent studies and state-of-the-art approaches in a general way.
- **Fundamental idea** ***(class1)***: citations about main previous work which inspired or gave specific hints on the current work.
- **Technical basis** ***(class2)***: citations of important tools, methods, data and other resources used or adapted in the current work.
- **Comparison** ***(class3)***: citations comparing methods or results with the current work.

We build these citation categories mainly due to the following reasons. First of all, these categories cover the most general and mutually exclusive citation functions. One could easily sketch a picture of a typical, arbitrary scientific publication based on citations from these categories. Secondly, rhetorical and syntactic characteristics are comparatively obvious in terms of functions in this basic level. Thus, our strategy might be valuable for the construction of further detailed automatic citation classification models with more fine-grained categories.

2.2 Corpus

Our corpus comes from the ACL (Association for Computational Linguistics) Anthology[2] (Bird et al., 2008), a comprehensive collection of scientific conference and workshop papers in the area of computational linguistics and language technology. We randomly chose papers from proceedings of the ACL conference in 2007 and 2008. Detailed information on our corpus is provided in Table 1. Corpus pre-processing and the annotation schema will be elaborated in the next subsections.

2.3 Corpus Pre-processing

For each paper in the corpus, we extract citation and reference information from the original PDF file by employing the citation parsing tool ParsCit (Councill et al., 2008). The *citation text* (a text snippet surrounding a citation) delivered by ParsCit is usually not sensitive to paragraph and sentence boundaries and may contain noise such as page number and footnotes. Therefore, we designed a text parser to get better citation sentences and related information by the following steps:

1. From the HTML output of a commercial PDF-to-text extraction tool, we generate a well-organized file with explicit paragraph and sentence boundaries.
2. We extract the titles of each section and its corresponding subsections, and map them into one of six predefined *section categories*[3]: ***Introduction***, ***Related work***, ***Method***, ***Experiment***, ***Evaluation***, and ***Conclusion***. We assign each sentence in the paper its corresponding section category.
3. We extract the corresponding correct citation sentence for a given reference based on its *citation marker* (denoted by authors and publishing year) and *citation text* from ParsCit.

2.4 Annotation Schema

Two annotators annotated the papers independently following our guidelines. The annotators not only focused on each citation sentence separately, but also read the paragraph and the whole section where the sentence is located, then made

[2] `http://aclweb.org/anthology`

[3] We associate section categories by means of synonyms which usually occur in the corresponding section titles.

ACL paper ID	# of distinct citation sentences	citation function distribution (class0 : class1 : class2 : class3)	remarks
P08-1009 ∼ P08-1050	731	485 : 160 : 52 : 34	long-paper set1
P07-1001 ∼ P07-1050	784	492 : 196 : 67 : 29	long-paper set2
P08-2001 ∼ P08-2030	253	173 : 65 : 8 : 7	short-paper set

Table 1: Annotated corpus

a decision on the function of the citation over the whole paper, trying to be in the same perspective as the authors. The inter-annotator agreement between these two annotators is 0.757 measured by Cohen's kappa coefficient (Cohen, 1960), with parameter $n = 4$, $N = 1768$, and $k = 2$. This is quite high given the fact that a kappa value of 0.69 is considered as marginally stable, and 0.8 is considered as stable (Teufel et al., 2006).

3 Feature Set Construction

In this work, we consider the features of each citation sentence in three views: textual, physical and syntactic.

3.1 Textual Features

From the perspective of natural language processing, without any external information, the words in a citation sentence provide the textual distinction in classification. That's the reason why most of the previous work on citation classification is dominated by cue words. We also extract cue words representing certain citation functions, which are listed in Table 2.

From the table, one can observe that firstly only a few cue words exist in each group. Secondly, most cue words in the same group are synonyms. Thirdly, these cue words are domain-independent. We define subject_{cue} to indicate if the agent of the action described in the given citation sentence is related to the current work. It plays an important role in improving the distinguishing capability of other cue words. Besides, as mentioned before, DiMarco et al. (2006) showed the frequency of hedging cues in citation contexts and their importance in citation classification. We also observe that some hedging words listed in hedge_{cue} and suggest_{cue} occur more often in the class Background compared to other classes.

The textual features we defined are as follows:

- a Boolean feature for each group in Table 2, which indicates the existence of *any* cue word from the group in the citation sentence.
- a numerical weight for each group in Table 2, denoting the number of cue words from the group occurring in the citation sentence.
- a Boolean feature and corresponding weight feature for subject_{cue} in *neighbor sentences*[4]. Normally, the more frequently subject_{cue} occurs in consecutive sentences, the more likely the corresponding citation sentence is related to the current work.

3.2 Physical Features

As observed by other researchers on this topic, e.g. Teufel et al. (2006), the sentence location is an important feature, since it might be the most reliable information on citation function one could obtain from the paper directly. Specifically, we take the following physical features into account to distinguish between different citation functions:

- *Location*: section category, belonging to one of the predefined six categories described in Section 2.3.
- *Popularity*: number of references cited in the same sentence.
- *Density*: number of different references in the citation sentence and its neighbor sentences.
- *AvgDens*: average of *Density* among neighbor sentences surrounding the citation sentence.

3.3 Syntactic Features

During annotation, we found that the sentence structure of citation sentences varies according to their function. For example, citation sentences describing background of work are usually in active voice, while basic methods or tools used in the papers are in most cases introduced in passive voice. When the authors review some previous work in a general way, they tend to use present perfect tense, while using simple present tense to elaborate on their own work. These syntactic and writing styles can be extracted based on the POS sequences of citation sentences. In our work, the POS tags are generated by TreeTagger (Schmid, 1994), trained on the Penn Treebank (Marcus et al., 1994).

The typical syntactic patterns we defined are listed as follows. All examples are extracted from papers in our corpus, and the source paper id (ACL

[4]We define *neighbor sentences* as the sentences right before and after the given citation sentence.

Function	Group	Cue words
	subject$_{cue}$	we, our, us, table, figure, paper, algorithm, here
Background *(class0)*	**quantity**$_{cue}$	many, some, most, several, number of, numerous, variety, range of
	frequency$_{cue}$	usually, often, common(ly), typical(ly), traditional(ly)
	tense$_{cue}$	recent(ly), prior, previous, early
	example$_{cue}$	such as, for example, for instance, e.g.
	suggest$_{cue}$	may, might, could, would, will, can, should
	hedge$_{cue}$	suppose, conjecture, want, possible
Fundamental idea *(class1)*	**idea**$_{cue}$	following, similar to, motivate, inspired, idea, spirit
Technical basis *(class2)*	**basis**$_{cue}$	provided by, taken from, extracted from, based on, use, run, apply, extend, measure, evaluate, modify, extract
Comparison *(class3)*	**compare**$_{cue}$	compare, differ, deviate, contrast, exceed, outperform, opposed, consistent with, significant
	result$_{cue}$	result, accuracy, precision, performance, baseline

Table 2: Group of cue words corresponding to citation functions

ID) is denoted in square brackets following each example sentence. We also mark the text corresponding to each specific syntactic structure by underlines. For the POS sequence of each citation sentence, we delete the citation marker in parentheses for convenience.

1. **".*\\(\\) VV[DPZN].*":** *Fox <u>() showed</u> that cohesion is held in the vast majority of cases for English-French* [P08-1009]
2. **".*(VHP|VHZ) VV.*":** *while Cherry and Lin () <u>have shown</u> it to be a strong feature for word alignment* [P08-1009]
3. **".*VH(D|G|N|P|Z) (RB)*VBN.*":** *Inducing features for taggers by clustering <u>has been</u> tried by several researchers ().* [P08-1048]
4. **".*MD (RB)*VB(RB)* VVN.*":** *For example, the likelihood of those generative procedures <u>can be accumulated</u> to get the likelihood of the phrase pair ().* [P08-1010]
5. **"[^IW.]*VB(D|P|Z) (RB)*VV[ND].*":** *Our experimental set-up <u>is modeled</u> after the human evaluation presented in ().* [P08-1009]
6. **"(RB)*PP (RB)*V.*":** *<u>We use</u> Conditional Random Fields (CRFs) () to perform this tagging.* [P08-1047]
7. **".*VVG (NP)*(CC)*(NP).*":** *<u>Following ()</u>, we provide the annotators with only short sentences: those with source sentences between 10 and 25 tokens long.* [P08-1009]

Figure 1 illustrates the distribution of these patterns in different classes (we consider class1 and class2 together, denoted as class1+2) in long-paper set1 and short-paper set (long-paper set2 is used separately for further validating the feature sets). Among these syntactic patterns, the figures showed that the distribution of these patterns in the set of short papers and the set of long papers are consistent, i.e., the first 4 patterns are representative for class Background, while the other 3 patterns are typical for the other 3 classes.

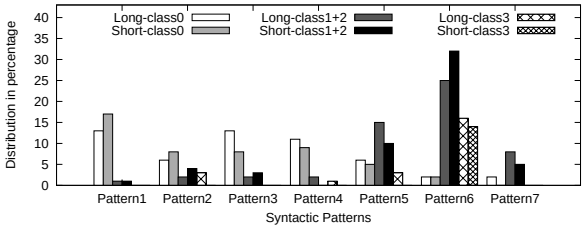

Figure 1: Distribution of syntactic patterns

We define a Boolean feature for each syntactic pattern indicating whether the pattern matches the POS sequence of the citation sentence. Combined with the cue words defined in Table 2, especially with subject$_{cue}$ and typical verbs in class1 to class3, the contribution of these patterns to overall performance increases significantly.

Thus, our final feature set is the collection of these textual, physical and syntactic features.

4 Citation Classification

4.1 Effectiveness of Syntactic Features

First of all, we build a set of experiments to test the effectiveness of syntactic features in citation classification. We compare the classification performance of our feature set with and without syntactic features on different machine learning algorithms, and with various training-testing ratios. We employ the meta class *AttributeSelectedClassifier* in Weka (Hall et al., 2009), and set *ChiSquaredAttributeEval* and *Ranker* (threshold 0) as evaluator and search method for attribute selection. The following 5 machine learning algorithms provided in Weka are employed as basic classifiers: *BayesNet*, *NaiveBayes*, *SMO* (*PolyKernel* is chosen as support vector kernel), *J48* and *RandomForest*.

We randomly split our whole corpus (including long-paper set2) into training dataset and test dataset with training instance ratios of 80%, 60%, 20% and 10%, respectively. For each of these four training-testing ratio configurations, we use 20 different random seeds to generate 20 different datasets. With each dataset, we measure the testing result by Macro-F (the mean of the F-measures of all classes), following Teufel et al. (2006). Then the final performance is measured by the average Macro-F of these 20 experiments with the same training-testing ratio configuration.

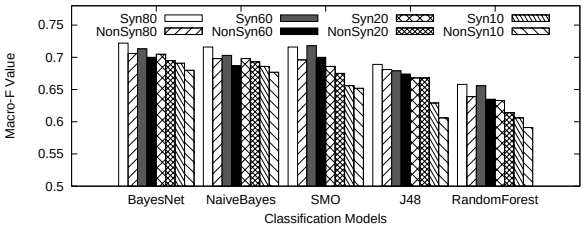

Figure 2: Performance of feature sets with and without syntactic features

Figure 2 illustrates the performance of feature sets with and without syntactic features on different sizes of training data. *Syn80* and *NonSyn80* denote feature sets with and without syntactic features when the ratio of training data is 80% respectively, analogously for other training data ratios. We can see that the feature sets with syntactic features can always beat the ones without syntactic features for all the datasets with different sizes of training data, independently of the classification model used. Besides, for all these datasets in different configurations, BayesNet and NaiveBayes are not very sensitive to the size of the training data. That is, these two supervised classification models can well learn our feature sets and make a good classification performance with only few training data (training ratio as 10% here, about 170 instances). It proves the effectiveness of our feature set to some extent.

4.2 Ensemble-style Self-training for Citation Classification

As in many other natural language processing tasks, large training datasets need to be annotated manually in order to improve the performance of citation classification. That is, a good annotation schema and abundant annotated training data are the basis for building a good automatic citation classification model. Because annotation is time-consuming, we design a semi-supervised learning algorithm to make use of unlabeled data under small training datasets in citation classification. Specifically, we adopt the idea of self-training (Zhu and Goldberg, 2009) to employ unlabeled data, but select new labeled data in the process of self-training in a more reliable way by taking advantage of the ensemble learning (Opitz and Maclin, 1999) algorithm.

4.2.1 Basic Self-training Algorithm

As a typical algorithm in semi-supervised learning, the self-training algorithm tries to extend the training dataset by changing some unlabeled data to labeled data with its own current predicted labels. We describe the basic self-training process in detail in Algorithm 1[5]. There are two main approaches to select the unlabeled data: one is to select the instances with highest predictive confidence *(prob-selfTrain)*, which is the original approach; the other is to randomly select some instances from unlabeled dataset *(random-selfTrain)*, which has been shown to be effective in some applications. As shown in line 6 and line 7, we implement these two approaches in parallel. Three different basic classifiers are used in this algorithm. From the main procedure of this algorithm, one can see that each classifier maintains its own labeled and unlabeled datasets in each iteration independently. This algorithm is set to be our baseline algorithm.

4.2.2 Ensemble-style Self-training Algorithm

Every supervised learning algorithm tries to search for the best hypothesis through a hypothesis space, therefore makes good predictions with a particular problem, i.e, based on given training data. Taking advantage of this property, ensemble learning tries to improve the prediction accuracy by combining different supervised learning algorithms. In self-training, each prediction process is actually supervised learning, therefore the quality of the training data is very important. Furthermore, self-training is based on the assumption that one's own high confidence predictions are correct, i.e. the final results could be worse if the model repeatedly learns from its own previous wrong decisions. To avoid such a situation, we devise an ensemble-style self-training algorithm by using ensemble learning to choose reliable new labeled

[5]Set $\{a,b,c,d\}$ denotes the number of instances in class0, class1, class2 and class3 as a, b, c, d, respectively. Analogously for set $\{m,n,p,q\}$ for indicating the number of added instances in each iteration.

Algorithm 1 Baseline: basic self-training algorithm

Require:
Whole dataset D ; training set ratio α ; Basic classifiers *Base1*, *Base2*, *Base3*;
Iteration times K; Initial number of labeled instances $\{a,b,c,d\}$;
Number of instances added to labeled dataset in each loop: $\{m,n,p,q\}$;

Pre-process:
Training dataset *Train* with number of instances $|D| * \alpha$; Test dataset *Test* with instances $\{D\} - \{Train\}$;
Labeled dataset L with initial number of instances $\{a,b,c,d\}$ randomly selected from *Train*;
Unlabeled dataset U with instances $\{Train\} - \{L\}$;
Labeled dataset $L_1 = L$, L_2=L and L_3=L; Unlabeled dataset $U_1 = U$, U_2=U and U_3=U;

Procedure:
1: **for** $k = 0$ **to** K **do**
2: **for** each classifier $Base_i$ $(i = 1,2,3)$ **do**
3: Use L_i to train classifiers $Base_i$
4: Obtain the test results on *Test* by classifier $Base_i$
5: Make prediction for each instance in U_i by classifier $Base_i$
6: ***a. prob-selfTrain*:** Select $\{m,n,p,q\}$ instances which have highest prediction confidence from U, denoted as L_{i-add}
7: ***b. random-selfTrain*:** Randomly select $\{m,n,p,q\}$ instances from U, denoted as L_{i-add}
8: $L_i = L_i + L_{i-add}$; $U_i = U_i - L_{i-add}$
9: **end for**
10: **end for**

Algorithm 2 Ensemble-style self-training algorithm

Require: configuration of *Train*, *Test*, L, U, and value of parameters $\{a,b,c,d\}$, $\{m,n,p,q\}$, K as well as basic classifiers *Base1*, *Base2*, *Base3* are the same as those in Algorithm 1;

Procedure:
1: **for** $k = 0$ **to** K **do**
2: Use L to train classifiers *Base1*, *Base2*, *Base3*, respectively
3: Obtain the test results on *Test* by classifier *Base1*, *Base2*, *Base3* respectively
4: Obtain the test results on *Test* by ensemble model *Ensemble*, consist of *Base1*, *Base2* and *Base3*
5: Make prediction for each instance in U by *Ensemble*
6: Randomly select $\{m,n,p,q\}$ instances from U, denoted as L_{add}
7: $L = L + L_{add}$; $U = U - L_{add}$
8: **end for**

data in each iteration. The detailed procedure is displayed in Algorithm 2. Here, the datasets and parameters are set to be the same as those in Algorithm 1, in order to compare the performance of both algorithms. In this ensemble-style self-training algorithm, one can see that all the basic classifiers and ensemble model *Ensemble* share the same labeled dataset L and unlabeled dataset U, which is maintained by *Ensemble* via choosing new labeled data in ensemble way (line 5 and 6).

4.2.3 Ensemble Learning

Normally, there are two main combination rules in ensemble learning to make the final prediction for a given instance. One is probability-based, that is, choosing the decision of the basic classifier which produces the highest prediction confidence for the instance. Another is to use majority voting. In our experiments, we choose BayesNet, SMO and NaiveBayes as the basic classifiers in our ensemble model and adopt the majority voting combination rule, due to the following reasons: 1) these three models have better overall performance according to Figure 2; 2) Usually, the more diverse the member algorithms, the more effective their ensemble model can be (Rokach, 2010). The classification mechanisms of BayesNet and SMO are totally different, which can ensure the performance of the ensemble model to some extent; 3) it is impossible to use probability-based combination rules due to the uninterpretable prediction probability in SMO. Thus, using a classifier with good overall performance such as NaiveBayes in majority vote could ensure the accuracy of ensemble learning to a certain degree.

4.2.4 The Class Imbalance Problem

From previous research on citation classification, independently of how many different functions were defined, one can observe that the dataset is class-imbalanced. For example, in a sentiment-oriented classification schema, negative citations are much less frequent than positive citations. Conversely, a high volume of citations actually is used to describe the background. Thus, class imbalance is actually a key issue in automatic citation classification. Previous research often ignored this fact, possibly because pattern-driven or rule-based models are less sensitive to such a distribution of datasets. Usually, standard classifiers try to get the overall accuracy with the cost of misclassifying the instances in small classes (Zhou and

Liu, 2006), while small classes are always those classes people are most interested in. Taking our citation classification as an example, "organic" citations are more attractive than the "perfunctory" ones. In our experiments, we try to balance the instances of these classes to protect small classes.

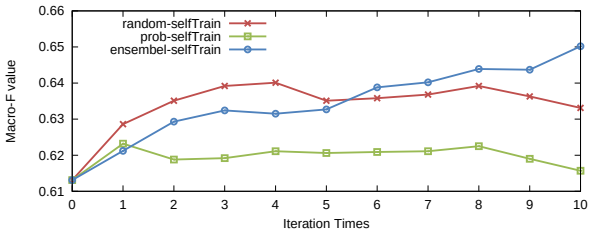
4.2.5 Experiments

In this set of experiments, we also wrap these three base classifiers with the meta class *AttributeSelectedClassifier* in the same configuration as in the last experiments in Section 3.1. As listed in Table 1, the average ratios among these 4 classes are imbalanced, around *16:6:1.8:1*. On the one hand, we try to keep the natural distribution to some extent (number of instances in the two bigger classes: class0:class1≈2:1; number of instances in the two smaller classes: class2:class3≈2:1). On the other hand, we slightly reduce the intensity of the class imbalance to avoid misclassifying too many instances from the small classes (here, we limit the ratio of class0 and class3 to be less than 5). To protect the small classes, we set the distribution of the initial labeled dataset to around *5:2.5:2:1*. A few new labeled data with similar distributions are added in each iteration to avoid introducing too much noise. We conduct two experiments.

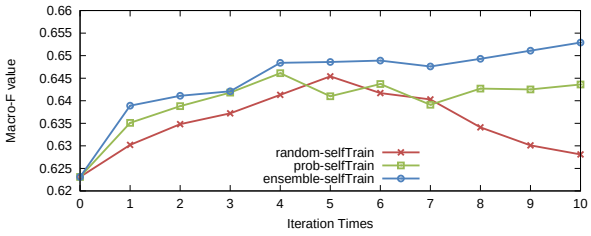
Exp-a: We set the number of instances in the smallest class class3 as 5, in order to ensure the accuracy. The iteration time K is 10. So α is set to be 0.3 in case insufficient unlabeled data to be added as labeled data. That is, 30% of the instances are randomly extracted as training set and the remaining instances are set as test data. Thus, according to our predefined class distribution, we set initial labeled data $\{20,10,8,5\}$, and the rest of the training data are regarded as unlabeled data. The number of new labeled data in each iteration is $\{6,4,3,1\}$.

Exp-b: In this experiment, we use 3 labeled instances in class3 to conduct the self-training process, initial labeled data $\{a,b,c,d\}$ is set to be $\{15,8,6,3\}$ following predefined class distribution. Less new labeled data is added each time, $\{m,n,p,q\}$=$\{5,3,2,1\}$ with more iterations, K=30. α is set to 0.3 due to the long iterations.

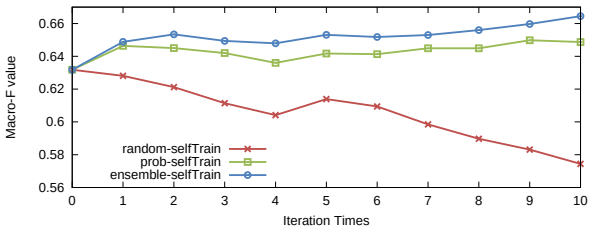
As mentioned before, self-training has a high demand on training data, especially initial labeled data. That is, the quality of the initial labeled data can largely affect the final overall performance. In order to obtain fairly general results, we repeat each experiment described above 10 times



(a) SMO



(b) BayesNet

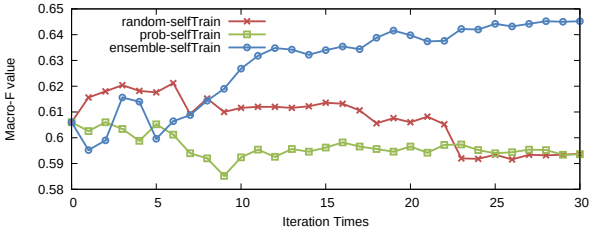


(c) NaiveBayes

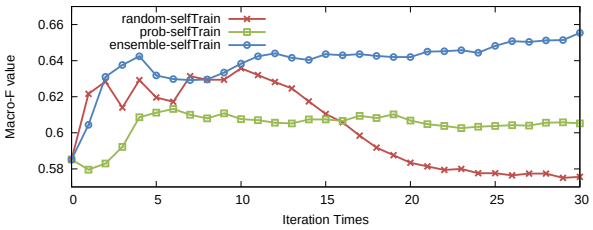
Figure 3: *Exp-a:* Basic self-training vs. ensemble-style self-training with different basic classifiers

with different seeds, splitting the dataset into training set and test set and therefore the initial labeled data each time are different. The final results are measured by the average value of Macro-F in these ten experiments. Figure 3 and Figure 4 illustrate the final average Macro-F values obtained by different basic classifiers with parameters given in *Exp-a* and *Exp-b*, respectively. Here, Macro-F in iteration 0 is obtained based on initial labeled data, so the algorithms with *prob-selfTrain*, *random-selfTrain* and ensemble-style self-training (denoted as *ensemble-selfTrain*) start at the same point for the same basic classifier.

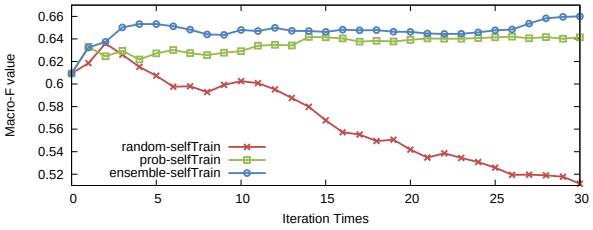
From Figure 3 and Figure 4, we can observe that for the two probability-driven classifiers BayesNet and NaiveBayes, their *prob-selfTrain* process is better than *random-selfTrain* on the whole. We observe the opposite for classifier SMO since its prediction confidence is meaningless. In general, our ensemble-style self-training algorithm outperforms both kinds of basic self-training algorithms independently of the basic classifier used. Its self-training process is quite stable due to the relatively reliable new labeled data ensured by ensemble learning strategies. Among all three basic clas-



(a) SMO



(b) BayesNet



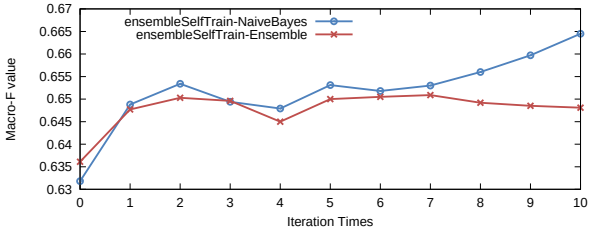
(c) NaiveBayes

Figure 4: *Exp-b:* Basic self-training vs. ensemble-style self-training with different basic classifiers

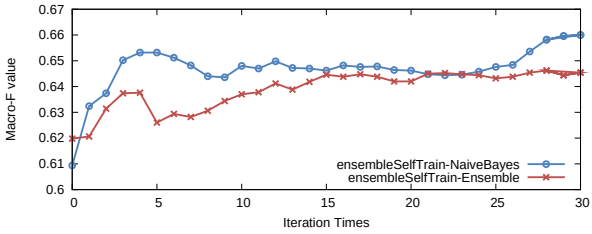
sifiers with the same experimental setup, NaiveBayes has the best performance not only at the starting point (iteration 0), but also in the whole ensemble-style self-training process.

In our ensemble-style self-training algorithm, we also build an ensemble model *Ensemble*. In Figure 5, we compare the performance of ensemble-style self-training with basic classifier *Ensemble* (denoted as *ensembleSelfTrain-Ensemble*) and NaiveBayes under experimental setup *Exp-a* and *Exp-b*, respectively.

Based on the observation, we found that although *Ensemble* is a good guide on selecting new labeled data, its self-training performance is not as good as NaiveBayes. There might be two main reasons. First of all, without self-training, NaiveBayes itself fits our feature sets quite well and shows the best performance among all the classifiers. Combining with other classifier as done in model *Ensemble* could affect its good performance. Secondly, ensemble models tend to be over-fitting to the training data. During the self-training process, the training data changes slightly by adding few new labeled data each time, so the over-fitting problem occurs soon. Thus, we choose



(a) *Exp-a*



(b) *Exp-b*

Figure 5: Ensemble-style self-training on NaiveBayes vs. *Ensemble*

ensemble-style self-training with main basic classifier NaiveBayes as our final classifier for citation classification.

5 Summary

In this work, we defined a citation classification schema to better sketch the skeleton of a scientific paper from its background, fundamental ideas, technical basis and performance comparison. These citation functions are distinguished by features from textual, physical and syntactic aspects, which are simple but comprehensive, and domain-independent. Using different supervised learning classifiers on various sizes of training datasets, we improved and demonstrated the efficiency of our feature set by adding syntactic patterns extracted from POS tags. The supervised classification models NaiveBayes and BayesNet have shown their robustness on our feature set, with only about 170 training instances. Furthermore, we built an ensemble-style self-training algorithm to better use and extend training data. Using about only 40 labeled instances, our final classifier can improve the Macro-F value by almost 5%. This model could largely alleviate manual annotation in citation classification.

Abstract

The term "genre" covers different aspects of both texts and documents, and it has led to many classification schemes. This makes different approaches to genre identification incomparable and the task itself unclear. We introduce the linguistically motivated text classification task *language function analysis*, LFA, which focuses on one well-defined aspect of genres. The aim of LFA is to determine whether a text is predominantly expressive, appellative, or informative. LFA can be used in search and mining applications to efficiently filter documents of interest. Our approach to LFA relies on fast machine learning classifiers with features from different research areas. We evaluate this approach on a new corpus with 4,806 product texts from two domains. Within one domain, we correctly classify up to 82% of the texts, but differences in feature distribution limit accuracy on out-of-domain data.

1 Introduction

Text classification has been successfully applied to various natural language processing tasks, among which some of the most popular are topic detection, authorship attribution, sentiment analysis, and genre identification. While the first three refer to single aspects of a text, genres cover different properties of both documents and texts, such as their form, function, purpose, and target audience. As a consequence, many different genre classification schemes exist, which makes most approaches to genre identification badly comparable as a recent study showed (Sharoff *et al.*, 2010). Correspondingly, the question which features work best in genre identification still remains open. We argue that one major reason behind is a missing common understanding of genres and that we need to focus on the single aspects of genres in order to overcome this situation.

In this paper, we investigate *why* a text was written. Therefore, we introduce the ambitious task *language function analysis*, abbreviated as LFA, i.e., to classify the predominant function of a text as intended by its author. In line with the work of the psychologist Karl Bühler (1934), we distinguish three abstract and very general classes, namely, *expressive*, *appellative*, and *informative* texts. Several search and text mining applications can benefit from applying LFA as a document filtering step with respect to both efficiency and effectiveness. A search engine, for instance, might restrict its result list to hits that mainly serve an informative purpose. Similarly, LFA can be used in opinion mining to cancel out promotional texts in favor of personal attitudes. While, of course, LFA does not replace genre identification, we think that language functions constitute one root of a common and clear genre concept.

Language functions are well-studied in linguistic pragmatics, but we analyze whether they also correlate with statistical text characteristics. For this purpose, we built a manually annotated corpus with 4,806 product-related texts from two separated domains (music and smartphones) in close collaboration with industry. Each text is tagged as *personal*, *commercial*, or *informational*, which can be seen as an application-specific classification by language function. Also, the texts have been categorized by sentiment polarity.

Our approach to LFA relies on machine learning of lexical and shallow linguistic features from different research areas. We evaluate this approach both for classification within one corpus domain and for the transfer to another domain. With respect to the in-domain task, our results indicate that a text collection of homogeneous quality and style allows for high accuracy. In particular, we

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 632–640,
Chiang Mai, Thailand, November 8 – 13, 2011.

correctly classify 81.9% of the music texts using a very efficiently computable feature set. This makes our approach suitable for document filtering purposes. However, classification of out-of-domain data seems difficult because of the *covariate shift* (Shimodaira, 2000) in feature distribution between domains. Interestingly, though, the best-performing features for this task come from the area of authorship attribution.

1.1 Summary of Contributions

Altogether, the main contributions of this paper are the following:

- We introduce the linguistically motivated text classification task language function analysis, which addresses one well-defined aspect of genres (Section 2).
- We provide a corpus for language function analysis and sentiment analysis with product-related texts that were manually annotated by one of our industrial partners (Section 4).
- We analyze the impact of machine learning features from different research areas on the language function analysis of texts from two domains (Sections 5 and 6).

2 Language Function Analysis

One of the most influential attempts to categorize language functions was introduced by the famous psychologist Karl Bühler (1934). In his *Organon model*, which is rooted in Plato's view of language as a tool, Bühler identifies and interrelates three fundamental functions of natural language in communication: the *expression* of the speaker, the *appeal* to the receiver, and the *representation* of the object or state of affair being communicated. As illustrated in Figure 1 they all refer to a linguistic sign, which can be understood as the unit of all forms of language.

Based on the three language functions, Katharina Reiß (1971) defined a classification of text types, which relates to the intention of the author of a text. In particular, she distinguished between the form-focused expression of the author's attitudes in *expressive* texts, the aim of making an appeal to the reader in *appellative* (or *operative*) texts, and the content-focused description of objects and facts in *informative* texts. Reiß assigned several concrete text types such as "report" (informative), "novel" (expressive), or "comment" (informative and appellative) to one or more of these classes. While she claimed that a hybrid type is the regular case, she observed that one function is predominant in most texts. We adopt Reiß' typology to define the language function analysis task.

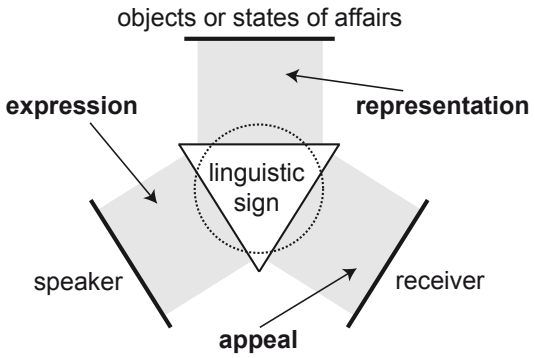

Figure 1: The organon model, formulated by Karl Bühler (1934), with its three language functions expression, appeal, and representation.

Definition 1 (Language Function Analysis) *Let $C = \{$expressive, appellative, informative$\}$ be the set of abstract language functions and let d be a text. Then the task of language function analysis, LFA, is to find the mapping $d \mapsto c \in C$ such that c is the predominant language function of d.*

We argue that LFA can help in many practical problems where document filtering is needed, especially because of its generic nature. For product-related texts, the use of LFA emerges, when we map the abstract functions in C to the following concrete language function classes of text:

- *personal (expressive).* Text that aims to express the personal attitude of an individual towards a product of interest.
- *commercial (appellative).* Text that follows commercial purposes with respect to a product of interest.
- *informational (informative).* Text that reports on a product of interest in an objective and journalistic manner.

Another example for a set of concrete language function classes might be *review* (expressive), *proposal* (appellative), and *report* (informative) in the research project context. Notice, though, that the mapping from abstract functions to concrete classes of text is meant to be an interpretation for a concrete learning situation rather than a redefinition of the task. In the remaining sections, we

use the classes *personal*, *commercial*, and *informational* for a first evaluation of LFA. Our intuition is that, statistically, language functions imply shallow linguistic features, such as certain parts-of-speech or writing style characteristics.

3 Related Work

Classification by intention has been recently addressed in (Kröll and Strohmaier, 2009). The authors infer a subset of 145 intentions from the transcriptions of speeches based on actions mentioned *within* the text. Similar problems refer to the analysis of speaker intentions in conversation (Kadoya *et al.*, 2005) and to the area of textual entailment (Michael, 2009), which is about the information implied by text. In contrast, LFA is about the question why a text was written and, thus, refers to the authorial intention *behind* a text.[1]

In that, our work resembles (Santini, 2005) where a linguistic expert system analyzes the gradation of four text types that convey the purpose and function of a text. Two of these types fit to the abstract functions introduced in Section 2, namely, the types "explicatory/informational" and "argumentative/persuasive". However, the other types ("descriptive/narrative" and "instructional") seem quite arbitrary and appear to intersect with the first type. Moreover, a class for the expression of personal views is missing. This might result from the used SPIRIT corpus (Clarke et. al., 2002), which was created for question answering purposes. Besides, language functions constitute a general classification scheme that may be concretized for a task at hand, while Santini regards text types only as input to web genre identification.

In terms of the communicative purpose of a text, language functions can be considered as the most abstract view on genres. Indeed, Kessler *et al.* (1997) argue that the class of texts that aim at persuading someone would not be seen as a genre merely because that class is too generic. While the authors simply define a genre to refer to a certain functional trait as well as to some formal properties, several abstract and concrete classification schemes have been proposed for genre identification. In a pioneer study on genres, Biber (1986) analyzes basic textual dimensions, such as "informative vs. involved", while Karlgren and Cutting (1994) try to automatically separate informative from imaginative texts. Stamatatos *et. al.* (2000) rely on more concrete press-related genres (e.g. "Letter to the editor" or "Spot news"), and Garera and Yarowsky (2009) investigate modern conversational genres, such as "Email".

The two latter show that genres do not only describe the function and purpose of a text, but also its form and target audience and, thus, also represent concepts orthogonal to language functions. Correspondingly, a great deal of genre research in the last decade focused on web genres as surveyed in (Stein *et al.*, 2010). Two standard corpora for web genre identification, KI-04 (Meyer zu Eissen and Stein, 2004) and SANTINIS (Santini, 2010), illustrate a common situation in genre research: Their classification schemes partly overlap, e.g. the class "Help" from KI-04 can be mapped to "FAQ" in SANTINIS, but partly also contain unique and quite specific classes, such as "Search pages" in SANTINIS. Moreover, Sharoff *et. al.* (2010) found out that seemingly similar classes ("Portrayal" and "Personal home page") differ strongly in terms of discriminative features. This supports our argumentation that there is neither a clear common understanding of genres, nor a well-defined genre concept. Additionally, Boese and Howe (2005) recognized that, in the web, genres may evolve over time to other genres.

However, language functions still represent one important aspect of genres. Accordingly, genre identification and LFA have similarities with respect to both practical applications (e.g. document filtering) and potentially helpful features. Since our focus is on a text itself as opposed to a document, we follow Webber (2009) who emphasizes the importance of text-internal and linguistic features, such as particular parts-of-speech. Also, we investigate both character-based and word-based n-grams, which were most successful in the above-mentioned evaluation of genre collections of Sharoff *et al.* (2010).

Further promising features relate to sentiment analysis and authorship attribution. Like LFA, sentiment analysis covers the issue of subjectivity (Pang and Lee, 2008), but it addresses *what* is said. Correspondingly, research in sentiment analysis often focuses only on characteristic terms as in (Prettenhofer and Stein, 2010). In contrast, approaches to authorship attribution aim at measuring the writing style of a text; sometimes based on

[1] While literature theory also addresses the intention of the reader and the intention of the text itself (Eco, 1990), only authorial intention is relevant for the purpose of this paper.

lexical and shallow linguistic information (Luyckx and Daelemans, 2008), sometimes using deeper analyses like parsing (Raghavan *et al.*, 2010). We adopt some of these features in Section 5 and 6.

4 The LFA-11 Corpus

To evaluate LFA, we built the LFA-11 corpus with manually annotated German texts from two separated domains: *music* and *smartphones*. The purpose of the corpus is to provide textual data for the development and evaluation of approaches to LFA and sentiment analysis. The corpus is freely available at http://infexba.upb.de.

The music collection of LFA-11 contains 2,713 promotional texts, professional and user reviews that were taken from a social network platform. Accordingly, these texts are well-written and of homogeneous style. In contrast, a set of 2,093 blog posts from the *Spinn3r corpus*[2] addresses smartphones. The Spinn3r project aims at crawling and indexing the whole blogosphere. Hence, the texts in the smartphone collection vary strongly in quality and writing style. While the music texts span 9.4 sentences with 23.0 tokens on average, the blog posts have an average length of 11.8 sentences but only 18.6 tokens per sentence.

4.1 Annotations

The corpus consists of UTF-8 encoded XMI files preformatted for the Apache UIMA framework[3], which implements the *Unstructured Information Management Architecture* (Ferrucci and Lally, 2004). Each file includes the text together with one of the language function annotations *personal*, *commercial*, and *informational*. Also, the texts have been classified by sentiment polarity as positive, negative, or neutral. Tagging was done by two employees of the *Digital Collections Verlagsgesellschaft mbH*, a leading supplier of digital asset management systems.

Figure 2 shows excerpts from three texts of the music collection, one out of each language function class. The excerpts have been translated to English for clarity. While some indicators of language functions might have been lost due to translation, the examples underline the strong connection of the concrete language function classes to the abstract functions from Section 2. In order to support a consistent categorization, the following guidelines were given to the two employees for the language function annotations:

personal. *... How did Alex recently ask when he saw Kravitz' latest best-of collection: Is it his own liking, the voting on his website, or the chart position what counts? Good question. However, in our case, there is nothing to argue about: 27 songs, all were number one. The Beatles. Biggest band on the globe. ...*

commercial. *... The sitars sound authentically Indian. In combination with the three-part harmonious singing and the jingle-jangle of the Rickenbacker guitars, they create an oriental flair without losing their Beatlesque elegance. If that doesn't make you smile! ...*

informational. *... "It's All Too Much"? No, no, still okay, though an enormous hype was made for decades about the seemingly new Beatles song. The point is that exactly this song "Hey Bulldog" has already been published long time ago, most recently on a reprint of "Yellow Submarine" in the year 1987. ...*

Figure 2: Translated excerpts from three texts of the music collection. Note that the translation to English might have affected the indicators of the corresponding language functions.

- *personal.* "Use this annotation if the text seems not to be of commercial interest, but probably represents the personal view on the product of a private individual."
- *commercial.* "Use this annotation if the text is of obvious commercial interest. The text seems to predominantly aim at persuading the reader to buy or like the product."
- *informational.* "Use this annotation if the text seems not to be of commercial interest with respect to the product. Instead, it predominantly appears to be informative in a journalistic manner."

About 20% of the music texts and 40% of the smartphone texts were tagged twice in order to compute inter-annotator agreement. The resulting values κ_m = 0.78 (music) and κ_s = 0.67 (smartphone) of Cohen's Kappa (Carletta, 1996) for the language function annotations constitute "substantial agreement". Especially κ_s is far from perfect, which can be problematic for text classification purposes. Under consideration of the hybridity of language functions in texts (cf. Section 2), κ_m and κ_s appear to be quite high, though.

Table 2: Distribution of sentiment polarity classes in the music and smartphone sets of the corpus.

4.2 Evaluation Sets

We created splits for each domain with half of the texts in the training set and each one fourth in the validation set and test set, respectively. Table 1 and Table 2 show the class distributions of language functions and sentiment polarities. The distributions indicate that the training, validation, and test sets differ significantly from each other. Also, Table 1 and 2 give a first hint that the correlation between language functions and sentiment is low. With regard to the distribution of language functions, we observe a large imbalance between the three classes. In case of double-annotated texts, we chose the annotations of the employee who categorized more texts as *commercial*. Still, this class remains by far the minority class with only about 5% to 10% of the texts in all sets. This, of course, makes the task at hand more difficult.

5 Features

To investigate whether LFA has correlations with other text classification tasks, we experimented with several lexical and shallow linguistic features that relate to some of the research areas mentioned in Section 3. For a concise evaluation, we organized these features into the following six types.

1. *Simple genre features.* Simple approaches from genre identification: the frequency of each part-of-speech tag that occurs at least 15 times in the training set, the average word length, and the *Lix* readability index (Anderson, 1983).

2. *Text type.* Features inspired by linguistic expert knowledge from (Santini, 2005), namely, the frequency of time and money entities as well as the frequency of two sets of part-of-speech tags: a) personal and possessive pronouns, b) nouns and adjectives.

3. *Writing style.* A selection of measures used in authorship attribution (Stamatatos, 2009): the frequency of the most common words, part-of-speech trigrams, and character trigrams as well as the frequency of capitalized, upper-case, and lower-case words. The same for parentheses, punctuation and quotation marks, and the portion of "?" and "!" under all sentence delimiters.

4. *Sentiment.* Indicators for sentiment, namely, the frequency of 15 common emoticons such as ";-)" and the sentiment polarity of the text.

5. *Core trigrams.* The frequency of the most discriminative part-of-speech and character trigrams of each language function class. Similar features performed best in (Sharoff *et al.*, 2010). Here, we use all trigrams that occur over six times as often in one class c as in any other class $c' \neq c$.

6. *Core vocabularies.* The frequency of the most discriminative words, introduced as a genre feature by Lee and Myaeng (2002). We define such a word to occur at least in 15 training texts of class c and over six times as often in c as in any other class $c' \neq c$.

6 Experiments

We now report on an evaluation of our approach to text classification by language function. As text classification often suffers from domain dependency, i.e., effective results are only achieved in the learning domain, we experimented with both corpus domains. The goal of our evaluation can be seen as three-fold: first, to evaluate the effectiveness of an LFA classifier on in-domain and out-of-domain data, second, to analyze the impact of each single feature type from Section 5, and third,

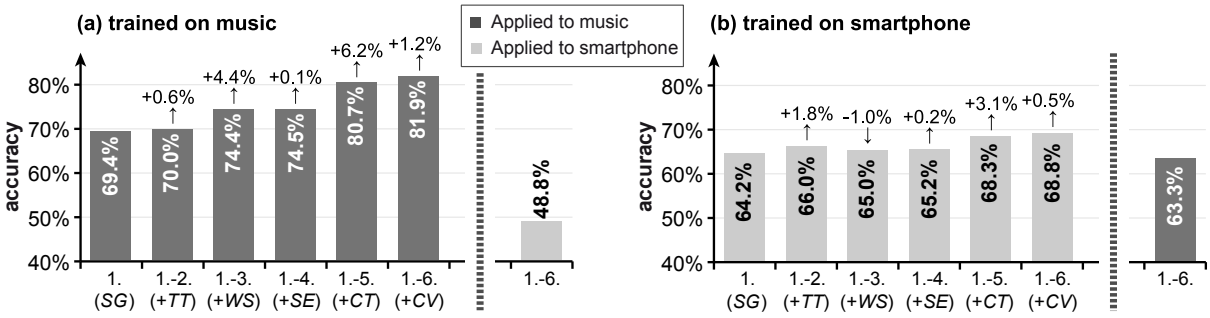

Figure 3: Classification accuracy in the LFA task for a stepwise integration of the six feature types and the transfer to another domain: (a) Training on the music training set, application to the music test set, and transfer to the smartphone test set. (b) Training on the smartphone training set, application to the smartphone test set, and transfer to the music test set.

to check whether LFA based on supervised learning qualifies for document filtering purposes.[4]

6.1 Experimental Set-up

Since commercial texts are largely underrepresented in the music and the smartphone collection, the two training sets were balanced with oversampling. After sentence splitting and tokenization, we applied the highly efficient *TreeTagger* (Schmid, 1995) for part-of-speech tagging and we extracted time and money entities with fast regular expressions. Regarding sentiment polarity, we used the corpus annotations for simplicity.

For the writing style features, we determined the 48 most common words, the 55 most common part-of-speech trigrams, and the 35 most common character trigrams on the training set of each collection. Accordingly, we computed the most discriminative trigrams for feature type 5. The core vocabularies sum up to 30 words for the music collection and to 36 words for the smartphone collection (proper names were discarded). Some of these words are quite specific, e.g. "single" in the music domain (an indicator for *commercial*), while others seem less domain-dependent such as "zumindest" ("at least", *informational*).

Altogether, the six feature types were instantiated by 299 music and 373 smartphone features, respectively. On both training sets, we trained one linear multi-class support vector machine (hereafter called SVM) using feature type 1 to m for each $m \in [1, 6]$ as well as one such SVM using only type m. For this, we applied the *LibSVM* integration in *Weka* (Hall et. al., 2009; Fan et. al., 2001), where we selected the cost parameters of all SVMs on the validation sets. Finally, we analyzed the impact of the resulting classifiers on both test sets. We measured their effectiveness in terms of accuracy, precision, and recall and their efficiency in milliseconds per processed input text.

[4]The Java source code and the feature files used for evaluation can be accessed at http://infexba.upb.de.

6.2 Results

Effectiveness of the classifiers. Figure 3a illustrates classification accuracy on the music test set for a stepwise integration of feature type 1 to 6 into an SVM trained on the music training set. Additionally, the accuracy for the transfer of the SVM with all features to the smartphone domain is depicted. The simple genre features (*SG*) already achieved 69.4%. While text type (*TT*) and sentiment (*SE*) contributed only little, the writing style features (*WS*) and the core trigrams (*CT*) boosted accuracy by 4.4% and 6.2%, respectively. At last, the core vocabularies (*CV*) added 1.2 percentage points to the resulting overall accuracy of 81.9% (86.7% on the validation set).

When we applied the SVM with all features to the smartphone test set, its accuracy dropped to 48.8%. To find out whether this dramatic decrease indicates a covariate shift in the feature distribution between the two domains, we retrained the SVM on the smartphone training set. Indeed, its accuracy was re-increased to 68.8%, as shown in Figure 3b. Interestingly, though, the domain transfer worked fine in the opposite direction, i.e., the SVM trained on smartphone texts still correctly classified 63.3% of the texts in the music test set. We suppose that this effect originates from the heterogeneity of the smartphone texts, which prevented the learning of features from being biased towards a certain style of speech. Such a bias naturally exists in music reviews and the like.

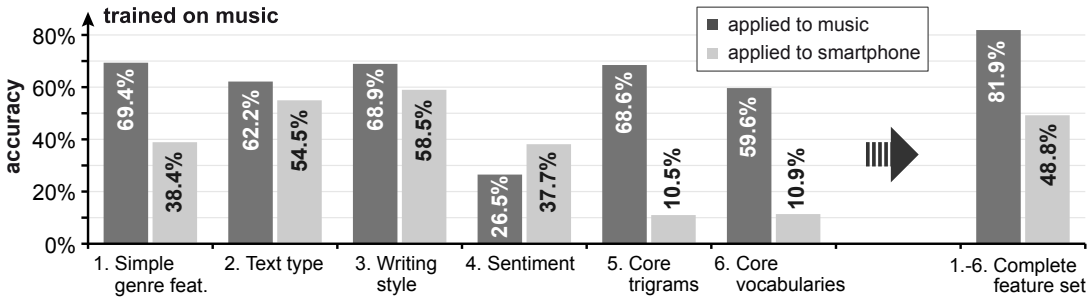

Figure 4: Classification accuracy of each feature type trained on the music training set and applied to both the music test set and the smartphone test set. The accuracy of all features is given on the right.

Domain	Class	Precision	Recall	F_1
music	personal	88.7%	84.8%	86.7%
	commercial	61.9%	88.2%	72.7%
	informational	80.8%	76.6%	78.6%
smartphone	personal	83.5%	68.5%	75.3%
	commercial	23.2%	46.4%	31.0%
	informational	63.9%	72.5%	68.0%

Table 3: Precision, recall and F_1-score for the three language function classes on the in-domain test sets using the SVM with all six feature types.

Nevertheless, Figure 3b also conveys that we achieved 13.1% less accuracy in the smartphone domain than in the music domain (68.8% vs. 81.9%). The accuracy of *SG*, 64.2%, was over five points lower, and only the integration of *TT* (+1.8%) and *CT* (+3.1%) yielded notable improvements afterwards. Adding *WS* even led to a decrease of one percentage point. However, this does not mean that the writing style features failed, as we see later on, but seems to be only noise from the optimization process of the SVM.

While a kappa value of 0.67 (cf. Section 4) renders high accuracy difficult, in general, one reason for the weak performance on the smartphone test set can be inferred from Table 3. This table lists effectiveness results of the SVMs with all features for each class. On the music test set, we observe a recall of more than 75% for all three classes. Though precision significantly dropped for *commercial*, given a class imbalance of 1:9 (commercial:rest), 61.9% is still over five times better than the expected precision of guessing. In contrast, the recognition of commercial texts failed on the smartphone test set with an F_1-score of only 31.0%. Apparently, the SVM did not determine meaningful features for *commercial*, probably because of the small number of commercial texts (cf. Table 1) in combination with the heterogeneity of the smartphone collection. This, in turn, also affected the effectiveness of the other classes.

Effectiveness of the feature types. We measured the effectiveness of each feature type in isolation in order to investigate their impact on LFA. Within music, the simple genre features, the writing style type, and the core trigrams did best, each of them with nearly 70% accuracy as shown in Figure 4. However, there is not *one* discriminative type, i.e., the complete feature set clearly outperformed all single types. Under the transfer to the smartphone domain, only the text type and writing style features reasonably maintained effectiveness. The core vocabularies failed on out-of-domain data, and also the core trigrams did unexpectedly bad, dropping from 68.6% to 10.5%.

With regard to sentiment, our evaluation underpins the observation from Section 4 that sentiment polarities and language functions hardly correlate: the according features learned on the music training set did not work out on both test sets, and the same holds for the opposite direction in Figure 5. There, we see that feature type 1, 3, and 5 also performed best within the smartphone domain. In particular, the writing style type (64.8%) is only 4% worse than the complete feature set. Moreover, while the domain transfer worked well in general, again the most impact was achieved by the text type features with 59.8% accuracy and by the writing style features with 58.9%. This suggests that the distribution of these features is only weakly domain-dependent in LFA. With respect to the writing style type, this is an interesting result, as it indicates that the genre-related task LFA significantly benefits from features that are most prominent in the area of authorship attribution.

Efficiency. We measured the run-time of the classifier with the complete feature set ten times on the music test set using a *2 GHz Intel Core*

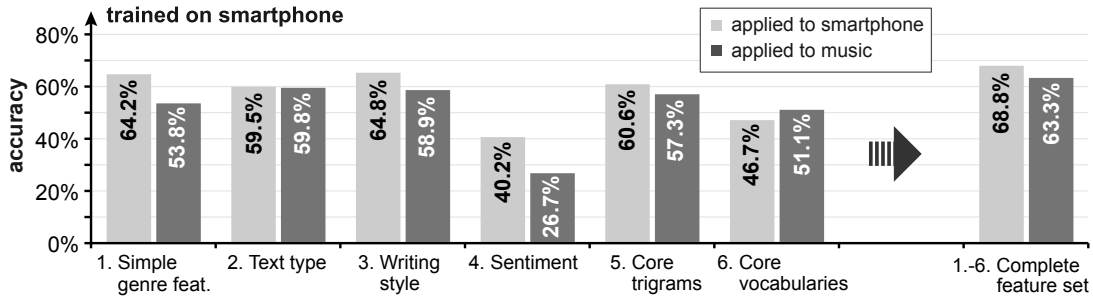

Figure 5: Classification accuracy of each feature type trained on the smartphone training set and applied to both the smartphone test set and the music test set. The accuracy of all features is given on the right.

2 Duo MacBook with *4 GB RAM*. Including all processing steps (sentence splitting, tokenization, part-of-speech tagging, entity recognition, feature extraction, and classification), the average runtime was 37.0 ms per text (σ = 0.6 ms) compared to 6.2 ms needed for tokenization alone. At least for the homogeneous music domain, where we achieved high accuracy, we thus claim that our approach is suitable for fast document filtering.

7 Conclusion

We presented the text classification task language function analysis, LFA, which addresses *why* a text was written and which is motivated by Karl Bühler's functions of natural language. We see language functions as one root of a well-defined genre concept and we argue that a common understanding of such a concept is needed in order to achieve real progress in genre research.

For evaluation of LFA, we provide the LFA-11 corpus with product-related texts from two very different domains that was developed in collaboration with industry. Each text in the corpus has been manually classified by its concrete language function. Approaching LFA with machine learning, we achieved promising results within one homogeneous domain. Moreover, we found out that features commonly used in authorship attribution have the most impact on LFA in both evaluated domains and that they also qualify for domain transfer. This indicates that language functions relate to the writing style of a text. In contrast, the correlation with sentiment appeared to be low.

However, in general, both the language function analysis of more heterogeneous texts and the domain transfer remain unsolved. In future work, we hence aim to investigate the use of sentence-level classification and domain adaptation techniques to further improve our approach to LFA.

Abstract

This paper investigates parameter adaptation in Statistical Machine Translation(SMT). To overcome the parameter bias-estimation problem with Minimum Error Rate Training(MERT), we extend it under a transductive learning framework, by iteratively re-estimating the parameters using both development and test data, in which the translation hypotheses of the test data are used as pseudo references. Furthermore, in order to overcome the over-training and unstableness problems respectively in employing such pseudo references, a termination criterion using a hyper-parameter and a Minimum Bayes Risk(MBR)-based hypothesis selection method are proposed in our work. Experimental results show that the transductive MERT method could yield significant performance improvements over a strong baseline on a large-scale Chinese-to-English translation task.

1 Introduction

Machine translation (MT) is the automatic translation from one natural language into another using computer, while SMT is an approach to MT that is characterized by the use of machine learning methods (Lopez, 2008). Nowadays, SMT is usually built on a log-linear model (Och and Ney, 2002), which can be abstracted into two steps: the first one is model training, i.e., learning features from large collection of bilingual parallel corpus; and the other is parameter estimation, in which the feature weight is tuned on an independent development dataset.

More specifically, for each source sentence f, we search for its final translation e^* among all possible translations based on the following equation:

$$P(e^*|f) = \arg\max_e Pr(e|f) \quad (1)$$

Under the log-linear model, the posterior probability $Pr(e|f)$ can be decomposed as:

$$Pr(e|f) = p_\lambda(e|f)$$

$$= \frac{\exp(\sum_{m=1}^{M}(\lambda_m \cdot h_m(e,f)))}{\sum_{e'}\exp(\sum_{m=1}^{M}(\lambda_m \cdot h_m(e',f)))} \quad (2)$$

where each $h_m(e,f)$ is a feature function and λ_m is the corresponding weight for m=1,...,M.

In SMT, there are three sections of data: the training data for feature estimation, the development data for weight tuning, and the test data for final evaluation. However, these three parts may belong to different domains, leading to distribution variations, which indicates that the features and weights learned from the data may be bias-estimated. As a result, the adaptation for features and their corresponding weights are both important issues in SMT.

In this article we focus on the latter issue, i.e., the model parameter adaptation. From the viewpoint of machine learning, development data is labeled data used for parameter learning, while test data is unlabeled and applied for evaluation. In

*Part of this work is done during the first author's internship at Microsoft Research Asia.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 641–648,
Chiang Mai, Thailand, November 8 – 13, 2011.

the previous works of transductive learning(Liu et al., 2010; Chan and Ng, 2007), the unlabeled data can be used to improve the model training so as to tackle the bias-estimation problem. Under such framework, the weight learned on both development and test dataset, in which the test dataset is constructed using n-best translations as pseudo references, moves towards the test data with regularization of development data, which alleviates the overtraining in normal MERT and matches the test data better.

The remainder of this paper is structured as follows: Related works on model adaptation in SMT are presented in Section 2, and our transductive MERT is proposed in Section 3. Experimental results are shown in Section 4, followed by conclusions and future work in the last section.

2 Related Work

Model adaptation in SMT has attracted increasing attentions in recent years. As mentioned in the previous section, corresponding to the two steps in SMT pipeline, there are two directions for adaptations.

The first one is feature adaptation, which tries to build model (translation model & language model) that could fit the development or test dataset better. This direction includes data selection (Lü et al., 2007; Hildebrand et al., 2005) and data weighting (Foster and Kuhn, 2007; Matsoukas et al., 2009). However, efficiency is the main obstacle for these methods (esp. data selection approach) since model building is time consuming.

The second direction is model parameter adaptation, which includes the transductive MERT method we propose in this article. Nevertheless, little attention has been paid to this direction to date. Mohit et al (2009) tried to build a classifier to predict whether or not a phrase is difficult. The language model weight is then adapted for each phrase segment based on this difficulty. In Li et al (2010), a related subset of development dataset is extracted for given test dataset. The test dataset is then translated under weight learned on this subset. Besides, Sanchis-Trilles and Casacuberta (2010) propose Bayesian adaptation for weight optimization based on a small amount of labeled test data, which is not necessary in our work.

The most similar previous work with ours is Ueffing et al (2007), who also propose a transductive learning framework for SMT. However, our method is different from their in the following three aspects:

Firstly, our method focuses on model parameter adaptation, while Ueffing et al (2007) pays attention to feature adaptation. In their work, the training model is rebuilt by combining original training data with n-best translation outputs of development and test data, in order to overcome the data sparseness problem. In contrast, we try to solve the parameter bias-estimated problem using the information of both development and test data.

Secondly, the parameter adaptation problem is more complicated in SMT, since overtraining is serious due to the limited size of development data. In this work, we use hyper-parameter to indicate the overtraining in the estimation step.

Finally, our method is more efficient than adaptation on the translation & language model. In Ueffing et al.(2007), training model building is necessary for each round, which is time consuming. By comparison, the running time is much shorter for our method, since no model building is required, although it is still longer than simple one-pass translation under baseline.

3 Transductive MERT for Machine Translation

3.1 Minimum Error Rate Training

In SMT, given a development dataset containing source sentences F_1^S with corresponding reference translations R_1^S, the purpose of MERT (Och, 2003) is to find a set of parameters λ_1^M which optimizes an automated evaluation metric (e.g., BLEU) under a log-linear model:

$$\hat{\lambda}_1^M = \arg\min_{\lambda_1^M} \sum_{s=1}^{S} (Err(R_s, \hat{E}(F_s; \lambda_1^M))) \quad (3)$$

in which the number of errors in sentence E is obtained by comparing it with a reference sentence R using function $Err(R, E)$ and

$$\hat{E}(F_s; \lambda_1^M) = \arg\max_{E} \sum_{s=1}^{S} (\lambda_m h_m(E, F_s)) \quad (4)$$

As shown in Algorithm 1, the decoder translates development dataset under current weight(default weight for first round), and generates N-best translation hypotheses for each sentence. The weight is then updated according to equation 3. This procedure repeats until performance converges.

Algorithm 1 MERT for SMT

Input: Development data :$\{F_1^S, R_1^S, C_1^S\}$
Set λ= init-weight and C_1^S=$\{\}$
Translate F_1^S and get N-Best list L_1^S
while C_1^S != $C_1^S \bigcup L_1^S$ **do**
  $C_1^S = C_1^S \bigcup L_1^S$
  Update λ using translation candidates C_1^S
  Translate F_1^S using λ to generate N-Best list L_1^S
end while

3.2 Transductive MERT

The basic idea of transductive learning is to use predicted labels from unlabeled data to improve learning performance. Based on the this assumption and normal MERT method, our transductive MERT (T-MERT) works as follows: Firstly, the feature weight is estimated on the development data with references. Test dataset is then translated using current weight. For each source sentence of test data, its 4-best translations are used as pseudo references. The feature weight is further re-estimated based on both the development dataset and the test dataset with pseudo references. Meanwhile, the pseudo references of test dataset are replaced in each round, while the development dataset is fixed throughout the procedure. The whole process runs M rounds so that we could get M different results, which are used in the hypothesis selection step (discussed in section 3.4).

As shown in Algorithm 2, the T-MERT algorithm could be divided into two loops: in the outer loop (outer-translation step), the test dataset is translated under current weight and new pseudo labeled test dataset is constructed; while in inner loop (inner-MERT step), the parameter weight is learned from the combined dataset. Meanwhile, there still remains two problems in algorithm 2: when the loop will terminate in inner-MERT step, and how we can select final hypothesis from the multiple results for test data T. These two issues will be discussed respectively in following parts of this section.

3.3 Stop Criterion

In MERT, the loop terminates until the performance converges. While in T-MERT, the weight would be overtrained to the pseudo references of the test data, which could not guarantee that the translations obtained in each iteration are good e-

Algorithm 2 Transductive MERT for SMT

Input: Development data $\{D_1^S, R_1^S, C_1^S\}$, Test data $\{T_1^W\}$, total round M
Let L=$\{D_1^S, R_1^S, C_1^S\}$ and U= $\{T_1^W\}$
Do MERT based on L and get weight λ
Let C_1^S=$\{\}$
Translate U under λ and get N-Best list N_1^W
for $i = 1$ **to** M **do**
  Select 4-best translations to build $\tilde{U}_1^W$ from N_1^W
  Let $L = \{\{D_1^S, R_1^S, C_1^S\} \bigcup \{T_1^W, \tilde{U}_1^W, N_1^W\}\}$
  Set λ= init-weight
  repeat
    Translation L and get N-Best translations LB_1^{S+W}
    Let $L = L \bigcup LB_1^{S+W}$
    Update λ on L
  until Certain condition satisfies(Section 3.3)
  Translate U under λ and get N-Best list N_1^W, in which we select 1-best translation as T_i
end for
Select final translation(Section 3.4) from collections T_i (i=1, . . . , M)

nough. Here we introduce a hyper-parameter H to indicate the overtraining. In each inner round i, let SD_i stands for the BLEU score of development data D, SpT_i represents the BLEU score of test data T under pseudo references and $SDpT_i$ indicates the BLEU score of combined dataset L , then we define the hyper-parameter H_i as follows:

$$H_i = \frac{SD_i}{SD_{i-1}} \cdot exp\frac{SpT_i}{SpT_{i-1}} \cdot exp\frac{SDpT_i}{SDpT_{i-1}} \quad (5)$$

Here, H_i represents the relative improvement between the performance of inner round i and that of the previous round. A smaller H_i value indicates the inner-MERT turns to be converged on combined dataset L, showing that the weight would be overtrained. Due to the fact that the test dataset owns no references, we cannot attain its BLEU score in each round. As an alternative, we could only obtain SD_i, SpT_i and $SDpT_i$, as shown in above equation. In optimization step of normal MERT, what we need to do is to update the parameter to maximize the score on development data. While here we encounter the overtraining, we use ratio of scores to indicate the training. Instead of maximizing the score, we want to optimize the relative improvement of the system performance. In

T-MERT, we observe that the performance is always the best when the inner-MERT terminates as H_i reaches peak[1].

3.4 Hypothesis Selection with Minimum Bayes Risk(MBR)

From T-MERT algorithm, we can get M different results from M outer-translation rounds. Due to intrinsic property and the randomness in MERT, the results from outer-translation step of T-MERT are not quite stable, making the hypotheses selection a necessity.

According to (Ehling et al., 2007), for each source sentence with N different translations, we could select the final translation based on the following Minimum Bayes Risk principal:

$$\hat{e} = \arg\min_{e}\{\sum_{e'}(Pr(e'|f)\cdot(1-BLEU(e',e)))\} \quad (6)$$

Here $Pr(e'|f)$ denotes the posterior probability for translation e' and $BLEU(e',e)$ represents the sentence-level BLEU score for e' using e as reference.

However, since the translation hypotheses are generated under different groups of weights, the corresponding posterior probability is no longer comparable. Here we simplify this problem under the assumption that all available translations are generated equally. Then equation 6 could be converted into:

$$\hat{e} = \arg\min_{e}\{\sum_{e'}(1 - BLEU(e',e))\} \quad (7)$$

Based on equation 7, we can select the hypothesis from the collections of translations efficiently. And the primary purpose of using MBR selection in this work is to stabilize the translation performance, as we select final result using only sentence-level BLEU scores between different hypotheses.

4 Experimental Results

4.1 Experimental Setup

In the experiments, we re-implement a hierarchical phrase-based decoder based on (Chiang, 2005). The word alignment is trained by GIZA++ under an intersect-diag-grow heuristics refinement. The plain phrases are extracted from all bilingual training data available from LDC, including LDC2002E18, LDC2003E07, LDC2003E14, LDC2004E12, LDC2004T08, LDC2005E83, LDC2005T06, LDC2005T10, LDC2006E26, LDC2006E34, LDC2006E85, LDC2006E92, and LDC2007T09, which consists in total of about 8.5M sentence pairs while hierarchical rules are only extracted from selected data sets, including LDC2003E14, LDC2003E07, LDC2005T10, LDC2006E34, LDC2006E85, and LDC2006E92, which contain about 467K sentence pairs. We build the 5-gram language model on the English section of all bilingual training data together with the Xinhua portion of the English Gigaword corpus.

[1] And we find that in experiments, hyper-parameter H_i of the second round is always maximal.

Table 1: Statistics on development and test data sets.

DATA SET	#SENTENCE	#WORD
MT03	919	36,021
MT05	1,082	43,765
MT06	1,664	38,209
MT08	1,357	33,042

The development and test dataset pairs are selected from NIST2003 (MT03), NIST2005 (MT05), NIST2006 (MT06) and NIST2008 (MT08). The data statistics are shown in Table 1. In the experiments, all translation results are measured in case-insensitive BLEU scores (Papineni et al., 2002).

4.2 Results under Transductive MERT

Figure 1 and Figure 2 show the hyper-parameter $H(iter_{number})$ for each iteration in the 10-round inner-MERT step. In both figures, MT03 is development dataset while MT05 & MT08 are test datasets. We find that the hyper-parameter H always reaches the peak at the 2nd iteration, showing fast convergence during parameter estimation on the combination of development data and pseudo labeled test data. Similar phenomenon could also be observed on other dataset pairs.

Here, the reason might be that the pseudo translate references for the test data are generated with the current SMT model and its parameters. So the newly generated translation references on the test data are intuitively similar to translations obtained using the current model parameters. When we re-estimate the parameters on the combined dataset starting from the initial parameters, the learning procedure can quickly fit the newly generated data. While parameter estimation step continues iteratively, the learning algorithm may fa-

vor those incorrectly generated translation references, which makes the overtraining more serious and hurts the final performance. By applying the hyper-parameter as the stop metric, we could control the learning procedure to avoid the overtraining.

We can also review the roles that the development and test datasets play in the procedure of avoiding over-training. The reason for that we transductively generate translations as pseudo references for test data is that we expect the estimation procedure biases towards the test data when incorporated in the learning procedure. Meanwhile, the development data also plays an important role in the learning process. Because development data owns true references, it acts as a regularization term to ensure that the feature weight will not excessively biased toward the test data with generated pseudo references in the learning procedure.

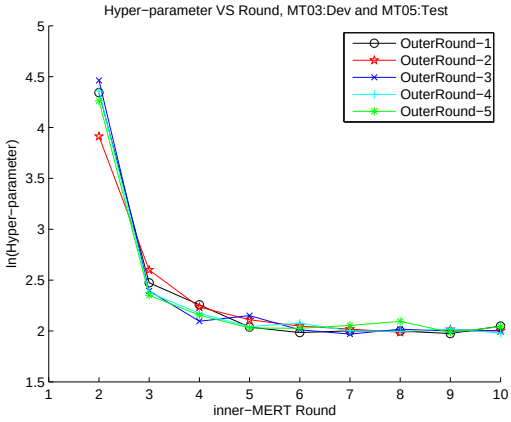

Figure 1: Hyper-parameter of 10 inner-MERT loops under 5 outer-translation rounds(OutRound-i) in T-MERT algorithm(without MBR), MT03:Dev and MT05:Test.

Based on the above discussion, we also compare results under different rounds for inner-MERT to verify the role of the hyper-parameter. As shown in figure 3(MT03 development and MT05 test) and figure 4(MT03 development and MT08 test), the results under T-MERT with 2-rounds inner-MERT are always best among different rounds, which is close to the baseline in figure 3 and much better in figure 4. Here the baseline for the test dataset is translated under weight learned from normal MERT on the development data, and remains constant for the following parts. For both

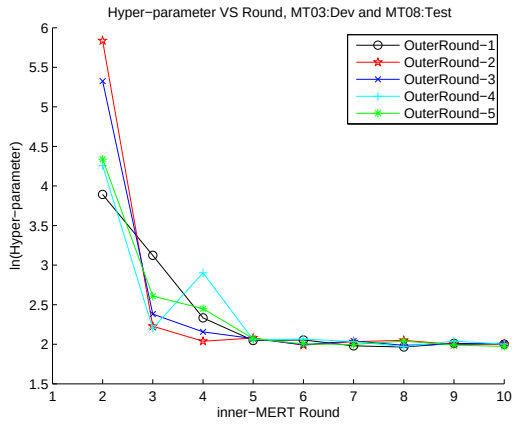

Figure 2: Hyper-parameter of 10 inner-MERT loops under 5 outer-translation rounds in T-MERT algorithm(without MBR), MT03:Dev and MT08:Test.

figures, we observe that 1-round inner-MERT is not sufficient to learn the weight well, while inner-MERT using more than 2 rounds leads to significant overtraining, which is consistent with the results obtained from the hyper-parameter.

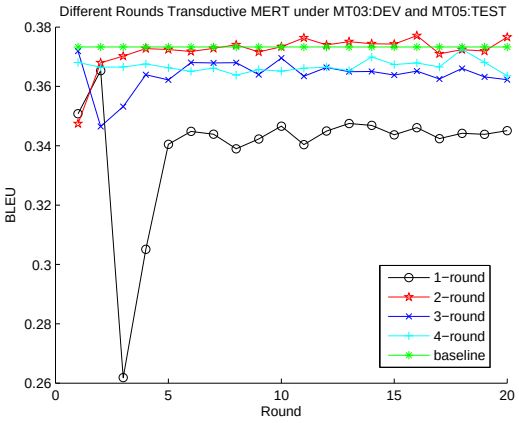

Figure 3: Results under T-MERT algorithm(without MBR) with fixed inner-MERT loops from 1 to 4, 20 outer-translation rounds, and baseline. MT03:Dev and MT05:Test.

Although the score of T-MERT under 2-round inner-MERT is comparable to or even better than baseline, the performance is still unstable, changing drastically for different rounds of outer-translation step (over 4 BLEU points for MT03:Dev and MT05:Test, and even larger for MT03:Dev and MT08:Test). We use the MBR s-

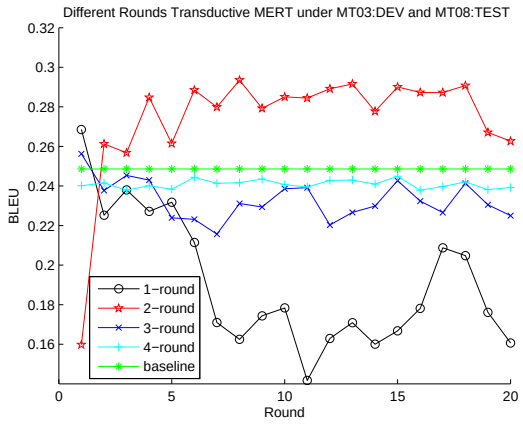

Figure 4: Results under T-MERT algorithm(without MBR) with fixed inner-MERT loops from 1 to 4, 20 outer-translation rounds, and baseline. MT03:Dev and MT08:Test.

election proposed in section 3.4 to choose a suitable hypothesis, and the corresponding results are shown in figure 5 and figure 6. It could be found that as the number of outer-translation rounds increases, the algorithm generates more groups of translation outputs, from which the performance under MBR selection turns to be more and more stable.

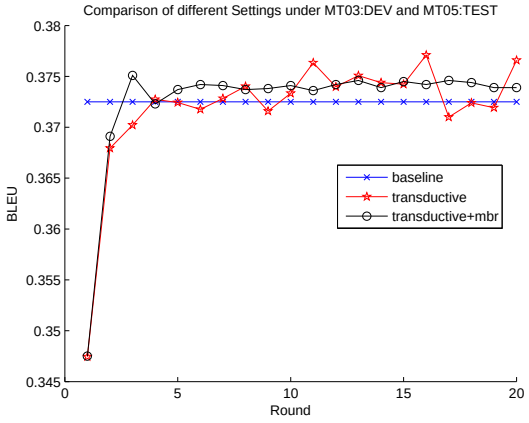

Figure 5: Result of baseline,T-MERT under 2 inner-MERT rounds without and with MBR selection. MT03:DEV and MT05:Test.

The above parts discuss two solutions for the problems we encounter in the transductive MERT, i.e., the inner-MERT stop criterion and MBR selection. We further evaluate our method (under 2 round inner-MERT and MBR selection) on all

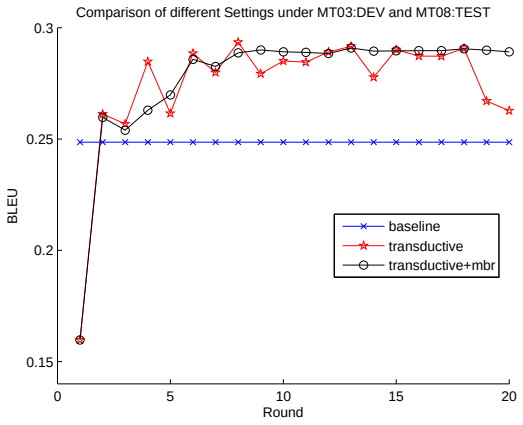

Figure 6: Result of baseline,T-MERT under 2 inner rounds without and with MBR selection. MT03:DEV and MT08:Test.

dataset pairs, which is any pair of MT03, MT05, MT06 and MT08. The final results are shown in table 2, from which we observe that for the dataset pair MT03 and MT05 the result under T-MERT is close to baseline, while for the pair MT03 and MT08, the improvement is significant in both directions. The result is similar with the observation on these evaluation datasets, i.e., MT03 and MT05 are under similar distribution, while MT03 and MT08 are quite different. Generally speaking, MT03 and MT05 are both composed of only news data, while MT06 and MT08 are consisted of news and web-blog data. As we know, the news data is significantly different from the web-blog data. We can find that our method could achieve significant improvement on 9 of total 12 dataset pairs, indicating that the distribution variation between dataset pairs is quite a common phenomenon. For datasets under similar distribution, the baseline performance is close to oracle, which means that potential space for improvement under the adaptation is limited; while for datasets that are quite different, there is much room for further increase in performance, since the baseline weight estimated on development is seriously biased for the test.

Besides, we try one extra comparison, i.e., using same dataset for both development and test under T-MERT. The result is also shown in table 2. We find that for MT03 and MT05, the result under T-MERT is close to baseline (a little higher), while for MT06 and MT08, the result is fairly lower. The reason that the adapted result on MT03 is slightly higher than baseline is that the result in

Table 2: Results of baseline and T-MERT under MBR Selections for different dataset pairs. Here symbol ↑ shows that the improvement is significant, ↓ indicates decrease is significant, and | means no significant changes

DEV	MT03		MT05		MT06		MT08

MT03	0.3914	0.3933(|)	0.3861	0.3908(|)	0.3731	0.3830(↑)	0.3586	0.3704(↑)
MT05	0.3733	0.3739(|)	0.3687	0.3724(|)	0.3592	0.3700(↑)	0.3414	0.3576(↑)
MT06	0.3358	0.3582(↑)	0.3344	0.3569(↑)	0.3636	0.3579(↓)	0.3504	0.3653(↑)
MT08	0.2486	0.2892(↑)	0.2543	0.2755(↑)	0.2774	0.2768(|)	0.2929	0.2809(↓)

each round is close to baseline, making it possible for the selection performance to be slightly higher than baseline, while for others the result in each round is lower than baseline. However, we do not hope that our method could be significantly better than baseline in this case, as baseline performance is also the oracle performance for the test dataset. We assume that we know the development and the test datasets are distinct in advance before applying the T-MERT algorithm.

5 Conclusion and Future Work

In this paper, we investigate the parameter adaptation issue in SMT. In particular, a transductive MERT algorithm is proposed to better explore both development and test datasets. Besides, a hyper-parameter is proposed to control the over-training problem in the parameter estimation step and a Minimum Bayes Risk (MBR)-based hypothesis selection method is adopted to stabilize the final performance. Compared with a state-of-the-art baseline, our method achieves significant and sustainable improvement.

In future, we plan to incorporate better hypothesis selection algorithms to choose high quality sentences from the test dataset, since sentences with bad translations would bring side effect during the learning procedure. Besides, we plan to further investigate the mechanism of transductive MERT in boosting the performance of SMT.

Abstract

The direct optimization of a translation metric is an integral part of building state-of-the-art SMT systems. Unfortunately, widely used translation metrics such as BLEU-score are non-smooth, non-convex, and non-trivial to optimize. Thus, standard optimizers such as minimum error rate training (MERT) can be extremely time-consuming, leading to a slow turn-around rate for SMT research and experimentation. We propose an alternative approach based on particle swarm optimization (PSO), which can easily exploit the fast growth of distributed computing to obtain solutions quickly. For example in our experiments on NIST 2008 Chinese-to-English data with 512 cores, we demonstrate a speed increase of up to 15x and reduce the parameter tuning time from 10 hours to 40 minutes with no degradation in BLEU-score.

1 Introduction

Recent statistical machine translation (**SMT**) systems employ a linear combination of several model components, such as translation models, language models, and reordering models. Translation is performed by selecting the most-likely translation, which is the candidate translation with the highest score based on the different model components. We usually refer to this search process as 'decoding'. Although the development of decoding algorithms is a key topic in SMT research, if we are to construct better SMT systems it is also important to find a way to determine the weights of different model components. We refer to this process as 'parameter tuning'.

The current standard strategy for tuning the parameters of SMT systems is to search for the weights that maximize a given translation quality metric such as BLEU-score (Papineni et al., 2002). In fact, minimum error rate training (MERT) proposed by (Och, 2003) is the most widely used parameter tuning method in SMT community. This is because, empirically, we obtain better translation system performance by directly optimizing the translation metric than by maximizing the likelihood function. However, translation metrics such as BLEU-score are often non-smooth, non-convex, and non-trivial to optimize, and direct maximization does not allow us simply to apply well-known fast and robust optimization techniques such as the gradient-ascent method. This restriction makes the parameter tuning process extremely slow.

In this paper, we propose a novel distributed MERT framework based on particle swarm optimization (**PSO**) (Kennedy and Eberhart, 1995), a population based stochastic optimization technique, to improve the slow parameter tuning process. The main characteristics of our method are that: (1) it directly optimizes a metric such as BLEU-score, (2) it greatly reduces the parameter tuning time compared with the conventional MERT, and (3) it is highly scalable, meaning that additional distributed processors lead to better and faster performance.

Our main motivation is to *improve the experiment turn-around time* for SMT system development. A faster parameter tuning algorithm would have a positive impact on research on all the components of the SMT system. Imagine a researcher designing a new pruning algorithm for decoding, a new word alignment model, or a new domain adaptation method. Any of these methods need to be evaluated in the context of a full SMT system, which requires parameter tuning. If we can reduce the parameter tuning time from 10 hours to 1 hour, this can greatly increase the pace of innovation. Thus our motivation is orthogonal to recent research on improving MERT, such as efforts to escape local maxima problems (Cer et al., 2008;

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 649–657,
Chiang Mai, Thailand, November 8 – 13, 2011.

Foster and Kuhn, 2009; Moore and Quirk, 2008), or incorporate lattices (Macherey et al., 2008).

2 Parameter Tuning for SMT Systems

Most recently developed SMT systems consist of several model components, such as translation models, language models, and reordering models. To combine evidence obtained from these different components, we often define a discriminative (log-)linear model.

Suppose the SMT system has D components. The log probabilities of the components are usually treated as features in the discriminative model. We denote the d-th feature, or log probability of the d-th component given a source sentence $\mathbf{f}$ and its translation $\mathbf{e}$, as $\phi_d(\mathbf{e}, \mathbf{f})$. We also denote the d-th weight as λ_d. Then, finding the most likely translation $\hat{\mathbf{e}}$ of a given source sentence $\mathbf{f}$ with the SMT system can be written in the following maximization problem:

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}} \sum_{d=\{1,\ldots,D\}} \lambda_d \phi_d(\mathbf{e}, \mathbf{f}). \quad (1)$$

This process is called 'decoding' in SMT.

Next, to obtain better translation quality for any translations, we need somehow to tune the component weights λ_d for all d. The current standard strategy for parameter tuning is to directly maximize a translation quality measure such as BLEU-score rather than likelihood.

Suppose we have a dataset consisting of S sentences. Let $\mathbf{f}_s$ be the s-th input sentence (source language) in the tuning dataset. We also suppose that each $\mathbf{f}_s$ has Q reference translations that are usually generated by hand. Thus, let $\mathbf{r}_{s,q}$ be the q-th reference translation of $\mathbf{f}_s$. We write the weights in the vector representation as, for example, $\boldsymbol{\lambda} = \{\lambda_d\}_{d=1}^{D}$, and a system translation of $\mathbf{f}_s$ obtained when the weights are $\boldsymbol{\lambda}$ as $\hat{\mathbf{e}}(\mathbf{f}, \boldsymbol{\lambda})$ to provide a better explanation. Then, the direct maximization of a translation metric $\mathcal{M}$ can be written in the following form:

$$\boldsymbol{\lambda}^* = \arg\max_{\boldsymbol{\lambda}} \mathcal{M}(\{\mathbf{f}_s, \{\mathbf{r}_{s,q}\}_{q=1}^{Q}, \hat{\mathbf{e}}_s(\mathbf{f}_s, \boldsymbol{\lambda})\}_{s=1}^{S}). \quad (2)$$

where $\boldsymbol{\lambda}^*$ represents the optimal solution.

2.1 Outline of Och's MERT

The most widely used parameter tuning framework for solving Equation 2 in SMT is MERT proposed by (Och, 2003). There are several variations for updating weights during the iterative tuning process in MERT. The most commonly used algorithm for MERT is usually called Koehn-coordinate descent (KCD), which is used in the MERT utility packaged in the popular Moses statistical machine translation system (Koehn et al., 2007). Another choice is Powell's method that was advocated when MERT was first introduced for SMT (Och, 2003). Since KCD tends to be marginally more effective at optimizing the MERT objective, and is much simpler to implement than Powell's method, this paper focuses only on KCD.

KCD is a variant of a coordinate ascent (or descent) algorithm. At each iteration, it moves along the coordinate, which allows for the greatest progress of the maximization. The routine performs a trial line maximization along each coordinate to determine which one should be selected. It then updates the weight vector with the coordinate that it found to be the best objective in the trial.

To perform an iterative parameter update with MERT, it is necessary to evaluate the system translation quality given by the current weights by the translation metric to be optimized. This process obviously requires us to perform decoding (Equation 1), and decoding is usually a very expensive process. Thus, it often becomes infeasible to undertake decoding every iteration if the size of the tuning dataset is relatively large. To overcome this issue, Och (2003) has also introduced the N-best approximation method. This method separates decoding and the parameter tuning process into an outer and an inner loop. The outer loop first runs the decoder over the source sentences in the tuning dataset with the current weights to generate N-best lists of translations. Then, the method employs the inner loop procedure to optimize the weights based on those N-best lists instead of decoding the tuning dataset. After obtaining the optimal weights from the inner loop, we repeat the outer loop to generate a new N-best list. Figure 1 shows the system outline, which is described in detail elsewhere (Bertoldi et al., 2009).

We note here that the method proposed in this paper essentially involves the replacement of the inner loop algorithm of the conventional MERT.

3 Particle Swarm Optimization (PSO)

Particle Swarm Optimization (**PSO**) is an (iterative) stochastic optimization technique proposed

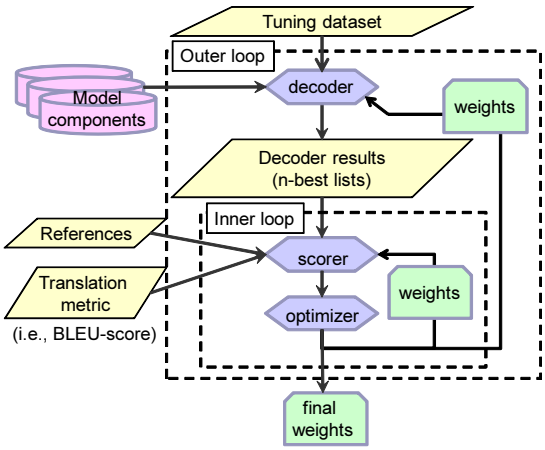

Figure 1: System outline of MERT proposed by (Och, 2003); This system diagram was first published in (Bertoldi et al., 2009)

in (Kennedy and Eberhart, 1995). This optimization technique is explained in terms of emulating the social behavior of flocks of birds and shoals of fish, or taking advantage of the concept of the social sharing of information.

The basic strategy of this optimization technique is that each particle flies individually through the search space to find the best position in the search space. By this iterative search process, each particle can learn from the experience of other particles in the same population (called a swarm). In other words, each particle in the iterative search process would adjust its flying velocity as well as position based on both its own acquaintance and the flying experience of other particles in the swarm. PSO has been shown to be effective in solving a variety of complex optimization problems in practice. Thus, PSO may also work relatively well in MERT since optimizing translation metric such as BLEU-score is also a complex optimization problem.

3.1 Basic definition

Suppose we have a D-dimensional problem space (search space) given by the task at hand. Then, we also assume that we have an objective function F, which is generally called a fitness function in the context of PSO, to evaluate the solution. Basically, solving the task is equivalent to either maximizing or minimizing the objective function. For example, with the parameter tuning of SMT systems, the objective function F is BLEU-score, and the solution should be the parameter set that maximizes the BLEU-score over a given tuning dataset. Hereafter, we assume a maximization problem.

For PSO, we assume that the swarm consists of K particles. Each individual particle P_k, where $k \in \{1, \ldots, K\}$, can be represented as a three-tuple $P_k = (\mathbf{x}_k, \mathbf{v}_k, \mathbf{b}_k)$, where $\mathbf{x}_k$ is the current position in the search space, $\mathbf{v}_k$ is the current velocity, and $\mathbf{b}_k$ is the personal best position in the search space. Note that $\mathbf{x}_k$, $\mathbf{v}_k$,and $\mathbf{b}_k$ are all represented as D-dimensional vectors. As briefly explained in Section 3, PSO is an iterative optimization technique. The personal best position, $\mathbf{b}_k$, corresponds to the position in the search space where particle k has the largest value of objective function F over all the past iterations. Hereafter, let t represent the PSO iteration counter, where $t \in \{1, \ldots, T\}$, and T represents the maximum iteration number given by a user, or is possibly set at infinity. In our case, we set $T = 100,000$.

Formally, the personal best values for the k-th particle at the t-th iteration, $\mathbf{b}_k(t)$, is updated by the following equation:

$$\mathbf{b}_k(t+1) = \begin{cases} \mathbf{x}_k(t+1) & \text{if } F(\mathbf{x}_k(t+1)) > F(\mathbf{b}_k(t)) \\ \mathbf{b}_k(t) & \text{otherwise} \end{cases}, \quad (3)$$

where we set $\mathbf{b}_k(0) = \mathbf{x}_k(0)$ for all k.

The position yielding the largest objective among all the particles in the swarm is called the global best position. We denote this global best position as $\mathbf{g}$, and denote the global best position at t-iteration as $\mathbf{g}(t)$. $\mathbf{g}(t)$ can be easily obtained by finding the $\mathbf{b}_k(t)$ that has the largest objective, which is written as follows:

$$\mathbf{g}(t) = \underset{\mathbf{b} \in \{\mathbf{b}_1(t), \mathbf{b}_2(t), \ldots, \mathbf{b}_K(t)\}}{\arg\max} F(\mathbf{b}). \quad (4)$$

We assume $U(a, b)$ is a function that returns a value between a and b drawn from a uniform distribution. We denote $\mathbf{U}(a, b)$ as a D-dimensional vector all of whose elements are $U(a, b)$. Then, the iterative PSO tuning process is mainly built on the following equations:

$$\begin{aligned} \mathbf{v}_k(t+1) = & \xi(t)\mathbf{v}_k(t) \\ & + c_1\mathbf{U}(0,1)(\mathbf{b}_k(t) - \mathbf{x}_k(t)) \\ & + c_2\mathbf{U}(0,1)(\mathbf{g}(t) - \mathbf{x}_k(t)), \end{aligned} \quad (5)$$

$$\mathbf{x}_k(t+1) = \mathbf{x}_k(t) + \mathbf{v}_k(t+1). \quad (6)$$

where ξ is the inertia weight of the past velocity, and c_1 and c_2 are acceleration constants regulating the relative velocities with respect to the best personal and global positions. We use $c_1 = 2.0$,

$c_2 = 2.0$, and $\xi(t) = 1.0 - t/T$, which are one standard setting for PSO. We also define $\mathbf{v}_k(0) = \mathbf{U}(-1, 1)$ and $\mathbf{x}_k(0) = \mathbf{U}(-1, 1)$ for all k.

To summarize the process, the velocities $\mathbf{v}_k$ for all particles P_k are individually updated at the beginning of each iteration t by using the (personal) past velocity, and information about the personal and global best position. The new velocity for each particle is then added to its own current position $\mathbf{x}_k$ to obtain the next position of the particle. After that, each particle updates its personal best position by using Equation 3, and finally the global best position of the swarm is updated by the mutual sharing of the personal best positions. PSO performs the above process iteratively until convergence is reached or iterations attain the maximum number T defined by the user.

The key feature of the PSO architecture is that information regarding the global best position $\mathbf{g}$ is shared by all particles as shown in Equation 5.

3.2 Extension to guarantee local convergence

The standard PSO algorithm described in the previous section does not guarantee convergence on a local maximum. It merely means that all the particles have converged on the best position discovered so far by the swarm. To address this issue, we use the modified version of PSO proposed in (van den Bergh and Engelbrecht, 2002) that can guarantees convergence to a local maximum. The basic idea of the modification is allow the global best particle to move until it has reached a local maximum. To achieve this, they introduced a new velocity update equation for the global best particle. Note that particles other than the global best particle in the swarm continue to use the usual velocity update as shown in Equation 5.

Let τ be the index of the global best particle. Then, we use the following equation to update the velocity of the global best particle at the t-th iteration:

$$\begin{aligned}\mathbf{v}_\tau(t+1) = &-\mathbf{x}_\tau(t) + \mathbf{g}(t) + \xi(t)\mathbf{v}_\tau(t) \\ &+\rho(t)\mathbf{U}(-1, 1),\end{aligned} \tag{7}$$

where ρ is a scaling factor of the stochastic term $\mathbf{U}(-1, 1)$, which is defined as follows:

$$\rho(t+1) = \begin{cases} 2\rho(t) \text{ if } \#S > T_s \\ 0.5\rho(t) \text{ if } \#F > T_f \\ \rho(t) \text{ otherwise} \end{cases}, \tag{8}$$

where $\#S$ and $\#F$, respectively, denote the number of consecutive failures or successes in finding a new global best point where a failure is defined as $f(\mathbf{g}(t)) = f(\mathbf{g}(t-1))$.

Then, in the same manner as Equation 6, the new position can be calculated by adding the new velocity:

$$\begin{aligned}\mathbf{x}_\tau(t+1) &= \mathbf{x}_\tau(t) + \mathbf{v}_\tau(t+1) \\ &= \mathbf{g}(t) + \xi(t)\mathbf{v}_\tau(t) + \rho(t)\mathbf{U}(-1, 1).\end{aligned} \tag{9}$$

The $-\mathbf{x}_\tau(t)$ term in the velocity update is canceled when updating the position. This means that a new position is always updated from the global best position $\mathbf{g}(t)$. This is one of the key tricks of the modification; the global best particle always searches for a new position around the current best position until new global best position is found. ρ also plays an important role in guaranteeing the locally convergence of the method. The diameter of this search area is controlled by the parameter ρ. The updating of ρ means that if the global best objective function value does not change, then ρ shrinks to half its original size and the search space around the global best position becomes smaller. The initial default value of $\rho(0) = 1.0$.

Finally, if we cannot find a new global best position around the current global best position in a certain number of iterations T_c then the current global best position can be considered a local maximum. We use $T_c = 15$.

A proof of guaranteed convergence to local maxima for this algorithm can be found in (van den Bergh and Engelbrecht, 2002). Note that this modification still does not guarantee convergence to the global optimum position unless the objective function is a convex function.

4 MERT-PSO for SMT

This section describes a way to incorporate PSO into the MERT framework. First, the position $\mathbf{x}$ in PSO corresponds to the component weights in the SMT system $\boldsymbol{\lambda}$. Next, the objective function F in PSO can be defined as a translation metric such as BLEU-score $\mathcal{M}$ shown in Equation 2. Therefore, in our case, F is calculated by using a tuning dataset $\mathcal{D}$ and system translations of the tuning dataset given by the current weight (position) $\mathbf{x}$. We denote a translation metric such as BLEU-score as $F(\mathbf{x}, \mathcal{D})$ for MERT-PSO.

In PSO, each particle can individually update its velocity, position and personal best position. Thus, we design MERT-PSO to work in a parallel computing environment. Basically, we uti-

Algorithm: MERT-PSO

Input: K: number of particles, D: degree of parameter dimension, T: maximum number of iterations, T_c: threshold of convergence evaluation, I: iteration number for update trial, $\mathcal{D}$: tuning dataset, F: objective function.

Main procedure:

initParticle(P_k) $\forall k$ in parallel processing
$(\tau, \mathbf{g}(0)) \leftarrow$ Eq. 4
$T' \leftarrow 0$
for t in $0, \ldots, T-1$
  execParticle(t, P_k, τ) $\forall k$ in parallel processing
  $(\tau, \mathbf{g}(t+1)) \leftarrow$ Eq. 4
  $T' = T' + 1$ if $F(\mathbf{g}(t+1), \mathcal{D}) = F(\mathbf{g}(t), \mathcal{D})$, or $T' = 0$ otherwise
  break if $T' \geq T_c$
end_for
output $\mathbf{g}(t+1)$

procedure: **initParticle**(P_k)

$\mathbf{v}'_k \leftarrow \mathbf{U}(-1, 1)$ and $\mathbf{x}'_k \leftarrow \mathbf{U}(-1, 1)$
$\mathbf{v}_k(0) \leftarrow \mathcal{P}(\mathbf{v}'_k)$ and $\mathbf{x}_k(0) \leftarrow \mathcal{P}'(\mathbf{x}'_k)$
$\mathbf{b}_k(0) \leftarrow \mathbf{x}_k(0)$

procedure: **execParticle**(t, P_k, τ)

for i in $1, \ldots, I$
  $\mathbf{v}' \leftarrow \mathbf{V}(k,t)$ or $\mathbf{V}'(k,t)$ if $k = \tau$ (Eq. 5 or 7)
  $\mathbf{v}^{\text{tmp}} \leftarrow \mathcal{P}(\mathbf{v}')$ (Eq. 10)
  $\mathbf{x}' \leftarrow \mathbf{x}_k(t) + \mathbf{v}^{\text{tmp}}$ (Eq. 6)
  $\mathbf{x}^{\text{tmp}} \leftarrow \mathcal{P}'(\mathbf{x}')$ (Eq. 11)
  if $F(\mathbf{x}^{\text{tb}}, \mathcal{D}) < F(\mathbf{x}^{\text{tmp}}, \mathcal{D})$
    $\mathbf{x}^{\text{tb}} \leftarrow \mathbf{x}^{\text{tmp}}$ and $\mathbf{v}^{\text{tb}} \leftarrow \mathbf{v}^{\text{tmp}}$
  end_if
end_for
$\mathbf{x}_k(t+1) \leftarrow \mathbf{x}^{\text{tb}}$, and $\mathbf{v}_k(t+1) \leftarrow \mathbf{v}^{\text{tb}}$
$\mathbf{b}_k(t+1) \leftarrow$ Eq. 3 using $\mathcal{D}$

lize a master-slave architecture for parallelization. We simply allocate one particle to one slave node (or processor), and the master node manages the global best position and the convergence test.

4.1 Extensions

This section describes our four proposed extensions for PSO that make it possible to fit PSO to parameter tuning for SMT systems.

The value of each dimension of every velocity is usually clamped to the range $[-v_{\max}, v_{\max}]$ to avoid having too large an absolute velocity and thus realizing better convergence. Here, we introduce another procedure that can also avoid having velocities that are too large. Our proposed procedure is well-known as a 'norm projection' in the discriminative machine learning community, *i.e.*, (Shalev-Shwartz et al., 2007), which can be defined as follows:

$$\mathcal{P}(\mathbf{v}) = \min\left\{1, \frac{\beta}{||\mathbf{v}||_p}\right\}\mathbf{v}, \tag{10}$$

where β represents the radius of L_p-norm ball. In our experiments, we set $\beta = 1$ and $p = 1$. We project the velocity vector into the L_p-norm ball immediately after we update the velocities.

Next, in a similar manner to Equation 10, we also project the current positions for all particles 'onto' L_p-norm ball after updating. We use the following function:

$$\mathcal{P}'(\mathbf{x}) = \frac{1}{||\mathbf{x}||_p}\mathbf{x}, \tag{11}$$

Suppose $\mathbf{x}' = \mathcal{P}(\mathbf{x})$, then note that $\hat{\mathbf{e}}(\mathbf{f}, \mathbf{x})$ and $\hat{\mathbf{e}}(\mathbf{f}, \mathbf{x}')$ for any $\mathbf{f}$ can be identical. This is because we assume the translation models used in our method to be the linear model described by Equation 1. This assumption guarantees that any system translation $\hat{e}$ given by Equation 1 is never changed as a result of this position projection. This fact implies that we can find the solution onto an L_p-norm ball with a fixed radius. Thus, this projection may lead to faster convergence since it enables us to reduce the search space of PSO.

Third, for each iteration, we update the velocity and position of each particle to those with the best objective value among I trials, in our case $I = 10$. Let the right-hand side of Equations 5 and 7 be $\mathbf{V}(k,t)$ and $\mathbf{V}'(\tau,t)$, respectively, that is $\mathbf{V}(k,t) = \xi(t)\mathbf{v}_k(t) + c_1\mathbf{U}(0,1)(\mathbf{b}_k(t) - \mathbf{x}_k(t)) + c_2\mathbf{U}(0,1)(\mathbf{g}(t) - \mathbf{x}_k(t))$, and $\mathbf{V}'(\tau,t) = -\mathbf{x}_\tau(t) + \mathbf{g}(t) + \xi(t)\mathbf{v}_\tau(t) + \rho(t)\mathbf{U}(-1,1)$. Both $\mathbf{V}(k,t)$ and $\mathbf{V}'(\tau,t)$ have randomness characterized by $\mathbf{U}$. Therefore, we select the best position and velocity in I random trials as the position and velocity of $t+1$ in t iterations. This extension reduces the number of inefficient searches (and also the communication cost between particles). Thus, this may also lead to a faster tuning process.

Finally, we slightly modify the update scheme of ρ explained in Equation 8 to simplify the process as follows:

$$\rho(t+1) = \begin{cases} 0.5\rho(t) & \text{if } F(\mathbf{g}(t)) = F(\mathbf{g}(t-1)) \\ 1.0 & \text{otherwise} \end{cases}.$$

To summarize our method, Figure 2 shows its overall algorithm.

4.2 Implementations

Basically, we implemented the PSO algorithm described above in Moses, one of the leading open source implementations of phrase-based machine translation (Koehn et al., 2007). More specifically, we substituted our PSO method for the inner loop

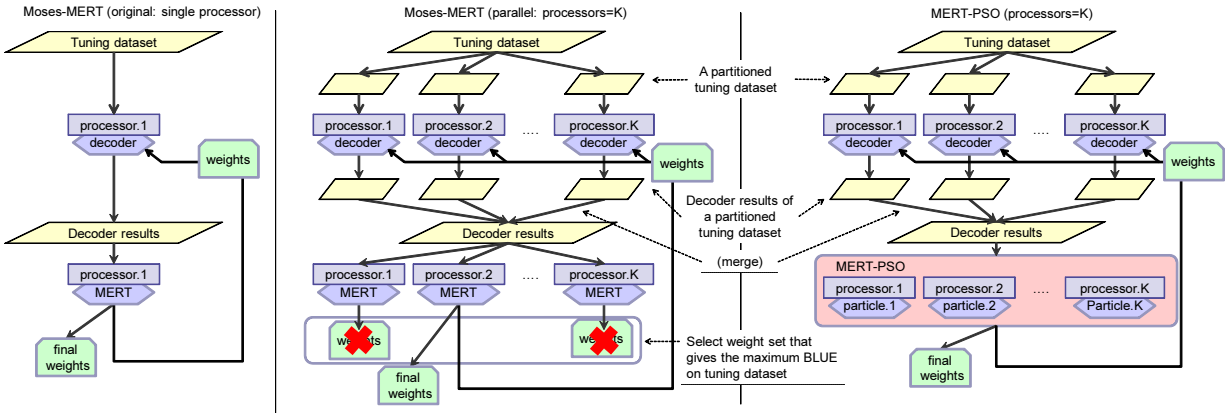

Figure 3: Outline process images (a) Moses-MERT (original), (b) Moses-MERT (our parallel version), and (c) MERT-PSO

of Moses MERT. The source code was written in C++ with boost:::MPI libraries for parallelization.

Moreover, we also substituted the code we developed for the outer loop code to run a decoder in parallel to work on a large number of computational resources such as cluster PCs. This is simply accomplished by separating the tuning dataset, and then each computational resource executes the decoder independently to decode part of the partitioned dataset.

Additionally, in our experiments, we also implemented a parallel version of Moses-MERT as a competitor for comparison with our method. In this case, we independently performed the inner-loop algorithm of the original Moses-MERT in many computers with randomly selected initial weights. After completing all the Moses-MERT procedures, we selected a weight set that provided the best BLED-score.

Outline process images for three different implementations are shown in Figure 3.

5 Experiments

In our experiments, we evaluated the effectiveness of the proposed MERT-PSO in terms of both performance and runtime by comparison with a MERT package in Moses (Moses-MERT), and our parallel extended version of Moses (Moses-MERT parallel). All three algorithms use the Moses decoder (Koehn et al., 2007) to select the best translation given a source sentence (Equation 1).

We conducted our experiments on NIST-08 and WMT-10 datasets. Table 1 summarizes the data statistics used in our experiments. Note that the tuning datasets are formed from NIST-04 and NIST-05 test data for NIST-08, and WMT-09 test data for WMT-10. For both tasks, we train phrase tables from the provided training data using the standard GIZA++ pipeline and train language models using SRILM. The feature set consists of the standard 5 translation model probabilities, 1 language model probability, 1 distortion feature and 1 word penalty feature for 8 features, and an additional 6 reordering models for 14 features.

6 Results and Discussion

6.1 Evaluations for overall tuning process

Tables 2, and 3 show the results of our experiments comparing the parameter tuning qualities of the original Moses-MERT, Moses-MERT (parallel) and MERT-PSO. All the experiments were performed ten times using different random seeds for each trial. We assumed the number of available computational resources, which we refer to as '#PN', to be 512 in these experiments. In the tables, Ave, Max., Min., and Std. represent the average, maximum, minimum and standard deviation of ten trials, respectively.

Clearly, MERT-PSO greatly reduced the total runtime compared with the original Moses-MERT. Although MERT-PSO used a lot more computational resources than the original Moses-MERT, the original Moses-MERT can never achieve the tuning speed of MERT-PSO.[1] Additionally, we

[1]It should be noted that Moses-MERT (parallel) is our

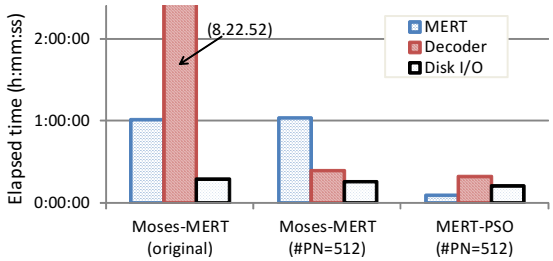

Figure 4: Detailed rates of parameter tuning process (inner loop), decoding (outer loop), and disk I/O times in total runtimes for NIST-08 dataset.

can find the tendency that the standard deviations of the BLEU-scores for MERT-PSO are relatively small. This implies that MERT-PSO has the power to produce a robust solution. This property is important for stochastic optimization algorithms.

The results of our developed parallel Moses-MERT are largely similar to those obtained by MERT-PSO in terms of BLEU-scores. However, the average runtimes of MERT-PSO are at least three times faster than those of Moses-MERT (parallel). These observations may be interesting; PSO searches almost randomly for the model component weights during the parameter tuning process, but it can still find good weights sufficiently quickly. The faster runtime of MERT-PSO is also explained by this simple randomized update procedure of PSO in contrast to KCD used in Moses-MERT, which tries to find the optimal coordinate by using an iterative line search.

Another interesting finding is that MERT-PSO tends to reduce the number of outer loops. This can be a good characteristic for the current MERT framework since decoding (outer loop) is usually expensive.

own developed system that is not implemented in the original Moses open source software.

Figure 4 summarizes the parameter tuning process (inner loop), decoding (outer loop), and disk I/O times for each method for NIST-08 dataset. Most SMT researchers would agree that the most of the MERT runtime is spent on decoding (outer loop). As shown in this figure, this is basically true for Moses-MERT (original) when the tuning dataset is large. However, with the parallel method, it appears not always to be true. For example, the dominant process of Moses-MERT (parallel) is parameter tuning process (inner loop). Thus, developing a faster parameter tuning algorithms is still meaningful.

6.2 Evaluations for inner loop process

This section evaluates the compared methods in terms of single inner loop process. To allow fair comparisons, all the methods are evaluated using the same N-best lists, even though running multiple iterations of MERT would normally produce different N-best lists. To perform this experiment, we first constructed models using the original Moses. Then, we utilized the generated intermediate files for the experiments described in this section.

6.2.1 Effect of parallelization

Figure 5 shows the effect of parallelization in terms of BLEU-score and runtime. It is clear that smaller #PN provided lower BLEU-score in MERT-PSO. MERT-PSO generally requires a certain number of particles (processors) to work well. It seems that we need at least 64 particles for a stable tuning in our setting. However, when MERT-PSO employed sufficiently many particles, it outperformed Moses-MERT and provided stable convergence even though MERT-PSO is a stochastic optimization method.

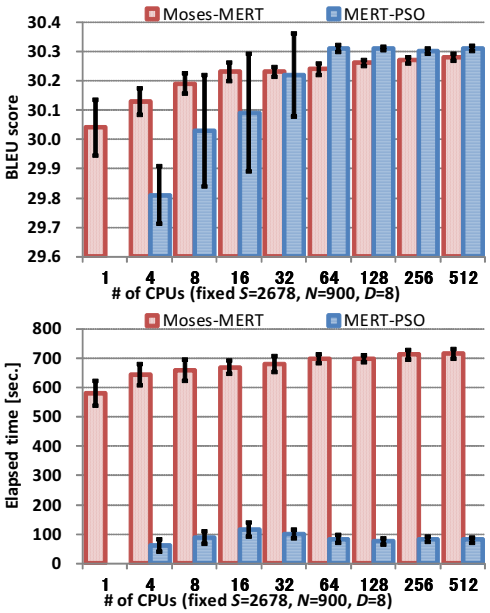

Figure 5: Runtimes and BLEU-score of changing parallelization number in a single inner loop process for NIST-08 dataset (vertical line at each bar represents Std.).

Note that larger #PN provided better BLEU-score but slower runtime in Moses-MERT. This is because Moses-MERT (parallel) runs the original MERT processes individually on every processors. Thus, the runtime of Moses-MERT depends on the slowest MERT process for all MERT processes. Instead, it can select the weights that provide the best BLEU score among all the results of the MERT processes. This is the reason of this observation.

6.2.2 Robustness against S and N

Figure 6 shows the runtimes against the average number of N-best lists in a single inner loop, where the number of sentences in a tuning set is fixed, and runtimes against the sentences in a single inner loop, where the average number of N-best list is fixed.

We can find MERT-PSO has an almost linear relation in both figures in the same way as Moses-MERT. These figures also clarified that MERT-PSO is very robust as regards increasing the number of sentences and the average N-best list size per sentence.

6.3 Test data performance

Table 4 shows the average BLEU-scores provided by ten models of Moses-MERT and MERT-PSO with 512 parallel processing for the test data. We

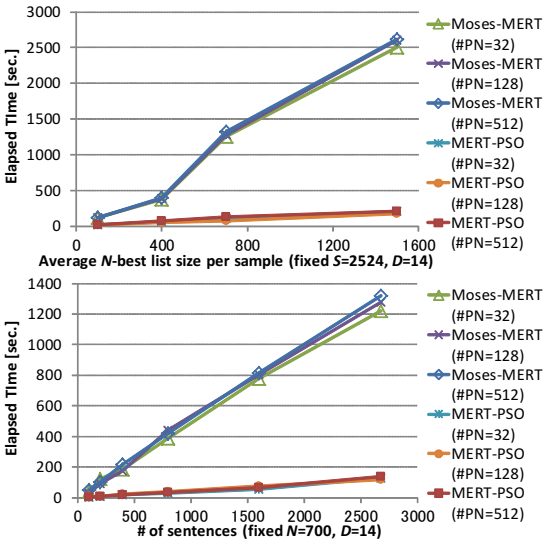

Figure 6: Runtimes vs. average N-best list size per sentence (top), and number of sentences in tuning dataset (bottom) in a single inner loop process for WMT-10 dataset.

		Moses-MERT (#PN=512)	MERT-PSO (#PN=512)
NIST-08 (Ch-En)	Ave.	21.32	**21.40**
WMT-10 (Ge-En)	Ave.	**21.25**	21.22

Table 4: Results for test data comparing Moses-MERT (parallel: #PN=512) and MERT-PSO (#PN=512).

confirmed that the translation qualities of MERT-PSO for unseen sentences are nearly the same level as those of Moses-MERT in terms of BLEU-score. This empirical evidence encourage us to use MERT-PSO as a replacement of Moses-MERT: MERT-PSO can provide the same quality level models as those provided by Moses-MERT with much faster runtime.

7 Conclusion

Our main goal was to provide a method to *improve the experiment turn-around time* for SMT system development. This paper proposed a novel distributed MERT framework based on particle swarm optimization (MERT-PSO). When there are abundant computational resources such as cluster PCs, our method can provide very much faster parameter tuning for SMT systems while maintaining the translation quality provided by the standard parameter tuning algorithms such as BLEU-score. Even though MERT-PSO is a stochastic approach, the experimental results showed that MERT-PSO is very robust, and in most cases, provides better results than the original Moses-MERT.

Abstract

Phrase-based statistical machine translation (PBSMT) decoders translate source sentences one phrase at a time using strong independence assumptions over the source phrases. Translation table scores are typically independent of context, language model scores depend on a few words surrounding the target phrase and distortion models do not influence directly the choice of target phrases.

In this work, we propose to condition the selection of each target word on the whole source sentence using a multilayer perceptron (MLP). Our interest in MLP lies in their hidden layer which encodes source sentences in a representation that is not directly tied to the notion of word.

We evaluated our approach on an English to French translation task. Our MLP model was able to improve BLEU scores over a standard PBSMT system.

1 Introduction

Phrase-based statistical machine translation systems translate source sentences step by step, starting with an empty sentence and ending when all source words have been translated (Koehn et al., 2003). At each step, an untranslated phrase is selected and one of its translation is appended at the end of the translation.

In this work, we are interested in the selection of a target phrase to translate a given source phrase. This selection is usually guided by three families of models. Translation models evaluate the intrinsic quality of a given phrase pair using evidences such as cooccurrence statistics between source and target words or phrases. These models always compute the same scores for a given pair of phrases, wherever it is used. A second family are language models, which evaluate the likeliness of target n-grams[1] independently from the source sentence. A third family are distortion models, whose main purpose is to evaluate the likelihood of phrase reorderings.

All these models only consider a fraction of the information available at a time. Figure 1 presents a partial translation that could be encountered by a decoder where these fractions of information are not enough to make a good decision. In this example, the decoder has already translated all but the last source word and it must decide if *plant* is translated by *usine* (a building) or *plante* (the botanic sense). As the position of the source word is fixed, the distortion model will not be of any help. If the system uses a 3-gram, only the last two words (*de cette*) of the partial hypothesis will be considered. Finally, the translation model will score the two options considering only *plant*. Therefore, the word *leaves* is never considered and the final decision largely depends on whether the training corpus is more biased toward one translation or the other.

This problem is not new and has even been addressed by the creators of CANDIDE (Berger et al., 1994), one of the first SMT system. We know of three groups of approaches for tackling it.

A first group of approaches acknowledge the bias of the system and use it at its advantage by customizing the training corpus for each source sentence. This bias can be introduced with thematic training corpora (Xu et al., 2007; Lü et al., 2007) or with custom corpora built dynamically to

[1] Sequences of n words where n usually varies between 3 and 5.

be similar to the source sentence (Hildebrand et al., 2005; Lü et al., 2007).

A second group of approaches cast the target phrase selection problem in a word sense disambiguation setting where source phrases are considered as ambiguous words and their translations as different meanings (Vickrey et al., 2005). This usually boils down to training one classifier per source phrase. These classifiers use a variety of features like surrounding source words, target words, part-of-speech or lemmas(Berger et al., 1994; Carpuat and Wu, 2007; Stroppa et al., 2007; Chan et al., 2007). Instead of training one classifier per source phrase, Gimpel and Smith (2008) use the same contextual scores for all the source phrases. The weights of those scores are then optimized with the other weights of the decoder.

Finally a third group of approaches assign a probability to every words in the target vocabulary given a source sentence (Venkatapathy and Bangalore, 2009; Mauser et al., 2009; Patry and Langlais, 2009). This predicted vocabulary can guide the decoder at translation time.

Our approach stands in this last group and we present its general idea in section 2. While previous approaches used linear or logistic regression models, we opted for the multilayer perceptron presented in section 3. Section 4 motivates this choice with a simple example. Section 5 details the algorithm to train our MLP. Experimental results, previous works and conclusion then follow in sections 6, 7 and 8 respectively.

2 Target vocabulary prediction

Standard PBSMT systems condition their translation on one source phrase at a time. In this work, we propose a new model conditioning its score on the complete source sentence. We treat the prediction of each target word as a Bernouilli trial where the presence of a word is a success and its absence a failure. The probability of a target sentence can thus be evaluated with:

$$\Pr(\mathbf{t} \mid \mathbf{s}) = \overbrace{\prod_{t \in \mathbf{t}} \Pr(t \mid \mathbf{s})}^{\text{Present}} \overbrace{\prod_{t \notin \mathcal{T} - \mathbf{t}} 1 - \Pr(t \mid \mathbf{s})}^{\text{Absent}} \quad (1)$$

where t is a target word, $\mathbf{t}$ a target sentence, $\mathcal{T}$ the target vocabulary and $\mathbf{s}$ the source sentence.

We are now left with the problem of evaluating $\Pr(t \mid \mathbf{s})$, the probability of a target word given a source sentence. Previous work have modelled this distribution with linear models like IBM Model 1 (Mauser et al., 2009):

$$\Pr_{\text{IBM1}}(t \mid \mathbf{s}) = \frac{1}{|\mathbf{s}|} \sum_{s \in \mathbf{s}} \Pr(t \mid s) \quad (2)$$

or a logistic regression model (Venkatapathy and Bangalore, 2009; Mauser et al., 2009):

$$\Pr_{lr}(t \mid \mathbf{s}) = \text{sigmoid}\left(\sum_{s \in \mathbf{s}} w_{t,s}\right) \quad (3)$$

$$\text{sigmoid}(z) = \frac{1}{1 + e^{-z}} \quad (4)$$

where $w_{t,s}$ is a weight between the tokens s and t.

Both models assign weights directly between source and target words. We opted instead for a multilayer perceptron where source and target words are connected indirectly through an hidden layer.

3 Multilayer perceptrons

Instead of assigning weights between source and target words, our MLP project the source words in an artificial representation offered by the hidden layer, and then project this artificial representation on the target vocabulary. The architecture of our MLP is as follow:

$$\vec{h} = \tanh(W\vec{s}) \quad (5)$$

$$\vec{y} = \text{tsigmoid}(V\vec{h}) \quad (6)$$

$$\text{tsigmoid}(z) = \text{sigmoid}(z - 4.6) \quad (7)$$

where V and W are weight matrices to optimize, $\vec{s}$ the source sentence encoded in an one-hot vector, $\vec{h}$ contains the values of the hidden units and $\vec{y}$ contains the prediction probabilities of all target words in $\mathcal{T}$.

We use a sigmoidal activation function on the output layer (eq. 6) because it returns values between 0 and 1 that can be interpreted as probabilities. Sigmoid returns 0.5 when its input is 0,

Source	Target
the floor of the plant	le plancher de l'usine
the stem of the plant	la tige de la plante
the leaves and stem of the flower	les feuilles et la tige de la fleur
the floors and walls of the house	les planchers et les murs de la maison

Figure 2: Training corpus for our motivating example.

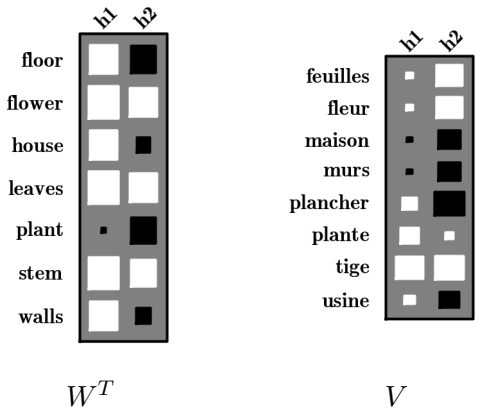

Figure 4: Weights learned for a MLP.

meaning that empty sentences encoded by vectors containing only zeros yield probabilities of 0.5 for all target word. It is clearly not what we want, so we use instead a modified sigmoid function (eq. 7) where empty sentences entail small probabilities for all target words (0.01 in our case). We could have used the same function for the hidden layer, but we opted for the hyperbolic tangent as it is known to shorten training time (LeCun et al., 1998).

More details on the training of our MLP are given in section 5.

4 Motivating Example

Conditioning the translation on the whole source sentence has already been studied. Previous approaches used linear or logistic regression models assigning a weight between every pair of source and target words. The number of connections in those models is thus quadratic in the size of the source and target vocabularies. Figure 3 shows the weight matrix of a logistic regression models trained by gradient descent on the sentences of Figure 2. The matrix is displayed in an Hinton diagram where white squares represent positive weights and black squares represent negative weights. The size of the squares are proportional to the absolute value of the weights.

Only pairs of words cooccurring in the training corpus get a weight different from zero, making the weight matrix sparse. This sparsity helps the model to scale well to larger vocabulary, but it cannot model relations in translation beyond word cooccurrences.

On the other hand, a MLP where source words are first projected into an artificial representation, and then on the target words, is not sparse. Figure 4 presents the weight matrices that were learnt from our training corpus. Any source word can thus contribute to the probability of any target word even when both words do not cooccur in the training corpus.

To show this fundamental difference between both kinds of models, we trained a logistic regression model and a MLP on the training corpus presented in Figure 2. We used these two models to predict the French words from the content words of *the leaves of the plant*. Both set of predictions are presented in Figure 5.

The regression model is unable to favour *plante* over *usine* because both words cooccur the same number of times with *plant* but do not cooccur with *leaves*. On the other hand, the MLP is able to favour *plante* because its artificial representation can separate words related to botanic (white squares in h_2 columns of Figure 4) from words related to buildings (black squares in h_2 columns of Figure 4).

Figure 6 shows the projection of four sentences on the artificial representation. Even if the four sentences share all the same words but one, the MLP is able to group sentences about botanic and

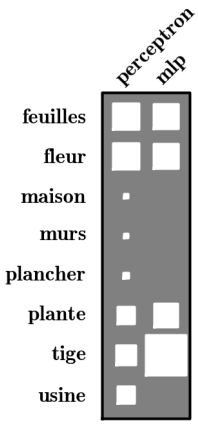

Figure 5: Predictions of the logistic regression model and the MLP for *the leaves of this plant*.

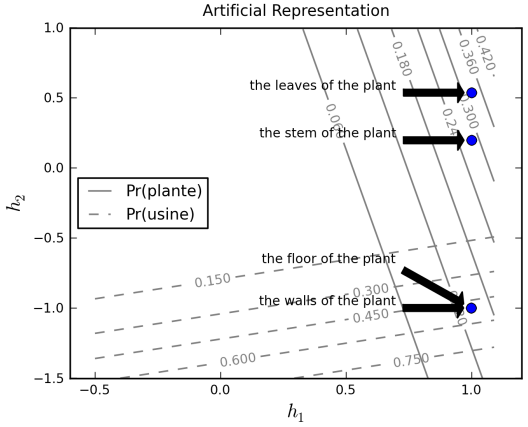

Figure 6: Projection of four sentences on the artificial representation.

buildings in different zones.

Leveraging the artificial representation offered by MLP to overcome data sparsity is not a novel idea: Bengio et al. (2003) and Schwenk (2007) trained state-of-the-art language models for speech recognition and machine translation using MLP.

5 MLP Training

To train our MLP, we must select values for V and W that will optimize the likelihood of our training data (eq. 1). We do so by minimizing the following error function using a gradient descent algorithm:

$$E(\mathbf{s}, \mathbf{t}) = \sum_{t \in \mathcal{T} - \mathbf{t}} \log\left(1 - y_{t|\mathbf{s}}\right) - \sum_{t \in \mathbf{t}} \log y_{t|\mathbf{s}} \quad (8)$$

1. Initialize V and W with $U(-0.05, 0.05)$.
2. For iterations 1 to 20:
   (a) For each batch of 100 sentences pairs:
      i. Compute the gradients of V and W with respect to eq. 8.
      ii. Test the following learning rates in orders 0.5, 0.05, 0.01 and select the first that decreases the error (eq. 9).
      iii. When such a learning rate exists, update V and W in the direction of their negative gradients multiplied by the learning rate.
3. Return V and W.

Figure 7: Gradient descent algorithm that we used to train our MLP.

where $y_{t|\mathbf{s}}$ is the probability that t appears in a translation of $\mathbf{s}$ according to our MLP. Gradient descent algorithms for MLP are already covered in many textbooks (Bishop, 1995), but because our models contain millions of weights, we had to develop some heuristics in order to keep the training time reasonable. Our modified gradient descent algorithm is presented in Figure 7.

This algorithm starts by initializing the values of V and W with a uniform between $(-0.05, 0.05)$. We varied the range of this uniform without notable variations in the results.

Computing gradients on the whole dataset before each update is too time consuming. Therefore, we computed the gradients on mini-batch of 100 sentence pairs instead. We could have used a stochastic gradient descent as well (mini-batches of size 1), but mini-batches are an opportunity to easily parallelize the training algorithm. We can encode all the source sentences of a mini-batch in a matrix where each sentence stands on a column, thus ending up with matrices-matrices multiplications instead of matrices-vectors multiplications in equations 5 and 6. This is desired as the former are faster to compute than the latter for modern linear algebra toolkit like ATLAS (Whaley and Petitet, 2005).

Once the gradients are computed, we must select a learning rate. We found this step to be critical to the success of our models. We first tried with a fixed learning rates, but the results were disappointing. We then implemented Brent line

search algorithm (Press et al., 1992, §10.2), but it was painfully slow. We finally ended up with the line search algorithm described on lines 2(a)ii and 2(a)iii. Even though this algorithm is simple, it did as well as Brent line search to optimize the log-likelihood in our experiments but it was faster.

We added a L1 regularizer to the error function during the line search to penalize big updates that bring small improvements:

$$E_{\text{L1}}(\mathbf{s},\mathbf{t}) = E(\mathbf{s},\mathbf{t}) + 0.1\left(\sum_{ki}|w_{ki}| + \sum_{jk}|v_{jk}|\right) \quad (9)$$

However, we did not used this regularized error to compute the gradients because it tends to push all weights toward zero at each update. This behaviour is not desired in our setting because only the weights associated to present source words are updated in W. Many words only appear in a couple of batches and their weights would all be pushed toward zero if we would include the regularizer when computing the gradients.

6 Experiments

We integrated our prediction models (see section 6.1) in an in house multi-stack phrase-based decoder which has performances similar to those of PHARAOH (Koehn, 2004a) when used in the same conditions.

We trained our phrase-table using TRAIN-FACTORED-MODEL.PERL, a script available with the MOSES PBSMT (Koehn et al., 2007). We optimized the weights of our log-linear model to maximize BLEU on our development set with the Nelder-Mead algorithm (Press et al., 1992) on n-best lists of 2000 sentences. To keep the decoding time reasonable, we limited the number of translations per source phrase to 30 and the number of hypotheses per stack to 50. We conducted our experiments with a trigram language model.

We are aware that our system could be enhanced in several ways. The distortion models embedded in MOSES are known to improve quality upon the translations produced by PHARAOH, and larger n-gram models, such as 5-gram models, might deliver as well slightly better results. This is left as future work. As will be discussed in section 6.5, our system performs comparably to other state-of-the-art systems tested in similar settings, and therefore, the gains we observed by integrating our prediction model into the decoder are representative.

6.1 Prediction scores

We investigated two ways (scores) to integrate our trained prediction models to the decoder.

As our MLP are trained to maximize the likelihood of the training data (eq. 1), it would be natural to add the likelihood score to the log-linear model optimized by the decoder. Likelihood is however heavy to compute because it sums over the complete target vocabulary. We followed Mauser et al. (2009) who suggested to use the *odd* score instead:

$$odd(\mathbf{t}|\mathbf{s}) = \prod_{t\in\mathbf{t}} \frac{y_{t|\mathbf{s}}}{1-y_{t|\mathbf{s}}} \quad (10)$$

An odd of x for a given word means that this word is x times more likely to be present in the translation than to be absent from it. An interesting property of this score is that it is proportional to eq. 1 once the source sentence is known.

We evaluated a second score that counts the number of target words with a probability higher than a given threshold α:

$$pred(\mathbf{t} \mid \mathbf{s}) = \left|\{t \in \mathbf{t} \mid y_{t|\mathbf{s}} > \alpha\}\right| \quad (11)$$

We selected the threshold to maximize the f-measure when the predicted words are compared against the reference translation of our development corpus, as suggested in (Patry and Langlais, 2009).

A convenient property of these scores is that they can be computed one target word at a time. Each time a new phrase is appended to a partial translation, the decoder can thus compute odd and $pred$ on this new phrase and update the partial translation score accordingly.

6.2 Models and data

We evaluated our system on a French-English translation task. We used corpora that were made available for the *Fourth Workshop on Machine Translation* (Callison-Burch et al., 2009). We trained our models on EUROPARL and the NEWS-COMMENTARY sections. We used TEST2007 as our development corpus, TEST2008 as our in-domain test corpus and NEWSTEST2009 as our out-of-domain test corpus.

We used those data to train three prediction models:

IBM1 An IBM1 model (eq. 2) trained with GIZA++ (Och and Ney, 2003).

PERCEPTRON A perceptron with a translated sigmoidal activation function:

$$\Pr_{\text{PERCEPTRON}}(t \mid \mathbf{s}) = \text{tsigmoid}(U\vec{s}) \quad (12)$$

where U is a sparse matrix linking each source word with its 10 best translations according to IBM1.[2] This model is equivalent to logistic regression (eq. 12).

MLP-64 A MLP with 64 hidden units. This number of hidden units was selected after informal experiments on the development corpus.

Both MLP-64 and PERCEPTRON were trained using the algorithm of Figure 7. In our first attempts, we observed that our prediction models caused the decoder to include many spurious stop words in the translations. We thus restricted their source and target vocabulary to content words.

MLP-64 and perceptron do not handle large vocabulary as easily as IBM1, we thus limited their vocabulary to words appearing at least 20 times in the training corpus. The English vocabulary diminished from 133 141 to 21 915 words and the French vocabulary from 143 980 to 28 095 words. This simplification allowed us to trained our MLP in less than 3 hours on an Intel Xeon quad-core processor with a clock-rate of 2.8 GHz.

6.3 In-domain

The results of the in-domain evaluation are presented in Table 1. We first observe that all models predicting a target vocabulary get better BLEU than the baseline. Those improvements are statistically significant with a confidence of 95% according to our bootstrap resampling with replacement tests (Koehn, 2004b). We also observed that MLP-64 systems are significantly better than all the other three systems.

We compared MLP-64 translation against those of our baseline and noticed that both systems agree for one sentence out of four. The other translations usually differ in one or two words having similar senses, but MLP-64 tends to select translations that are closer to the reference translations.

[2]We limited the number of links because our training algorithm implementation had a hard time without it.

System	BLEU (%)	
	odd	pred
baseline	30.06	30.06
+ IBM1	30.32	30.65
+ PERCEPTRON	30.68	30.71
+ MLP-64	**30.86**	**31.00**

Table 1: In-domain evaluation. Bold scores are significantly better than the other scores of their column.

System	BLEU (%)	
	odd	pred
baseline	19.05	19.05
+ IBM1	20.00	**19.92**
+ PERCEPTRON	19.93	**19.82**
+ MLP-64	**20.45**	**19.89**

Table 2: Out-of-domain evaluation.

6.4 Out-of-domain

The results for news translations are presented in Table 2.

We first observe a decrease of 10 BLEU point when compared against the results of the in-domain translation. This decrease asserts the challenge we face when designing a system that should translate many genres of documents. We still observe that all models predicting a target vocabulary are better than the baseline.

The best system is MLP-64 combined with *odd* score. The translations of the system are significantly better than the translations of all the other systems according to BLEU. We observe modest gains for *pred* scores where IBM1 is the best system, but there are no significant differences among all the models predicting a target vocabulary.

6.5 Comparison to state-of-the-art

The best SMT systems of the *Fourth Workshop on Machine Translation* (Callison-Burch et al., 2009) for the English-French translation task were evaluated at 28 BLEU points comparatively to our best system which got 20.45. This is a huge difference, but news translation was the main task of this workshop and participant used much more data than we used in our experiments. It is thus not fair to compare our out-of-domains results against those ones.

We can however compare our results to those

of the *Third Workshop on Machine Translation* (Callison-Burch et al., 2008) where a news corpus was translated by systems tuned to translate parliament proceedings. The best systems for in-domain English-French translations obtained 32 BLEU points and the best systems for out-of-domain translations 20 BLEU points. Our results are thus competitive with those of state-of-the-art systems in a comparable situation.

7 Previous Works

To our knowledge, IBM1 is the first target vocabulary prediction models that was used in SMT. It was one of the best model among many others in a rescoring module for a PBSMT (Och et al., 2004).

The term *global lexical selection* was coined by Bangalore et al. (2007) who pushed the idea of target vocabulary prediction further than us. They devised a system that first predicted a set of target words and then reordered those words to produce a final translation. This system is particularly suited for languages that are not sensitive to word reordering like Hindi (Venkatapathy and Bangalore, 2009). Their system use a logistic regression model to predict the target words from the set of n-grams in the source sentence. Our $pred$ score is a softer version of this idea. It encourages the decoder to select the predicted words without forcing it and it allows the reordering to take place in the PBSMT.

Mauser et al. (2009) integrated a logistic regression model predicting target words from all the source words in a PBSMT. Using this model, they gained one BLEU point over their baseline on a Chinese to English translation task.

IBM1 is a linear regression model over probability of target words given each source words individually. Mauser et al. (2009) extended this model to condition it on source word cooccurrences (word and trigger pairs). This models improved BLEU score of one point over their baseline system. Note that our MLP consider all source words jointly, word cooccurrences are thus automatically modelled.

Patry and Langlais (2009) were the first to use a MLP to predict target words, but they did not tested it in a SMT system. They got their best results when they added a bilingual lexicon to their MLP. We tested this extension in our system but it did not improve over MLP-64.

8 Conclusion

Phrase-based statistical machine translation systems condition their scores on few source words at a time to produce their translations. While previous works used linear or logistic regression models to capture broader dependencies on the source sentence, we presented, motivated and evaluated the use of a multilayer perceptron for such a task. We opted for MLP because of their hidden units which offer an artificial representation of source sentences.

We compared three different models for target words prediction: IBM1, PERCEPTRON and MLP-64. In all our experiments, we observed a significant improvement for all these models over the baseline system, but the best of our contextual model was MLP-64 with improvements of 0.94 and 1.4 BLEU points on in-domain and out-of-domain translations respectively. These results are encouraging, especially since several choices have been made that we could revisit, thus leaving an open space for further improvements.

In this study, we controlled the size of the source and target vocabularies by selecting only words appearing at least 20 times. Since translation systems are usually good with frequent words, we would like to select our vocabularies in order to maximize the gains of the translation system.

We selected a L1 regularizer because it is known to be efficient and simple to implement. We would however like to devise another regularizer that would encourage the MLP to group together artificial representations of source sentences having similar translations.

Also, we would like to validate our model on other language pairs and other corpora and we plan to investigate the influence of the corpus size and the number of hidden units on the translation quality.

An important limitation of our MLP is their ignorance of sentence structures. One partial solution to this problem is to model source n-grams instead of source words like Venkatapathy and Bangalore (2009) suggested. This approach has its limitation because it only captures local structures and cannot consider grammatical or semantic relations. We are thus thinking about alternative ways to encode the source sentences and how these new representations could be included to our model.

Abstract

Cross-adaptation (CA) based methods of machine translation (MT) system combination work by adapting the decoding step of a baseline system using information from alternate systems. Generally, the required information is very deep, such as a full decoding forest. In this paper, we describe a method of cross-adaptation based system combination which only requires the final output from each alternate system. This is achieved by adding a discriminatively weighted n-gram confidence feature to our decoder. In order to optimize the confidence weight of each system, we present a novel procedure called *non-linear Expected-BLEU optimization* that can be used to optimize arbitrary non-linear parameters for any decoding feature. We also describe a method for explicitly creating an adapted system that is *dissimilar* from each particular input system, which we have found to be useful in combination. Although our new method does not outperform a state-of-the-art confusion network (CN) based combination system on its own, we obtain statistically significant gains of 0.21-0.45 BLEU when the CA output is used as an additional system in CN combination.

1 Introduction

In general terms, *system combination* is the task of using multiple machine translation (MT) systems to produce an output that is better than any input system could produce by itself. The method for doing this is largely shaped by the information available: some require an actual MT decoder for each system (Li et al., 2009), some require a full forest of derivations (DeNero et al., 2010), and some only require the final output translations from each system (Rosti et al., 2009). Our research was done as part of a project where multiple sites develop their decoding systems independently, and then these outputs are combined together to produce a "team" output. Because these systems widely differ in structure, the only information we have available for system combination is an n-best list of hypotheses. No source-side correspondences are available, and some systems are only capable of producing a 1-best list.

Additionally, in this procedure, we assume that a strong baseline decoding system is available for each condition where system combination is performed. The general principle behind this procedure is to run a baseline decoding system with the output *adapted* towards the output of the other systems. In this case, we perform the adaptation by effectively increasing the probability of language model n-grams that are seen in other systems' outputs, as well as including translation rules extracted from the other systems' outputs. The relative weight of each system is estimated discriminatively using a novel extension to the Expected-BLEU optimization procedure which allows for the tuning of non-linear feature weights.

Currently, we use a state-of-the-art confusion network based procedure for system combination

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 667–675,
Chiang Mai, Thailand, November 8 – 13, 2011.

based on (Rosti et al., 2009). Although our new method *does* produce a significant gain over the best single system, it does not perform as well as our confusion network decoding on any condition that we tried. However, this new procedure was not designed to replace our existing method, but rather to complement it. When we used the output of the adaptation-based combination as an additional system in our standard confusion network decoding, we obtained a moderate gain in Arabic web, and a smaller gain on Arabic newswire.

2 Related Work

Existing research in MT system combination can generally be divided into two major approaches: confusion networks and cross-adaptation.[1] Confusion network based methods align the various input hypotheses against one another to form the confusion network, and then generate the most likely path through this network to produce a combined 1-best (Bangalore et al., 2001). However, as mentioned previously, we already have state-of-the-art confusion network system in place, which is based on (Rosti et al., 2007; Rosti et al., 2009). It is known that combining the outputs of multiple system combination procedures can produce further gains. Therefore, our goal was to design a *complementary* combination system which could be used in conjunction with our current system to produce better results than either could independently.

In automated speech recognition (ASR), generalized forms of adaptation have widely been used for a number of years (Rozzi and Stern, 1991) and more recently, cross-adaptation has been used as a method of ASR system combination (Stüker et al., 2006; Gales et al., 2007). In machine translation, a number of cross-adaptation based combination methods have been developed under a multitude of names. However, nearly all of these methods require rich information about each system which is not available for our task. Collaborative decoding (Li et al., 2009) requires that each system's decoder be run multiple times in an iterative fashion. DeNero's model combination (DeNero et al., 2010) requires a full decoding forest from each system. Joint optimization (He and Toutanova, 2009) and hybrid decoding (Cui et al., 2010) require that the input models[2] for each system be available to the combination decoder.

Crego et al. (2010) describes a method for LM-based combination which is most similar to the work presented in this paper, but their method does not discriminatively estimate weights for an arbitrary number of input systems.[3] In fact, they only present results where their main system is adapted using the output of a *single* other systems. By contrast, we present results where our main system is adapted by 7-14 other systems, and the weight for each of these is estimated discriminatively. As far as we know, there has been no previous work in developing a method of cross-adaptation which (a) requires only the final output from each system, and (b) discriminatively estimates the adaptation weight for each system. The latter is highly desirable when combining a large number of systems of varying quality, as with our task.

In order to discriminatively estimate the adaptation weight of each input system, we use a highly-scalable MT-specific optimization procedure called *Expected-BLEU* (Devlin, 2009; Rosti et al., 2010). The Expected-BLEU procedure is very similar to the Co-BLEU metric (Pauls et al., 2009), and is more distantly related to earlier work such as Tromble's linear approximation of BLEU (Tromble et al., 2008) and Smith's minimum risk annealing (Smith and Eisner, 2006). In this paper, we describe a novel extension to Expected-BLEU that allows for the optimization of arbitrary non-linear feature parameters. This allows for any feature parameters that are differentiable with respect to the feature score to be optimized alongside the normal log-linear decoding weights during the standard optimization procedure.

3 Description of MT System

Our baseline machine translation system, which is also used to perform the cross-adaptation, is a state-of-the-art hierarchical decoder based on (Shen et al., 2008) and (Chiang, 2007). Bottom-up chart parsing is performed to produce a shared forest of derivations, and possible path through the

[1] There is a third approach, known as "hypothesis selection," which simply selects the best input hypotheses as the "combined" output, based on some features (Hildebrand and Vogel, 2008). However, there has been comparatively little research on this method due to its simplicity and lack of room for improvement.

[2] Such as the set of translation rules and the language model.

[3] The *adaptation weight* represents how much each system should influence the adaptation process.

forest defines one hypothesis h.[4] The decoder uses a log-linear translation model, so the score of hypothesis h is defined as:

$$S_h(\vec{w}) = \sum_{i=1}^{m} w_i \sum_{r \in R(h)} F_{ri} \quad (1)$$

where $R(h)$ is the set of translation rules that make up hypothesis h, m is the number of features, F_{ri} is the score of the i^{th} feature in rule r, and w_i is the weight of feature i. This weight vector is optimized discriminatively to maximize BLEU score on a tuning set, using the Expected-BLEU optimization procedure.

Our decoder uses all of the standard statistical MT features, such as:

- $P(T|S)$ = forward rule translation
- $P(S|T)$ = backward rule translation
- $LS(T|S)$ = lexical smoothing
- $P(q_j|q_{j-1}, ...)$ = language model

Additionally, we use approximately 50,000 sparse, binary-valued features which model specific events such as "Is the bigram 'united states' seen in the target side of the translation rule?" These features do cause some amount of overfitting on the tuning set, but we have not found this to be harmful to the test sets. However, this also causes a certain amount of variability on the tune set results, so minor variations in BLEU score on the tuning set from condition to condition are to be expected.

The cross adaptation models described below are used as standard log-linear feature scores, and the weights are optimized jointly with the normal decoding features.

4 Discriminative Model Adaptation

In this section, we describe how the cross-adaptation is actually implemented in our system. We perform the adaptation by defining additional decoding features which affect both the language model and the translation model, in order to make the MT output appear more like the output of the other systems.

4.1 Discriminative Language Model Adaptation

We perform language model adaptation by effectively increasing the language model probability of n-grams that are seen in the other systems' outputs. Since we use a 3-gram decoder, we adapt the probability of all 1-grams, 2-grams, and 3-grams.

In the past, Snover et al. (2008) performed language model adaptation using simple linear interpolation:

$$P(q_j|q_{j-1}, ...) = \sum_{i=1}^{K} v_i P_i(q_j|q_{j-1}, ...) \quad (2)$$

where K is the number of models, $q = (q_j, q_{j-1}, ...)$ is the n-gram in question, and v_i is the weight for model i, constrained so that $\sum_i v_i = 1$. This formula replaces the standard language model probability in the log-linear decoding model. When this feature was used by Snover, it combined the standard language model with a test-sentence-specific language model that was trained on several hundred documents. However, in the case of system combination, we are adapting towards a much smaller amount of data, so $P(q_j|q_{j-1}, ..., q_{j-n+1})$ will not be well estimated. Therefore, we use a modified formula which uses a binary function $\delta(q)$ to indicate the presence or absence of the n-gram q. This formula is used as an additional feature in the log-linear decoding model:[5]

$$F(q, \vec{v}) = \log(\epsilon + \frac{\sum_{i=1}^{K} e^{v_i} G_i(q)}{\epsilon + \sum_{i=1}^{K} e^{v_i}}) \quad (3)$$

$$G_i(q) = \frac{\sum_{j=1}^{H_i} b_{ij} \delta_{ij}(q)}{\sum_{j=1}^{H_i} b_{ij}} \quad (4)$$

where K is the number of systems, ϵ is a small positive value fixed at 10^{-8}, and v_i is the discriminatively estimated weight for system i.[6] If an n-gram is seen in exactly *zero* system outputs, it does *not* receive a score of $\log(\epsilon)$, but instead receives a score of $\log(1)$ and triggers an additional binary feature. This additional feature acts as a discriminative backoff log-probability for unseen n-grams, and generally optimizes to a large negative value in the range of -10 to -15.

The function $G_i(q)$ represents the "count" of n-gram q in system i's n-best list. In it, H_i is the number of hypotheses in system i, $\delta_{ij}(q)$ is a binary "occurrence function" that returns 1 if n-gram q is seen in hypothesis ij, and b_{ij} is a

[4] In this case, *hypothesis* refers to a specific path through the shared forest, rather than a specific output string.

[5] Therefore, the standard language model probability remains unchanged.

[6] ϵ is used to prevent $\log()$ underflow or divide-by-zero errors, since v_i is unbounded.

hypothesis-specific positive weighting which assigns mass to each hypothesis as a function of its rank. Obviously, if q is seen in every hypothesis of system i, $G_i(q) = 1$. Note that $\delta_{ij}(q)$ does not return the actual *count* of q, because we never want $G_i(q)$ or $F(q, v)$ to return a value over 1 (or $\log(1)$).

Theoretically, b_{ij} could be estimated discriminatively, but for simplicity we use the following formula which assigns mass to each hypothesis based on its rank in the n-best list:

$$b_{ij} = H_i - j + 1 \quad (5)$$

As an example, if system i has a 5-best output, and n-gram q is seen in hypotheses 1 and 4, then $G_i(q) = \frac{5+2}{5+4+3+2+1} = 0.467$.

Equation 3 can be thought of as the log-confidence that n-gram q is consistent with the other systems' outputs. Note that $F(q, \vec{v})$ is continuous and differentiable with respect to the weights $\vec{v}$, and $F(q, \vec{v})$ returns a value in the range $[\log(\epsilon), 0]$ for all values of $\vec{v}$. These properties make it possible to discriminatively estimate $\vec{v}$ within our standard optimization framework, which is discussed in Section 5.

4.2 Discriminative Translation Model Adaptation

We extract adapted translation rules using the method described in (Snover et al., 2008). Essentially, for each source phrase s, we consider every target phrase t from each of the input system hypotheses as a possible translation of s.[7] We limit the maximum length of s and t to 3 and 5, respectively. Clearly, this produces many extraneous rules. We prune these rules only keeping the top 20 most likely target translations of each s, sorted by the "noisy-or" lexical smoothing score between s and t (Zens and Ney, 2004). This lexical smoothing score is used as an additional decoding feature.

The formula for the discriminative adapted rule confidence is exactly the same as Equation 3:

$$H(r, \vec{z}) = \log(\epsilon + \frac{\sum_{i=1}^{K} e^{z_i} G_i(r)}{\epsilon + \sum_{i=1}^{K} e^{z_i}}) \quad (6)$$

$$G_i(r) = \frac{\sum_{j=1}^{H_i} b_{ij} \delta_{ij}(r)}{\sum_{j=1}^{H_i} b_{ij}} \quad (7)$$

where r is the adapted rule and $\vec{z}$ are the discriminative system weights. The "occurrence function" $\delta_{ij}(r)$ function returns 1 when the rule r's target phrase $\vec{t}$ is seen *anywhere* in hypothesis ij.

[7] This adaptation performed independently for each test sentence.

5 Parameter Optimization

In this section, we describe a novel procedure for discriminatively optimizing the non-linear parameters $\vec{v}$ and $\vec{z}$ used in Equations 3 and 6. These parameters are jointly optimized alongside the standard log-linear decoding weights to directly maximize BLEU score on a tuning set. In order to perform this optimization, we use a modified version of *maximum BLEU* tuning, called *Expected-BLEU* (Rosti et al., 2010). For the benefit of the reader, we will first give a brief overview of maximum BLEU and Expected-BLEU optimization. Afterwards, we will describe a novel extension to Expected-BLEU which allows for the optimization of non-linear feature parameters.

5.1 Expected-BLEU Optimization

Standard maximum BLEU optimization attempts to find the set of weights $\vec{w}$ that maximizes the 1-best BLEU score over an n-best list, with BLEU (Papineni et al., 2002) defined as:

$$BLEU(\vec{w}) = \left(\prod_{m=1}^{4} \frac{\sum_{i=1}^{N} c_{ib_i(\vec{w})}^{(m)}}{\sum_{i=1}^{N} t_{ib_i(\vec{w})}^{(m)}} \right)^{1/4} \cdot \theta \left(1 - \frac{\sum_i r_{ib_i(\vec{w})}}{\sum_{i=1}^{N} h_{ib_i(\vec{w})}} \right) \quad (8)$$

$$b_i(\vec{w}) = \text{argmax}_{h \in H_i}(S_h(\vec{w})) \quad (9)$$

where $\theta(x) = \min(1.0, e^x)$, N is the number of test sentences, b_i is the 1-best hypothesis of the i^{th} sentence selected using weights $\vec{w}$, and $\{c_{b_i}^{(1)}, c_{b_i}^{(2)}, ...h_{b_i}\}$ are the 10 pre-computed BLEU statistics for hypothesis b_i.[8] Crucially, the selection of 1-best hypotheses with respect to $\vec{w}$ is *discrete*, and therefore the max BLEU function is non-differentiable. Because of this, a line search algorithm such as Powell's method (Powell, 1964) must be used to optimize the weights, which does not perform well when more than few dozen weights are optimized simultaneously.

Expected-BLEU optimization seeks to approximate max BLEU using a continuous objective function. The advantage of this is that it quickly

[8] $c^{(m)}$ is the number of matching m-grams, $t^{(m)}$ is the number of total hypothesis m-grams, r is the reference length, h is the hypothesis length, and $\theta(x)$ is a "brevity penalty" which penalizes short hypotheses.

converges even when tens of thousands of weights are estimated simultaneously. Therefore, instead of discretely selecting a 1-best hypothesis from each of the m test sentences, the BLEU statistics are summed over *every* hypothesis weighted by its corresponding posterior probability. Note that we compute the expectation of each of the 10 BLEU statistics *independently*, so the Expected-BLEU formula is not technically equivalent to the "expected value of BLEU." However, in practice this has not been an issue.

The posterior probability for hypothesis ij is simply the normalized decoding probability:

$$p_{ij}(\vec{w}) = \frac{e^{\gamma S_{ij}(\vec{w})}}{\sum_{k=1}^{n} e^{\gamma S_{ik}(\vec{w})}} \quad (10)$$

The free parameter γ controls the shape of the distribution, with a higher γ shifting more mass towards the 1-best hypothesis.

As a final step, we replace Equation 8's "brevity penalty" $\theta(x) = \min(1, e^x)$ with a differentiable approximate over the range $0.9 \leq x \leq 1.1$. The function is defined as:

$$\phi(x) = \frac{e^x - 1}{e^{1000x} + 1} + 1 \quad (11)$$

The final Expected-BLEU objective function is then:

$$ExpBLEU(\vec{w}) = \left(\prod_{m=1}^{4} \frac{\sum_i \sum_j p_{ij} c_{ij}^{(m)}}{\sum_i \sum_j p_{ij} t_{ij}^{(m)}} \right)^{1/4} \cdot \phi\left(1 - \frac{\sum_i \sum_j p_{ij} r_{ij}}{\sum_i \sum_j p_{ij} h_{ij}}\right) \quad (12)$$

where p_{ij} is short for $p_{ij}(\vec{w})$, as defined in Equation 10. The values $\{c_{ij}^{(m)}, ...\}$ are the same precomputed BLEU statistics as in Equation 8.

The differentiation of this function with respect to $\vec{w}$ can be performed in a fairly small number of steps using basic calculus, the details of which are provided in (Devlin, 2009). The functions $ExpBLEU(\vec{w})$ and $\frac{dExpBLEU}{dw}$ are used with LBFGS (Liu and Nocedal, 1989) to perform n-best based parameter optimization. We use a standard iterative optimization procedure: (1) Decode tuning set with initial weights $\vec{w}$ and generate n-best list, (2) Optimize $\vec{w}$ on n-best list, (3) Repeat (1) and (2) until convergence, (4) Decode validation set.

In order to prevent over-fitting, we add a standard $L2$-norm regularization term to our objective function:

$$Obj(\vec{w}) = ExpBLEU(\vec{w}) - \alpha||\vec{w} - \vec{w}'||^2 \quad (13)$$

where $\vec{w}'$ is the initial weight vector at the current iteration of optimization, and α is the regularization term, fixed at 10^{-5}.

5.2 Non-Linear Feature Optimization

The previous section describes the optimization procedure for standard linear decoding weights, but it can also be extended to optimize non-linear weights, as in Equation 3 and Equation 6. We simply modify Equation 1 so that F_i is a function of parameters $\vec{v}_i$:

$$S_h(\vec{w}, \vec{v}) = \sum_{i=1}^{m} w_i \sum_{r \in R_h} F_{ri}(\vec{v}_i) \quad (14)$$

For each non-linear feature type, we must implement $\frac{dF_{ri}}{d\vec{v}_i}$. Then, we can "generically" compute $\frac{dExpBLEU}{dF_{ri}}$ inside of the optimizer and apply the chain rule to compute:

$$\frac{dExpBLEU}{d\vec{v}_i} = \sum_h \sum_{r \in R_h} \frac{dExpBLEU}{dF_{ri}} \frac{dF_{ri}}{d\vec{v}_i} \quad (15)$$

where R_h is the set of rules associated with hypothesis h. This information is usually not available to the optimizer, so this functionality must be added.

The non-linear weights $\vec{v}$ are jointly optimized with the standard decoding weights $\vec{w}$ using the function $ExpBLEU(\vec{w}, \vec{v})$.

5.3 Dissimilarity Optimization

Because the ultimate goal of the cross-adaptation combination is to use it as an additional system in confusion network decoding, it would be beneficial if we could ensure that it contains complementary information. In the past, we have seen that that system combination performs best when the input systems have similar performance but are very different from one another. We model this difference or *dissimilarity* between two sentences using the TER metric, which measures the normalized number of "edits" required to transform the one sentence into another (Snover et al., 2006). Normally, TER is computed on an MT hypothesis against its reference translation. In this case, we instead measured the TER of the cross-adaptation

output against the external input system hypotheses.[9]

We attempted to explicitly increase TER dissimilarity by discriminatively optimizing against the input system hypotheses.[10] In other words, we used the input hypotheses as reference translation and optimized in the *opposite* direction that we normally would. We added this as a linear term in our existing Expected-BLEU objective function. Note that Expected-BLEU is computed against the reference translations and Expected TER is computed against the external input systems:

$$\begin{aligned} Obj(\vec{w},\vec{v}) &= ExpBLEU_{Ref}(\vec{w},\vec{v}) \\ &+0.1{\cdot}ExpTER_{ExSys}(\vec{w},\vec{v}) \\ &-\alpha||\vec{w}-\vec{w}'||^2 \end{aligned} \quad (16)$$

The dissimilarity term is weighted at 0.1 in order to prevent the BLEU score from degrading by a significant amount. Note that it is not contradictory to adapt *towards* the input hypotheses while simultaneously optimizing *against* those same hypotheses, because the adaptation is done at the n-gram level and TER is computed on the sentence level. We want to use words and phrases from the input systems, but we don't want the final sentence to be too similar to any one particular input hypothesis.

6 Experiments

The input to our system combination procedure consists of output from 14 different machine translation systems developed independently at 5 different sites. Of these, 7 were "internal" systems developed at our site, while 7 were "external" systems developed at the 4 outside sites. The 7 internal systems all used the same hierarchical decoder and feature set described in Section 3, but varied by source tokenization and method of word alignment. The 7 external systems include a phrasal system, two hierarchical systems, a syntax system, a tree-to-string system, a string-to-tree system, and a hand-crafted rule based system. We will present results on Arabic-to-English web and newswire.

Our parallel training data and development sets consist of publicly available LDC/NIST data, as well as data specific to DARPA's Global Autonomous Language Exploitation (GALE) project. The publicly available training data consists of 3.3 million words of newswire/treebank LDC-released data as well as 118 million words of LDC-released UN data. The GALE-only training data consists of 46 million words of LDC-released data plus 30 million words released by Sakhr Software. The monolingual LM training consists of 4 billion words from the GigaWord corpus and 4 billion words from various other sources such as Google News and New York Times. We use a 3-gram LM for decoding and 5-gram LM for rescoring.

Our development sets were constructed using the NIST MT04, MT05, MT06, and MT08 data sets, as well as the GALE Phase1-Phase4 development/evaluation sets. We use one tuning set, referred to as "Tune," to optimize both the cross-adaptation and confusion network based systems. Our validation set is referred to as "Test." [11]

Our cross-adaptation system uses the features described in Section 4 to actually perform the adaptation, but is otherwise identical to our baseline system, referred to as "Best Single System" or "Internal Best."

Because we use a large number of discriminative features in our baseline MT system, there is a moderate-to-significant over-fitting effect when optimizing on any new set. However, in the past we have found that even a large amount of over-fitting (e.g., 3-4 BLEU points) on the tuning set does *not* have a negative affect on the test set results. Here, we see less than 1.0 BLEU over-fitting during cross-adaptation and less than 0.5 BLEU on the final combination, so we did not take any steps to mitigate it. The proper solution would likely be to use separate sets to optimize the cross-adaptation and the confusion network. The descriptions of the "Tune" and "Test" sets are shown in Table 1.

	Tune		*Test*	
	# sents	# refs	# sents	# refs
ara nw	5456	2.1	1986	1.4
ara web	5454	2.3	2276	2.4

Table 1: "Number of sentences" and "average number of references per sentence" for the development sets.

[9] The "external" input systems are those that were developed at outside sites. Since our internal system is used to perform the cross-adaptation, we do not perform dissimilarity optimization against its baseline output.

[10] Alternately, we could optimize against the confusion network baseline output, but we found that this did not perform well.

[11] The input systems were optimized on a third set, which is not used here.

Since it is not practical to present the scores on all input systems, Table 2 shows BLEU scores for the best internal system as well as the top three external systems. In both cases, the best internal system outperforms all of the external systems. It is interesting to note that the best internal system outperforms the top two external systems by a greater margin on Arabic web than Arabic newswire.

	ara nw		**ara web**	
	Tune	*Test*	*Tune*	*Test*
	BLEU	BLEU	BLEU	BLEU
Internal Best	48.48	45.00	39.77	41.44
External 1st	47.74	44.35	38.27	40.20
External 2nd	47.71	44.20	37.49	39.01
External 3rd	44.84	42.29	36.77	38.54

Table 2: Comparison of best internal system vs. top three external systems. Here, "Tune" is a valid test set, since none of the *input* systems were optimized on it.

One final detail to note is that on Arabic web we performed adaptation using all 14 input systems, while on Arabic newswire we only used the 7 external systems. The reason is that on newswire we encountered an optimization issue where the weights for the internal systems would receive a large value during the first few iterations of tuning, which would cause the optimization to converge at a sub-optimal local maximum. However, even when we manually finessed the optimization, we did not see a gain on cross-adaptation from using all 14 systems on newswire. Because the weights are estimated discriminatively, it should theoretically never be harmful to include additional systems,[12] so we plan to experiment with different types of regularization to solve this optimization issue. On Arabic web, this issue did not occur, so we were able to use all 14 systems without any "manual finessing."

6.1 Cross-Adaptation Results

Tables 3 and 4 show the effect of using the cross-adaptation features from Equations 3 and 6. We use separate weights for each n-gram order as well as the adapted rules, which results in $4K$ total weights, where K is the number of systems.[13]

On Arabic web, our optimized cross-adaptation system (*CA*) gains 3.1 BLEU over our best single system (*BSS*), and gets within 0.4 BLEU of our confusion network baseline (*CN*). When the cross-adaptation output is used as an additional system during confusion network decoding, we see a gain of 0.37 BLEU (*CN w/ CA*). Using the dissimilarity cross-adaptation as a second additional system helps slightly more, bringing the total gain to 0.45 BLEU (*CN w/ CA+DCA*). In both cases, the gain is statistically significant.

On Arabic newswire, the optimized cross-adaptation system gains 2.3 BLEU over the best single system, but performs 0.8 BLEU worse than our confusion network baseline. Using the cross-adaptation output as an additional system yields no gain, while using the dissimilarity optimized cross-adaptation output as an additional system yields a minor gain of 0.2 BLEU. However, the gain on BLEU is statistically significant.

We also provide the results on two additional test conditions for Arabic web. The condition *BSS*

	ara web			
	Tune		*Test*	
	BLEU	TER	BLEU	TER
BSS	39.77	47.81	41.44	46.69
BSS w/ "Tune"	42.41	46.39	41.69	46.61
CA, No Opt	43.32	45.55	43.95	44.75
CA	43.52	45.27	44.58	44.49
DCA	41.88	46.44	43.15	45.48
CN	43.10	45.52	45.00	44.56
CN w/ CA	43.70	45.20	45.37*	44.46
CN w/ DCA	43.47	45.27	45.12	44.27*
CN w/ CA+DCA	43.76	45.23	45.45*	44.36*

Table 3: Combination results on Arabic web using 14 input system. * indicates that the system is significantly better than *CN* using a 95% confidence interval, as defined in (Koehn, 2004). Significance is only shown on the Test set. **BSS** = Best single system. **BSS w/ "Tune"** = Tuning on "Tune" using only standard features, instead of the normal decoding tuning set. **CN** = Confusion network baseline. **CA, No Opt** = Cross-adaptation, fixing all of the non-linear system weight to $a_i = 0$, but the standard linear feature weights optimized as normal. **CA** = Cross-adaptation, allowing the non-linear system weights to optimize. **CN w/ CA** = Using the output of *CA* as an additional input in *CN*. **DCA** = Cross adaptation with dissimilarity optimization. **CN w/ DCA** = Using the output of *DCA* as an additional input in *CN*. **CN w/ CA+DCA** = Using the output of both *CA* and *DCA* as an additional input in *CN*.

[12] It should never harm the results on the tuning set, although it could be harmful on the test set.

[13] We estimate a separate set of weights for (1) unigrams, (2) bigrams, (3) trigrams, and (4) adapted rules.

	ara nw			
	Tune		*Test*	
	BLEU	TER	BLEU	TER
BSS	48.48	38.59	45.00	38.51
CA	51.54	36.37	47.30	36.72
DCA	49.94	37.33	46.27	37.35
CN	51.67	35.87	48.07	35.87
CN w/ CA	52.03	35.91	48.05	35.87
CN w/ DCA	51.81	35.95	48.27*	35.77
CN w/ CA+DCA	52.06	35.84	48.28*	35.71

Table 4: Combination results on Arabic newswire using 7 input systems. Conditions have same meaning as in Table 3.

w/ "Tune" shows the results of optimizing on the system combination tuning set, as opposed to the standard tuning set which all of the input systems were optimized on. We can see that the gain on "Test" is very small, meaning that this difference was not an issue. For the condition *CA, No Opt* we set all of the adaptation weights to a fixed value of $a_i = 0$, so all systems receive an equal "vote" in the adaptation features.[14] As expected, this has a detrimental effect on the results, losing 0.6 BLEU compared to *CA*.

6.2 Dissimilarity Optimization Results

The previous tables demonstrate that although dissimilarity optimization performs worse than standard cross-adaptation, it is still beneficial to use it as an additional system in the confusion network decoding. Table 5 shows how dissimilar the *DCA* output is from the input systems compared to *CA*. The *DisTER* score is computed on the MT output of each condition against the 7 external input systems. We see that on newswire the *DCA* output is 4.5 TER points more dissimilar than the *CA* output, while on web it is 3.1 TER more dissimilar. At the same time, both *DCA* conditions gains 1.0-1.5 BLEU points over the best single system.

	ara nw		ara web	
	Test		*Test*	
	BLEU	DisTER	BLEU	DisTER
BSS	45.00	23.16	41.44	29.65
CA	47.30	15.63	44.58	22.38
DCA	46.27	20.17	43.15	25.50

Table 5: **BSS** = Best single system. **CA** = Cross-adaptation. **DCA** = Cross-adaptation with dissimilarity optimization. **BLEU** is computed against the reference translations, while **DisTER** is computed against the input systems.

[14] Recall that the true weight is e^{a_i}

7 Conclusions and Future Work

In this paper, we presented a novel method of cross-adaptation based system combination which obtains statistically significant BLEU gains over best single system. The advantages of this method are that it can be implemented using only simple decoding features, and that it requires just an n-best list from the input systems, as opposed to alternate cross-adaptation methods that require deeper information. Although this new method does not perform as well as our existing confusion network based combination, we showed that it is beneficial when used as additional system in the confusion network decoding.

We also showed that it is possible to explicitly create a system with complementary information by using *dissimilarity optimization*, where the TER score between the cross adaptation output and the input systems is used as part of the optimization objective function. Although this method of optimization degrades the BLEU score compared to standard cross-adaptation, we showed that it is useful to use this output as a second additional system during confusion network decoding.

In the future, we plan to use the dissimilarity optimization procedure to produce multiple input systems which are explicitly optimized to be different from one another. We already know that it is beneficial to combine multiple systems that use the same decoder/feature set but vary by tokenization/alignment/etc. If we can discriminatively optimize these systems so that they have higher pair wise TER scores without harming their BLEU scores, it may be possible to obtain a larger gain during combination.

Additionally, we presented a highly-scalable, robust method for optimizing arbitrary non-linear feature parameters alongside the standard log-linear decoding weights. We have already used this method to explore many types of new features, such as using a neural net based language model and discriminatively optimizing sentence-level confidence weights on the training data. We plan to further refine our optimization procedure to use additional regularization and normalization, so that very high-dimensional non-linear feature sets can be used without any issues.

Word Sense Disambiguation by Combining Labeled Data Expansion and Semi-Supervised Learning Method

fujino.akinori@lab.ntt.co.jp

Abstract

Lack of training data is one of the severest problems facing word sense disambiguation (WSD). To overcome the problem, we propose a method that combines automatic labeled data expansion (Step-1) and semi-supervised learning (Step-2). The Step-1 and 2 methods are both effective, but their combination has a synergistic effect.

In this paper, in Step-1, we automatically extract reliable labeled data from raw corpora using dictionary example sentences, even for infrequent and unseen senses (which do not appear in training data, but appear in a dictionary). Then, in Step-2, we apply a semi-supervised classifier and obtain a improvement using easy-to-get unlabeled data. In this step, we also show that we can guess even unseen senses.

We target a SemEval-2010 Japanese lexical sample WSD task. Both the Step-1 and Step-2 methods performed better than the best published result (76.4 %). Furthermore, the combined method achieved much higher accuracy (84.2 %).

1 Introduction

Many words have multiple meanings that change depending on the context. Recently, it has been confirmed that word sense disambiguation (WSD) improves certain NLP applications such as parse selection (Fujita et al., 2007) or Machine Translation (Chan et al., 2007). In international WSD competitions such as SemEval, many tasks have been proposed, which shows that WSD is a problem that attracts a lot of interest. In this paper, we experiment on the Japanese WSD task from the most recent competition, SemEval-2010 (Okumura et al., 2010).

Various methods have been proposed for WSD (Navigli, 2009). Unsupervised approaches such as clustering based methods (Pedersen, 2006) and extended Lesk (Lesk, 1986) have been shown to do well (Baldwin et al., 2010), although in general, they are beaten by supervised approaches if training data are provided (Tanaka et al., 2007). With the Japanese WSD tasks at SENSEVAL-2 and SemEval-2010, supervised approaches achieved the best results (Murata et al., 2003; Okumura et al., 2010). However, the lack of training data is a severe problem with non-English languages. Also in the Japanese WSD task, there are only 50 given training instances for each target word and this is insufficient.

Two main types of methods have been proposed to compensate for a lack of training data. One type is the semi-supervised learning method (Niu et al., 2005; Pham et al., 2005) or bootstrapping (Mihalcea, 2002, 2004; Yarowsky, 1995). These methods use labeled data and unlabeled data, and this is beneficial because unlabeled training data is easy to obtain. These methods are effective and have high applicability, but unfortunately, there is one problem in that this method cannot obtain training data for senses in the lexicon that do not appear in the training data (we call this an **unseen sense**).

Another type of method designed to make up for a lack of training data, is automatic labeled data expansion (Mihalcea and Moldovan, 1999; Agirre and Martinez, 2000) . They proposed expanding the amount of labeled data through a Web search using monosemous synonyms or unique expressions in definitions from WordNet (Fellbaum, 1998). These methods are also effective, and may be able to obtain labeled data even for unseen senses. But one expected problem will be that the performance is influenced by a sense bias (that is sense frequency) that varies with corpora (Agirre and Martinez, 2004).

Therefore, in this paper, we propose a method

that combines automatic labeled data expansion and semi-supervised learning aiming a synergistic effect. That is, we propose a two-step approach: in the first step (Step-1), we automatically expand the labeled training data from raw corpora. In this step, we aim to expand the labeled training data even for unseen and infrequent senses.

Then, in the second step (Step-2), we apply a semi-supervised classifier. In this step, we aim to achieve on improvement using easy-to-get unlabeled data. In this step, we also compare the results obtained using given training data only and show the benefits of our combination method. We also show its effectiveness for unseen senses.

This paper is structured as follows. We describe the target task in § 2. We describe our automatic labeled data expansion method (Step-1) in § 3, the evaluate the data quality using an experiment and human evaluation in § 4. Then we apply a semi-supervised learning method (Step-2) in § 5. We conclude the paper in § 6.

2 SemEval-2010: Japanese WSD

In this paper, we experiment on the SemEval-2010 Japanese WSD task. The sense inventory used in this task was the Iwanami Japanese Dictionary (Nishio et al. (1994)). Iwanami was originally paper dictionary. We show an example entry for Iwanami in Figure 1. As shown in Figure 1, each entry in Iwanami has POS information and definition sentences, and most of entries have example sentences. Iwanami has four hierarchical layers in word sense descriptions. In this task, senses at the third layer are used at the evaluation phase. For example, 0-0-1 and 0-0-8 in Figure 1. Iwanami includes 60,321 entries split into 85,870 senses, which are merged into 79,611 senses at the third layer. For this task, 50 words (22 nouns, 23 verbs, and 5 adjectives) are selected as the targets, which are split into 219 senses at the third layer; of these, 144 senses appear in the training data. On the other hand, 9 senses are unseen senses that appear in both Iwanami and the test data, but do not appear in the training data.

Both the training and test data are part of the Balanced Corpus of Contemporary Japanese: BCCWJ[1], which is morphologically analyzed by UniDic[2] and hand-corrected. For each target word, 50 instances are provided in both the training and test data. We show an example of the given training data in (1). The given training data are morphologically analyzed, but have no information about the base forms, therefore we added the base forms (lemma) automatically. The given data are also partly tagged with sense IDs of Iwanami.

(1) <mor pos=' 動詞-一般' rd=' トッ' bfm=' トル' sense='37713-0-0-1-1' lemma=' 取る'> 取っ</mor>

One feature of this task is that the training and test data come from heterogeneous corpora. The training data include books or magazines (PB), newspaper articles (PN), and government white papers (OW). The test data also include documents from a Q&A site on the WWW (OC). However, in this paper, we do not focus on domain adaptation, because 50 instances are insufficient, especially for investigating domain adaptation as reported by Fujita et al. (2010) and Shirai and Nakamura (2010).

3 Method for Automatic Labeled Data Expansion: Step-1

In this section, we introduce our automatic labeled data expansion method (Step-1). The main aim of this step is to obtain reliable labeled data even for unseen and infrequent senses.

[1] http://www.ninjal.ac.jp/kotonoha/
[2] http://www.tokuteicorpus.jp/dist/

As mentioned in § 1, several labeled data expansion methods have been proposed such as Mihalcea and Moldovan (1999) and Agirre and Martinez (2000, 2004). They mainly used WordNet's monosemous synsets (for example,"*recollect*" for *remember*$_1$) for Web search. This kind of method is effective, and offers the possibility of supplying training data for unseen senses. But unfortunately, we cannot obtain monosemous synonyms because our target task is not tagged with WordNet.

Therefore, in this paper, instead of these methods, we propose a method that provides reliable training data using example sentences from a dictionary. Such sentences are informative, but in most case of paper dictionaries such as Iwanami, the examples are fragmentary to save spaces (in Iwanami, an average of 4 words). Therefore, we attempt to extract longer, more natural and high quality labeled data from the raw corpus, under strict conditions using fragmentary examples.

That is, first, we extract example sentences (EX) from Iwanami. Then, we collect sentences that include an exact match for Iwanami's example for sense (s_k) of headword (h). Finally, we morphologically analyze the candidate sentences, and if both the base form and the coarse POS correspond to those of h, we tag the words with s_k and add the sentences to the labeled data.

For example, we can extract an example sentence as in (2), from 37713-0-0-1-2 in Figure 1. In (2), the headword is in **boldface** and is tagged with '37713-0-0-1-2' (at the third layer, '37713-0-0-1').

(2) 筆　を　**取る**
pens ACC pick up
"(I) start writing"

The data used in the Japanese WSD task is part of the BCCWJ corpus. Therefore, we use the remainder of the BCCWJ to extract the training data. Note that its morphological information is not hand-corrected. According to the readme file that comes with the BCCWJ, it includes about 43 million words.

We show an example of extracted labeled data in (3). The underlined part is exactly the same as the example sentence in (2). Therefore we tag 取る *toru* "pick up/take" with 37713-0-0-1-2 and add this entire sentence to the labeled training data.

(3) 筆　を　**取る**　気　は　起ら
pens ACC pick up feel TOP become
なかっ　た
not did
"(I) did not get into start writing"

Because of our strict condition, the size and variation of the extracted labeled data are limited. However, this method gave us longer and more natural reliable labeled data. Besides, most languages have dictionaries, and most of these dictionaries include examples, we expect our method to be applicable to other languages and dictionaries.

We show the size of the extracted and given training data (Trn) in Table 1. As shown in Table 1, the extracted labeled data give less coverage of sense types to the given training data, but give them many more instances. On average, 130 labeled sentences were extracted per example, for 326 example sentences. And training instances for 9 unseen senses were extracted from Iwanami's EX, and 5 unseen senses were extracted from BCCWJ.

Corpus	Sense Types All	Sense Types Unseen	Instances All	Instances Unseen
Trn	144	-	2,500	-
EX	156	9	1,450	46
BCCWJ	114	5	42,430	94

Table 1: Size of extracted and given training data

4 Evaluation of our Labeled Data Expansion Method: Step-1

In this section, we investigate the reliability and effectiveness of our automatic labeled data expansion. For this purpose, in § 4.1, we investigate the performance over the Japanese WSD task when we apply the supervised learning approach with and without the extracted labeled data. Then in § 4.2, we also provide a quantitative analysis of the extracted training data.

4.1 Performance over Japanese WSD Task

4.1.1 System Description

Machine Learning Methods We constructed supervised and semi-supervised WSD classifiers for each target word, based on machine learning methods. The classifiers for a target word were designed to select a sense from pre-defined senses for an instance of the target word.

In Step-1, we employed a *Maximum Entropy Model (*MEM*)* (Nigam et al., 1999) to design the

supervised WSD classifier. Let x denote the feature vector for an instance of a target word and $s \in \{s_1, \ldots, s_k, \ldots, s_K\}$ denote a sense of the target word. For the supervised WSD classifier, for the target words, the conditional probability of s given x is modeled as

$$P(s_k|x;W) = \frac{\exp(w_k^T x)}{\sum_{k'=1}^{K} \exp(w_{k'}^T x)}, \forall k, \quad (4)$$

where $W = [w_1, \ldots, w_k, \ldots, w_K]$ is a parameter matrix and w_k^T represents the transposed vector of w_k. We estimated the parameter matrix value by using labeled data.

Features For each target word w, we used the surface form, the base form, the POS tag, and the coarse POS categories, such as nouns, verbs, and adjectives of w. Then we also used bag-of-words in the same sentence. Here the target is the ith word, so we also used the same information for the $i-2, i-1, i+1$, and $i+2$nd words. We used bigrams, trigrams, and skipbigrams back and forth within three words. And we also used domain type `PB`, `PN`, `OW`, and `OC` as features.

Analytical Setting One anticipated problem with our expanding method in Step-1 is that the extracted data may have a different sense distribution from test data. Therefore, to investigate trends based on sense distribution, we employed the entropy $E(w)$ of the frequency distribution in given training data, which is given by

$$E(w) = -\sum_{k=1}^{K} p(s_k|w) \log p(s_k|w), \quad (5)$$

where $p(s_k|w)$ is the probability that word w will be sense s_k. In other words, $p(s_k|w)$ and then $E(w)$ reflect sense frequency bias. Note that $p(s_k|w)$ differs from $P(s_k|x)$, which is the probability of sense given *each instance* of the target word.

The entropy $E(w)$ will be lower if one paticular sense appears more frequently. Therefore, following the SENSEVAL-2 Japanese WSD task (Shirai, 2003), we divided the target words into three classes: difficult (D_{diff}: $E(w) \geq 1$), middle (D_{mid}: $0.5 \leq E(w) < 1$), and easy (D_{easy}: $E(w) < 0.5$). There were 9 target words for D_{diff}, 20 for D_{mid}, and 21 for D_{easy}.

4.1.2 Results and Discussion

Learning Curves Because of our strict condition, the variation in the extracted labeled data is limited, therefore, the system may cause overlearning. So first, we investigate the learning curves by limiting the number of added training instances for each `Iwanami` example.

Table 2 shows average accuracies over target words obtained with various number of added labeled instances per example. `L#` in the table shows the upper-bound for adding labeled instances per example. We used all extracted labeled instances when the number was less than `#`.

We adjusted the parameters based on a 5-fold cross-validation of the given training data. The best result (RALI-2, Brosseau-Villeneuve et al. (2010)) in a formal run of SemEval-2010 is also shown in Table 2 for reference, and the system uses the most frequent sense as a baseline.

	D_{easy}	D_{mid}	D_{diff}	Total
Base Line	**91.5**	67.0	51.3	69.0
RALI-2	-	-	-	76.4
`Trn` (No expansion)	90.6	70.9	61.1	77.4
+ `L1`	90.7	72.0	64.7	78.5†
+ `L5`	**90.8**	72.1	65.8	78.8†
+ `L10`	90.7	72.9	67.3	79.4 †
+ `L30`	90.7	73.8	68.2	**79.9**†
+ `L50`	90.5	**74.0**	68.0	79.8†
+ `L100`	90.3	73.4	68.2	79.6†
+ `L300`	90.4	73.5	68.2	79.6†
+ All extracted instances	89.7	73.6	**68.9**	79.5
+ `EX`	89.8	72.2	64.9	78.3
+ `L30` + `EX`	90.1	73.3	68.4	79.5
+ `L30` + `EXrL`	90.5	**74.8**	**68.4**	**80.2**†

Table 2: Results for given training data (`Trn`) or with extracted labeled data (by MEM) : where † shows that there is significant improvement over `Trn` by t-test at 5 % level of significance.

Using only the given training data (we call this `Trn`, 77.4 %), we achieved an improvement over the best published method (76.4 %). Even only one labeled instance per example gave better results (78.5 %) than the given training data alone, and 30 labeled instances gave the best result (79.9 %) in total[3].

Table 2 shows the accuracy per entropy based difficulty band. We found an interesting trend, namely that expanding the training data tended

[3]All results except "+All extracted instances" significantly improved over `Trn`.

to degrade the accuracy for easy words (D_{easy}), but improved it for the middle (D_{mid}) and difficult words (D_{diff}). With easy words, the best result (91.5 %) was provided by the selection of the most frequent sense. On the other hand, especially for difficult words, expansion was very effective, and using All extracted instances gave a +7.8 % ($= 68.9 - 61.1$) improvement over Trn. Difficult word means that many more senses appear in corpus. In other words, more instances are needed to guess the sense correctly, that is the reason for our method is especially effective for such difficult words.

Adding Original Example Sentences Then, we investigated other conditions. As shown in § 3, in Iwanami, there are 1,450 original example sentences, such as in a sentence (2), for the target words. However we could use only 362 example sentences to extract labeled instances, such as in a sentence (3). Therefore, 1,088 (=1,450-362) example sentences did not used to extract labeled data.

So, we also added original example sentences in 3 patterns: that is adding [1] all the original example sentences (EX), [2] 30 extracted labeled instances ($L30$) and EX, and [3] $L30$ and unused example sentences (EXrL) that could not be used to obtain labeled data. These results are also shown at the bottom of Table 2[4].

As shown in Table 2, the third pattern (+$L30$ +EXrL) gave the best results (80.2 %), and it is superior to the patterns using all original examples. The original examples tend to be short, but because shorter examples are easier to match to the raw corpus, we can filter out examples in EXrL that are too short.

4.2 Human Evaluation of Extracted Training Data

We also provide a quantitative analysis of the extracted training data. The first 5 sentences extracted from BCCWJ were checked manually. Which included 1,038 sentences for 47 words split into 114 senses. Of which 979 sentences (94.3 %) were considered correct.

Because Iwanami was different from WordNet, we could not make a direct comparison with another expansion method such as (Mihalcea and Moldovan, 1999). But the quality of this manual evaluation result is comparable to that (95.7 %) reported in (Mihalcea and Moldovan, 1999).

[4]Only one result using EXrL significantly improved over Trn.

4.3 Conclusion in Step-1

In this step, we extracted labeled data automatically using example sentences from Iwanami. This method gave us longer, more natural and higher quality labeled data from the raw corpus, and we could obtain the labeled data even for unseen and infrequent senses.

Step-1 provided superior performance (80.2 %) to the state-of-the-art result (76.4 %), and the high effectiveness of this method is proved.

However, it may be difficult to achieve any further improvement because the extracted data may have an unnatural sense distribution and limited variations. Therefore, to realize an improvement, we employ a semi-supervised learning method in Step-2.

5 Employing Semi-supervised Learning Method: Step-2

In Step-2, we constructed a semi-supervised WSD classfier for each target word by using a successful semi-supervised learning method called *Maximum Hybrid Log-likelihood Expectation (*MHLE*)* (Fujino et al., 2010). It was reported that the MHLE method was useful for obtaining better classification performance especially when there was a large difference between the distributions of the labeled and test data. As mentioned in § 2, the data of the Japanese WSD task is across very different types of corpus; ranging from formal government paper to rough Web data. That was the reason that we employed the MHLE method.

In this section, we first describe the outline of the MHLE-based semi-supervised WSD classifier (in § 5.1), and then we present our method for extracting unlabeled data (in § 5.2). Finally, we undertake an experiment and investigate the effectiveness of our combination of semi-supervised learning and labeled data expansion (in § 5.3).

5.1 MHLE-based semi-supervised WSD classifier

In the MHLE-based semi-supervised WSD classifier for a taget word, the conditional probability, $P(s|x)$, of sense $s \in \{s_1, \ldots, s_k, \ldots, s_K\}$ given the feature vector x of a word instance is modeled by a combination of discriminative and generative models, $P_d(s|x;W)$ and $p_g(x,s;\Theta)$, where W and Θ

are the parameters of these models. By applying the classifier form and training method presented in Fujino et al. (2010), we defined $P(s|x)$ as

$$P(s_k|x;W,\Theta,\beta) = \frac{P_d(s_k|x;W)p_g(x,s_k;\Theta)^\beta}{\sum_{k'=1}^{K} P_d(s_{k'}|x;W)p_g(x,s_{k'};\Theta)^\beta}, \ \forall k. \quad (6)$$

We also provided the objective function, J for the parameter estimation of $P(s_k|x;W,\Theta,\beta)$ by using labeled and unlabeled datasets, $L = \{(x_n,s_n)\}_{n=1}^N$, and $U = \{x_m\}_{m=1}^M$ as

$$\begin{aligned} J &= \sum_{n=1}^{N} \log P_d(s_n|x_n;W)p_g(x_n,s_n;\Theta)^\beta \\ &+ \sum_{m=1}^{M} \log \sum_{k=1}^{K} P_d(s_k|x_m;W)p_g(x_m,s_k;\Theta)^\beta \\ &+ \log p(W) + \beta \log p(\Theta). \end{aligned} \quad (7)$$

Here, $\beta(>0)$ is a combination weight. W and Θ can be estimated as the values that maximize J for a fixed β value. The local optimal solution of W and Θ around an initial value can be obtained by an iterative computation such as the EM algorithm (Dempster et al., 1977). Namely, the MHLE-based semi-supervised WSD classifier is constructed by combining the discriminative and generative models trained on both labeled and unlabeled samples (See Fujino et al. (2010) for the details of the combination and training methods).

We employed a maximum entropy model (multinomial logistic regression model) and a naive Bayes model as $P_d(s|x;W)$ and $p_g(x,s;\Theta)$, as well as the text classifier presented in Fujino et al. (2010). In the naive Bayes model, the probability distribution of $x = (x_1,\ldots,x_i,\ldots,x_V)$ given s is regarded as a multinomial distribution: $p_g(x|s;\Theta) \propto \prod_{i=1}^V (\theta_{si})^{x_i}$, and the joint probability distribution of x and s is modeled as $p_g(x,s;\Theta) = p_g(x|s;\Theta)P(s)$. Here, $\theta_{si} > 0$ and $\sum_{i=1}^V \theta_{si} = 1$. V represents the dimension of feature vector x, and θ_{si} is the probability that the ith feature appears in an instance whose sense is s. $\Theta = \{\theta_{si}\}_{s,i}$ is the paremeter set of the naive Bayes model. In our experiments, we set $P(s) = 1/K$. We used Gaussian and Dirichlet priors as $p(W)$ and $p(\Theta)$, respectively. We tuned the β ($\in 0.5,1,2,5,10$) value with a 5-fold cross-validation of the labeled data.

5.2 Extracting Unlabeled Data

As unlabeled data, we extract sentences that include the target words from BCCWJ corpus. We show an example in (8), the **boldface** part indicates the target word.

(8) 年貢 に **取る** べし
annual tax as assess should
"(You) should assess annual tax"

Because of the looser restriction, we can extract many more sentences than the labeled data in § 3. For example, from BCCWJ alone, we can extract more than 10,000 instances for 22 words and more than 1,000 instances for the remaining words except for one (一つ *hitotsu* "one").

5.3 Experiment and Evaluation: Step-2

In this section, we describe an experiment in which we employed a semi-supervised classifier based on MHLE.

This experiment has two purposes; that is to investigate the effectiveness of (a) MHLE based semi-supervised WSD, and (b) automatically expanded data as labeled data.

5.3.1 Results and Discussion

Table 3 shows the results we obtained using unlabeled data extracted from BCCWJ. *U#* in the table shows the number of used unlabeled instances. In this experiment, we limited the unlabeled data to 10, 100, 200, 300, 500 and 1000. The smaller unlabeled data are subsets of the larger unlabeled data. We also use the given training data and several types of expanded data as labeled data.

Effectiveness of MHLE When we used only the given training data as labeled data (Trn), 300 unlabeled data gave the best performance (82.8 %), and it achieved a +5.4 % (= 82.8 − 77.4) improvement.

In addition, in contrast with the results in § 4, some improvements were achieved even for easy words. As described in § 5.1, it has been reported that the MHLE was robust even when the labeled and test data were very different, as with the Japanese WSD task, which came from heterogeneous corpus. Therefore, we can say that this semi-supervised WSD using a hybrid generative/discriminative approach (MHLE) is effective (with respect to purpose (a) above).

Effectiveness of Automatically Expanded Labeled Data We used several types of expanded data as labeled data; that is, Trn +EX, +*L*1, +*L*30, +*L*1 +EXrL, and +*L*30 +EXrL. Note that Trn +*L*30 +EXrL gave the best result in Step-1.

As shown in Table 3, all of the automatically expanded labeled data provided better results than the given training data alone. Therefore, we can say that these automatically expanded data are better than the given training data as labeled data (as regards purpose (b) above).

The labeled data Trn +$L30$ +EXrL gave the best results in Step-1, but the data that achieved the best result overall was Trn +$L1$. This shows that ultimately the original (fragmentary) example sentences are no match for the real world sentences extracted from raw corpora. By comparing +$L1$ with $L30$, for easy words in particular, +$L1$ produced better results than +$L30$ probably because of the sense bias. But for difficult words, +$L30$ produced better results than +$L1$.

In conclusion, also in our combination method, larger labeled data expansion was effective for more difficult words.

Learning Curves for Sample Words As shown above, MHLE works very effectively, however, that's not to say that the larger unlabeled data give better results. We show some learning curves for sample target words in D_{mid}, using Trn +$L1$ as the labeled data in Figure 2. As this figure shows, the behavior is very different from that of the target words.

For some words, the accuracy still is not saturated (For example, 良い *yoi* "good"), but for some words, the accuracy is decreasing (For example, 持つ *motu* "have"). In future work, we will investigate the causes of improvement or degradation.

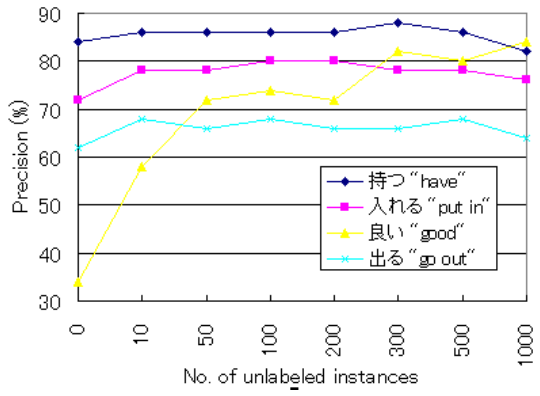

Figure 2: Learning curves for sample target words using expanded training data (Trn +$L1$) as the labeled data (MHLE) (%)

	D_{easy}	D_{mid}	D_{diff}	Total

+$U10$	92.1	77.1	70.7	82.2
+$U100$	92.2	79.7	71.1	83.4†
+$U300$	92.4	**80.9**	72.2	**84.2**†
+$U500$	92.1	80.8	73.1	**84.2**†
+$U1000$	91.4	79.7	70.4	83.0

Table 3: Results of semi-supervised learning (MHLE), using given/expanded training data as the labeled data (%): where † shows that there is significant improvement over results using Trn as labeled data by t-test at 5 % level of significance; that is we compared Trn +$L1$ to Trn, Trn +$L1$ +$U10$ to Trn + $U10$, and so on.

5.3.2 Effectiveness for Unseen Senses

One of the advantages of our method is that it can provide training data even for unseen senses (which did not appear in the given training data but were in the dictionary). Therefore, we investigated the accuracy for unseen senses. In the Japanese WSD task, there are 18 instances for 9 unseen senses (See § 3). Table 4 shows the result for the 18 instances.

When we use expanded labeled data, the system can sometimes guess the unseen senses. The best performance (9 correct (50.0 %)) was achieved by +*L*30, because more labeled data were provided even for unseen senses. But also with +*L*1, 6 instances (33.3 %) were correct.

Of course, these unseen senses have no given training data (Trn), so the accuracy is 0 % on Trn. Therefore, no method based on given training data alone (Trn) can guess these senses correctly. So this constitutes a significant improvement.

	No.	%
Trn	0	0.0
Trn + EX	0	0.0
+*U*10 - *U*1000	5	27.8
Trn + *L*30 + EXrL	0	0.0
+*U*10	3	16.7
+*U*100	7	38.9
+*U*200 - *U*1000	**9**	50.0
Trn +*L*1 +EXrL	0	0.0
+*U*10 - *U*1000	2	11.1
Trn + *L*30	0	0.0

+*U*100	5	27.8
+*U*200 - *U*500	**9**	50.0
+*U*1000	4	22.2
Trn + *L*1	0	0.0
+*U*10	2	11.1
+*U*100	4	22.2
+*U*200, *U*300,*U*1000	5	27.8
+*U*500	6	33.3

Table 4: Effectiveness for unseen senses (9 senses, 18 instances)

6 Conclusion

In this paper, we proposed a combination WSD method consisting of automatic labeled data expansion (Step-1) and semi-supervised learning (Step-2). We targeted the SemEval-2010 Japanese WSD task, and showed the effectiveness of our proposed method.

In Step-1, we automatically extracted labeled data from raw corpora. We could extract longer, more natural and higher quality labeled data even for unseen senses, with a strict condition using the fragment examples.

In this step, we had already achieved a better performance (80.2 %) than the best result (76.4 %) in the formal run of the Japanese WSD task.

In Step-2, we employed semi-supervised learning. As the semi-supervised learning method, we employed the hybrid generative/discriminative approach (MHLE), because this method has been reported to be robust even when the labeled and test data were very different as in the Japanese WSD task, which came from heterogeneous corpus.

As a result, in this step MHLE achieved a good improvement (82.8 %), even when using only given training data as labeled data. Moreover, we showed the effectiveness of our expanded data as labeled data. We investigated which type of expanded data was the best as labeled data, then showed that adding only one sentence per original example was the best as labeled data (84.2 %), and could make it possible for the system to guess even unseen senses (33.3 %). In other words, when using labeled data for semi-supervised learning, minimum expansion provides the best performance, and protects the system against sense bias.

In feature work, we intend to investigate the reasons for improvement or degradation. We also intend to perform experiments in which we change the amount of expanded labeled data based on entropy based difficulties.

Abstract

Knowledge-based Word sense Disambiguation (WSD) methods heavily depend on knowledge. Therefore enriching knowledge is one of the most important issues in WSD. This paper proposes a novel idea of combining WordNet and ConceptNet for WSD. First, we present a novel method to automatically disambiguate the concepts in ConceptNet; and then we enrich WordNet with large amounts of semantic relations from the disambiguated ConceptNet for WSD. The evaluation experiments on the Semeval-2007 coarse-grained all-words disambiguation task show that the enriched WordNet can significantly improve the performance of knowledge-based WSD methods.

1 Introduction & Motivation

1.1 Introduction

Word sense Disambiguation (WSD) is a task of selecting the proper sense of ambiguous terms in the text. WSD is an intermediary step within many Natural Language Processing (NLP) applications, such as text summarization, machine translation, text processing, and so on. Finding a solution to the WSD problem is essential or even compulsory for such NLP applications.

There are two main classes of WSD approaches: supervised WSD, and knowledge-based WSD. The former employs statistical learning to learn a classifier from training data. The preparation for these training data may be laborious and erroneous. Moreover, building a manually annotated corpus, as required by supervised WSD methods, to cover all word senses in lexicon is expensive, and even infeasible. In contrast, knowledge-based WSD methods rely on the use of wide-coverage knowledge resources. These methods do not need the human labeled training data. The widely used knowledge resource in such methods is WordNet (Fellbaum, 1998). However, WordNet-based WSD methods usually achieved lower performance compared to supervised methods, mainly due the fact that the lexical and semantic knowledge contained in WordNet is not sufficient for WSD.

Therefore, many methods (see Section2) have emerged to enrich WordNet with the lexical and semantic knowledge for WSD purpose, such as by using Wikipedia, on-line lexicons, domain, and so on. The literature research results show that the use of enriched knowledge does improve the performance of WordNet based WSD systems, in terms of both accuracy and coverage.

However, most of the present methods mainly focus on enriching WordNet with limited lexical and taxonomic knowledge. Though Wikipedia contains many semantic relations, the knowledge extracted from Wikipedia may contain noises, for some of them are derived from weak semantic links, and lack of confidence.

In this paper, we propose to use ConceptNet (Havasi&Alonso, 2007) with the large amounts of semantic relations between concepts, to enrich WordNet. For there are many ambiguous concepts existed, ConceptNet cannot be directly used to enrich WordNet. Thus, we develop a novel methodology to automatically disambiguate the ambiguous ConceptNet concepts. By using the disambiguated ConceptNet, we can enrich semantic relations in WordNet. To evaluate performance of WSD based on the extended WordNet, we implement a simple knowledge-based algorithm and its extension, embedded with WordNet, WordNet+ConceptNet, respectively. The comparison results show that using WordNet along with disambiguated ConceptNet can make even simple knowledge-based algorithms achieve state-of-the-art performances.

1.2 ConceptNet

ConceptNet is a large collaborative Web knowledge resource, which encompasses commonsense knowledge about the spatial, physical social, temporal and psychological aspects of everyday life (e.g., airplane is capable of flight, plane relates to geometry). It is useful in a wide variety of applications such as speech recognition (Lieberman et al., 2005), intelligent user interface (Speer et al., 2009), machine translation (Caseli et al., 2010), and so on.

Until 2011, ConceptNet contains nearly one million of assertions represented as triplets like *<concpet1, relation, concept2>*, to define the concrete semantic relations between two specific concepts. All the assertions are organized as a semantic network, where a node stands for a concept, and an edge stands for a relation between two concepts. There are above 400,000 concepts in ConceptNet, each of them are denoted as either a word or a phrase, and labeled by a unique identifier. In addition, ConceptNet defines nearly thirty kinds of semantic relations, such as CapableOf (agent's ability), SubeventOf (event hierarchy), MotivationOf (affect), DesireOf (want to), and so on, most of which are not included in WordNet. Therefore, if extending WordNet with the large amounts of semantic relations contained in ConceptNet, it is desirable to improve the performances of WordNet-based WSD methods.

However, ConceptNet cannot be directly used for WSD purpose due to the existence of polysemy and synonymy of the concepts in it.

Polysemy is the tendency for ConceptNet concepts to have multiple senses. For example, a ConceptNet concept *plane* has two word senses: "a fixed-wing aircraft", or "an unbounded two-dimensional shape". Which sense should be used depends on the considered assertion including the concept. Therefore, we should first assign the correct senses for those concepts in the assertions before using them to enrich WordNet.

Synonymy is another tendency for the concepts in ConceptNet to have a common word sense. For example, the concept *airplane* has only one sense: "a fix-wing aircraft", which is also the first sense of the concept *plane*. It is obvious that the concepts related to *airplane* should have the same relation with *plane*. However, it is not the case in ConceptNet. Concept *airplane* has an atLocation relation with the concept *airplane hangar*, whereas *plane* has not such relation with *airplane hangar*. This leads to the inconsistency of knowledge base. Therefore assigning the correct senses for the ambiguous concepts in the assertions to find the synonym concepts will improve the quality of the knowledge base.

2 Related Work

Up to now, there are many approaches to enrich the knowledge of WordNet for WSD tasks. For instances, Magnini&Cavagli à(2000) proposed to use domain knowledge to assign domain labels to most WordNet synsets. Some researchers (Mihalcea&Moldovan, 2001; Navigli, 2009; Hwang et al., 2011) proposed to enrich semantic relations by means of the disambiguation of the glosses of WordNet or other machine-readable dictionaries. Some other researches (Agirre et al., 2000; Cuadros&Rigau, 2008) extract semantic relations from Web to enrich WordNet. However, all above methods mainly aim to enrich lexical and taxonomic resources. Therefore some recent work (Mihalcea, 2007; Ponzetto&Navigli, 2010) exploits Wikipedia, a large collaborative Web encyclopedia, to extract the knowledge for WSD. However, the type of semantic relations extracted from Wikipedia is uncertain. Moreover, it is hard to know which semantic relations are transitive or belong to the same type (e.g. isA, part of).

Different with the existed methods, we propose to use Conceptnet to enrich the knowledge in WordNet, which has several advantages over previous works. First, ConceptNet is a large-scale commonsense knowledge base for many aspects of everyday life, such as spatial, physical social, temporal, psychological, and so on. Injecting such knowledge from ConceptNet into WSD system can effectively relieve the knowledge acquisition problem in WSD. Second, the semantic relations from some of the previous work such as Wikipedia are extracted in an indirect way, each of which has no a clear relation type. Thus some of those semantic relations are too weak to be filtered (Ponzetto&Navigli, 2010). In contrast, the semantic relations in ConceptNet are directly defined as assertions, each of which has a very clear relation type. Therefore, the semantic relations in ConceptNet are expected to be more robust than the others.

3 Disambiguating ConceptNet

For there are many ambiguous concepts existed in ConceptNet, it cannot be directly used to enrich WordNet for WSD. It is necessary to disambiguate the ambiguous ConceptNet concepts.

Assume concept *plane* have two senses. The first one is "a fixed-wing aircraft"; and the second one is "an unbounded two-dimensional shape". Given a ConceptNet assertion <*plane, usedFor, fly*>, one can easily judge the appropriate sense of *plane* in this assertion to be the first sense of *plane*. That is because people do not simply regard a sense of a word as an abstract symbol, but a concrete entity that has many properties. For the first sense of *plane*, people may think that it is an *aircraft*, also named *airplane*, and has *wings*, etc. For the second sense of *plane*, people may think that it is a *shape*, or a *form*, and relates to *mathematics*, etc. The concepts *aircraft*, *airplane*, and *wing* relate to *fly* more closely than *shape*, *form*, and *mathematics*. By integrating such information, people can easily know the correct sense of *plane* in the assertion <*plane, usedFor, fly*>.

We propose a method to simulate the human's processing of disambiguating ambiguous concepts by three steps. Given a ConceptNet assertion <*c, relation, d*>, where concept *c* is ambiguous (the cases of *d* being ambiguous or both *c* and *d* being ambiguous are the similar), in order to disambiguate *c* in this assertion, firstly, we construct a word sense profile (WSP) for each sense of *c*. A WSP is a set of terms (words) relating to a sense, it describes the sense in a whole (Section 3.1). Secondly, we measure the relatedness between the terms in WSP with *d* in the same assertion based on NGD (Section 3.2). Thirdly, we filter out the noisy terms in WSP, which would decrease the performance of ConceptNet disambiguating (Section 3.3).

As a result, we calculate the score of the WSP for each sense, and choose the sense with the lowest WSP score as appreciated one for the ambiguous concept in the assertion. Therefore, for each ambiguous concept of every ConceptNet assertion, we can assign the appropriate sense to it according to the WSP scores; and the resulted ConceptNet can be used to extend WordNet.

3.1 Constructing Word Sense Profile

As we all know, WordNet is structured as a semantic network in which nodes stand for a concept **sense**, and are linked by a small set of semantic relations such as hypernymy, hyponymy, meronymy, and so on. For ambiguous concepts with multiple senses, there are multiple nodes in the network. The concept sense is represented by a **synset** (a set of words sharing a common meaning, each word is called a synonymy in the synset). For an example, for concept *plane*, we can use plane_n^1 as the label of one of its senses, in which the subscript and superscript indicate its part of speech (e.g. "n" stands for noun) and sense no., respectively; and its synset is denoted as plane_n^1 = (airplane, aeroplane, plane), illustrating that this synset is consist of three synonymys: *airplane*, *aeroplane* and *plane*. Moreover, each synset has a textual definition, namely **gloss**. For instance, the gloss of synset plane_n^1 is "an aircraft that has a fixed wing and is powered by propellers or jets".

Given a WordNet synset *S*, we make use of the following knowledge resources to construct its **Word Sense Profile**, WSP(*S*).

Synonymy: all synonyms in *S*. For an example, three synonyms in the synset plane_n^1 will all be included in the WSP(plane_n^1).

Hypernymy/Hyponymy: all synonyms in the hypernym synset *H* of *S* (e.g., *S* is a kind of *H*) or in the hyponym synset *H* of *S* (e.g., *H* is a kind of *S*). For instance, the hypernym of synset plane_n^1 is $\text{heavier - than - air craft}_n^1$ = (heavier-than-air craft), then the synonym *heavier-than-air craft* will also be included in WSP(plane_n^1).

Meronymy/Holonymy: all synonyms in synsets *M* which has a meronymy (e.g., *M* is a part of *S*) or a holonymy (e.g., *S* is a part of *M*) relation with *S*, will be containd in WSP of S. For example, given a synset plane_n^1, one of the meronymies plane_n^1 is pod_n^4=(pod, fuel pod), so *pod* and *fuel pod* will also be included in WSP(plane_n^1).

Gloss: the set of words in the gloss of *S*. For example, the gloss of synset plane_n^1 is "an aircraft that has a fixed wing and is powered by propellers or jets". After removing the stop words, the remaining words will be included in WSP(plane_n^1).

Indirect Resources: Besides above direct relations in WordNet, we also use some indirect ones that are derived from the transitivity of WordNet semantic relations, to construct the WSP. Given a synset *A*, if *A* has a direct relation with synset *B*, *B* has a direct relation with synset *C*, and then *A* has an indirect relation with *C*. Therefore, *C* is regarded as an indirect resources for *A* and all synonyms of *C* are also added in the WSP(*A*).

For a synset *S*, WSP(*S*) is defined as the set of words obtained from direct or indirect resources.

3.2 Measuring Relatedness

Given a ConceptNet assertion <*c, relation, d*>, after getting the WSP of each sense of the am-

biguous concept *c*, we need to know which sense is the most likely one in this assertion by calculating a score for the WSP. To do so, we first measure the relatedness between a term in the WSP and *d*, and then compute the arithmetic mean of the values as the score of the WSP.

Normalized Google Distance (NGD) (Cilibrasi et al., 2007) was proposed to measure semantic relatedness between two terms using the vast available knowledge on the Web. Concretely, NGD takes advantage of the number of hits returned by search engine such as Google, to compute the distance between terms. Small NGD value indicates close relatedness, while large value suggests the opposite. Given a term pair <*x, y*>, the normalized Google distance between *x* and *y*, NGD(*x, y*), can be obtained as follows:

$$NGD(x,y) = \frac{\max\{\log f(x), \log f(y)\} - \log f(x,y)}{\log N - \min\{\log f(x), \log f(y)\}} \quad (1)$$

Where *f(x)* is the number of Google hits for the term *x*, *f(y)* is the number of Google hits for the term *y*, *f(x, y)* is the number of Google hits for both terms *x* and *y*, and *N* is the number of web pages indexed by Google. The smaller the NGD score, the more related the two terms are.

According to the definition, it is desirable to use NGD to measure the relatedness between any term in the WSP and *d*.

Note that we always compute the NGD scores in the context of ConceptNet assertion <*c, relation, d*>. That is, we only need to consider the relatedness between *d* and the term in WSP(*c*). Therefore, we sometimes simply say the NGD score of a term in this paper without confusion.

3.3 Filtering the Noise Terms

Ideally, the NGD score of any term in the WSP of the correct sense is lower than that in the WSP of incorrect sense, thus we can simply use the arithmetic mean of the scores to evaluate the relatedness of WSP and the assertion. However, it is inevitable that there are some noisy terms in WSPs, which will dramatically decrease the performance of disambiguating ConceptNet. Therefore, we need to pay efforts to reduce such noises.

There are two kinds of noises: those from WSP of the correct sense, and those from WSP of the wrong sense(s). Suppose we have an assertion <*c, relation, d*>, where concept *c* is ambiguous and has two senses c_n^1 and c_n^2. Corresponding to the assertion, the correct sense of *c* is c_n^1, and a wrong sense of *c* is c_n^2.

Then the first kind of noises are from WSP(c_n^1), which do not have close relation to *d*. Thus their NGD scores should be high, though they have a WordNet relation to c_n^1. For an example, given a ConceptNet assertion <*plane, isA, vehicle*>, the correct sense of *plane* is $plane_n^1$ (a fixed-wing aircraft). Term *navigation light* is in WSP($plane_n^1$), however there is no close relatedness between *navigation light* and *vehicle*, resulting that it is a noisy term in WSP($plane_n^1$), belonging to the first group. Obviously, this kind of noises have high NGD scores and would increase the score of the WSP of the correct sense, thus correspondingly decrease the probability of selecting the correct sense as the appreciated sense of ambiguous concept.

The second kind of noises are from WSP(c_n^2), which have close relation to *d* whereas occur in the incorrect WSP. Since they are closely related to *d*, their NGD scores are usually low, hence lower the score of the WSP of the wrong sense, which may lead to selecting the wrong sense as the appreciated one for ambiguous concept. Such noises mainly come from the ambiguous terms contained in the WSPs. For an instance, *basketball* has two word senses: $basketball_n^1$ ("a game played on a court by two opposing teams of 5 players"), or $basketball_n^2$ ("an inflated ball used in playing basketball"). Based on WordNet, it is easy to get WSP($basketball_n^1$) = (game, handball,…), and WSP($basketball_n^2$) = (ball, handball,…). We can see that *handball* occurs in both WSPs. In fact, *handball* is itself ambiguous and has two senses: $handball_n^1$ ("a small rubber ball used in playing the game of handball"), $handball_n^2$ ("a game played in a walled court"). Given a ConcepNet assertion <*basketball, isA, popular sport*>, it is clear that the correct sense of *basketball* should be $basketball_n^1$, while $basketball_n^2$ is not the appropriate one for this assertion. It is desirable that all terms in WSP($basketball_n^2$) have high NGD scores. However, it is not the case for term *handball*. According to $handball_n^1$, we know that the NGD score of *handball* should be low, for *handball* and *popular sport* frequently co-occur in the Web. There is no problem for the occurrence of *handball* in WSP($handball_n^1$). However, it is because the computation of NGD score does not consider different senses of the same term in different occurrences, different *handball*s in different WSPs actually have the

same NGD scores though they correspond to different senses. As a result, the term "*handball*" in WSP(basketball_n^2) becomes a noise to the assertion <*basketball, isA, popular sport*> for it improperly lower the score of WSP(basketball_n^2) and increase the risk of assigning the sense basketball_n^2 to concept *basketball* in the assertion.

Of course, in real applications, it is impossible to know which kind of noises exist and where they are in advance. Moreover, whether a term in a WSP is a noise may depend on the specific ConceptNet assertion, just as the *handball* in above example. We simply try three filters by using different strategies in the calculation of WSP scores: TopN filter, Threshold filter and Top r% filter.

TopN filter only selects the top *n* terms with the smallest NGD scores to take part in the calculation of WSP score. Threshold filter only retains the terms with NGD scores lower than a predetermined threshold value *t* to compute WSP score. Top r% filter supposes that the number of noise terms may be proportionate to the size of WSP, and only selects the top *r%* terms with the smallest NGD scores to compute the WSP score.

Obviously, all of above strategies aim to reducing the first kind of noises by disregarding the terms with larger NGD scores. In fact, it is hard to filter out the second kind of noises for most of them are related to the specific concept sense, which keeps unknown before the calculation of WSP scores. Furthermore, there is also the dilemma due to the filtering that the second kind of noises are more likely to be retained for they have lower NGD scores.

Nevertheless, we could still avert the second kind of noises to some extent, not by filtering, but by preventing them from being added into the WSP. Now that the second kind of noises mainly comes from the ambiguous terms, we can analyze which relationships defined in Section 3.1 may introduce more ambiguous terms thus could not be taken into consideration. We will address this problem in Section 4.1.3.

4 Experiments

Our evaluation experiments consist of two steps. The first step is to evaluate the intrinsic quality of the disambiguated ConceptNet (Section 4.1), including the selection of the noise filters and analysis of effects of different combinations of WordNet relationships on the disambiguation results. The second step is to evaluate the impact of combining disambiguated ConceptNet and WordNet for coarse-grained WSD by comparing different methods (Section 4.2).

4.1 Evaluation of the Disambiguating ConceptNet

To our best knowledge, there is no literature work for ConceptNet disambiguation before. So we first generate the test bed as the gold standard for evaluations; and then compare our disambiguated concepts to this gold standard to see how many of them are matched. We also compare different noise filtering strategies mentioned in Section 3.3 and accordingly choose the best one as the final noise filter. To avoid introducing more second kind of noises when generating WSPs, we also investigate different combinations of WordNet relationships mentioned in Section 3.1 by comparing by disambiguating accuracies.

4.1.1 Gold Standard Generation

To evaluate our ConcepNet disambiguating methods, we created a gold standard data as follows. First, we randomly selected a set of 1,000 assertions from the ConceptNet, and checked whether the included concepts have multiple senses in WordNet. By doing so, we found 425 ambiguous concepts with more than one WordNet senses, which are contained in 365 of the 1,000 assertions. Then we asked a language expert to annotate the WordNet senses for the ambiguous concepts in these ConceptNet assertions. To see whether the annotations are convincible, we asked a different expert to tag the same 425 ambiguous concepts in the 365 assertions independently. The kappa coefficient (Carletta, 1996), which is used to calculate the inter-annotator agreement, show that the two annotations achieved a perfect agreement with coefficient as 0.9. Therefore, we use the first annotation results as the gold standard to evaluate our methods.

4.1.2 Comparison of Three Filter Methods

To compare different filtering strategies mentioned in Section 3.3, we first construct WSP for each sense of the 425 concepts, and then calculating the WSP scores after noise filtering by different strategies separately; finally, we annotate each concept with a sense according to the WSP scores. We also did the concept annotation by calculating the WSP scores without noise filtering for reference. In the construction of WSP, we made use of the following six WordNet resources: synonymy, hypernymy, hyponymy,

meronymy/holonymy, gloss, and hyponymy → gloss (the gloss of the hyponymy; the similar denotations are also used in the following). Section 4.1.3 will show the reason.

To investigate the significance of the WSP score based annotation method against the random or dominant annotation, we also assigned a sense to each concept, by randomly selecting one from the available senses and by selecting the most frequent sense, respectively.

Table 1 shows annotation accuracies of different methods, where "MFS BL" and "Random BL" correspond to the performances of random and dominant annotation respectively. In the experiments, we set n=10 for TopN filter, t=0.2 for Threshold filter, and r=20 for Top r% filter. These parameter values were set by our experience, to achieve the best performances on the 425 concepts.

Filter	Accuracy
TopN Filter	**82.4%**
Threshold Filter	61.4%
Top r% Filter	60.5%
No Filter	44.0%
MFS BL	57.4%
Random BL	20.8%

Table1. Performance of the disambiguating ConceptNet using different filter methods

From Table 1 we can see that, the annotation results of WSP based methods are much more significant than the random method, and the use of noise filtering can significantly enhance the accuracy of the annotation. Without noise filtering, the WSP based method shows even worse performance than the MFS baseline (-17.4%), which demonstrates that there are actually some noise terms in WSP that decrease the performance of ConceptNet disambiguating.

In addition, we also see that though all of the filter methods can effectively filter out the noise terms from the WSP thus improve the performance of WSP method, TopN filter is significantly better than the other two (+21.9% and +21.0% compared to Top r% Filter and Threshold Filter respectively). This suggests that TopN would be the most appropriate filter method for removing the noise terms from WSPs. We think the result might due to the following factors. Firstly, Threshold filter cannot effectively remove the second kind of noise terms, because it may filter out too much right terms from the WSP of a wrong sense, while remain terms belonging to the second kind of noise. Therefore, there are not enough right terms to relieve the second kind of noise terms for the wrong sense. Secondly, the sizes of the WSPs may vary wildly. For the senses whose WSP size are small, Top r% filter may remain too few terms (e.g. only two or three terms), thus the WSP scores are very sensitive to the remain noises. Finally, for each sense, TopN filter remains a fixed number of terms. If the second kind of noise terms exists, there might be enough right terms to relieve the impact of those noise terms if we set the proper value to parameter n.

Therefore, in the comparative experiments, we only consider the TopN filter. In order to get a proper value of n, we investigated the performance of the filter by ranging n from 1 to 50 stepped by one and found that it is appropriate for TopN filter to set n in [6, 11]. In our work, we set n=10.

4.1.3 Investigation on the Resources Combination

Just mentioned in Section 3.3, WordNet resources defined in Section 3.1 may introduce the second kind of noises. Due to the fact that this kind of noises is hard to be filtered out, we should prevent such noises from entering the WSPs as possible as we can. Therefore, we tried different combinations and evaluate our ConceptNet disambiguating method, to investigate which combination is the best for our task.

Although hypernymy, hyponymy, and meronymy/holonymy are transitive, and can generate the indirect WordNet resources, the number of meronymy/holonymy is far below than those of the other two in the WordNet. Thus, we ignore the indirect WordNet resources derived from meronymy/holonymy. As a result, ten WordNet resources are used as the candidate resources to construct WSP. Five of them are direct WordNet resources (synonymy, hypernymy, hyponymy, meronymy/holonymy, and gloss), and five are indirect WordNet resources: hypernymy → hyponymy, hypernymy → gloss, hypernymy → hypernymy, hyponymy→hyponymy, and hyponymy→gloss.

Table 2 summarizes the highest accuracies of our ConceptNet disambiguating method with different combinations of WordNet resources against the 425 annotated concepts. The results show that our method achieves the highest accuracy with the six WordNet resources: hyponymy → gloss, gloss, hyponymy, hypernymy, mer-

onymy/holonymy, and synonymy. The combination of the six resources is abbreviated as "six resources" (We also tried to combine the direct resources with any of other four indirect resources, the results show that they cannot improve and even decrease the performance. Especially, hypernymy→hyponymy dramatically decreases accuracy (-8.94% compared to the "six resources"). Therefore, we do not list the accuracies of combining other indirect resources with the direct ones). We also noticed that based on the "six resources", the accuracy will be decreased by adding any new indirect WordNet resource. All of above facts imply that the indirect WordNet semantic resources except hyponymy→gloss may contain much more noise terms than the direct resources, especially the second kind of noises. Therefore, in order to avoid introducing too many noises, we chose the combination of "six resources" to construct WSP, and then disambiguate the ConceptNet for extending WordNet purpose.

Resources combination	**Accuracy**
Hyponymy→gloss	68.2%
Hyponymy→gloss + gloss	73.4%
Hyponymy→gloss + gloss + hyponymy	76.2%
Hyponymy→gloss + gloss + hyponymy+ Hypernymy	78.1%
Hyponymy→gloss + gloss + hyponymy+ hypernymy+ meronymy/holonymy	80.7%
Hyponymy→gloss + gloss + hyponymy+ hypernymy+ meronymy/holonymy+ synonymy	**82.4%**
Six resources+ hyponymy→hyponymy	80.5%
Six resources+ hypernymy→hypernymy	80.2%
Six resources+ hypernymy→gloss	79.8%
Six resources+ hypernymy→hyponymy	73.4%

Table2. The highest accuracies of disambiguating ConceptNet with different size of WordNet resources

4.2 Evaluation of WSD Methods

After disambiguated, the ConceptNet can be used to extend WordNet for WSD. In order to evaluate the impact of combining disambiguated ConceptNet and WordNet, we performed the comparative experiments on the Semeval-2007 coarse-grained all-words WSD dataset (Navigli et al., 2007) . We have chosen coarse-grained word sense disambiguation because the meanings of the ambiguous concepts in the ConceptNet assertions are naturally coarser than those in WordNet are. For example, given a ConceptNet assertion <*rain, isA, water*>, assigning either the first sense ("water falling in drops from vapor condensed in the atmosphere") or the second sense ("drops of fresh water that fall as precipitation from clouds") in WordNet to *rain* is suitable.

Since the aim of our experiment is to evaluate the impact of extended knowledge resource on WSD performance, the WSD algorithm is not the core of our work. Anyway, we implemented a simple knowledge-based algorithm, namely GM (Galley&McKeown, 2003), and our extending version. GM algorithm processes text sequentially, and compares current word to all of the previous words. If one of the senses of the current word has a semantic relation (synonymy, hypernym, hyponym, hypernymy→hyponymy) with any senses of previous words, then there is a weighted semantic edge between these two senses. After processing the whole text, a disambiguated graph is built, whose nodes represent the word senses and edges stand for the four kinds of semantic relations. Finally, for each sense of a target word, all scores of the edges linked to it are summed up as its score. The sense with the highest score is chosen as the correct sense for the target word.

In addition, we simply extend GM algorithm by considering more semantic relations. The extended algorithm is called as ExtGM. In details, in the semantic network of WordNet, if the length of the shortest path between two senses is not greater than four, we also consider that there exists a semantic relation between them, and assign the weight of this semantic relation as the inverse of the length. Since we did not focus on the WSD algorithms, the values of the two parameters (length, weight) of the implemented algorithms were not optimized.

Resource	**Method**	**P**	**R**	**F_1**
WordNet	GM	86.9	55.0	67.4
	ExtGM	**87.4**	70.6	78.0
WordNet + ConceptNet	GM	83.7	73.6	78.3
	ExtGM	85.5	**79.9**	**82.6**
WordNet + Wikipedia	Degree	87.3	72.7	79.4
	MFS BL	77.4	77.4	77.4
	Random BL	63.5	63.5	63.5

Table3. Performance on Semeval-2007 coarse-grained all words WSD (nouns only subset)

Table 3 shows the evaluation results of GM and ExtGM on Semeval-2007 coarse-grained all-words dataset, by using different knowledge resources: WordNet, WordNet+CocneptNet, where

P, R, and F_1 represent precision, recall and F1-measure respectively. We also use the random chosen sense (Random BL) and the most frequent sense (MFS BL) as baselines.

From this table, we can see that enriching WordNet with semantic relations from ConceptNet yields a significantly improvement against only using WordNet.

We also listed the result of Degree on WordNet+Wikipedia (Ponzetto&Navigli, 2010) in Table 3, from which we can see that compared to Degree, our method attains a slight variation in precision, but a significantly high increase in recall. The result shows that ConceptNet can increase recall for WSD more effectively than Wikipedia, though the size of Wikipedia is larger than that of ConceptNet. The reason may be that ConceptNet focuses on basic, unspoken knowledge which is obvious or common sense, therefore knowledge in ConceptNet may be more frequently used than those in Wikipedia.

Resource	**Method**	**P**	**R**	**F_1**
ConceptNet	ExtGM	**85.4**	**46.4**	**60.1**
ConceptNet(MFS)	ExtGM	80.9	43.4	56.5
	MFS BL	77.4	77.4	77.4

Table4. Performance on Semeval-2007 coarse-grained all words WSD (nouns only subset, and ConceptNet Only)

We further evaluate ExtGM on the two different ConceptNet: ConceptNet disambiguated by our method; ConceptNet disambiguated by MFS strategy, which assigns the most frequent sense to each ambiguous ConceptNet concept. The results are shown in Table 4, which illustrates that our method can attain significantly high increase in precision and recall. This proves that our ConceptNet disambiguating method is effective.

Algorithm	**Nouns only F_1**	**All word F_1**
ExtGM	**84.1**	**82.8**
SUSSX-FR	81.1	77.0
NUS-PT	82.3	**83.2**
MFS BL	77.4	78.9
Random BL	63.5	62.7

Table5. Performance on Semeval-2007 coarse-grained all-words WSD with MFS as a back-off strategy when no sense is assigned

Finally we compare the ExtGM with WordNet+ConceptNet to state-of-the-art WSD systems: SUSSX-FR (Koeling&McCarthy, 2007) and NUS-PT (Chan et al., 2007), which are the best unsupervised and supervised WSD systems participating in the Semeval-2007 coarse-grained all-words WSD task, respectively. Since the Semeval-2007 organizers allowed the algorithms to use the MFS as a back-off strategy when they did not return an answer, we apply this rule to ExtGM. Table 5 shows the results for nouns (1,108) and all words (2,269). The performance of ExtGM with WordNet+ConceptNet is significantly better than the best unsupervised system, and is not statistically different from the best supervised system NUS-PT. The result shows that enriching WordNet with the disambiguated ConceptNet can effectively improve the performance of knowledge-based WSD algorithms. In addition, using such enriched WordNet, even a simple knowledge-based algorithm can achieve state-of-the-art performance.

5 Conclusions

In this paper, we first proposed a novel method for the automatic disambiguation of a large-scale common sense knowledge base, namely ConceptNet. Then we used the disambiguated ConceptNet to enrichment WordNet. Our experiments show that enriching WordNet with the disambiguated ConceptNet can significantly improves the performance of knowledge-based WSD methods. On one hand, even a simple knowledge-based WSD algorithm using the enriched WordNet can perform as well as the highest-performing supervised ones. On the other hand, more sophisticated approaches (Agirre&Soroa, 2009; Navigli&Lapata, 2010) may achieve even higher performance by using such enriched WordNet. Moreover, the proposed ConceptNet disambiguating method can be easily applied for other knowledge resources to improve their quality too. We notice that ConceptNet is a multilingual common sense knowledge base, while we only concentrate on English Word Sense Disambiguation in this paper. It would be interesting to explore the impact of this knowledge resource in a multilingual setting.

Abstract

Several bilingual WSD algorithms which exploit translation correspondences between parallel corpora have been proposed. However, the availability of such parallel corpora itself is a tall task for some of the resource constrained languages of the world. We propose an ***unsupervised*** bilingual EM based algorithm which relies on the counts of translations to estimate sense distributions. ***No parallel or sense annotated corpora are needed***. The algorithm relies on a synset-aligned bilingual dictionary and in-domain corpora from the two languages. A symmetric generalized Expectation Maximization formulation is used wherein the sense distributions of words in one language are estimated based on the raw counts of the words in the aligned synset in the target language. The overall performance of our algorithm when tested on 4 language-domain pairs is better than current state-of-the-art knowledge based and bilingual unsupervised approaches.

1 Introduction

Word Sense Disambiguation (WSD) is one of the central and most widely investigated problems in Natural Language Processing (NLP). A wide variety of approaches ranging from supervised to unsupervised algorithms have been proposed. Of these, supervised approaches (Ng and Lee, 1996; Lee et al., 2004) which rely on sense annotated corpora have proven to be more successful, and they clearly outperform knowledge based and unsupervised approaches (Lesk, 1986; Walker and Amsler, 1986; Agirre and Rigau, 1996; Rada, 2005; Agirre and Soroa, 2009; McCarthy et al., 2004). However, creation of sense annotated corpora has always remained a costly proposition, especially for some of the resource deprived languages.

In this context, *"Disambiguation by Translation"* is a popular paradigm which tries to obviate the need for sense annotated corpora without compromising on accuracy. Such algorithms rely on the frequently made observation that a word in a given source language tends to have different translations in a target language depending on its sense. Given a sentence-and-word-aligned parallel corpus, these different translations in the target language can serve as automatically acquired sense labels for the source word. Although these algorithms (*e.g.*, (Diab and Resnik, 2002; Ng et al., 2003)) give high accuracies, the requirement of a significant amount of bilingual parallel corpora may be an unreasonable demand for many language pairs (perhaps more unreasonable than collecting sense annotated corpora itself).

Recent work by Khapra et al. (2009) has shown that, within a domain, it is possible to leverage the annotation work done for WSD on one language (L_2) for the purpose of another language (L_1), by projecting parameters learned from wordnet and sense annotated corpus of L_2 to L_1. This method does not require a parallel corpus. However, it requires sense marked corpus for one of the two languages. In this work, we focus on scenarios where no sense marked corpus is available in either language. Our method requires only untagged in-domain corpora from the two languages. Given such bilingual in-domain corpora (non-parallel) the counts of different translations appearing in the other language can be used to estimate the sense distributions in one language.

For example, consider the word *facility* which has two senses, *viz.*, "a building used for a particular industry" and "a service (*e.g., gym/internet facility*)". Given a set of documents from the Sports domain, it is intuitive to expect that the sec-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 695–704,
Chiang Mai, Thailand, November 8 – 13, 2011.

ond sense would be more prevalent. Similarly, if we are given a corpus of another language (say, Hindi) belonging to the same domain (*i.e.,* Sports) then we would expect to see more words which are manifestations of the second sense than the first sense. Thus, we can estimate the probabilities of different senses of the word *'facility'* by looking at the counts of its translations in different senses. In this case, the count of the translations belonging to the second sense would be more and hence this sense would emerge as the winner sense. However, the catch here is that the translations themselves might be ambiguous and hence simply relying on their counts would lead to errors. Hence, we propose a generalized Expectation Maximization based formulation where the counts get weighted by the sense probabilities estimated in the previous iteration.

The overall performance of our algorithm, when tested in an all-words scenario (as opposed to testing on specific target words) for two languages across two domains, is better than state-of-the-art knowledge based and bilingual unsupervised approaches. Further, when the evaluation is restricted to only those words which have different translations across senses, the overall performance of our algorithm is better than the wordnet first sense baseline for 2 out of the 4 language-domain pairs. Such words account for 82-83% of the total test words. This is appreciable as the wordnet first sense baseline is often *hard-to-beat* for an unsupervised approach even when restricted to specific domains. For example, in the SEMEVAL-2010 task on *"All Words WSD on a specific domain"* (Agirre et al., 2010), no unsupervised system was able to perform better than the wordnet first sense baseline.

The remainder of this paper is organized as follows. In section 2 we present related work. Section 3 describes the Synset aligned multilingual dictionary which lies at the heart of our work. In section 4 we discuss the EM formulation used for estimating sense distributions with the help of a motivating example. Section 5 presents the experimental setup. In section 6 we give the results followed by discussions in section 7. Section 8 concludes the paper.

2 Related Work

Monolingual approaches to Word Sense Disambiguation are abundant ranging from supervised, semi-supervised to unsupervised methods. Supervised approaches such as SVM (Lee et al., 2004) and k-NN (Ng and Lee, 1996) give high accuracies, but the requirement of large annotated corpora renders them unsuitable for resource scarce languages. On the other hand, Knowledge based approaches (Lesk, 1986; Walker and Amsler, 1986; Agirre and Rigau, 1996; Rada, 2005; Agirre and Soroa, 2009) which use wordnet, and unsupervised approaches (McCarthy et al., 2004) which use untagged corpus, are less demanding in terms of resources but fail to deliver good results. This situation underlines the need for high accuracy resource conscious approaches to WSD.

In this context, usupervised Word Sense Induction (WSI) methods (Jean, 2004; Klapaftis and Manandhar, 2008) which induce corpus senses by partitioning the co-occurrence graph of a target word have shown promise. One drawback of these approaches is that they require a large number of untagged instances (typically, collected from the web) for every target word to induce meaningful partitions in the co-occurrence graph. Collecting such target-word specific instances is a difficult proposition (especially in an all-words scenario) for resource constrained languages such as Hindi and Marathi which have very poor web presence. Further, in a bilingual setting where parameters need to be ported from one language to another, it is important to associate labels with the clusters induced from the graph partitions so that these clusters can be aligned across languages. This is a difficult proposition and does not fall under the purview of WSI. Hence, in this work we stick to dictionary defined senses as opposed to corpus induced senses.

Disambiguation by Translation (Gale et al., 1992; Dagan and Itai, 1994; Resnik and Yarowsky, 1999; Ide et al., 2001; Diab and Resnik, 2002; Ng et al., 2003; TufiŞ et al., 2004; Apidianaki, 2008) is another paradigm which attempts at reducing the need for annotated corpora, while ensuring high accuracy. The idea is to use the different target translations of a source word as automatically acquired sense labels. A severe drawback of these algorithms is the requirement of a significant amount of parallel corpora which may be difficult to obtain for many language pairs.

Li and Li (2004) proposed an approach based on bilingual bootstrapping which does not need parallel corpora and relies only on in-domain corpora

from two languages. However, their approach is semi-supervised in contrast to our approach which is unsupervised. Further, they focus on the more specific task of Word Translation Disambiguation (WTD) as opposed to our work which focuses on the broader task of WSD.

Kaji and Morimoto (2002) proposed an unsupervised bilingual approach which aligns statistically significant pairs of related words in language L_1 with their cross-lingual counterparts in language L_2 using a bilingual dictionary. This approach is based on two assumptions (i) words which are most significantly related to a target word provide clues about the sense of the target word and (ii) translations of these related words further reinforce the sense distinctions. The translations of related words thus act as cross-lingual clues for disambiguation. This algorithm when tested on 60 polysemous words (using English as L_1 and Japanese as L_2) delivered high accuracies (coverage=88.5% and precision=77.7%). However, when used in an all-words scenario on our dataset, this algorithm performed poorly (see section 6).

Our work focuses on a bilingual approach for estimating sense distributions and the only resources required for our work are in-domain corpora from two languages and a synset aligned multilingual dictionary which is described in the next section.

3 Synset Aligned Multilingual Dictionary

A novel and effective method of storage and use of dictionary in a multilingual setting was proposed by Mohanty et al. (2008). For the purpose of current discussion, we will refer to this multilingual dictionary framework as *MultiDict*. One important departure in this framework from the traditional dictionary is that **synsets are linked, and after that the words inside the synsets are linked.** The basic mapping is thus between synsets and thereafter between the words.

Concepts	L1 (English)	L2 (Hindi)	L3 (Marathi)
04321: a youthful male person	{malechild, boy}	{लड़का *(ladkaa)*, बालक *(baalak)*, बच्चा *(bachchaa)*}	{मुलगा *(mulgaa)*, पोरगा *(porgaa)*, पोर *(por)*}

Table 1: Multilingual Dictionary Framework

Table 1 shows the structure of MultiDict, with one example row standing for the concept of *boy*. The first column is the pivot describing a concept with a unique ID. The subsequent columns show the words expressing the concept in respective languages (in the example table, *English, Hindi and Marathi*). The pivot language to which other languages link is Hindi. This approach of creating wordnet for a new language by linking to the synsets of a pivot language - more popularly known as the expansion approach - has several advantages over creating a wordnet from scratch as discussed in Mohanty et al. (2008).

Note that every word in the Marathi synset is considered to be a translation of the corresponding words in the Hindi synset. Thus, the Marathi words *mulgaa*, *porgaa* and *por* are translations of the Hindi word *ladakaa* and so on. These synset-specific translations play a very important role in our work as explained in the next section.

4 Bilingual EM for estimating sense distributions

We first explain the intuition behind our approach and then derive the E and M steps of our algorithm with the help of an example.

4.1 Intuition

Our work relies on the key observation of Khapra et al. (2009) that within a domain, the co-occurrence counts of *(word, sense)* in one language can be used to estimate the sense distributions of their translations in another language. For example, consider two languages, say $L_1 = Hindi$ and $L_2 = Marathi$. Now, for a given word u in L_2 if a particular sense (say S_1) is more prevalent in a domain then a target language (L_1) corpus from the same domain will contain more words which are translations of sense S_1 as compared to words which are translations of other senses of this word. For example, the Marathi word *maan*, when used in the sense of *"body part (neck)"* gets translated in Hindi as *gardan* or *galaa* whereas when it is used in the sense of *"prestige"*, it gets translated as *aadar* or *izzat*. Now consider that corpora for the two languages are available from the Health domain. Since, in the Health domain, the *"body part (neck)"* sense is more prevalent we can expect the words *gardan* or *galaa* to be more prevalent in a Hindi Health corpus as compared to *aadar* or *izzat*. The probability of the dif-

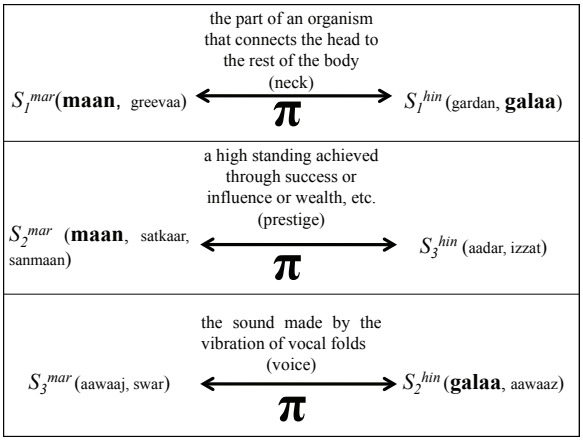

Figure 1: Alignment between different synsets of *maan* and *galaa*

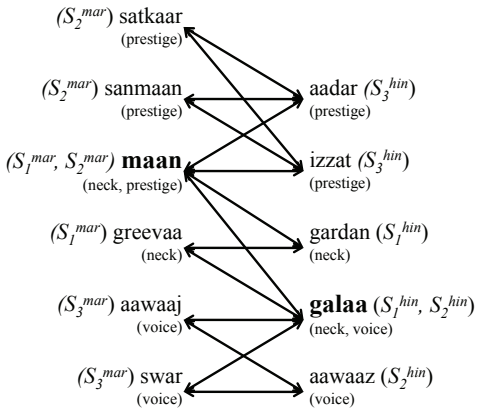

Figure 2: A bipartite graph of translation correspondences

ferent senses of *maan* can thus be estimated based on the counts of {*gardan, galaa*} and {*aadar, izzat*}. However, since the words {*gardan, galaa*} and {*aadar, izzat*} may themselves be ambiguous, their raw counts cannot be used directly for estimating the sense distributions of *maan*. Instead, these counts are refined iteratively using an EM algorithm as explained in the next subsection.

4.2 Derivation with illustration

With the basic intuition provided above, we can now start deriving the EM formulation for estimating sense distributions. For ease of understanding we present the derivation with the help of an illustration. We use the following notations,

- L_1 = first language (say, Hindi)
- L_2 = second language (say, Marathi)
- $synsets_L(word) = \{S^L | word \in S^L\}$ where, S^L denotes a synset in language L
- $words(S^L) = \{word | word \in S^L\}$
- $\pi_{L_2}(S^{L_1})$ = S^{L_2} $s.t.$ $Sense(S^{L_1}) = Sense(S^{L_2})$ *i.e.,* S^{L_1} & S^{L_2} represent the same concept in L_1 and L_2 respectively. The synsets S^{L_1} and $\pi_{L_2}(S^{L_1})$ will thus be aligned in the *MultiDict*.
- $translations_{L_2}(word, S^{L_1})$ = $words(\pi_{L_2}(S^{L_1}))$.The function $translations$ thus gives the translations of a $word \in S^{L_1}$ in the corresponding projected synset in L_2.

Now, consider the word $maan \in S_1^{mar}$ and the word $galaa \in S_1^{hin}$ where $\pi_{hin}(S_1^{mar})$ = S_1^{hin} and vice versa. Further, $galaa \in translations_{hin}(maan, S_1^{mar})$ and $maan \in translations_{mar}(galaa, S_1^{hin})$. The different synsets to which these words belong and the corresponding aligned synsets in the other language are shown in Figure 1. The complete set of translations of these words are shown in Figure 2. We are now interested in estimating $P(S_1^{mar}|maan)$ and $P(S_1^{hin}|galaa)$. Figures 1 and 2 should be referred to while reading the derivation below.

Using the basic definition of probability, we have,

$$P(S_1^{mar}|maan) = \frac{\#(S_1^{mar}, maan)}{\#(S_1^{mar}, maan) + \#(S_2^{mar}, maan)}$$

where,

$$\#(S_i^{mar}, maan) = \textit{no. of times maan appears with sense } S_i^{mar}$$

Following the approach of Khapra et al. (2009) we replace the counts of $(S_i^{mar}, maan)(i \in \{1,2\})$ by the collective counts of the translations in the aligned synsets. The rationale behind the above substitution is that if $v \in L_2$ is a translation of $u \in L_1$ in sense S then the co-occurrence count of (v, S) gives a good approximation for the co-occurrence count of (u, S). Thus,

$$P(S_1^{mar}|maan)$$
$$\approx \frac{\#(S_1^{hin}, gardan) + \#(S_1^{hin}, galaa)}{\#(S_1^{hin}, gardan) + \#(S_1^{hin}, galaa) + \#(S_3^{hin}, aadar) + \#(S_3^{hin}, izzat)}$$

where,

$S_1^{hin} = \pi_{hin}(S_1^{mar})$ $(see\ Figure\ 1)$

$S_3^{hin} = \pi_{hin}(S_2^{mar})$ $(see\ Figure\ 1)$

$(gardan, galaa) \in translations_{hin}(maan, S_1^{mar})$ $(see\ Figure\ 2)$

$(aadar, izzat) \in translations_{hin}(maan, S_2^{mar})$ $(see\ Figure\ 2)$

If we had a sense annotated corpus in Hindi then we could have easily estimated the above probability as shown by Khapra et al. (2009). We propose that even in the absence of such annotated corpus we can still estimate the sense distributions using the expected value of the terms in the above equation as shown below,

E-step

$$P(S_1^{mar}|maan) \approx \frac{P(S_1^{hin}|gardan)\cdot\#(gardan) + P(S_1^{hin}|galaa)\cdot\#(galaa)}{Z}$$

$$\begin{aligned}\text{where, } Z = {} & P(S_1^{hin}|gardan)\cdot\#(gardan) \\ & + P(S_1^{hin}|galaa)\cdot\#(galaa) \\ & + P(S_3^{hin}|aadar)\cdot\#(aadar) \\ & + P(S_3^{hin}|izzat)\cdot\#(izzat)\end{aligned}$$

The above equation takes care of the fact that the different translations of $maan$ would themselves be ambiguous and hence their raw counts (*e.g*, $\#(gardan)$, $\#(galaa)$, *etc.*) cannot be used directly for estimations. Instead, these counts are weighted with the appropriate probability to calculate the expected count (*e.g.*, $E[\#(S_1^{hin}, galaa)] = P(S_1^{hin}|galaa)\cdot\#(galaa)$). The parameters $P(S_1^{hin}|galaa)$, $P(S_1^{hin}|gardan)$, $P(S_3^{hin}|aadar)$ and $P(S_3^{hin}|izzat)$ above are unknown and can in turn be estimated using the counts of the corresponding translations of these words (see Figure 2) as shown below:

M-step

$$P(S_1^{hin}|galaa) \approx \frac{P(S_1^{mar}|maan)\cdot\#(maan) + P(S_1^{mar}|greeva)\cdot\#(greeva)}{Z}$$

$$\begin{aligned}Z = {} & P(S_1^{mar}|maan)\cdot\#(maan) \\ & + P(S_1^{mar}|greeva)\cdot\#(greeva) \\ & + P(S_3^{mar}|aawaaj)\cdot\#(aawaaj) \\ & + P(S_3^{mar}|swar)\cdot\#(swar) \\ & \text{where,} \\ & S_1^{mar} = \pi_{hin}(S_1^{hin})\ (see\ Figure\ 1) \\ & S_3^{mar} = \pi_{mar}(S_2^{hin})\ (see\ Figure\ 1) \\ & (maan, greeva) \in translations_{mar}(galaa, S_1^{hin})\ (see\ Figure\ 2) \\ & (aawaaj, swar) \in translations_{mar}(galaa, S_2^{hin})\ (see\ Figure\ 2)\end{aligned}$$

Similarly, the other parameters (*i.e.*, $P(S_1^{hin}|gardan)$, $P(S_3^{hin}|aadar)$ and $P(S_3^{hin}|izzat)$) can be estimated. The overall process of estimating sense distributions in the two languages can thus be considered to be a back-and-forth traversal over translation correspondences as shown in Figure 2. The two languages thus mutually help each other in estimating sense distributions. In general, for a word $u \in L_1$ and a word $v \in L_2$ the E and M steps can be written as shown below.

E-Step:

$$P(S_k^{L_1}|u) \approx \frac{\sum_v P(\pi_{L_2}(S_k^{L_1})|v)\cdot\#(v)}{\sum_{S_i^{L_1}}\sum_y P(\pi_{L_2}(S_i^{L_1})|y)\cdot\#(y)}$$

$$\begin{aligned}\text{where, } & S_k^{L_1}, S_i^{L_1} \in synsets_{L_1}(u) \\ & v \in translations_{L_2}(u, S_k^{L_1}) \\ & y \in translations_{L_2}(u, S_i^{L_1})\end{aligned}$$

M-Step:

$$P(S_j^{L_2}|v) \approx \frac{\sum_a P(\pi_{L_1}(S_j^{L_2})|a)\cdot\#(a)}{\sum_{S_i^{L_2}}\sum_b P(\pi_{L_1}(S_i^{L_2})|b)\cdot\#(b)}$$

$$\begin{aligned}\text{where, } & S_j^{L_2}, S_i^{L_2} \in synsets_{L_2}(v) \\ & a \in translations_{L_1}(v, S_j^{L_2}) \\ & b \in translations_{L_1}(v, S_i^{L_2})\end{aligned}$$

Note that the E and M steps are symmetrical except for the change in languages. Either of them could be the E-step, making the other as the M-step. Once the sense distributions have been estimated using the above EM algorithm, each word in the test corpus is disambiguated by assigning it the most frequent sense as learned from the sense distributions.

4.3 Problematic cases in estimating sense distributions using EM (non-progressiveness estimation)

Some words have the same translations in the target language across senses. For example, the word *samudra* in Marathi has two senses, *viz.*, S_1 = *a large water body* and S_2 = *a limitless quantity*, which is a metaphorical sense (*e.g.*, a *sea* of opportunities). The corresponding Hindi synsets contain the same word, *viz.*, *saagar*. In other words, *samudra* in Marathi gets translated as *saagar* in Hindi irrespective of its sense. Further, the back-translation of *saagar* in Marathi is *samudra* in both the senses. These words thus form a closed loop of translations. In such cases the algorithm

Category	Avg. degree of wordnet polysemy for polysemous words	
	Tourism	Health
Noun	3.06	3.18
Verb	4.96	5.18
Adjective	2.60	2.72
Adverb	2.44	2.45
All	3.14	3.29

Table 5: Average degree of wordnet polysemy per category in the 2 domains for Marathi

will not progress and get stuck with the initial values. It will thus fail to produce better estimates in successive iterations.

Further, for some language-specific words appearing in L_1 (or L_2), no projected synsets were available in L_2 (or L_1 respectively). As evident from the E and M steps, in the absence of such synsets, the algorithm will assign zero probabilities to all the senses of such words.

5 Experimental Setup

We used the publicly available dataset[1] described in Khapra et al. (2010) for all our experiments. The data was collected from two domains, *viz.*, Tourism and Health. The data for Tourism domain was collected by manually translating English documents downloaded from Indian Tourism websites into Hindi and Marathi. Similarly, English documents for Health domain were obtained from two doctors and were manually translated into Hindi and Marathi. The entire data was then manually annotated by three lexicographers adept in Hindi and Marathi. To calculate the inter-tagger agreement (ITA), we we got a small portion (around 5%) of the corpus annotated by two annotators[2]. The ITA on this small corpus was found to be around 85%.

Since ours is an unsupervised algorithm, we refer to the manually assigned sense labels only for evaluation and do not use them during training. The various statistics pertaining to the total number of words, number of words per POS category and average degree of polysemy are described in Tables 2 to 5. Although Tables 2 and 3 also report the number of monosemous words, we would like to clearly state that we do not include monosemous words while evaluating the performance of our algorithms (such words do not need any disambiguation).

We did a 2-fold cross validation of our algorithm using this corpus. The unsupervised parameter estimation was done using 1 fold and testing was done on the remaining fold. Each word in the test corpus is disambiguated by assigning it the most frequent sense as learned from the estimated sense distributions. Note that even though the corpora were parallel we have not used this property in any way in our experiments or EM formulation. In fact, the documents in the two languages were arbitrarily split into 2 folds so that the parallel documents do not fall in the same folds for the two languages. Further, we observed that whether the documents are split arbitrarily (such that parallel documents do not lie in the same fold) or carefully (such that parallel documents lie in the same fold) the overall F-scores remain comparable (within $\pm$ 0.5%). Also note that there was sufficient variety in our corpus as the Tourism documents were related to places from all over India. Similarly, the Health documents were related to a wide range of diseases from common cold to cancer.

6 Results

We report the results using following algorithms:

a. Wordnet first sense ***(WFS)***: The F-score obtained by selecting the first sense of every word. This is a typically reported baseline for supervised approaches as the WFS of a word in

[1] http://www.cfilt.iitb.ac.in/wsd/annotated_corpus

[2] It is very expensive to get the entire corpus tagged by 2 annotators. Hence, we calculated the ITA based on the agreement between two lexicographers on a small portion of the corpus

Table 9: Average 2-fold cross validation results for each Language-Domain pairs for words which do not face the problem of non-progressiveness estimation

Hindi and Marathi wordnets is determined manually by a lexicographer based on his/her native speaker intuition.

b. Random Baseline ***(RB)***: The F-score obtained by selecting a random sense of every word. This is a typically reported baseline for unsupervised approaches.

c. Bilingual Expectation Maximization ***(EM)***: The F-score obtained by using our approach.

d. Personalized PageRank ***(PPR)***: The F-score obtained by using a state-of-the-art knowledge based approach (Agirre and Soroa, 2009).

e. Mutual Information ***(MI)***: The F-score obtained by using the bilingual unsupervised approach of Kaji and Morimoto (2002) which uses cross-lingual clues based on in-domain corpora and aligned synsets.

6.1 A note on other state-of-the-art approaches

The unsupervised algorithm by McCarthy et al. (2004) which uses in-domain corpora to estimate predominant senses would have been more appropriate for comparison with our approach as it is a corpus based approach as opposed to PPR which is a wordnet based approach. However, this approach requires a dependency parser to extract syntactic relations to construct a feature vector for identifying the nearest neighbors of a target word. Unfortunately, such parsers are not available for Hindi and Marathi and hence we could not compare our algorithm with this approach. Further, there are other unsupervised approaches (see section 2) which use corpus induced senses and/or parallel corpora. However, our work focuses on dictionary defines senses and does not need parallel corpora. Hence we did not find it appropriate to present a comparison with these algorithms.

6.2 Non-progressiveness estimation

We observed that around 17-18% of the total words in the corpus face the problem discussed in section 4.3. Hence we report 2 sets of results:

(i) only for those words which do not face the problem of non-progressiveness estimation.

(ii) for all words.

The first set of results thus covers 82-83% of the words in the corpus depending on the language and the domain.

All the results are summarized in Tables 6 to 9. Table 6 gives the overall average F-score for

all-words over all language domain pairs. Similarly, Table 7 gives the overall average F-score for only those words which do not face the problem of non-progressiveness estimation. Tables 8 and 9 give the average F-score for each language-domain pair for all words and for words which do not face the problem of non-progressiveness estimation respectively. In all tables, we report F-scores for each POS category (N:-nouns, R:-adverbs, A:-adjectives, V:-verbs, O:-all).

7 Discussions

We discuss the important observations made from Tables 6 to 9.

7.1 Performance on all words

The overall performance of our algorithm (see Table 6) is better than state-of-the-art knowledge based approach (PPR) by 3%, bilingual unsupervised approach (MI) by 41% and random baseline (RB) by 17%. These results are consistent across all language-domain pairs except for MARATHI-TOURISM where the performance of PPR is better than our algorithm by 0.5%. On an average the performance of PPR on nouns is better than our algorithm by 3%. However, in 2 out of the 4 language-domain pairs our algorithm does better on nouns than PPR (by 6% in HINDI-HEALTH and 2% in MARATHI-HEALTH - see Table 8). PPR gives an F-score of 0% for adverbs in all language-domain pairs because Hindi and Marathi wordnets do not have any synset relations defined for adverbs.

The performance of all the algorithms is less than the wordnet first sense baseline. As stated earlier, this is a hard baseline for unsupervised approaches (Agirre et al., 2010). Note that the wordnet first sense baseline is more like a supervised approach because the first sense of a word is either determined manually by a lexicographer or by using counts from a mixed domain sense marked corpus. This is a laborious and expensive task which is difficult to do for wordnets of resource deprived languages.

7.2 Performance on words not facing the problem of non-progressiveness estimation

When the performance is restricted to words which do not face the problem of non-progressiveness estimation our approach still does better than PPR, MI and random baseline (see Table 7). Here, the results are consistent across all language-domain pairs (see Table 9). In addition, for two language-domain pairs (*viz.*, MARATHI-HEALTH and HINDI-HEALTH) our algorithm does better than the wordnet first sense baseline. Even though the overall improvement over WFS is small (1-2%) it is still appreciable for an unsupervised approach. Note that none of the other approaches (PPR, MI) are able to perform better than WFS in any language-domain pair.

7.3 Poor performance on verbs

Amongst all the POS categories, the performance of our algorithm is lowest for verbs. We observed that there are two main reasons for this. Firstly, the polysemy of verbs is much higher than that of other POS categories (see Tables 4 & 5). This is a commonly observed problem for all algorithms. Secondly, we observed that many verbs have very fine senses because of which they tend to have overlapping sets of translations across senses. Even though they do not form a closed loop of translations they share many translations across senses. For example, the Hindi word *karna* has the same Marathi translation *karne* in 8 out of the 21 senses that it appears in. Due to these shared translations, the approach of "disambiguation by translation" does not have much scope in the case of such verbs.

8 Conclusions

We presented an unsupervised bilingual approach for estimating sense distributions of words. The algorithm does not require any parallel corpora and uses only in-domain corpora from the two languages. The sense distributions are estimated using a novel bilingual EM formulation by performing a back-and-forth traversal over translation correspondences in the two languages. The algorithm consistently beats the random baseline and state-of-the-art knowledge based and unsupervised approaches. Further, when tested on words which have different translations across senses, the algorithm gives slight improvement over the wordnet first sense baseline in 2 out of the 4 language-domain pairs.

As future work, we would like to test our algorithm on language pairs which belong to distant families so that the number of words having same translations across senses would be less.

Abstract

Compositional Distributional Semantic methods model the distributional behavior of a compound word by exploiting the distributional behavior of its constituent words. In this setting, a constituent word is typically represented by a feature vector conflating all the senses of that word. However, not all the senses of a constituent word are relevant when composing the semantics of the compound. In this paper, we present two different methods for selecting the relevant senses of constituent words. The first one is based on Word Sense Induction and creates a static multi prototype vectors representing the senses of a constituent word. The second creates a single dynamic prototype vector for each constituent word based on the distributional properties of the other constituents in the compound. We use these prototype vectors for composing the semantics of noun-noun compounds and evaluate on a compositionality-based similarity task. Our results show that: (1) selecting relevant senses of the constituent words leads to a better semantic composition of the compound, and (2) dynamic prototypes perform better than static prototypes.

1 Introduction

Vector Space Models of lexical semantics have become a standard framework for representing a word's meaning. Typically these methods (Schütze, 1998; Pado and Lapata, 2007; Erk and Padó, 2008) utilize a bag-of-words model or syntactic dependencies such as subject/verb, object/verb relations, so as to extract the features which serve as the dimensions of the vector space. Each word is then represented as a vector of the extracted features, where the frequency of co-occurrence of the word with each feature is used to calculate the vector component asociated with that feature. Figure 1 provides an example of two nouns assuming a bag-of-words model.

	vector dimensions					
	animal	buy	apartment	price	rent	kill
house	⟨ 30	60	90	55	45	10 ⟩
hunting	⟨ 90	15	12	20	33	90 ⟩

Figure 1: A hypothetical vector space model.

Compositional Distributional Semantic methods formalise the meaning of a phrase by applying a vector composition function on the vectors associated with its constituent words (Mitchell and Lapata, 2008; Widdows, 2008). For example, the result of *vector addition* to compose the semantics of *house hunting* from the vectors **house** and **hunting** is the vector $\langle 120,\ 75,\ 102,\ 75,\ 78,\ 100 \rangle$.

As can be observed the resulting vector does not reflect the correct meaning of the compound *house hunting* due to the presence of irrelevant co-occurrences such as *animal* or *kill*. These co-occurrences are relevant to one sense of *hunting*, i.e. (*the activity of hunting animals*), but not to the sense of *hunting* meant in *house hunting*, i.e. *the activity of looking thoroughly*. Given that *hunting* has been associated with a single prototype (vector) by conflating all of its senses, the application of a composition function $\oplus$ is likely to include irrelevant co-occurrences in $\mathbf{house} \oplus \mathbf{hunting}$.

A potential solution to this problem would involve the following steps:

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 705–713,
Chiang Mai, Thailand, November 8 – 13, 2011.

1. build separate prototype vectors for each of the senses of *house* and *hunting*
2. select the relevant prototype vectors of *house* and *hunting* and then perform the semantic composition.

In this paper we present two methods (section 3) for carrying out the above steps on noun-noun compounds. The first one (section 3.1) applies Word Sense Induction (WSI) to identity different senses (also called static multi prototypes) of the constituent words of a compound noun and then applies composition by choosing the relevant senses. The second method (section 3.2) does not identify a fixed set of senses. Instead, it represents each constituent by a prototype vector which is built dynamically (also called as a dynamic prototype) by activating only those contexts considered to be relevant to the constituent in the presence of the other constituent, and then performs the composition on the dynamic prototypes. For performing composition, we use vector composition functions.

Our evaluation (section 5) on a task for rating similarity between noun-noun compound pairs shows: (1) sense disambiguation of constituents improves semantic composition and (2) dynamic prototypes are better than static multi prototypes for semantic composition.

2 Related work

Any distributional model that aims to describe language adequately needs to address the issue of compositionality. Many distributional composition functions have been proposed in order to estimate the semantics of compound words from the semantics of the constituent words. Mitchell and Lapata (2008) discussed and evaluated various composition functions for phrases consisting of two words. Among these, the simple additive (ADD) and simple multiplicative (MULT) functions are easy to implement and competitive with respect to existing sophisticated methods (Widdows, 2008; Vecchi et al., 2011).

Let us assume a target compound noun N that consists of two nouns n and n'. Bold letters represent their corresponding distributional vectors obtained from corpora. $\oplus(\mathbf{N})$ denotes the vector of N obtained by applying the composition function $\oplus$ on $\mathbf{n}$ and $\mathbf{n}'$. Real number v_i denote the i^{th} co-occurrence in $\mathbf{v}$. The functions ADD and MULT following Mitchell and Lapata (2008) are defined as follows:

$$\begin{aligned} &\text{ADD:} && \oplus(\mathbf{N}) = \alpha\,\mathbf{n} + \beta\,\mathbf{n}' \\ &&& \text{i.e. } \oplus(\mathbf{N})_i = \alpha\,\mathrm{n}_i + \beta\,\mathrm{n}'_i \\ &\text{MULT:} && \oplus(\mathbf{N}) = \mathbf{n}\mathbf{n}' \\ &&& \text{i.e. } \oplus(\mathbf{N})_i = \mathrm{n}_i \,.\, \mathrm{n}'_i \end{aligned} \tag{1}$$

where α and β are real numbers.

Relevant to our work is the work of Erk and Padó (2008) who utilize a structured vector space model. The prototype vector of a constituent word is initially built, and later refined by removing irrelevant co-occurrences with the help of the selectional preferences of other constituents. The refined vectors are then used for the semantic composition of the compound noun. The results are encouraging showing that polysemy is a problem in vector space models. Our approach differs to theirs in the way we represent meaning - we experiment with static multi prototypes and dynamic prototypes. Our vector space model is based on simple bag-of-words which does not require selectional preferences for sense disambiguation and can be applied to resource-poor languages.

There are several other researchers who tried to address polysemy for improving the performance of different tasks but not particularly to the task of semantic composition. Some of them are Navigli and Crisafulli (2010) for web search results clustering, Klapaftis and Manandhar (2010b) for taxonomy learning, Reisinger and Mooney (2010) for word similarity and Korkontzelos and Manandhar (2009) for compositionality detection. In all cases, the reported results demonstrate that handling polysemy lead to improved performance of the corresponding tasks. This motivates our research for handling polysemy for the task of semantic composition using two different methods described in the next section.

3 Sense Prototype Vectors for Semantic Composition

In this section we describe two approaches for building sense specific prototype vectors of constituent words in a noun-noun compound. The first approach performs WSI to build static multi prototype vectors. The other builds a single dynamic prototype vector for each constituent by activating only the relevant exemplars of the constituent

with respect to the other constituent. An exemplar is defined as a corpus instance of a target word.

These sense specific prototype vectors are then used for semantic composition. Let N be the compound noun with constituents n and n'. Our aim is to select the relevant senses of n and n'.

3.1 Static Multi Prototypes Based Sense Selection

In the first stage (section 3.1.1), a WSI method is applied to both n and n'. The outcome of this stage is a set of clusters (senses). Each of these clusters is associated with a prototype vector taking the centroid of the cluster. Following Reisinger and Mooney (2010) we use the terminology *multi prototype vectors* in the meaning of *sense clusters*. Let $S(n)$ (resp. $S(n')$) be the set of prototypes of n, where each $s_i^n \in S(n)$ denotes the i^{th} sense of the noun n. Since these prototypes of constituents are static and do not change when the compound changes we refer to them as *static multi prototypes*.

In the next stage (section 3.1.2), we calculate all the pairwise similarities between the clusters of n and n', so as to select a pair of clusters with the highest similarity. The selected clusters are then combined using a composition function, to produce a single vector representing the semantics of the target compound noun N.

3.1.1 Graph-based WSI

Word Sense Induction is the task of identifying the senses of a target word in a given text. We apply a graph-based sense induction method, which creates a graph of target word instances and then clusters that graph to induce the senses. We follow the work of Klapaftis and Manandhar (2010a) for creating the graph and apply *Chinese Whispers* (CW) (Biemann, 2006), a linear graph clustering method that automatically identifies the number of clusters.

Figure 2 provides a running example of the different stages of the WSI method. In the example, the target word *mouse* appears with the *electronic device* sense in the contexts *A*, *C*, and with the *animal* sense in the contexts *B* and *D*.

Corpus preprocessing: Let bc denote the base corpus consisting of the contexts containing the target word tw. In our work, a context is defined by a set of words in a window of size 100 around the target.

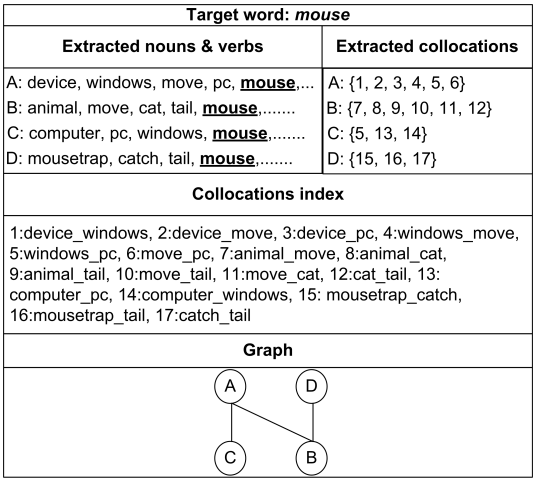

Figure 2: Running example of WSI

The aim of this stage is to capture words contextually related to tw. In the first step, the target word is removed from bc and part-of-speech tagging is applied to each context. Only nouns and verbs are kept and lemmatised. In the next step, the distribution of each word in the base corpus is compared to the distribution of the same noun in a reference corpus using the log-likelihood ratio (G^2) (Dunning, 1993). Words that have a G^2 below a pre-specified threshold (parameter p_1) are removed from each context of the base corpus. The result of this stage is shown in the upper left part of Figure 2.

Graph creation & clustering: Each context $c_i \in bc$ is represented as a vertex in a graph G. Edges between the vertices of the graph are drawn based on their similarity, defined in Equation 2, where $sm_{cl}(c_i, c_j)$ is the *collocational weight* of contexts c_i, c_j and $sm_{wd}(c_i, c_j)$ is their bag-of-words weight. If the edge weight $W(c_i, c_j)$ is above a prespecified threshold (parameter p_3), then an edge is drawn between the corresponding vertices in the graph.

$$W(c_i, c_j) = \frac{1}{2}(sm_{cl}(c_i, c_j) + sm_{wd}(c_i, c_j)) \quad (2)$$

Collocational weight: The limited polysemy of collocations is exploited to compute the similarity between contexts c_i and c_j. In this setting, a collocation is a juxtaposition of two words within the same context. Given a context c_i, a total of $\binom{N}{2}$ collocations are generated by combining each word with any other word in the context. Each collocation is weighted using the log-likelihood ratio (G^2) (Dunning, 1993) and is filtered out if the G^2

is below a prespecified threshold (parameter p_2). At the end of this process, each context c_i of tw is associated with a set of collocations (g_i) as shown in the upper right part of Figure 2 . Given two contexts c_i and c_j, the Jaccard coefficient is used to calculate the similarity between the collocational sets, i.e. $sm_{cl}(c_i, c_j) = \frac{|g_i \cap g_j|}{|g_i \cup g_j|}$.

Bag-of-words weight: Estimating context similarity using collocations may provide reliable estimates regarding the existence of an edge in the graph, however, it also suffers from data sparsity. For this reason, a bag-of-words model is also employed. Specifically, each context c_i is associated with a set of words (g_i) selected in the corpus preprocessing stage. The upper left part of Figure 2 shows the words associated with each context of our example. Given two contexts c_i and c_j, the bag-of-words weight is defined to be the Jaccard coefficient of the corresponding word sets, i.e. $sm_{wd}(c_i, c_j) = \frac{|g_i \cap g_j|}{|g_i \cup g_j|}$.

Finally, the collocational weight and bag-of-words weight are averaged to derive the edge weight between two contexts as defined in Equation 2. The resulting graph of our running example is shown on the bottom of Figure 2. This graph is the input to CW clustering algorithm. Initially, CW assigns all vertices to different classes. Each vertex i is processed for an x number of iterations and inherits the strongest class in its local neighborhood LN in an update step. LN is defined as the set of vertices which share a direct connection with vertex i. During the update step for a vertex i: each class C_k receives a score equal to the sum of the weights of edges (i, j), where j has been assigned class C_k. The maximum score determines the strongest class. In case of multiple strongest classes, one is chosen randomly. Classes are updated immediately, which means that a node can inherit classes from its LN that were introduced in the same iteration.

Experimental setting The parameters of the WSI method were fine-tuned on the nouns of the SemEval-2007 word sense induction task (Agirre and Soroa, 2007) under the second evaluation setting of that task, i.e. supervised (WSD) evaluation. We tried various parameter combinations shown in Table 1. Specifically, we selected the parameter combination p_1=15, p_2=10, p_3= 0.05 that maximized the performance in this evaluation. We use ukWaC (Ferraresi et al., 2008) corpus to retrieve all the instances of the target words.

Parameter	Range
G^2 word threshold (p_1)	15,25,35,45
G^2 collocation threshold (p_2)	10,15,20
Edge similarity threshold (p_3)	0.05,0.09,0.13

Table 1: WSI parameter values.

3.1.2 Cluster selection

The application of WSI on the nouns $n \in N$ and $n' \in N$ results in two sets of clusters (senses) $S(n)$ and $S(n')$. Cluster $S(n)$ is a set of contexts of the word n. Each context is represented as an exemplar $\mathbf{e}$, a vector specific to the context. Only the 10000 most frequent words in the ukWaC (along with their part-of-speech category) are treated as the valid co-occurrences i.e. the dimensionality of the vector space is 10000. For example, the exemplar of *hunting* in the context *"the-x purpose-n of-i autumn-n hunting-n be-v in-i part-n to-x cull-v the-x number-n of-i young-j autumn-n fox-n"* is ⟨ purpose-n:1, autumn-n:2, part-n:1, cull-v, number-n:1, young-j:1, fox-n:1 ⟩

For every cluster s_i^n in $S(n)$ we construct a prototype vector $\mathbf{v^{s_i^n}}$ by taking the centroid of all the exemplars in the cluster. Following Mitchell and Lapata (2008), the context words in the prototype vector are set to the ratio of probability of the context word given the target word to the overall probability of the context word[1].

The next step is to choose the relevant sense of each constituent for a given compound. We assume that the meaning of a compound noun can be approximated by identifying the most similar senses of each of its constituent nouns. Accordingly all the pairwise similarities between the $\mathbf{v^{s_i^n}}$ and $\mathbf{v^{s_i^{n'}}}$ are calculated using cosine similarity and the pair with maximum similarity is chosen for composition.

3.2 Dynamic Prototype Based Sense Selection

Kilgarriff (1997) argues that representing a word with a fixed set of senses is not a good way of modelling word senses. Instead word senses should be defined according to a given context. We propose a dynamic way of building word senses for the constituents of a given compound.

We use an exemplar-based approach to build the dynamic sense of a constituent with the help of other constituent. In exemplar-based modelling

Figure 3: Six random sentences of *light* from ukWaC

(Erk and Padó, 2010; Smith and Medin, 1981), each word is represented by all its exemplars without conflating them into a single vector. Depending upon the purpose, only relevant exemplars of the target word are activated. Exemplar-based models are more powerful than just prototype based ones because they retain specific instance information. As described in the previous section, an exemplar is a vector that represents a single instance of a given word in the corpus.

Let E_n be the set of exemplars of the word n. Given a compound N with constituents n and n', we remove irrelevant exemplars in E_n creating a refined set $E_n^{n'} \subset E_n$ with the help of the other constituent word n'. The prototype vector $\mathbf{n^{n'}}$ of n is then built from the centroid of the refined exemplar set $E_n^{n'}$. The vector $\mathbf{n^{n'}}$ represents the relevant prototype vector (sense) of n in the presence of the other constituent word n'. Unlike the static prototypes defined in the previous section, the prototype vectors of n and n' are built dynamically based on the given compound. Therefore, we refer to them as dynamic prototype vectors.

3.2.1 Building Dynamic Prototypes

We demonstrate our method of building dynamic prototypes with an example. Let us take the compound *traffic light*. Let $\mathbf{Traffic}$, $\mathbf{Light}$ and $\mathbf{TrafficLight}$ denote the prototype vectors of *traffic*, *light* and *traffic light* respectively. Word *light* occurs in many contexts such as quantum theory, optics, lamps and spiritual theory. In ukWaC, $light$ occurs with 316,126 exemplars. Figure 3 displays 6 random sentences of *light* from ukWaC. None of these exemplars are related to the target compound *traffic light*. When a prototype vector of *light* is built from all its exemplars, irrelevant exemplars add noise increasing the semantic differences between *traffic light* and *light* and thereby increasing the semantic differences between $\mathbf{TrafficLight}$ and $\mathbf{Traffic} \oplus \mathbf{Light}$. This is not desirable. The cosine similarity sim($\mathbf{Light}$, $\mathbf{TrafficLight}$) is found to be 0.27.

We aim to remove irrelevant exemplars of *light* with the help of the other constituent word *traffic* and then build a prototype vector of *light* which is related to the compound *traffic light*. Our intuition and motivation for exemplar removal is that it is beneficiary to choose only the exemplars of *light* which have context words related to *traffic* since the exemplars of *traffic light* will have context words related to both *traffic* and *light*. For example car, road, transport will generally be found within the contexts of all the words *traffic*, *light* and *traffic light*.

We rank each exemplar of *light* with the help of collocations of *traffic*. Collocations of *traffic* are defined as the context words which frequently occur with *traffic*, e.g. car, road etc. The exemplar of *light* representing the sentence "*Cameras capture **cars** running red **lights** ...*" will be ranked higher than the one which does not have context words related to *traffic*. We use Sketch Engine[2] (Kilgarriff et al., 2004) to retrieve the collocations of *traffic* from ukWaC. Sketch Engine computes the collocations using Dice metric (Dice, 1945). We build a collocation vector $\mathbf{Traffic^{colloc}}$ from the collocations of *traffic*.

We also rank each exemplar of *light* using the distributionally similar words to *traffic* i.e. words which are similar to *traffic* e.g. transport, flow etc. These distributionally similar words helps to reduce the impact of data sparseness and helps prioritize the contexts of *light* which are semantically related to *traffic*. Sketch Engine is again used to retrieve distributionally similar words of *traffic* from ukWaC. Sketch Engine ranks similar words using the method of Rychlý and Kilgarriff (2007). We build the vector $\mathbf{Traffic^{similar}}$ which consists of the similar words of *traffic*.

Every exemplar $\mathbf{e}$ from the exemplar set E_{light} [3] is finally ranked by

$$sim(\mathbf{e}, \mathbf{Traffic^{colloc}}) + sim(\mathbf{e}, \mathbf{Traffic^{similar}})$$

[2] Sketch Engine `http://www.sketchengine.co.uk`

[3] In E_{light}, we do not include the sentences which have the compound noun *traffic light* occurring in them.

We choose the top n% of the ranked exemplars in E_{light} to construct a refined exemplar set $E_{\text{light}}^{\text{traffic}}$. A prototype vector $\mathbf{Light}^{\mathbf{Traffic}}$ is then built by taking the centroid of $E_{\text{light}}^{\text{traffic}}$. $\mathbf{Light}^{\mathbf{Traffic}}$ denotes the sense of *light* in the presence of *traffic*. Since sense of *light* is built dynamically based on the given compound (here *traffic light*), we define $\mathbf{Light}^{\mathbf{Traffic}}$ as the dynamic prototype vector. The similarity sim($\mathbf{Light}^{\mathbf{Traffic}}$, $\mathbf{TrafficLight}$) is found to be 0.47 which is higher than the initial similarity 0.27 of $\mathbf{Light}$ and $\mathbf{TrafficLight}$. This shows that our new prototype vector of *light* is closer to the meaning of *traffic light*.

Similarly we build the dynamic prototype vector $\mathbf{Traffic}^{\mathbf{Light}}$ of *traffic* with the help of $light$. The dynamic prototypes $\mathbf{Traffic}^{\mathbf{Light}}$ and $\mathbf{Light}^{\mathbf{Traffic}}$ are used for semantic composition to construct $\mathbf{Traffic}^{\mathbf{Light}} \oplus \mathbf{Light}^{\mathbf{Traffic}}$

4 Composition functions

Given a compound, we perform composition using the sense based prototypes selected in the above section. We use the composition functions ADD and MULT described in Equation 1.

For the function ADD, we use equal weights for both constituent words i.e. $\alpha = \beta = 1$. For the function MULT there are no parameters.

5 Evaluation

Mitchell and Lapata (2010) introduced an evaluation scheme for semantic composition models. We evaluate on their dataset, describe the evaluation scheme, and present the results of various models.

5.1 Dataset

Mitchell and Lapata (2010) prepared a dataset[4] which contains pairs of compound nouns and their similarity judgments. The dataset consists of 108 compound noun pairs with each pair having 7 annotations from different annotators who judge the pair for similarity. A sample of 5 compound pairs is displayed in Table 2.

5.2 Evaluation Scheme

For each pair of the compound nouns, the mean value of all its annotations is taken to be the final similarity judgment of the compound.

[4]We would like to thank Jeff Mitchell and Mirella Lapata for sharing the dataset.

Annotator	N	N'	rating
4	phone call	committee meeting	2
25	phone call	committee meeting	7
11	football club	league match	6
11	health service	bus company	1
14	company director	assistant manager	7

Table 2: Evaluation dataset of Mitchell and Lapata (2010)

Let N and N' be a pair. To evaluate a model, we calculate the cosine similarity between the composed vectors $\oplus(\mathbf{N})$ and $\oplus(\mathbf{N}')$ obtained from the composition on sense based prototypes generated by the model. These similarity scores are correlated with human mean scores to judge the performance of the model.

5.3 Models Evaluated

We evaluate all the models w.r.t. the composition functions ADD and MULT.

Static Single Prototypes: This model does not perform any sense disambiguation and is similar to the method described in (Mitchell and Lapata, 2008). The prototype vector of each constituent formed by conflating all its instances is used to compose the vector of the compound.

Static Multi Prototypes: In the method described in section 3.1, word sense induction produces a large number of clusters i.e. static multi prototypes. We tried various parameters like choosing the target prototype of a constituent only from the top 5 or 10 large clusters.

Dynamic Prototypes: In the method described in section 3.2, the dynamic prototype of a constituent is produced from the top n% exemplars of the ranked exemplar set of the constituent. We tried various percent activation (n%) values - 2%, 5%, 10%, 20%, 50%, 80%.

Compound Prototype: We directly use the corpus instances of a compound to build the prototype vector of the compound. This method does not involve any composition. Ideally, one expects this model to give the best performance.

Static Multi Prototypes with Guided Selection: This is similar to Static Multi Prototypes model except in the way we choose the relevant prototype for each constituent. In section 3.1.2 we described an unsupervised way of prototype selection from multi prototypes. Unlike there, here we choose the constituent prototype (sense) which has the highest similarity to the prototype vector of the

Parameter Description	ADD	MULT
Static Single Prototypes		
	0.5173	0.6104
Static Multi Prototypes		
Top 5 clusters	0.1171	0.4150
Top 10 clusters	0.0663	0.2655
Dynamic Prototypes		
Top 2 % exemplars	0.6261	**0.6552**
Top 5 % exemplars	0.6326	0.6478
Top 10 % exemplars	**0.6402**	0.6515
Top 20 % exemplars	0.6273	0.6359
Top 50 % exemplars	0.5948	0.6340
Top 80 % exemplars	0.5612	0.6355
Static Multi Prototypes with Guided Selection		
Top 5 clusters	0.2290	0.4187
Top 10 clusters	0.2710	0.4140
Compound Prototype		
0.4152		

Table 3: Spearman Correlations of Model predictions with Human Predictions

compound. This is a guided way of sense selection since we are using the compound prototype vector which is built from the compound's corpus instances. The performance of this model gives us an idea of the upper boundary of multi prototype models for semantic composition.

5.4 Results and Discussion

All the above models are evaluated on the dataset described in section 5.1. Table 3 displays the Spearman correlations of all these models with the human annotations (mean values).

The results of Static Single Prototypes model are consistent with the previous findings of Mitchell and Lapata (2010), in which MULT performed better than ADD.

All the parameter settings of Dynamic Prototypes outperformed Static Single Prototypes. This shows that selecting the relevant sense prototypes of the constituents improve semantic composition. We also observe that the highest correlation is achieved by including just the top 2% exemplars for each constituent. It seems that as the sample of exemplars increases, noise increases as well, and this results in a worse performance.

The comparison between Static Single Prototypes and Static Multi Prototypes shows that the former performs significantly better than the latter. This is not according to our expectation. The possible reason for poor performance could be because of the sense selection process (section 3.1.2) which might have failed to choose the relevant sense of each constituent word.

However, Static Multi Prototypes with Guided Sense Selection still fail to perform better than Static Single Prototypes. Therefore, we can conclude that the lower performance of Static Multi Prototypes cannot be attributed to the sense selection process only. Despite that, the applied graph clustering method results in the generation of a very large number of clusters, some of which refer to the same word usage with subtle differences. Hence, our future work focuses on a selection process that chooses multiple relevant clusters of a constituent word. Additionally, our ongoing work suggests that the use of verbs as features in the graph creation process (section 3.1.1) causes the inclusion of noisy edges and results in worse clustering.

Our evaluation also shows that Dynamic Prototypes provide a better semantic composition than Static Multi Prototypes. The main reason for this result stems from the fact that Dynamic Prototypes explicitly identify the relevant usages of a constituent word with respect to the other constituent and vice versa, without having to deal with a set of issues that affect the performance of Static Multi Prototypes such as the clustering and the sense se-

lection process.

The performance of Compound Prototype is lower than the compositional models. The reason could be due to the data sparsity. Data sparsity is known to be a major problem for modelling the meaning of compounds. In a way, the results are encouraging for compositional models.

In all these models, the composition function MULT gave a better performance than ADD.

6 Conclusions

This paper presented two methods for dealing with polysemy when modeling the semantics of a noun-noun compound. The first one represents senses by creating static multi prototype vectors, while the second represents context-specific sense of a word by generating a dynamic prototype vector. Our experimental results show that: (1) sense disambiguation improves semantic composition, and (2) dynamic prototypes are a better representation of senses than static multi prototypes for the task of semantic composition.

In future, we would like to explore other static multi prototype approaches of Reisinger and Mooney (2010) and Klapaftis and Manandhar (2010a) in comparison with dynamic prototypes. Dynamic prototypes are found to be particularly encouraging since they present a different mechanism for sense representation unlike traditional methods.

Using Prediction from Sentential Scope to Build a Pseudo Co-Testing Learner for Event Extraction

Abstract

Event extraction involves the identification of instances of a type of event, along with their attributes and participants. Developing a training corpus by annotating events in text is very labor intensive, and so selecting informative instances to annotate can save a great deal of manual work. We present an active learning (AL) strategy, *pseudo co-testing*, based on one view from a classifier aiming to solve the original problem of event extraction, and another view from a classifier aiming to solve a coarser granularity task. As the second classifier can provide more graded matching from a wider scope, we can build a set of pseudo-contention-points which are very informative, and can speed up the AL process. Moreover, we incorporate multiple selection criteria into the pseudo co-testing, seeking training examples that are informative, representative, and varied. Experiments show that pseudo co-testing can reduce annotation labor by 81%; incorporating multiple selection criteria reduces the labor by a further 7%.

1 Introduction

The goal of event extraction is to identify instances of a class of events in text. There can be many event types; for example, the ACE 2005 event extraction task involved a set of 33 generic event types and subtypes appearing frequently in the news. A typical event extraction task, in addition to identifying the event itself, also identifies all of the participants and attributes of the event; these are the entities that are involved in that event. Annotating a corpus in order to train an event tagger is a costly task.

First of all, event extraction is difficult and requires substantial training data. The same event might be presented in various expressions, and an expression might represent different events in different contexts. For example, "retire" and "resign" can both represent an *End-Position* event, while "leave" can represent either an *End-Position* or *Move* event in different contexts. Moreover, for each event type, the event participants and attributes may also appear in multiple forms and exemplars of the different forms may be required.

Furthermore, compared to other tasks like name tagging or part of speech tagging, events of a particular type appear relatively rarely in a document. One document might only contain one or two events of a given type, or even none at all. For the ACE 2005 event extraction task, *Attack* events have the highest frequency in the training corpus (2240 times, an average of 4 events per document), while *Start-Position* events only appear 232 times (an average of 1/3 event per document). As a result, to acquire enough training samples, we need to annotate a lot of documents. If we can predict which documents, or even which sentences to annotate, we can save a lot of time.

Considering the complexity of event extraction and the labor of annotating an event, providing the annotator with an informative sample to annotate is especially important. Active learning (AL) is a good way to do so because it aims to keep the human annotation effort to a minimum, only asking for advice where the training utility of the result of such a query is high.

Active learning is a supervised machine learning technique in which the learner is in control of the selection of data used for learning. The intent is to ask an *oracle* - typically a human with extensive knowledge of the domain at hand

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 714–722,
Chiang Mai, Thailand, November 8 – 13, 2011.

- about the classes of instances for which the model trained so far makes unreliable predictions. Selective sampling methods, introduced by Cohn, Atlas and Ladner (1994), made the learner query the oracle about data that is likely to be misclassified. This is the crucial aspect of AL – finding "good" instances for a human to annotate.

In this paper, we investigate the use of AL in event extraction. In particular, we apply the active learning approach to the *Attack* event, because it is the most frequent event type in the ACE corpus, and is particularly challenging because of the large number of different expressions: there are 312 different words in the corpus that serve at least once as the main word (the "trigger") of an *Attack* event,

After studying several sampling strategies, we settled upon a *pseudo co-testing* approach where a second classifier which solves a coarser variant of the original task is used. Furthermore, we incorporate multiple selection criteria into the pseudo co-testing, not only selecting more informative sentences, but also considering their distribution in the sample pool, and the diversity of the instances added to the training set at the same time.

2 Event Extraction

2.1 Task Description

ACE defines an event as a specific occurrence involving participants[1], and it annotates 8 types and 33 subtypes of events. In this task, an *event mention* is a phrase or sentence within which an event is described, including trigger and arguments. An event mention must have one and only one trigger, and can have an arbitrary number of arguments. The *event trigger* is the main word that most clearly expresses an event occurrence. The *event mention arguments (roles)*[2] are the *Entity/Timex mentions*[3] that are involved in an event mention, and their relation to the event. For example, an *Attack* event might include participants like *Attacker* or *Target*, or attributes like *Time-Within* and *Place*. Arguments will be taggable only when they occur within the scope of the corresponding event, typically the same sentence.

Consider the sentence:

(1) This Friday in France, ***Bob Cole*** *was on his way home when* ***he*** *was* ***attacked****…*

Event extraction depends on previous phases like name identification, entity mention classification, and entity mention coreference. Table 1 shows the results of this preprocessing. Note that entity mentions that share the same EntityID are coreferential and treated as the same object.

Entity/Timex mention		**Head**	**Entity ID**	**Type**
1-1-1		France	1-1	GPE
1-T1-1		Friday	1-T1	Timex
1-2-1		Bob Cole	1-2	PER
1-2-2		He	1-2	PER
Event type	**Trigger**	**Role**		
		Place	**Target**	**Time**
Attack	attacked	1-1-1	1-2-2	1-T1-1

Table 1. An example of Entity /Timex mentions, and Attack events

In this example, there is one *Attack* event, which contains attributes and participants including place, target and time.

2.2 Baseline Event Tagger

Identifying a potential trigger – the word most clearly expressing the event – is essential for event extraction. Usually, the trigger itself is the most important clue in detecting and classifying the type of an event; for example, words like "attack", "conflict", and "beat" are more likely to represent an *Attack* event, while "meet", "eat", and "shopping" are not likely to be triggers of *Attack* events. Then, once we find possible triggers, we can apply the argument / role identification to find the participants or attributes of the event. For example, the subject of the trigger word "attack" is usually the *Attacker* argument, while the object is the *Target* argument.

However, although the trigger itself is crucial to determine whether or not there is a reportable event, it is not always sufficient. As a result, most current event extraction systems consider trigger and argument information together to tag a reportable event.

[1] See http://projects.ldc.upenn.edu/ace/docs/English-Events-Guidelines_v5.4.3.pdf for a description of this task.

[2] Note that we do not deal with event mention coreference in this paper, so each event mention is treated as a separate event.

[3] An *Entity mention* is a reference (typically, a noun phrase) to an object or a set of objects in one of the semantic categories of interest. A *Timex mention* is a reference to a time expression.

In this paper, we adapted an existing state-of-the-art English IE system [Grishman et al. 2005][4] to serve as our baseline system. This system extracts events independently for each sentence, because the definition of event mention argument constrains them to appear in the same sentence.

In the training process, a pattern collector is first applied to all annotated events to build features used in later classifiers, and then three Maximum Entropy-based classifiers are trained. For each word (trigger candidate) in the training data, if it is a verb, noun or adjective (the three possible parts-of-speech for a trigger in ACE), we update the following three classifiers:

- **Argument Classifier:** Given the trigger candidate and a *Entity / Timex mention* in the sentence, to distinguish whether the mention is a possible argument of a specific event type;
- **Role Classifier:** for each argument identified by the argument classifier, to determine its role with respect to a specific event type;
- **Trigger Classifier:** Given the trigger candidate, the pattern representing the local syntactic context, and a set of roles identified by the role classifier, to determine whether this word is a true trigger, and this is a reportable event.

In the test procedure, for each word (each potential trigger), the argument / role classifier is applied to collect the possible arguments/roles connected to this word, and then the trigger classifier is used to decide whether it is a trigger or not. If it is, an event mention including the trigger and all its roles will be reported, else the word will not be tagged as a trigger, and all the arguments/roles collected by previous classifiers are discarded.

3 Active Learning for Event Extraction

Active learning has been successfully applied to a number of natural language processing tasks, such as named entity recognition (Shen et al. 2004; Hachey, Alex and Becker 2005; Kim et al. 2006), text categorization (Schohn and Cohn 2000; Tong and Koller 2002; Hoi, Jin & Lyu 2006), part of speech tagging (Ringger et al. 2007), parsing (Osborne and Baldridge 2004; Becker and Osborne 2005; Reichart and Rappoport 2007), and word sense disambiguation (Chen et al. 2006; Zhu and Hovy 2007). However, there have not yet been any studies to use active learning in event extraction.

There are several sampling methods in active learning; the most commonly used ones include uncertainty-based sampling, committee-based sampling, and co-testing. Co-testing (Muslea et al. 2000) involves two (or more) redundant views; it simultaneously trains a separate classifier for each view, and the system selects a query based on the degree of disagreement among the learners. Because well-informed classifiers for the two views should agree, co-testing will select an example which is informative for at least one of the classifier models.

In theory, co-testing has some advantages over uncertainty sampling and committee-based sampling. However, the disadvantage of co-testing is that it has more constraints: the two views should be disjoint and each sufficient to learn a classifier. As discussed above, event extraction is complicated and involves several classifiers on different levels interacting together. This makes it difficult to split the feature set into two views. In particular, the identity of the trigger will be a critical feature for any successful classifier. Committee-based sampling faces similar problem as co-testing: it is hard to generate several classifiers that are consistent with the training set or sub-samples of it, respectively.

This leaves uncertainty-based sampling as an attractive option. Although Muslea (2000) points out that uncertainty sampling may make queries that lead to minimal improvements of the classifier, and therefore require more queries to build an accurate classifier, it is simple and can be applied to almost all kinds of statistical models.

We could do active learning at the token level: – asking the *oracle* whether a specific token triggers an event – but that is not very practical. Rather, for each query, we return a sentence that might contain an event to ask the oracle to annotate. We do so because the oracle needs to read the whole sentence to decide whether it is a reportable event, and annotate all its arguments. Thus, a sentence-based sampling pool is built where each sentence is treated as a sample query.

3.1 Applying Uncertainty-based Sampling

Event extraction is a compound classification task, which involves the identification of argu-

[4] The existing system had both pattern matching and statistical components; we integrated these components so that the resulting system would have a uniform probabilistic model suitable for the active learning strategies we employed.

ments/roles, and the event trigger. These classifiers are separately trained, but not independent; results from previous classifiers are used as features for the following classifier, and the decision by the following classifier will affect the previous results (arguments confidently tagged by the argument/role classifier will be discarded if the trigger labeling treats it as not a event). Because the final classifier – the trigger classifier – takes all the considerations we mentioned above as input, and makes a final decision of a reportable event, we use its output as the probability of the event tagger. The traditional approach in uncertainty sampling (Lewis and Gale 1994) queries one of the samples on which the classifier is the least confident. In our case, the greatest uncertainty regarding the presence of an event corresponds to the trigger probability closest to 0.5. We treat the uncertainty of the sentence as the maximum of the uncertainties of the constituent words (i.e., the uncertainty attributable to the word with probability closest to 0.5):

$$e\_Info(S_i) = 1 - \min_{w_j \in S_i} |0.5 - prob\_e(w_j)|$$

where $prob\_e(w_j)$ is the trigger probability of the word w_j in S_i , as returned by the event tagger.

3.2 Problems with Uncertainty-based Sampling

However, the results of uncertainty-based sampling are somewhat disappointing (see Figures 3, 4, and 5 in section 5.3). It performs quite well at first: within a few iterations, trigger labeling (event detection) quickly achieves a performance (F score) of 65%, but beyond that point the gain is very slow. At this point there is still a 7% gap between its performance and that of a classifier trained on the whole sampling pool.

Why does uncertainty-based AL perform this way? The event tagger depends primarily on the particular trigger and secondarily on its local structure, for example, the potential arguments in the immediate vicinity of the trigger and the dependency paths between them. Such information is effective at identifying the trigger and arguments, but is responsive only to particular words and patterns. Triggers and structures which have not been seen in the training data will be assigned uniformly low probabilities. When trained on the whole ACE 2005 corpus (in a supervised training scenario) this is appropriate behavior: we don't want to report an event in testing if we haven't seen the trigger before.[5] However, for active learning, the inability to differentiate among potential new triggers and local structures is critical. Only a few words ever serve as possible triggers for a specific event type. For the *Attack* event, only 2.0% of the words in the ACE training data ever act as an event trigger. The uncertainty of the event tagger, by itself, does not provide useful guidance regarding possible additional triggers the user should be asked about, and the system might query a lot of irrelevant sentences with unseen words before a sentence with a new trigger is found.

We can see this as an instance of a more general problem. Our goal in AL is to select for labeling those data points which are most likely to improve the accuracy of the model. Methods like uncertainty-based sampling are heuristics towards that end, but are not always effective; their success depends on characteristics of the classifier and the feature space. For event extraction, the classifier is most likely to benefit from finding *new*, *frequently-occurring* triggers. We need a way of identifying likely candidates.

Furthermore, we note that – while the final trigger classifier which we train from the labeled data must operate at the token level – we will be presenting the user with a sentence to label, so it is sufficient for the classifier we use for AL to operate at the sentence level.

3.3 Another View from Sentential Scope

Can we find a classifier which suits the needs of our active learner by identifying sentences which are likely to contain an event? A simple (bag-of-words) classifier based on the words in the sentence can do quite well at this task. For example, a sentence with "troops", "victim", "bloody" and "soldier" might be more likely to contain an *Attack* event, even if these words might not be elements of the event.

These bag-of-words features are not particularly helpful for the original task of identifying an event (trigger and arguments) – they don't pinpoint a particular word as the trigger. But that's not a problem if the data selection for AL is operating at a coarser level.[6]

[5] Unlike some other tasks such as named entity and part-of-speech tagging, local contextual clues by themselves are generally not strong enough to reliably tag an event.

[6] Note that some active learners for tasks such as named entities and part-of-speech which also train token-level annotators choose to present data to the user at the sentence level, because it is more convenient and efficient for the user. These taggers could select data at the token level using

3.4 Pseudo Co-Testing

The sentence-level bag-of-words classifier is far from perfect – the predictions at the sentence level are somewhat noisy. But considering that only 6.5% of the sentences in the ACE data contain an *Attack* event, returning a possibly relevant sentence is much more useful than returning a totally irrelevant sentence. If a sentence *S* in the sample pool shares many words with another sentence in the training data known to contain an event, and the event tagger does not find a trigger word in *S*, there is a good chance that *S* contains a new (previously unseen) trigger word and new local structure, because the two sentences may be describing the same event, but using different verbs and word sequences.

Thus, we apply a pseudo co-testing algorithm with one view from an event tagger based on local information, and another view, which aimed to solve an approximate task: whether there is a possible event in a sentence.

We call this algorithm "*pseudo* co-testing" because one of the views is not sufficient to solve the target problem, but is sufficient to solve a subproblem at a coarser granularity, in contrast to traditional co-testing. People might argue that when a *pseudo contention point* is found in this algorithm, it means that at least one of the classifiers is wrong, but we do not know (until we query the oracle) which one. If it is the event tagger, this sample is informative for the event tagger and adding this sample will improve the performance; if it is the sentence classifier, it is not guaranteed that this sample is informative for the event tagger. However, since the updated sentence classifier will serve to select subsequent queries, samples informative for the sentence classifier should accelerate subsequent active learning. Furthermore, the event tagger and the sentence classifier each have their own advantages in finding an event to query. The event tagger prefers sentences with already-known local patterns, like a trigger and its arguments, although the overall sentence (the choice of words and wider structure) might be very different. The sentence classifier prefers sentences sharing the same words, but which may have different local structures. Together they offer the potential for finding new triggers which do not appear in the existing training data (via the sentence classifier) and then acquiring event and non-event exemplars of these triggers (through the event tagger).

In pseudo co-testing, we use the probabilities from the event tagger and sentence classifier to build a contention set consisting of those sentences where the event tagger and sentential event recognizer make different predictions. Among these sentences, we assume that the larger the margin between the event tagger and sentential event recognizer, the less certain the sample is. So, instead of randomly choosing samples from the contention set, we order the samples by their margins between the event tagger and sentential event recognizer, and pick the ones with largest margin:

$$co\_Info(S_i) = \underset{w_j \in S_i \& isCP}{Max} \left| prob\_e(w_j) - prob\_s(S_i) \right|$$

where $prob\_s(S_i)$ is the probability from the sentence classifier; while $prob\_e(w_j)$ is the trigger probability from the event tagger for the word w_j in sentence S_i, and w_j is a *contention point* (CP) where the event tagger's prediction is opposite that of the sentence classifier.

4 Multi-criteria-based AL

Normally active learning only considers the *informativeness* of the sample. In uncertainty-based query, *informativeness* is represented by the least confident sample; in committee-based querying, it is represented by the samples on which the committee vote is the most equally split; in co-testing, it is represented by the contention sample. Shen et al. (2004) pointed out that we should maximize the contribution of the selected instances based on multiple criteria besides *informativeness*. For example, the *representativeness* and *diversity* of the sentence should also be considered. In this way, we not only consider whether the current model contains enough information to classify this sentence (as containing an event), but also consider the distribution of this sample in the whole sampling pool (*representativeness*), and moreover, insure that we select different kind of samples in a batch to make the selection more diverse (*diversity*).

4.1 Features used in Similarity of Samples

To evaluate the *representativeness* and *diversity*, we first need to calculate the similarity between two samples, in our case, two sentences. In general, a sentence will be represented as a vector of features $S_1 = \{f_{11}, f_{12}, f_{13}, ..., f_{1n}\}$ and

two views based on the identity of a token and its immediate context. We share these user considerations, but in addition selecting data at the sentence level enables us to create effective complementary views for event extraction not available at a finer (token) level.

the similarity is calculated based on the feature vectors of the two sentences. Thus, the essential problem becomes how to build the feature vector for a sentence. Since there are two classifiers in the pseudo co-testing, we use features from both classifiers, and measure the similarity using a cosine measure, following Shen et al (2004):

$$Sim(S_1,S_2) = \frac{\sum_{f_i \in S_1} \sum_{f_j \in S_2} sim(f_i,f_j)}{|S_1| \quad |S_2|}$$

where $sim(f_i,f_j)$ is 1 when f_i and f_j are the same, otherwise 0.

4.2 Representativeness

A few prior studies have considered this selection criterion (McCallum and Nigam 1998; Tang et al. 2002; Shen et al. 2004). The *representativeness* of a sample can be evaluated based on how many samples are similar to this sample. Adding samples which are more representative to the training set will have an effect on a larger number of unlabeled samples.

For every sentence in the sampling pool, we measure its *representativeness* based on its average similarity to other sentences in the sampling pool:

$$Represent(S_i) = \frac{\sum_{S_j \in P, i \neq j} sim(S_i,S_j)}{|P|-1}$$

where P is the current sampling pool. In this way, we will filter out the samples that are rare in the whole sampling pool, and focus our effort on the samples that appear more frequently in the whole corpus.

In addition to favoring the most informative example, we also prefer the most representative example. To combine scores from *informativeness* and *representativeness*, we followed Shen et al (2004)'s metric:

$$Score(S_i) = \lambda \cdot co\_Info(S_i) + (1-\lambda) Represent(S_i)$$

where the relative importance of each criterion is determined by the parameter λ ($0 \le \lambda \le 1$). In our experiment, λ is set to 0.7.

4.3 Diversity

The role of the *diversity* criterion is to maximize the training utility of a batch of samples. As we add a batch of samples into the training data in one iteration (for efficiency in updating the model), we want to make sure we provide various types of sentences, which provide the most information as a whole, and avoid selecting very similar sentences for a single batch. To this end, after we rank the sentences in the sampling pool, based on the different strategies mentioned above, we skip over any sentence whose similarity to one already selected in the same batch exceeds a threshold (see Figure 2).

The diversity metric is involved in selecting a batch of instances, as follows:

```
==========================
Given: SenSet = (S1,...,SN) and the BatchSet with the
maximal size K.
Initialization: BatchSet = empty
Loop until BatchSet is full
        Select Si based on some measure from SenSet;
        RepeatFlag = false;
        Loop from j = 1 to CurrentSize of BatchSet
                If Score(Si, Sj) > threshold Then
                        RepeatFlag = true;
                        break;
        If RepeatFlag == false Then
                Add Si into BatchSet.
==========================
```

Figure 2. Diversity criterion in batch-based active learning

5 Experiments

We use the ACE 2005 training corpus, which contains in total 598 annotated documents, to simulate the active learning process. For evaluation, we conduct a blind test on a set of 54 randomly chosen documents. For each active learning strategy, we make 4 runs and use the average scores as our final results. For each run, 10 documents are randomly chosen as the initial training data, and the rest (534 documents) are used to build the sampling pool. Overall, the average initial training set contains 369 sentences, and the sampling pool contains an average of 12074 sentences.

A Maxent model based on bag-of-words features serves as the sentence classifier. To reduce data sparseness, all inflected words are changed to their lemma form (e.g. "attackers"→"attacker"). A list of stop words is also applied.

For each iteration, we picked 50 sample sentences at the top of the ranked list based on different query strategies. To simulate the user queries, annotations extracted from the key annotations are returned as user feedback, and added into the training data.

5.1 Query Strategies

In the following sections, we compare the performance of the query strategies mentioned above – uncertainty-based query (*Uncertainty*), pseudo co-testing (*pCT*), and multi-criteria pseudo co-testing(*multi_pCT*). We employ a random sampling (*Random*) method as a baseline, where samples are selected randomly to add to the training data. Also, to assess the benefit of active learning, we report the performance from the event tagger trained on the entire ACE2005 data except for the test set (*Full_Corpus*).

5.2 Results

The performances (F-measure) of different strategies are evaluated based on three metrics: argument/role labeling (Figures 3 & 4) and trigger labeling (Figure 5).

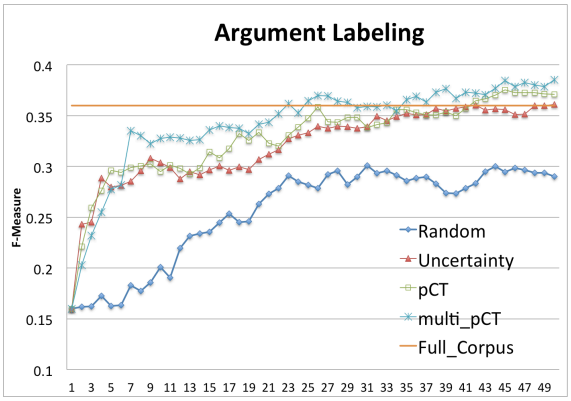

Figure 3. Performance (F-Measure) of argument labeling

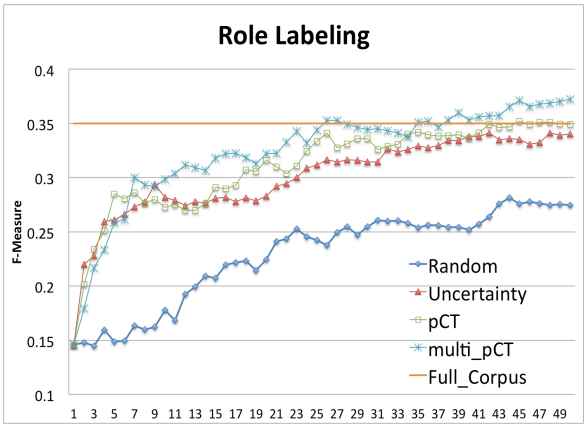

Figure 4. Performance (F-Measure) of role labeling

Uncertainty-based querying (*Uncertainty*) yields poorer results than the other active learning strategies, because of the event tagger's relatively rigid matching procedure. Thus, it lacks the ability to recognize new potential triggers or patterns. For example, if we have pattern *A* which is very similar to some event-bearing patterns in the training data, and pattern *B* which is quite different from any pattern in the training data, the event tagger will treat them the same. However, the sentence classifier provides more graded matching, and gives the sentence containing pattern *A* higher score because they share a lot of words. Thus, the pseudo co-testing (*pCT*) would give a higher score to pattern *A*, and achieve better performance. Also, we observed that multi-criteria pseudo co-testing (*multi_pCT)* performs best in all three evaluations.

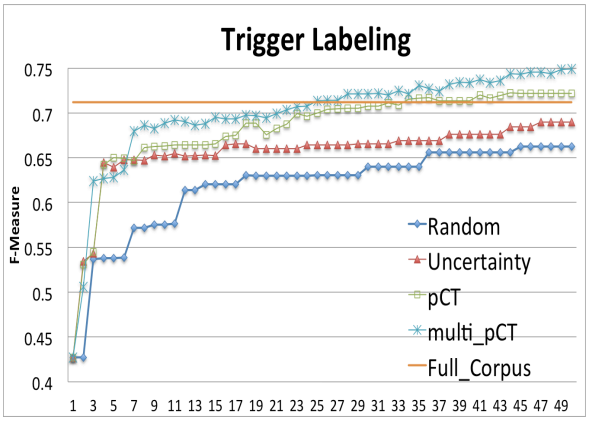

Figure 5. Performance (F-Measure) of trigger labeling

The differences between the approaches are particularly marked for trigger labeling after just a few iterations. Consider how much data must be annotated to get to 95% of full corpus score for trigger labeling (F-Measure 67.5%): *multi_pCT* only takes 7 iterations; *pCT* takes 17 iterations; *Uncertainty* takes 38 iterations. In other words, 5.8%, 9.8%, 18.2% of the whole corpus needs to be annotated to reach the same performance. Thus, using *pCT* is almost twice as fast as *Uncertainty* to reach a reasonable performance, while *multi_pCT* will shorten this process by half again. The benefits of better query selection are clearest for the first few batches of queries, which may be the range of greatest practical import for developers wanting to quickly add new event types.

Overall, we observe that pseudo co-testing performs better on all three evaluation measures than uncertainty-based active learning. Uncertainty-based active learning requires more than 100 iterations before it reaches the level of performance on all three measures achieved by the

supervised system, trained on the entire corpus (*Full_Corpus)*. *pCT* takes 41 iterations to reach this level. At this point, there are in total 369+2050 = 2419 sentences in the training data; this represents a reduction in labor over sequential annotation of 80.6%. Applying the multi-criteria-based strategy (*multi_pCT*), we can reach this point even earlier, in iteration 23, where the labor is reduced by 87.8%[7].

6 Related Work

Many existing active learning methods are based on selecting the most uncertain examples using various measures (Thompson et al. 1999; Schohn and Cohn 2000; Tong and Koller 2000; Engelson and Dagan 1999; Ngai and Yarowsky 2000). (McCallum and Nigam 1998; Tang et al. 2002) proposed methods that consider the representativeness criterion in active learning. (Tang et al. 2002) use the density information to weight the selected examples but do not use it to select a sample. (Brinker 2003) first incorporated diversity in active learning for text classification. Shen et al. (2004) proposed a multi-criteria-based active learning approach and applied it to named entity recognition. They jointly consider multiple criteria, including *informativenes*s, *representativeness* and *diversity*. Experiments showed that incorporating all the criteria together is more efficient than single-criterion-based methods.

Traditional active learning with redundant views splits the feature set into several sub-sets or views, each of which is enough, to some extent, to describe the underlying problem. Muslea et al. (2000) presented an approach in which two classifiers are trained only on labeled data, then run over the unlabeled data. A contention set of examples is then created, consisting of all unlabeled examples on which the classifiers disagree. Samples are randomly selected from this set for query, and then both classifiers are retrained.

To the best of our knowledge, there is no study yet of active learning in event extraction. However, Patwardhan and Riloff (2009) presented a model for role filling in event extraction that jointly considers both the local context around a phrase and the wider sentential context in a probabilistic framework. They used a sentential event recognizer and a plausible role-filler recognizer to jointly make decisions on a sentence, and find the roles of the events. Although it is not a co-testing process, it gave us the intuition of using a sentential view to predict possible events in a sentence.

7 Conclusion

In this paper, we investigate strategies of active learning for event extraction, and propose a novel way of selecting good samples to be added to the training pool. Experiments show that a classifier for a coarser task can provide an extra view to build a pseudo co-testing strategy. Although the ultimate goal involves training the original (fine-grained) classifier, the coarser task can provide useful information for query selection. In the special case of event extraction, we find that a sentence classifier can help an event tagger select a better query, because it is not only good at finding new trigger and local structures from graded matching over a wider scope, but also provides a better way of judge the representativeness and diversity of the samples. In our experiment, we reduced human labor by 80.6% to 87.8%.

[7] We observe that the AL can perform better than training on the whole corpus; we believe that this is a result of AL selecting more positive training data. After 50 iterations of *multi-pcT*, 31.4% of the selected sentences have positive *Aattack* examples, whereas only 6.1% of the entire corpus has such positive examples. Separate experiments suggest that using a corpus richer in positive examples can produce a small improvement in performance.

Text Segmentation and Graph-based Method for Template Filling in Information Extraction

Ludovic Jean-Louis, Romaric Besançon, Olivier Ferret

{ludovic.jean-louis,romaric.besancon,olivier.ferret}@cea.fr

Abstract

In event-based Information Extraction systems, a major task is the automated filling from unstructured texts of a template gathering information related to a particular event. Such template filling may be a hard task when the information is scattered throughout the text and mixed with similar pieces of information relative to a different event. We propose in this paper a two-step approach for template filling: first, an event-based segmentation is performed to select the parts of the text related to the target event; then, a graph-based method is applied to choose the most relevant entities in these parts for characterizing the event. An evaluation of this model based on an annotated corpus for earthquake events shows that we achieve a 77% F1-measure for the template-filling task.

1 Introduction

Information Extraction (IE) is a process that aims at extracting pieces of information from texts. Following the paradigm defined in the Message Understanding Conferences (MUC) (Grishman and Sundheim, 1996), IE systems focus on extracting structured information concerning events to fill predefined *templates*. These templates make it possible to highlight the information that is specific to a type of events and to discard pieces of information that are not relevant in this respect. Figure 1 gives an example of the filling of a template by information extracted from a news article.

Common issues addressed by IE systems for filling a template include identifying named entities, finding relations between these entities, resolving entity coreference, gathering scattered information, etc. (Turmo et al., 2006).

Currently, there is no standard approach for filling templates. However, most IE systems have been relying on a sentence-oriented approach: first, domain-specific patterns or classifiers are used to process sentences separately; then, ad-hoc strategies for merging these local results into templates are applied. Even if such approach has been used widely, it does not take into account two important problems: *(i)* events can be described in more than one sentence; *(ii)* patterns/classifiers mainly capture binary relations among entities while events are not limited to binary relations.

Text	Template
EV1 There are no reports of damage or injuries after a small **earthquake** rattled the **Chino Hills** area **Tuesday morning**. EV1 The **3.1**-magnitude **quake** hit at **6:40 a.m.** and was centered about two miles west of **Chino Hills**. EV1 It was felt in several surrounding communities. EV2 **Last July**, a **5.4**-magnitude **quake** hit the same area. EV2 That **quake** resulted in cracked walls and broken water and gas lines.	*EV1* • **EVENT**: earthquake • **DATE**: Tuesday morning • **TIME**: 6:40 a.m • **MAGNITUDE**: 3.1 • **LOCATION**: Chino Hills *EV2* • **EVENT**: quake • **DATE**: Last July • **TIME**: • **MAGNITUDE**: 5.4 • **LOCATION**:

Figure 1: Example of template filling

An illustration of the first problem is given by Figure 1, where information relative to the event *EV1* is expressed beyond the sentence scope. This problem raises more generally the question of defining event-related spans of text or, in other words, determining whether a sentence refers to an event, and eventually the type of this event. In this article, we tackle this issue through the means of discourse segmentation. More specifically, we propose segmenting texts according to the events they refer to. Our objective is to narrow the span of text to explore in order to link a named entity to an event mention. As time is an important feature for discriminating events, we chose to perform this segmentation by relying on temporal cues.

Concerning the second problem, we can observe in Figure 1 that most of the sentences comprise an event mention with more than 2 related entities: the first sentence involves 3 entities while

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 723–731,
Chiang Mai, Thailand, November 8 – 13, 2011.

the second one involves 4 entities. Similarly to (McDonald et al., 2005), we refer to such relations as *complex relations*, namely any *n*-ary relation among *n* typed entities. In this context, each event can be seen as a complex relation where the arity of the relation *n* is equal to the number of entity types that should be filled in the template (*n=5* in the previous example). Several methods were proposed for extracting complex relations such as graph-based methods (McDonald et al., 2005; Wick et al., 2006) or inference-based methods (Goertzel et al., 2006). In this article, we tackle the complex relation extraction by proposing a graph-based method. We start by building an entity graph based on the result of text segmentation; then we use several domain-independent strategies for the reconstruction of the complex relation.

The remainder of this article is organized as follows: the next section discusses related work while Section 3 presents a general overview of our approach. Sections 4 and 5 detail the methods used for the two steps: event segmentation and template filling. Finally, Section 6 gives the results of the evaluation of each step.

2 Motivation and Related Work

Template filling is a central task for IE systems and has been the object of numerous studies. For instance, in the context of the MUC (Message Understanding Conferences) and ACE (Automatic Content Extraction) (Doddington et al., 2004) evaluation campaigns, one of the objectives assigned to the systems was to fill predefined templates with a static/fixed structure. Although this is the most widespread approach, a work such as (Chambers and Jurafsky, 2011) adopts a different view and proposes an unsupervised approach for filling templates without prior knowledge about their structure: they rely on clustering techniques for learning the structure of templates and on syntactic patterns for extracting their fillers.

A wide range of IE systems, particularly those based on learning approaches, have been relying on the idea that an event is often described within a single sentence, which leads to the hypothesis that pieces of information across sentences are less important. This idea is called the *single sentence assumption* by Stevenson (2006), who reported that only 60% of the facts mentioned in three MUC corpora (MUC 4-6-7) could be identified following this hypothesis. More recently, Ji et al. (2010) showed that around 40% of relations among entities require using cross-sentence inference techniques for their extraction.

Few approaches have been proposed for information extraction at a discourse level. Among them, (Gu and Cercone, 2006) and (Patwardhan and Riloff, 2007) are the closest to ours. (Gu and Cercone, 2006) is a segment-based HMM (Hidden Markov Model) approach. It relies on a first HMM model for identifying text units (sentences) that are relevant for the extraction of template fillers and on another HMM to extract the fillers from the retrieved sentences. Similarly, Patwardhan and Riloff (2007) proposed first to identify relevant sentences by using a self-trained SVM (Support Vector Machine) and then, to apply extraction patterns (primary and secondary patterns) to find the template fillers.

One of the first successful approach for the extraction of *n*-ary relations came from the biomedical community (McDonald et al., 2005) and was later applied to the domain of corporate management successions (Afzal, 2009). Other works tackled the complex relation problem in the context of *database record extraction*. They proposed to focus on the compatibility of a set of entities rather than on the compatibility of pairs of entities, which led them to take into account intersentential relations between entities (Wick et al., 2006; Mansuri and Sarawagi, 2006; Feng et al., 2007).

3 Overview

Event extraction as presented in this article takes place in a wider context of technology watch in which users are mainly interested in the most recent events. In this context, our goal is to synthesize from news articles the information about such recent events into a dashboard. However, news articles often refer to several comparable events, generally for pointing out the similarities and differences between a recent event and past events. In our specific application, we are not interested in the past events and we consider them as a source of noise for extracting information about the main event of a news article. We made the assumption, as in (Feng et al., 2007), that one document is associated with one record (event in our case). We adopted a two-step strategy to tackle this problem:

- segmenting texts into events: events might

be described over a single sentence. Therefore, we need to segment texts according to the events they refer to. These segments are frequently discontinuous as the structure of news articles is often dominated by moves between the main event and past similar events;

- filling event templates from relations: since event segments go beyond the sentence level, they are even more likely to contain complex relations than sentences. Therefore, we have to verify which entities mentioned in these segments are eligible to be part of the complex relation.

4 Segmenting Texts into Events

The goal of our segmentation of texts is to delimit segment units in relation with a target event. In previous work such as (Gu and Cercone, 2006; Patwardhan and Riloff, 2007), the methods for identifying such segments relied on fully lexicalized models that were learned using word surface forms. (Naughton, 2007) adopted a more generic approach by exploiting text structure. Our proposal is based on the idea that using temporal cues can help discriminate events, in particular similar events. In the example of Figure 2 for instance, two kinds of temporal cues can be used for this task: date values and verb tenses.

{MAIN} An earthquake measuring 5.6 on the Richter scale hit Jayapura, Papua, shortly after midnight on **Sunday**.
{SUB} Previously on **Saturday** the agency recorded a magnitude 5.6 earthquake had hit Melonguane in North Sulawesi.
{OUT} Indonesia, sits on a vulnerable quake-hit zone called the Pacific Ring of Fire.

Figure 2: Example of text segmentation: {MAIN}=Main event, {SUB}=Secondary event, {OUT}=Background

Our segmentation approach is based on an event-oriented representation of texts: a text is viewed as a sequence of sentences in which each sentence is characterized by the presence or the absence of an event. As in previous work, we have made the hypothesis that one sentence is linked to one event[1]. Hence, we tackle the segmentation task as a classification problem where each sentence of a text must be associated with an event type.

We classify sentences according to the following three categories. **Main event**: all sentences referring to the main event of the text; **Secondary event**: all sentences containing data that are related to an event different from the *Main Event*; **Background**: all sentences that belong neither to the *Main Event* nor a *Secondary Event*. An example for each category is given in Figure 2.

Our intuition is that for segmenting texts, the most interesting criteria rely not only on the nature of sentences but also on their linking at a discourse level, with the idea that categories of events don't follow one another in an arbitrary way. For instance, in the example of Figure 2, the shift from one event to another is associated with the change of verb tense *preterit/past perfect*. Our focus compared to previous segmentation approaches is to capture the dependencies between the shifts of temporal frames and the shifts of events.

For this purpose, we trained a linear Conditional Random Field (CRF) model (Lafferty et al., 2001) using the following temporal cues as features. *verb tenses*: a binary feature is associated with each possible verb tense (feature is 1 if at least one verb of the sentence has the considered tense); *presence of dates*: if a sentence contains a date, it is likely to refer to an event different from the previous sentence (except for the first occurrence of a date); *temporal expressions*: this feature accounts for the presence of temporal expressions in a sentence, such as *"over the past two weeks, in recent years"*, often related to generalities. The dependencies between successive event types are taken into account by the linear structure of our CRF model. More details about this segmentation model can be found in (Jean-Louis et al., 2010).

5 Filling Event Templates from Relations

For the filling of event templates, we propose a graph-based approach relying on the paradigm of complex relation extraction. Its first step (*graph construction*) detects relations between entity pairs in the same sentence to build an entity graph. The second step (*template filling*) applies generic strategies for selecting the most relevant entities associated with the template by exploiting the entity graph. These two steps are described in more details in the following sections.

[1]This hypothesis is not verified for all texts but can be considered as a reasonable simplification in the context of our study.

5.1 Graph Construction

The entity graph we build in this first step characterizes at the document level the presence/absence of semantic relations between each pair of entities. For building such a graph, we propose to rely on the most relevant text segments in relation to the target event instead of considering the entire document. In our case, these segments are those built from the sentences classified as {MAIN} by the segmentation model presented in Section 4.

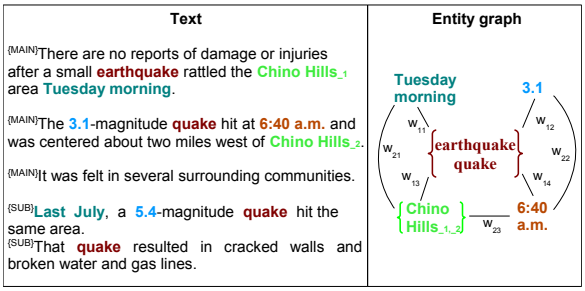

Figure 3: Example of entity graph

The entity graph is a weighted graph whose nodes are associated with named entity mentions while edges are associated with the relations between these mentions. The weight associated with each edge measures the confidence that a semantic relation exists between its two entities in a sentence. The graph is undirected as we mainly rely on relation confidence, a symmetric notion in our case, for filling templates. Figure 3 shows an example of such entity graph. Note that we assume that all entity mentions having the same value are equivalent (as the two mentions of *Chino Hills*) since they are located in the same event segment. Similarly, we consider all event mentions as equivalent (as *earthquake* in the first sentence and *quake* in the second sentence).

The presence of a relation between two entities in a sentence is classically determined by a statistical classifier. Following the standard approach of (McDonald et al., 2005) or (Liu et al., 2007), the weight of a relation is evaluated by the confidence score of this classifier and ranges in [0,1] in all the experiments of Section 6.3. In most previous works, such classifier mainly relies on a set of lexicalized features, without any syntactic feature (Afzal, 2009; Gu and Cercone, 2006; Wick et al., 2006). In (Liu et al., 2007), syntactic features are used in addition to lexicalized features. In contrast, our aim is to build a model that only makes use of syntactic features and does not rely on lexical information (such as inflected forms or lemma) in order to have a more generic model that can be easily adapted to another domain. For evaluating the contribution of lexicalized features compared to syntactic features, we trained different classifiers based on three distinct sets of features, detailed in Table 1:

Features description	FEAT-BASE	FEAT-LEX	FEAT-NOLEX
Entity type of E1 and E2	✓	✓	✓
POS of E1 and E2	✓	✓	✓
Words in E1 and E2	✓		
Word bigrams in E1 and E2	✓	✓	✓
Words between E1 and E2	✓	✓	
Word bigrams between E1 and E2	✓	✓	
POS between E1 and E2	✓	✓	✓
# words between E1 and E2	✓	✓	✓
POS bigrams between E1 and E2		✓	✓
# synt. relations between E1 and E2		✓	✓
Syntactic path between E1 and E2		✓	✓
Relative position and POS[2]		✓	✓
# entities between E1 and E2		✓	✓
# event mentions between E1 and E2		✓	✓
POS of two words after/before E1		✓	✓
POS of two words after/before E2		✓	✓

Table 1: Features for relation classification

- *FEAT-BASE*: same feature set as (Afzal, 2009), based on lexicalized features;
- *FEAT-LEX*: a feature set that contains lexicalized features, and syntactic features inspired by (Liu et al., 2007)[3];
- *FEAT-NOLEX*: same feature set as *FEAT-LEX*, but without the lexicalized features.

5.2 Template Filling

Template filling aims at selecting the best entities for the template slots. In our approach, this selection relies on the relations between entities in the entity graph. Note that we are trying to fill domain-specific templates that have a fixed number of slots though it is not mandatory that every slot gets a value. As every slot is associated with an entity type, we need to select (when it is possible) one entity value for each slot. This problem can be seen as the complex relation reconstruction task described in (Afzal, 2009; McDonald et al., 2005). We compared several approaches to tackle this issue:

[2]If either E1 or E2 is an event mention, indicate whether the other entity is after/before its POS.

[3]Some of their features are not relevant in our context since they are only applicable in the biomedical domain.

Heuristic is a simple but efficient approach that selects for each entity type the first entity mention occurring in the main event segment.

Confidence is an approach that selects, for each entity type, the entity connected to the event mention with the highest confidence weight.

PageRank is a link analysis based approach that relies on the PageRank algorithm (Brin and Page, 1998). The idea is to use the graph structure to rank entities according to their importance in the graph and to select, for each entity type, the entity mention with the highest PageRank score.

Vote is a voting-based approach exploiting the output of the *Confidence*, *PageRank* and *Heuristic* approaches: a majority vote is performed for each entity type and the entity mention with the highest number of votes (one vote by approach) is chosen.

Hybrid is an hybrid approach that applies for each entity type the best selection approach for this type. The main idea is to increase overall performance by allowing one entity type to be selected with one approach and another entity type to be selected by a different approach. For instance, the best selection approach for dates is *Confidence* whereas it is *Heuristic* for geographical coordinates.

Except for the first approach, the output is complemented by the use of the heuristic approach as back-off when no entity has been retrieved for a given entity type. Such a situation happens when a template filler is the only entity of a sentence and therefore, cannot be extracted by the binary relation classifier.

6 Evaluation

This section provides details concerning the experimental evaluation of our template-filling process. We present the corpus in Section 6.1 and the individual results for the different steps of our process in Sections 6.2, 6.3 and 6.4. We also evaluate the impact of the segmentation step on the final results in Section 6.5 and finally propose an analysis of errors in Section 6.6.

6.1 Corpus

The work presented in this paper was developed for an application dedicated to the surveillance of earthquake event mentions in news articles. The earthquake event template summarizes the main characteristics of a seismic event, namely its date, time, location, magnitude, geographical coordinates and its mention (earthquake, afterquake, etc.)[4]. An example of such template is provided in Figure 1, knowing that our target application is not interested in the secondary event *EV2*.

We carried out all the experiments on a corpus of 501 French news articles concerning earthquakes. These articles were collected between February 2008 and early September 2008 from a *Agence France Presse* (AFP) newswire (1/3 of the corpus) and from Google News (2/3 of the corpus). The corpus was manually annotated by domain analysts for filling the earthquake event template. The annotators identified a total of 2,775 entities divided into 6 entity types: event mention (18%), location (34%), date (17%), time (12%), magnitude (17%) and geo-coordinates (1%)[5].

Each document was preprocessed by the LIMA linguistic analyzer (Besançon et al., 2010), performing tokenization, sentence boundary detection, part-of-speech tagging, verb tense analysis, named entity recognition and dependency parsing.

6.2 Segmenting Text into Events

We used a subset of 140 articles from our corpus as training data for the CRF-based segmentation model. These articles were manually annotated into 1,659 segments according to the categories defined in Section 4: *Main event (70%), Secondary event (17%), Background (13%)*. Most of these articles contain a main event and at least one secondary event (short articles might not refer to a secondary event). Note that the *Secondary event* class includes without distinction all secondary events. The implementation was achieved using the CRF++[6] toolkit. We report in Table 2 results of our CRF model (*CrfSeg*) compared to a baseline (*ParaSeg*) in terms of F1-measure using a 5-fold cross-validation. The baseline *ParaSeg* is a paragraph-based heuristic that assigns *Main event* category to all the sentences in the first two paragraphs and considers others

[4]Casualties were not considered here because their correct identification would require a chunker.

[5]Several entities could be annotated for the same slot when variants or different levels of granularity were present: for locations, both a city and a country name for instance.

[6]http://crfpp.sourceforge.net

as secondary event[7]. Results in Table 2 show

Event type	ParaSeg (%)	CrfSeg (%)
Main event	11.14	92.71
Secondary event	21.7	67.91
Background	0	79.42

Table 2: Results of text segmentation into events (F1-Measure)

that our model obtains fairly good classification performance for all categories and is particularly suited for identifying the main event section. They also show the impact of taking temporal cues into account compared to relying on text structure only. Note that the poor results of our baseline partly come from its ignorance of the *Background* category. The *Relevant Sentence Classifier* of (Patwardhan and Riloff, 2007) has a goal similar to our segmentation with Recall|Precision|F1-Measure scores of 63%|46%|53% on terrorism documents and 72%|41%|52% on disease outbreak documents. We provide these figures as indicative results but not for direct comparison since their approach is different: they used a SVM classifier with lexicalized features and not temporal cues, classified sentences according to two classes (Irrelevant, Relevant) and performed their evaluation for English, on the MUC-4 terrorism and ProMed corpora.

6.3 Graph Construction

Our graph construction method relies on a binary relation classifier for assessing the existence of a semantic relation between two entities in a sentence. We experimented several types of statistical classifiers with the three sets of features (*FEAT-BASE, FEAT-LEX, FEAT-NOLEX*) presented in Section 5.1. A set of 44 articles from our corpus was used to annotate binary relations. Among the 5,000 binary relations in these articles, 969 were in-sentence relations. 43 relations were discarded because one of their entities was actually included in the span of a larger entity not recognized because of its type (such as organizations), the rest was used for training the classifiers: 690 in the *POSITIVE* class, in which the two entities of the candidate relation refer to the same earthquake event, and 236 in the *NEGATIVE* class, where the two entities are associated with different earthquake events. The following sentence contains examples of both *POSITIVE* and *NEGATIVE* relations:

[POSITIVE]: The first *quake*, with a magnitude of *5.3*, struck at about 11.05am and was followed a few minutes later by a stronger quake with a 6.5 magnitude...

[NEGATIVE]: The first *quake*, with a magnitude of 5.3, struck at about 11.05am and was followed a few minutes later by a stronger quake with a *6.5* magnitude...

We tested three types of learning algorithms with these quite unbalanced training data by relying on the Mallet toolkit[8] for their implementation: Naive Bayes (*NB*), Maximum Entropy (*ME*), Decision Tree (*DT*). We report in Table 3 the results obtained for each feature set and algorithm in terms of recall (*R*), precision (*P*) and F1-Measure (*F*) using a 5-fold cross-validation. The results of a simple baseline that assigns the *POSITIVE* category to each relation are also given.

Feature set	Algo.	R(%)	P(%)	F(%)
FEAT-LEX	ME	96.30	95.92	96.10
FEAT-BASE	ME	91.22	96.09	93.57
FEAT-NOLEX	ME	91.66	94.99	93.26
FEAT-LEX	DT	89.01	96.45	92.55
FEAT-LEX	NB	93.44	90.69	92.02
FEAT-NOLEX	DT	91.17	88.74	89.83
FEAT-NOLEX	NB	89.58	89.23	89.37
FEAT-BASE	DT	84.35	94.70	89.16
FEAT-BASE	NB	86.73	87.86	87.27
Baseline	–	100.00	25.50	40.49

Table 3: Results for binary relation classifiers

Table 3 first shows the interest of using syntactic features as FEAT-LEX outperforms FEAT-BASE. Moreover, the non-lexicalized feature set FEAT-NOLEX obtains results equivalent to the lexicalized feature set FEAT-BASE. Concerning the learning algorithms, we observe the following hierarchy: ME $>$ DT $>$ NB. (Afzal, 2009) observes a different hierarchy, DT $>$ ME $>$ NB, but on a different corpus and a different language, which makes the comparison difficult. In terms of general performances, our results are in the same range as those reported in (Afzal, 2009), his best score being R=0.95%|P=0.87%|F=0.91% with a decision tree. Finally, we adopted the Maximum Entropy model trained with the FEAT-NOLEX feature set instead of FEAT-LEX. This choice is motivated by the fact that FEAT-NOLEX obtains

[7]We experimented other learning approaches such as HMM and Maximum Entropy models but we only provide results for the best approach, that is to say, CRF.

[8]http://mallet.cs.umass.edu

reasonable results without relying on strongly domain-dependent information such as lexicalized features.

6.4 Template Filling

As we mentioned in Section 5.2, our approach for template filling relies on the selection of relevant entities from the entity graph. Our idea is to compute for each entity a weight that quantifies its importance in the graph and consequently, makes it possible to rank the entities. We assume that the best ranked entities are more likely to be good fillers than others.

Before applying the entity selection strategies described in Section 5.2 to the entity graph, we apply a node merging step. The goal of this step is, on the one hand, to identify all the nodes that refer to the same entity value and remove duplicates and, on the other hand, to establish cross-sentence relations between entities. In our case, we used the node merging step for event mentions and date and location entity types: all dates having the same normalization and all locations having the same surface form are considered equivalent.

All annotated documents in our corpus were used for evaluating the different entity selection strategies. We report in Table 4 the results of template filling in terms of recall (*R*), precision (*P*) and F1-Measure (*F*), aggregated for all entity types.

Approach	**R(%)**	**P(%)**	**F(%)**
Hybrid	77.55	76.87	77.15
Vote	74.93	74.27	74.54
Confidence	74.89	74.16	74.47
Heuristic	73.40	73.06	73.17
PageRank	72.41	71.73	72.01

Table 4: Association of entities to events

These results confirm that the basic heuristic strategy is a powerful approach since it performs slightly better than the PageRank strategy. As the PageRank strategy only relies on the graph structure without considering the weight of the edges, its highest ranked entities are those that are highly connected regardless of the weight of the edges. As a consequence, if several non fillers entities are strongly linked, they get better scores than the others. Mihalcea (2004) proposed a weighted version of the PageRank algorithm that deals with this issue and should be tested in this context. Table 4 also shows that the best strategy is the *Hybrid* approach, which associates each entity type with a given selection approach: this method corrects the fact that an approach can perform well on a given entity type but poorly on another type.

6.5 Impact of Event Segmentation

In this section, we propose to evaluate the impact of our text segmentation procedure on the template filling task. Our text segmentation method focuses on identifying relevant text spans for the extraction. However, all documents do not mention several earthquake events and some only focus on a single event. In the latter case, our temporal segmentation might seem less relevant since all the sentences refer to the same event.

Our purpose in this section is to evaluate the impact of the segmentation on documents that mention a single event compared to those that mention multiple events. Our intuition is that the temporal segmentation should have a limited effect on single event documents and improve results on multiple event documents. In order to verify this hypothesis, we manually split the initial corpus into two sets according to the number of earthquake events they discuss. We obtained 227 multi-event documents (*M*) and 274 single-event documents (*S*). Finally, we applied each template-filling strategy on both (*M*) and (*S*) document sets, including the segmentation step or not. We report the results in Table 5 in terms of F1-Measure aggregated for all entity types.

	Without segmentation		**With segmentation**	
Approach	S(%)	M(%)	S(%)	M(%)
Hybrid	79.20	73.61	78.34	75.61
Vote	77.67	68.68	76.89	71.81
Confidence	72.55	66.07	71.79	69.10
Heuristic	73.96	73.16	73.07	73.10
PageRank	70.92	59.72	70.67	65.32

Table 5: Impact of segmentation on single/multi-event texts (F1-Measure)

Concerning single-event documents, results in Table 5 show that the best performing strategies do not use segmentation though the global difference is not highly significant (+0.71% in average). At the opposite, strategies based on segmentation perform better on multi-event documents (+2.74% in average). Moreover, our best strategy (hybrid ap-

proach with segmentation) outperforms our baseline (heuristic without segmentation) on both document sets. Globally, these findings demonstrate that our temporal segmentation preserves results on single-event documents and improves results on multi-event documents.

6.6 Error Analysis

In order to have a more comprehensive view of the performance of our method for template filling, we performed an analysis of errors. The idea of this analysis is to identify the reason why a given entity filler is not found. In this context we identified three major types of errors:

- named entity recognition errors (*NE-err*): the entity is not identified by the linguistic preprocessing;
- event segmentation errors (*Seg-err*): the entity is identified by the linguistic preprocessing but its sentence is not tagged as part of a {MAIN} segment;
- template filling errors (*Fill-err*): the entity was identified in the correct event segment but was not selected as a template filler;
- *Correct*: the entity was correctly identified and selected as a template filler.

Figure 4 presents the percentage of each type of errors on all our evaluation corpus for two template filling strategies[9]: one without segmentation, the heuristic strategy *(Heuristic)*, and the other with segmentation, the hybrid strategy *(Hybrid)*. The

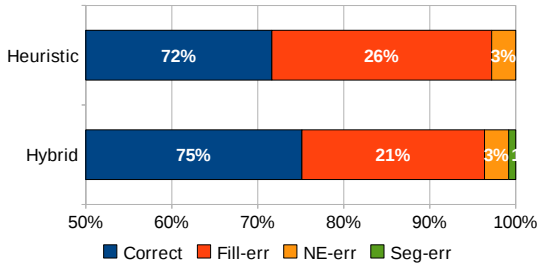

Figure 4: Classification of errors

graph shows that the baseline heuristic strategy achieves a high level of correctly identified entities (*72%*) but a significant level of template filling errors (*26%*). Our best strategy reduces this type of errors while it increases the percentage of correct fillers. Moreover, it only induces a limited number of errors due to event segmentation (*1%*).

[9]The percentages on the graph are rounded up, which explains why they do not sum to 100%.

7 Conclusion

Most of IE approaches focus on sentence-based evidences for filling templates and rely on few discourse level information. In this article, we have presented an approach for template filling based on event segmentation and graph-based entity selection. Our event segmentation takes place at the discourse level and relies on temporal cues. It uses a CRF model to find the sentences that are most relevant for filling the event template. These sentences are then used to build an entity graph from which template filler entities are selected. We have proposed several strategies for selecting the entities – heuristic, confidence-based, PageRank-based – and various ways of combining these strategies: vote and hybrid approaches.

We have presented detailed results of our IE approach on a corpus of French news articles about earthquake events. Our experiments have shown that this approach improves the simple, but powerful heuristic in this field, that always selects the first entity found in a document for each type of fillers. These results have also shown that our approach is well suited for documents that mention several comparable events. Finally, our analysis of errors have demonstrated that there is still room for improvement since 21% of remaining errors are due to incorrect entity selection.

Concerning future work, our next experiments will be dedicated to the generalization of our template filling method to different contexts and more precisely, to other languages and domains. We have already obtained promising results by testing our event segmentation module on a set of English news articles in the seismic domain with only a limited effort of adaptation. For domain generalization, we are planning experiments in the financial domain.

Abstract

Supervised approaches to Relation Extraction (RE) are characterized by higher accuracy than unsupervised models. Unfortunately, their applicability is limited by the need of training data for each relation type. Automatic creation of such data using Distant Supervision (DS) provides a promising solution to the problem. In this paper, we study DS for designing end-to-end systems of sentence-level RE. In particular, we propose a joint model between Web data derived with DS and manually annotated data from ACE. The results show (i) an improvement on the previous state-of-the-art in ACE, which provides important evidence of the benefit of DS; and (ii) a rather good accuracy on extracting 52 types of relations from Web data, which suggests the applicability of DS for general RE.

1 Introduction

Automatic Relation Extraction (RE) as defined in ACE (Doddington et al., 2004) achieves the highest accuracy when supervised approaches are applied, e.g., (Zelenko et al., 2002). Unfortunately, they require labeled data and tend to be domain-dependent as different domains involve different relations. Distant supervision (DS), e.g., using Wikipedia (Banko et al., 2007; Mintz et al., 2009; Hoffmann et al., 2010), can be applied for automatically acquiring relation types and their training data.

The main idea behind DS is to exploit (i) relation repositories, e.g., the *Infobox*, x, of Wikipedia to define a set of relation types $RT(x)$ and (ii) the text of the page associated with x to produce the training sentences, which are supposed to express instances of $RT(x)$.

Previous work has applied DS to RE at *corpus level*, e.g., (Banko et al., 2007; Mintz et al., 2009): relation extractors are (i) learned using such not completely accurate data and (ii) applied to extract relation instances from the whole corpus. The multiple pieces of evidence for each relation instance are then exploited to recover from errors of the automatic extractors. Additionally, a recent approach, i.e., (Hoffmann et al., 2010), has shown that DS can be also applied at level of Wikipedia article: given a target *Infobox* template, all its attributes[1] can be extracted from a given document matching such template.

Sentence-level RE (SLRE) has been typically modeled with the traditional supervised approach, e.g., using the data manually annotated in ACE (Culotta and Sorensen, 2004; Kambhatla, 2004; Bunescu and Mooney, 2005; Zhang et al., 2005; Zhang et al., 2006; Bunescu and Mooney, 2007; Nguyen et al., 2009). The resulting extractors are very valuable as they find rare relation instances that might be expressed in only one document. For example, the relation *President(Barrack Obama, United States*) can be extracted from thousands of documents thus there is a large chance of acquiring it. In contrast, *President(Eneko Agirre, SIGLEX)* is probably expressed in very few documents (if not just one sentence), increasing the complexity for obtaining it.

In (Nguyen and Moschitti, 2011), we firstly used DS from Wikipedia for SLRE by exploiting state-of-the-art models based on Support Vector Machines (SVMs) and kernel methods (KM). The experiments showed that our approach is robust to Web documents and can achieve high accuracy, i.e., an F1 of 74.29% on 52 YAGO relations.

In this paper, to accurately assess the benefit of using DS for SLRE, we manually mapped relations from YAGO to ACE based on their descrip-

[1] This is a simpler tasks as one of the two entity is fixed.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 732–740,
Chiang Mai, Thailand, November 8 – 13, 2011.

tions. Then, we designed a joint RE model combining DS and ACE data and tested it on ACE gold standard. This way the results are validated with the data provided by the expert linguistic annotators of ACE. The improvement produced by DS in these tests provides a strong evidence of the benefits of our joint model.

Additionally, since our aim is to produce RE for real-world applications, we experimented with end-to-end systems, which use Named Entity Recognizers (NERs). For this purpose, we also exploited Freebase for creating DS data for our robust NER (Nguyen et al., 2010). The results show that our RE systems can be applied to any document/sentence achieving an appreciable F1 of 67%.

In the remainder of this paper, Section 2 presents the related work, Section 3 describes the datasets for distant and direct supervision and the mapping between ACE and YAGO relations, Section 4 illustrates our RE models, including the joint ACE-Wikipedia model, Section 5 reports on all experiments with our models and finally Section 6 summarizes the conclusions.

2 Related Work

The extraction of relational data from text has drawn popularity for its potential application in a broad range of tasks. It refers to the automated extraction of relational facts, or world knowledge from the Web (Yates, 2009). To identify semantic relations using machine learning, three learning settings have mainly been applied, namely supervised methods (Zelenko et al., 2002; Culotta and Sorensen, 2004; Kambhatla, 2004; Zhou et al., 2005), semi supervised methods (Brin, 1998; Agichtein and Gravano, 2000), and unsupervised methods (Hasegawa et al., 2004; Banko et al., 2007).

Early work on Relation Extraction has mostly employed kernel-based approaches (Zelenko et al., 2002; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Zhang et al., 2005). Structural kernels on parse trees were proposed in (Collins and Duffy, 2001) for parse reranking and (Culotta and Sorensen, 2004) extended them for RE using augmented dependency trees. Recent literature has shown that efficient and appropriate kernels can be used to solve the RE problem, exploiting constituency trees (Zhang et al., 2006) and their combination with dependency trees (Nguyen et al., 2009)

Traditional relation classifiers use only labeled data for training. However, these are expensive to obtain, as they require efforts of experienced human annotators. In contrast, unlabeled data is relatively easy to collect, but its use is still an open problem. (Bunescu and Mooney, 2007) proposed a way of using a handful training set for RE. However, such model was applied to very few relation types. Distant supervised learning (Mintz et al., 2009) addresses this problem by using large amount of data to build classifiers.

The DS algorithm creates training data by selecting sentences that probably contain the target relation type. For example, suppose that $r(e1, e2)$ expresses one relation between pair of entities $e1$ and $e2$, then all sentences containing both $e1$ and $e2$ could be useful training examples. (Riedel et al., 2010) improved the DS assumption by only requiring that at least one of the sentences containing $e1$ and $e2$ expresses $r(e1; e2)$. They achieved a substantial improvement in extraction performance.

The most similar model to our DS algorithm is the method in (Hoffmann et al., 2010), which extracts relations from Wikipedia pages by using supervision from the page's infobox. In contrast, our approach allows for acquiring training data for relations defined in different sources.

3 Resources for designing and evaluating Generalized Distant Supervision

The resources we used to implement DS are YAGO, a large knowledge base of entities and relations, and Freebase, a collection of Wikipedia news articles. Our procedure uses entities and facts from YAGO to provide relation instances. For each pair of entities that appears in some YAGO relations, we retrieve all the sentences of the Freebase documents that contain such entities.

Additionally, as DS data is noisy, for accurately evaluating our extractors, we (i) manually annotated a small dataset and (ii) mapped some YAGO relations to ACE. This way we can measure the impact of Wikipedia training data on the ACE data.

3.1 ACE (Automatic Content Extraction)

The ACE effort (Doddington et al., 2004) aims at developing technology for automatically carrying out inference in natural language text. The

data includes the entities being mentioned, the relations among these entities that are directly expressed, and the events in which these entities participate. Moreover, data includes various source types (image, audio, text) and languages (English, Arabic). We use the ACE 2004 corpus with seven relation types: Physical (PHYS), Person/Social (PER-SOC), Employment/Membership/Subsidiary (EMP-ORG), Agent-Artifact (ART), PER/ORG Affiliation (Other-AFF), GPE Affiliation (GPE-AFF), and Discourse (DISC). These relationships are explicitly described in the ACE document guidelines.

RE, as defined in ACE, is the task of finding relevant semantic relations between pairs of entities in texts. For example, the following sentence from the ACE 2004 corpus:

> ***Tara Singh Hayer**, editor of **The Indo-Canadian Times.***

expresses the employee/organization relation (EMP-ORG) between the first entity, i.e., *Tara Singh Hayer* (of type *person*) and the second entity, i.e., *The Indo-Canadian Times* (of type *organization*).

3.2 YAGO

This is a huge semantic knowledge base derived from WordNet and Wikipedia. It comprises about more than 2 million entities (like *persons*, *organizations*, *cities*, etc.) and 20 million facts connecting such entities. These include the taxonomic Is-A hierarchy as well as semantic relations between entities. The facts of YAGO have been extracted from the category system and the *Infoboxes* of Wikipedia and have been combined with taxonomic relations from Wordnet.

We use the YAGO ontology and the knowledge base, version *2008-w40-2*, whose validation has shown an accuracy of 95% for 99 relations. However, some of them are (a) rather trivial, e.g. *familyNameOf* or *givenNameOf*; (b) describe numerical attributes that change over time, e.g. *hasBudget*, *hasGDP* or *hasPopulation*; (c) symmetric, e.g. *hasPredecessor* and *hasSuccessor*; and (d) used for data management and do not convey semantics, e.g. *describes* or *foundIn*. Therefore, we removed trivial relations, unstable relations, and those used for data management. We obtained 1,489,156 instances of 52 relation types to be used with our DS approach. Some examples are shown in Table 1.

Algorithm 3.1: ACQUIRE_LABELED_DATA()

$DS = \emptyset$
$YAGO(R) : Instances\ of\ Relation\ R$
for each $\langle Wikipedia\ article : W \rangle \in Freebase$
do {
  $\mathcal{S} \leftarrow set\ of\ sentences\ from\ W$
  for each $s \in \mathcal{S}$
  do {
    $\mathcal{E} \leftarrow set\ of\ entities\ from\ s$
    for each $E_1 \in \mathcal{E}$ **and** $E_2 \in \mathcal{E}$ **and** $R \in YAGO$
    do {
      if $R(E_1, E_2) \in YAGO(R)$
      then $DS \leftarrow DS \cup \{s, R^+\}$
      else $DS \leftarrow DS \cup \{s, R^-\}$
    }
  }
}
return $(\mathcal{DS})$

3.3 Freebase

To access to the Wikipedia documents, we used Freebase (version March 27, 2010), which is a dump of the full text of all Wikipedia articles. It has been sentence-tokenized by Metaweb Technologies. For our experiments, we used 100,000 articles of which only 28,074 contain at least one relation for a total of 68,429 of relation instances. These connect 744,060 entities, 97,828 dates and 203,981 numerical attributes. Statistics are shown in Table 2.

In Freebase articles, Wikipedia entities like *Person*, *Organization* or *Location* are marked whereas numbers or dates are not. This prevents to extract interesting relations between entities and dates, e.g. *John F. Kennedy was born on May 29, 1917* or between entities and numerical attributes, e.g. *The novel Gone with the wind has 1037 pages*. Thus, we designed 18 regular expressions to extract dates and other 25 rules to extract numerical attributes, which range from integer numbers to ordinal numbers, percentage, monetary, speed, height, weight, area, time, and ISBN.

3.4 Distant Supervision

DS for RE is based on the following assumption, if (i) a sentence is connected *in some way* to a database of relations and (ii) it contains the pair of entities participating in such relation then it is likely that such sentence expresses the relation. For our DS, we relax (i) by allowing for the use of an external DB of relations such as YAGO and any document of Freebase. The alignment between YAGO and Freebase is implemented by the Wikipedia page link: for example the

Table 1: Some of selected YAGO relation types and their number of instances.

link *http://en.wikipedia.org/wiki/James_Cameron* refers to the entity *James_Cameron*.

A simplified version of our approach is the following: for any YAGO relation instance, scan all the sentences of all Wikipedia articles to test point (ii). Unfortunately, this procedure is impossible in practice since there are millions of relation instances in YAGO and millions of Wikipedia articles in Freebase, i.e. an order of magnitude of 10^{14} iterations[2]. Thus we use a more efficient procedure formally described in Alg. 3.1: for each Wikipedia article in Freebase, we scan all of its NEs. Then, for each pair of entities seen in the sentence, we query YAGO to retrieve the relation instance connecting these entities.

It should be noted that, our approach solves most of the problems for DS pointed out in (Bunescu and Mooney, 2007). Indeed, such issues are due to the sampling method used to acquire DS sentences: NEs were used as query to a search engine, whose weighting schemes introduce a bias. As, we utilize whole documents randomly drawn from Freebase and extract from them all possible positive and negative relation instances, no artificial feature (e.g. word) distribution is generated.

3.5 Mapping relations between YAGO-ACE

The YAGO knowledge base created from Wordnet and Wikipedia contains 99 relations whereas the ACE 2004 corpus only defines 7 relation types between 7 entity types. To further measure the impact of our Wikipedia dataset and the relations learnt, we mapped 33 relations of YAGO into those of ACE 2004. Surprisingly, we have found a fair correlation between the two different sources, which can help to validate our DS approach. The projection is shown in Table 3.

[2]Assuming 100 sentences for each article.

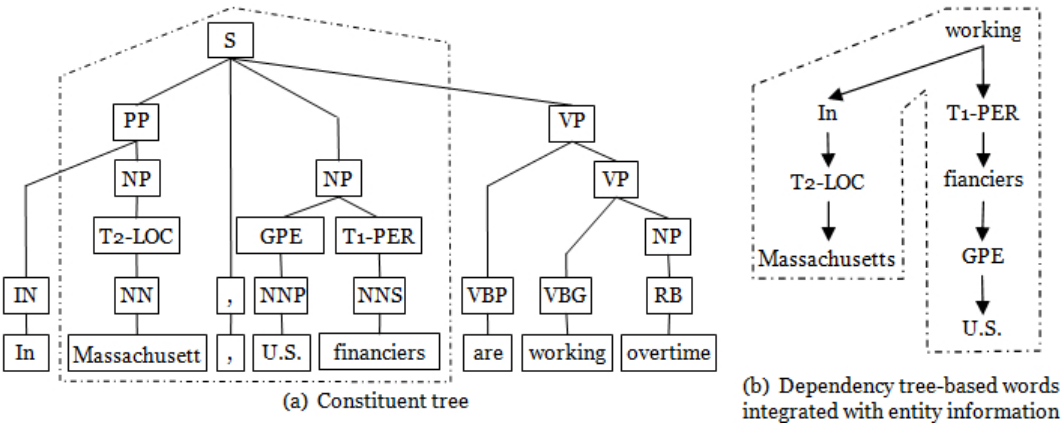

Figure 1: The constituent and dependency parse trees integrated with entity information

4 Direct, distant and joint supervised learning

We model RE using state-of-the-art kernel methods: syntactic structures are used to represent relation instances whereas kernel functions measure the similarity between pairs of them. Such functions correspond to scalar products between implicit feature vectors in the space of substructures. Additionally, we define a joint model between the RE classifier trained on ACE and trained on DS data such that we can merge together the information from the two datasets on similar relation type.

4.1 RE based on Kernel Methods

State-of-the-art ACE RE, i.e. (Zhang et al., 2006; Nguyen et al., 2009), uses tree kernels applied to constituent and dependency syntactic structures, extracted from the sentences expressing the target relations. Given a parse tree, the path-enclosed tree (PET) is used as input of a tree kernel function. PET is the smallest common subtree including the two entities of a relation. Figure 1.a shows the constituent tree and figure 1.b shows a fragment of the dependency tree of the sentence: *In Massachussets, U.S. financiers are working overtime*. The dashed frame in Figure 1.a surrounds PET associated with the two mentions, *financiers* and *Massachussets*. Moreover, to improve the representation, two extra nodes T1-PER and T2-LOC, denoting the type PERSON and LOCATION, are added to the parse tree, above the two target NEs, respectively.

In our experiments, we use the model defined in (Zhang et al., 2006), which combines a syntactic tree kernel applied to constituent parse trees and a polynomial kernel over feature extracted from the entities:

$$CK_1 = \alpha \cdot K_P + (1 - \alpha) \cdot TK, \quad (1)$$

where α is a coefficient to give more or less impact to the polynomial kernel, K_P, and TK is the syntactic tree kernel (Collins and Duffy, 2001) applied to PET.

We also use the best model in (Nguyen et al., 2009), which combines the advantages of the two parsing paradigms by adding six sequence kernels. These are applied to paths derived from the dependency tree and enriched with node labels of the constituent tree as follows:

$$CSK = \alpha \cdot K_P + (1 - \alpha) \cdot (TK + \sum_{i=1,..,6} SK_i), \quad (2)$$

where SK_i are the sequence kernels applied to the structure i defined in (Nguyen et al., 2009).

In our application domain there are many different categories of name entities, e.g. Editor, President, Employer, and so on. Thus the typically available NE types, e.g. Person, Organization, Location, Time, Numbers, do not provide much selective information. For this purpose, we also provide adapted kernels by simply removing the category label in the nodes of the trees and in the sequences. This data transformation corresponds to define different kernel functions (Cristianini and Shawe-Taylor, 2000).

4.2 Joint Model for Distant and Direct Supervision

An interesting test of the quality of our DS data can be carried out by using it for ACE RE experiments. This way, we can use the gold and well

annotated dataset of ACE to accurately measure the impact of DS data. For this purpose, we define a joint model as follows: first, we select the portion of hand-labeled ACE 2004 corpus containing common relations (see the mapping in Section 3.5).

Second, we create a huge labeled dataset under distant supervision assumption (described in Section 3.4) from Wikipedia news articles and YAGO knowledge base. Thanks to the projection from YAGO to ACE relations, we generate the two datasets under the same set of labels. This way, labeled data can be automatically acquired from a huge corpus and used to enrich ACE relation extractors.

Third, we train (i) the M_{ace} RE model on ACE dataset and (ii) the M_{mixed} model on ACE dataset mixed with the labeled data from Wikipedia (by using for example CSK).

Next, as standard SVM classifiers do not provide calibrated posterior probabilities we apply Platt transformation (Platt, 2000) improved by (Lin et al., 2007) with an additional sigmoid function. This allows us to map the SVM outputs of the two models M_{ace} and M_{mixed} into probabilities.

Finally, we linearly combine the probability of the two classifiers as follows:

$$P(C|r) = \alpha \cdot P(C|r, C_1) + \beta \cdot P(C|r, C_2), \quad (3)$$

where C_i is the output of classifier i, α and β are the weights learned from a validation set to encode the importance of the classifier for detecting the relation r. This combination provides a more robust model with respect to domain change.

5 Experiments

The aim of the experiments is to demonstrate that our DS produces reliable and practical usable relation extractors. For this purpose, we test SLRE trained with DS and with the joint DS and ACE data. We also test end-to-end RE, which also requires the experimentation of our automatic Named Entity Recognizer.

5.1 Experimental setting

We used the English portion of the ACE 2004 corpus including 443 documents, annotated with seven entity types and seven relation types. We obtained 5,784 positive and 55,650 negative examples when generating pairs of entity mentions as candidate relations. We employed the Stanford Parser (Klein and Manning, 2003) to produce parse trees. The candidate relations are generated by iterating all pairs of entity mentions in the same sentence.

Regarding the DS data extraction (see Table 2), we used two PCs, one with Intel X5270 3.50GHz CPU, 32GB RAM, another with 3.40GHz CPU and 8GB RAM to run the Algorithm 3.1. We processed about 25,000 Wikipedia documents per day per machine. When we added the generation of structures and features, the whole procedure required one day to process 5,000 Wikipedia documents (per machine). Thus, it took about 10 days to create the dataset and the computational learning files.

To train and test our binary relation classifier, we used SVMs, where relation detection is formulated as a multiclass classification problem. We employed *one vs. rest*, selecting the instance with largest margin as the final label. We used the Tree Kernel toolkit[3] (Moschitti, 2004; Moschitti, 2006; Moschitti, 2008) as SVM platform to implement CK_1 and CSK (see Section 4.1). The training phase with convolution kernels on syntactic parse tree and diverse sequence kernels on the large DS data took 3 days.

For testing on ACE data, we applied 5-fold cross-validation and evaluated single classifiers with the average of Precision, Recall and F1 on the 5-folds. The overall accuracy is measured with the mean of the Micro-Average (All) over the 5-folds.

For testing on Wikipedia, as DS data may be incorrect, we created a test set by sampling 200 articles from Freebase (these articles are not used for training). An expert annotator then examined one sentence at a time and took all possible pairs of entities, where the latter were already marked in the sentence. For each pair of entities, the considered 52 relations from YAGO (and used in our RE system) are marked as positive or negative, respectively. The annotator obtained 2,601 relation instances used for evaluation.

Regarding NE recognition, we applied CRFs to Wikipedia data but we could not use the whole amount of data. Thus we sampled 18,198 Wikipedia articles, selecting 4/5 for training and the rest for testing. The training phase took 14 hours and 30 minutes, whereas the classification took less than 10 minutes.

Table 5: Results on ACE 2004 considering all the type of entities and all the 7 ACE relations.

5.2 Using Wikipedia Relational Extractors to improve on ACE

In the ACE program, relations are defined between pairs of entities. These not only refer to NEs but also to mentions, e.g. indicated by a common noun or noun phrase, or represented by a pronoun. In contrast, Wikipedia instances mainly refer to NEs, e.g. *Leonardo Da Vinci*, *Canada* or *Titanic*, and we do not use pronominal references for building RE instances. Thus, we carried out two kinds of experiments: using (i) RE task as defined in ACE with all kind of entities and (ii) only relations between named entities. We have observed that the NE relations only exist for the classes: Physical (PHYS), Employment/Membership/Subsidiary (EMP-ORG) and GPE Affiliation (GPE-AFF).

Table 5 presents the combination results. Overall, using Wikipedia data improves the state-of-the-art of standard RE from 64.74% to 67.59%. Moreover, if we focus on *proper* NE relations, i.e. of the type indicated in point (ii), the relation extractors improve from 73.94% to 76.23%. These results are interesting as show that (a) we can improve the best systems with DS and (b) relations learned from Wikipedia can be mapped into those defined by expert linguists on ACE. We also tested a model learned from only DS data. For space reason, we do not report the complete results: as expected, its overall F1 is lower than the model trained on only ACE (about 10 absolute percent points less).

5.3 End-to-end Relation Extraction

In this section, we describe the experiments using automatic NEs. Previous work, e.g. (Zhang et al., 2006; Zhou et al., 2007; Nguyen et al., 2009) performed extraction using gold entity features such as entity types (*Person*, *Location*, *Organization*), entity subtypes (*Nation*, *Population-Center* for *GPE*). For example, in the sentence *Bush went to Washington*, the type of the first named entity, *Bush*, is PERSON and for the second named entity, *Washington*, is LOCATION. When accurate, such features improve performance. In case of fully automatic systems they introduce noise and in Wikipedia they are not available. Thus, we removed all gold entity features (entity type, entity subtype, mention type, and LDC mention type) from ACE annotations. We modeled tree and sequence kernels based on constituent and dependency parse trees along with a few features that can be extracted automatically such as the string and the head word of the entity. Note that in (Nguyen et al., 2009; Zhou et al., 2007; Zhang et al., 2006), even for tree kernels, the tree structures were also integrated with entity types (see Figure 1 as an example). Therefore, in the parse trees in Figure 1, we replaced entity types PER, ORG, LOC with a generic type ETYPE.

5.3.1 Entity Extraction from ACE and Wikipedia

For entity extraction, we followed the design in (Nguyen et al., 2010) by applying CRF++ [4]. We

[4] http://crfpp.sourceforge.net

Corpus	ACE	Wikipedia
Precision	77.84	68.84
Recall	70.26	64.56
F1	73.85	66.63

Table 6: Results of entity extraction from ACE and entity detection from Wikipedia.

performed automatic entity extraction from seven classes from ACE 2004 and entity detection from Wikipedia. While ACE documents have been annotated with seven classes *Person, Organization, Facility, Location, GPE, Vehicle, Weapon*, for Wikipedia, we used Freebase as learning source, where entities have been annotated in each Wikipedia article. Note that for Wikipedia, the entity detection has been done for only entities, like *Person, Organization, Location*. For dates and numerical attributes, we used the extraction patterns described in Section 3.4. The results reported in Table 6 are rather lower than in standard NE recognition. We should consider that our NER also tags mentions in ACE, which is a hard task whereas for Wikipedia, the entity instances from YAGO potentially belong to thousands of different categories. Although we do not categorize entities, it makes the complexity of detecting of NE boundaries higher.

5.3.2 RE from Automatic Entity Extraction

Web data entities are often not annotated and not available as in hand-labeled corpora like ACE or in Wikipedia pages. In this new experiment, we move to a novel task where entities are detected and classified automatically from a classifier. This way, we aim at designing an end-to-end RE system, where entities are not known beforehand. We also introduce a new task, that is the extraction of Wikipedia relations from any web text, i.e. detection of Wikipedia instances from any web page and not only from Wikipedia articles (where links often exist for Wikipedia instances).

Setting	Gold Features/ Gold NEs	No gold Features/ Gold NEs	No gold Features/ Auto NEs
Precision	76.60	74.47	70.27
Recall	67.00	57.26	47.52
F1	71.50	64.74	56.70

Table 7: Results on end-to-end RE from ACE.

The results are shown in Table 7 and Table 8. We note that the gold entity features lead to very good F1. When we remove these, the F1 decreases from 71.50% to 64.74%. Nevertheless, without gold entity features, RE from Wikipedia still achieves very good performance, i.e. an F1 of 74.29%.

Setting	Gold NEs	Automatic NEs
Precision	91.42	82.16
Recall	62.57	56.57
F1	74.29	67.00

Table 8: Results on end-to-end RE from Wikipedia.

6 Conclusion

In this paper, we proposed a study on novel training methods using semi-structured resources such as Wikipedia. As the NLP field always requires new methods to leverage the ever-increasing amounts of user-generated data available on the web, ours is a particularly important achievement for RE. We presented adaptation and experimentation of state-of-the-art RE models also exploiting a mapping between Wikipedia and ACE relations. We also extensively experimented with end-to-end systems applicable both to Wikipedia pages as well as to any natural language text. Our method is general and we suggest that it could be applicable to other external resources or other NLP tasks.

A Cross-lingual Annotation Projection-based Self-supervision Approach for Open Information Extraction

Seokhwan Kim, Minwoo Jeong†, Jonghoon Lee, Gary Geunbae Lee

Abstract

Open information extraction (IE) is a weakly supervised IE paradigm that aims to extract relation-independent information from large-scale natural language documents without significant annotation efforts. A key challenge for Open IE is to achieve self-supervision, in which the training examples are automatically obtained. Although the feasibility of Open IE systems has been demonstrated for English, utilizing such techniques to build the systems for other languages is problematic because previous self-supervision approaches require language-specific knowledge. To improve the cross-language portability of Open IE systems, this paper presents a self-supervision approach that exploits parallel corpora to obtain training examples for the target language by projecting the annotations onto the source language. The merit of our method is demonstrated using a Korean Open IE system developed without any language-specific knowledge.

1 Introduction

The objective of information extraction (IE) is to generate structured information representing semantic relationships among a set of arguments from natural language documents. Although many supervised machine learning approaches have been successfully applied to IE tasks, applications of these approaches are still limited because large amounts of training data are required to achieve good extraction results. Because manual annotation for training examples is very expensive, weakly-supervised techniques to learn the IE system without significant annotation efforts have been sought (Zhang, 2004; Chen et al., 2006).

Open IE is an alternative weakly-supervised IE paradigm (Banko et al., 2007). The goal of Open IE is to yield both domain-independent and relation-independent extractions from a large amount of natural language text without requiring hand-crafted rules or hand-annotated training examples. A key challenge to implementing Open IE is to learn extractors without manually annotated training examples. Self-supervised learning approaches have allowed Open IE systems such as TextRunner (Banko et al., 2007) and WOE (Wu and Weld, 2010) to extract relations from large-scale English text with automatically annotated training examples obtained using external knowledge.

However, applying the self-supervision approaches adopted by previously reported Open IE systems to build a new system is problematic in languages other than English, because these approaches mainly depend on language-specific knowledge for English. For example, TextRunner obtains training examples from the English Penn Treebank by triggering a set of hand-written heuristics denoting syntactic structural constraints to decide whether or not a given instance has a semantic relationship. To learn an extractor for a new language, this approach requires a syntactically annotated corpus and language-specific heuristics for the target language. WOE achieves self-supervised learning of Open IE by using heuristic matches between attribute values in Wikipedia infoboxes and their corresponding sentences. This method can reduce the cost of

Chiang Mai, Thailand, November 8 – 13, 2011.

building an Open IE system for a new language, because Wikipedia articles and their infoboxes are available not only for English, but also for most other languages. But differences among languages in the amount of available resources from Wikipedia are still severe; for example, English Wikipedia includes about 3.5 million articles, but Korean Wikipedia includes only about 150,000 articles as of January 2011.

In this paper, we propose a cross-lingual annotation projection-based self-supervision approach to improve the cross-language portability of Open IE systems. This method exploits parallel corpora to obtain training examples in the target language by projecting the annotations generated by the Open IE system for the source language. The goal is to determine whether a semantic relationship in a pair of noun phrases in the target language L_T is the same as in the corresponding pair of noun phrases in the source language L_S; this process is called cross-lingual annotation projection. Using our self-supervision approach, we developed the first English-to-Korean Open IE system that does not require any language-specific knowledge. We use an English-Korean parallel corpus to project the results of an English Open IE system onto training examples for the target Korean system.

We present the definition of Open IE problem in Section 2, describe our cross-lingual annotation projection-based self-supervision approach for Open IE in Section 3, present details about implementation of the Korean Open IE system developed based on our proposed approach in Section 4, report the evaluation result of the system in Section 5, present related work in Section 6, and conclude this paper in Section 7.

2 Open Information Extraction

The problem of Open IE is to learn a function $f : D \rightarrow \{\langle e_i, r_{i,j}, e_j \rangle | 1 \leq i, j \leq N\}$, where D is a given natural language document, e_i and e_j are entities which have a semantic relationship that is explicitly expressed in a contextual subtext $r_{i,j}$, and N is the total number of entities in D. For example, the output of an Open IE system for an input sentence "*Obama was born in Hawaii.*" will be a tuple $\langle$ *Obama, was born in, Hawaii* $\rangle$. Whereas traditional relation extraction problems such as ACE RDC have attempted to process both explicit and implicit relationships, Open IE aims to only extract explicit relationships $r_{i,j}$ in the context (Banko et al., 2007). Following Banko (2007), this paper concerns semantic relationships between entity pairs within a single sentence and considers each base noun phrase as an entity candidate.

Because the goal of Open IE paradigm is to eliminate direct human supervision, an extractor should be learned from the training examples obtained automatically without requiring handcrafted rules or hand-labeled annotations: this process is called self-supervised learning. Self-supervised learning for Open IE is performed in two steps: (1) self-supervision and (2) extractor learning. In the self-supervision step, the training examples to learn an extractor are generated for each instance, i.e., pair of noun phrases in the given sentence. Next, self-supervised learning determines whether or not each instance is semantically related. The key to achieving self-supervision is to determine how to automatically identify the existence of a semantic relationship between noun phrases. Whereas previously reported Open IE systems have performed this determination based on syntactic structural heuristics or structured information from Wikipedia, our proposed self-supervision approach utilizes the projected annotations from the results of Open IE system developed for another language. Details about our self-supervision approach are provided in Section 3.

In the learning step, a set of training examples obtained from self-supervision is utilized to learn an extractor f. The extractor has been successfully implemented using statistical models such as the Naive Bayes classifier (Banko et al., 2007) and conditional random fields (CRF) (Banko et al., 2008).

3 Cross-Lingual Annotation Projection-Based Self-Supervision

Cross-lingual annotation projection is an approach to obtain training examples for L_T by projecting the annotations for L_S using parallel corpora between L_T and L_S. This approach has been applied for several natural language processing tasks which have differences in the amounts of available resources among target languages (Yarowsky and Ngai, 2001; Yarowsky et al., 2001; Merlo et al., 2002; Hwa et al., 2002; Zitouni and Florian, 2008; Pado and Lapata, 2009). A premise of our method is that parallel corpora between L_T and L_S are

much easier to obtain than is a task-specific training dataset for L_T: this premise is generally reasonable because large numbers of parallel corpora for various language pairs are available.

We consider the Open IE as a task with an imbalance problem in resource according to the target language, because most reported systems for Open IE were developed only for English and because they depend on language-specific knowledge. We propose a cross-lingual annotation projection-based self-supervision method of obtaining training examples for Open IE. The cross-lingual annotation projection for self-supervision can be performed for each bi-sentence pair $\langle S_S^i, S_T^i \rangle$ in parallel corpora between L_T and L_S as follows:

1) **Annotation:** Given an input sentence S_S^i, a set of extracted tuples O_S^i is yielded by the extractor f_s for the source language L_S.

2) **Projection:** The annotations O_T^i for the sentence S_T^i are generated by projecting from O_S^i based on word alignment between S_S^i and S_T^i.

3.1 Annotation

The first step in projecting annotations from L_S onto L_T is to obtain annotations for the sentences in L_S, as follows:

1) A set of entities $\{e_S^1, \cdots, e_S^N\}$ in the given sentence S_S^i is identified using a base phrase chunker in L_S. Each base noun phrase is considered as an entity candidate.

2) Each instance is composed of a pair of entities $\langle e_S^l, e_S^m \rangle$ in S_S^i, where $1 \leq l < m \leq N$.

3) For each instance $\langle e_S^l, e_S^m \rangle$, the extractor f_s for the source language L_S outputs the existence of semantic relation between e_S^l and e_S^m and the textual fragment $r_S^{i,j}$ indicating the detected relationship.

As an example of annotation projection for self-supervision of Korean Open IE with a bi-text in an L_T Korean and an L_S English (Figure 1), the annotation of the sentence in English shows that the pair of entities "Barack Obama" and "Honolulu" has a semantic relationship and "was born in" indicates the relationship between two entities.

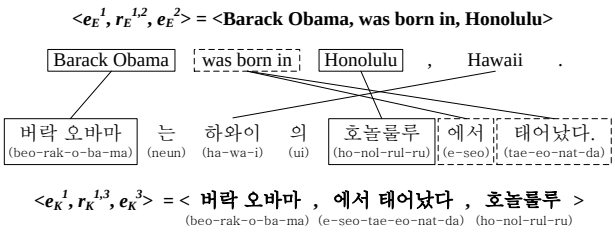

Figure 1: An example of cross-lingual annotation projection for Open IE of a bitext in English and Korean

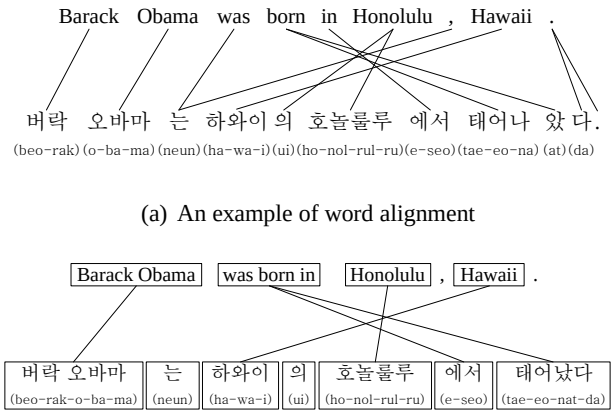

(a) An example of word alignment

(b) An example of chunk alignment

Figure 2: Comparision between word and chunk alignments

3.2 Projection

To use cross-lingual annotation projection to project the annotations from the sentences in L_S onto the sentences in L_T, we utilize word alignment information, which is an important component of statistical machine translation techniques. The objective of the word alignment task is to identify translational relationships among the words in a bi-text, and to produce a bipartite graph with a set of edges between words with translational relationships (Figure 2(a)). However, the results of automatic word alignment may include incorrect alignments because of technical difficulties. For example, the alignments (Figure 2(a)) have some errors such as ⟨Honolulu, ui⟩, ⟨COMMA, neun⟩ and ⟨PERIOD, da⟩.

The success of annotation projection is highly dependent on the quality of word alignment, to obtain quality results, the efforts to minimize harmful effects of erroneous word alignments should be minimized. In this work, we use alignments (Fig-

$A_P \leftarrow \vec{C}_S \times \vec{C}_T$
$A_C \leftarrow \emptyset$
for all $\left(C_S^i, C_T^j\right) \in A_P$ **do**
  $M(i,j) \leftarrow$ # of aligned words among C_S^i and C_T^j
end for
while $A_P \neq \emptyset$ **do**
  $(i,j) \leftarrow \underset{(i',j')}{\text{argmax}} \left(M(i',j') | (C_S^{i'}, C_T^{j'}) \in A_P\right)$
  if $(i,*) \notin A_C$ and $(*,j) \notin A_C$ **then**
    $A_C \leftarrow A_C \bigcup \{(i,j)\}$
  else if $(i, \vec{j_i}) \in A_C$ and j is adjacent to $\vec{j_i}$ **then**
    $A_C \leftarrow \left(A_C - (i, \vec{j_i})\right) \bigcup \left\{\left(i, \vec{j_i} \bigcup \{j\}\right)\right\}$
  else if $(\vec{i_j}, j) \in A_C$ and i is adjacent to $\vec{i_j}$ **then**
    $A_C \leftarrow \left(A_C - (\vec{i_j}, j)\right) \bigcup \left\{\left(\vec{i_j} \bigcup \{i\}, j\right)\right\}$
  end if
  $A_P \leftarrow A_P - (C_S^i, C_T^j)$
end while
return A_C

Figure 3: A chunk alignment algorithm

ure 3) between pairs of base phrase chunks instead of between pairs of words. For a given bi-text $\langle S_S^i, S_T^i \rangle$, a base phrase chunker for corresponding language produces chunk lists $\vec{C}_S$ for the source language and $\vec{C}_T$ for the target language. To identify the translational alignment between each pair of chunks C_S^i and C_T^j, the algorithm is performed in a simple greedy manner, i.e., a chunk pair that includes more word alignments is aligned before a chunk pair with few alignments, and a series of adjacent chunks aligned with the same counterpart can be merged. Chunk-based reorganization (Figure 3) of the word alignment in Figure 2(a) reduced the number of erroneous word alignments (Figure 2(b)).

Using chunk alignment, the annotations in the target language sentence S_T^i are projected from the annotations in the source language sentence S_S^i as follows:

1) As in the annotation phase, each instance is composed of a pair of base noun phrases $\langle e_T^l, e_T^m \rangle$ in S_T^i, where $1 \leq l < m \leq N$.

2) For each instance $\langle e_T^l, e_T^m \rangle$, its translational instance $\langle e_S^o, e_S^p \rangle$ in S_S^i is explored based on the result of chunk alignment.

3) The existence of semantic relationship in $\langle e_T^l, e_T^m \rangle$ is determined by projection.

4) If $\langle e_T^l, e_T^m \rangle$ is projected as a positive instance, the contextual subtext in S_T^i aligned with $r_S^{o,p}$ in S_S^i is extracted as $r_T^{l,m}$, and the final annotation $\langle e_T^l, r_T^{l,m}, e_T^m \rangle$ is produced.

In the Figure 1, an instance $\langle e_K^1, e_K^3 \rangle = \langle$ beo-rak-o-ba-ma, ho-nol-rul-ul $\rangle$ in the Korean sentence is aligned with the instance $\langle e_E^1, e_E^2 \rangle = \langle$ Barack Obama, Honolulu $\rangle$ in the English sentence. Because $\langle e_E^1, e_E^2 \rangle$ is predicted as a positive instance in the annotation phase, $\langle e_K^1, e_K^3 \rangle$ can be also considered to be a semantically related instance. Then, "e-seo-tae-eo-nat-da" in the Korean sentence is identified as $r_K^{1,3}$ which is aligned to $r_E^{1,2}$ = "was born in" in S_E^i, and finally, $\langle e_K^1, r_K^1, 3, e_K^3 \rangle = \langle$beo-rak-o-ba-ma, e-seo-tae-eo-nat-da, ho-nol-rul-ul$\rangle$ is yielded.

4 Implementation

We developed a Korean Open IE system (Figure 4) based on our proposed cross-lingual annotation projection-based self-supervised learning. Our system is operated with no language-specific knowledge or resource for the target language, Korean. It requires only an Open IE system for another source language and a parallel corpus between source and target languages. In this system, we have used English as the source language, because most reported techniques for Open IE were developed for English. According to the advantages of English Open IE systems, the objective of our system is to perform domain-independent and relation-independent extraction. Furthermore, the fact that manual annotations are not needed to obtain training examples is also valid for applying the system to a new language. The system consists of three parts: self-supervision, learning and extraction.

4.1 Self-supervision

The sole input of our self-supervision method is a parallel corpus of L_S and L_T. We used an English-Korean parallel corpus [1] which consists of 266,892 bi-sentence pairs in English and Korean. Each sentence in the corpus was processed for POS tagging and base phrase chunking using OpenNLP [2]

[1] The parallel corpus collected is available in our website http://isoft.postech.ac.kr/~megaup/ijcnlp/datasets

[2] http://incubator.apache.org/opennlp/

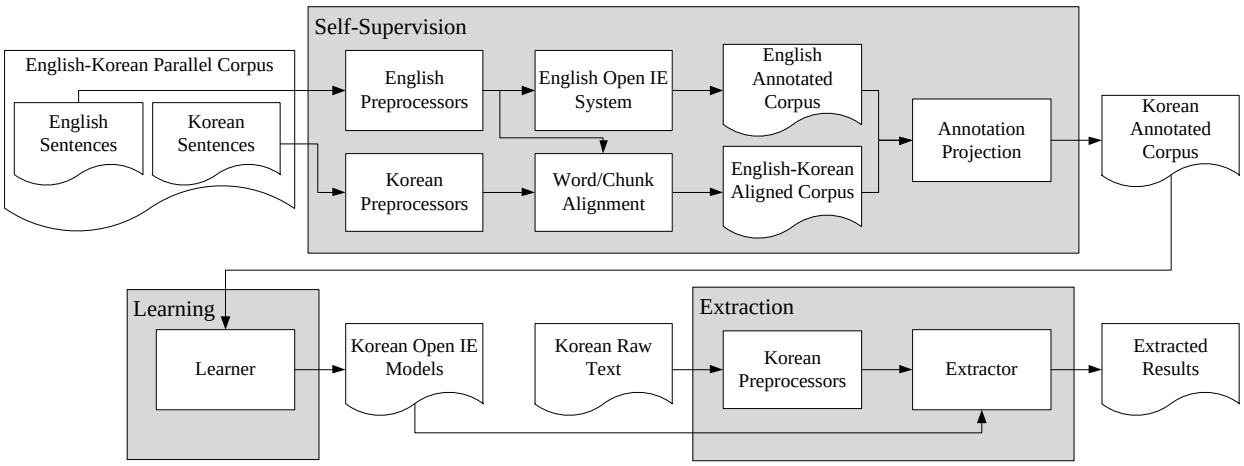

Figure 4: Overall architecture of the Korean Open IE system

for English sentences and Espresso [3] for Korean sentences.

For each preprocessed bi-sentence, word alignment was performed using GIZA++ software [4] (Och and Ney, 2003) in the standard configuration in both English-Korean and Korean-English directions. The bi-directional alignments were joined using the grow-diag-final algorithm (Koehn et al., 2003). The results of word alignment were reorganized by the chunk alignment algorithm 3.

The other prerequisite of the self-supervision in our system is that the Open IE system for the source language should obtain the annotations for source language sentences in the parallel corpus. We used our own implementation of the English Open IE system (Banko et al., 2007). We obtained a set of training examples to learn the extractor by applying a series of heuristics to the WSJ part of the Penn Treebank. From 49,208 sentences, 1,028,361 instances were generated; 9.0% of them were determined to be positive instances by the heuristic-based self-supervision. Using these instances, lexical and POS tag features were used to learn a CRF model. The CRF++ toolkit [5] was used to learn the extractor for English.

For the given preprocessed parallel corpus and Open IE system for the source sentences, annotation projection was performed. First, each English sentence in the parallel corpus was analyzed using the English Open IE system. Of 598,115 acquired instances, 169,771 positive annotations were produced by the annotation phase. These annotations were projected to the corresponding instances in the Korean part of the parallel corpus. This operation was performed based on the information obtained from chunk alignment. Finally, a set of training examples for the Korean Open IE system was projected. The projected dataset included 278,730 instances; 89,743 were positive.

4.2 Learning

Using training examples obtained by self-supervision, an extractor for Korean Open IE was generated. The extractor is composed of two statistical models. One is a maximum entropy (ME) classifier to detect whether or not each given instance is positive; the other is a CRF model to identify the contextual subtext indicating the semantic relationship for each positive instance. Both models utilized lexical and POS tag features in the node sequence of the dependency path between two entities organizing a given instance. The dependency path for each instance was generated using MSTParser (McDonald et al., 2005) [6] with a model trained on the Sejong corpus (Kim, 2006). The extractor was implemented using CRF++ and Maximum Entropy Modeling toolkits [7].

4.3 Extraction

During execution, the input of the system is raw text in Korean and the output is a set of extractions

for the given text. The input text should be preprocessed by the analyzers for Korean sentences in the previously mentioned parts of the system. Then the instances and their features are extracted for each preprocessed sentence. The two models (Section 4.2) are operated in a cascaded manner for a given instance and its features: first the ME model identifies the existence of semantic relationship in a given instance, then the CRF model explores the context indicator only for instances determined to be positive by the ME model. Based on the results of two cascaded models, the system outputs the extracted results in the form of a triple, $\langle e_i, r_{i,j}, e_j \rangle$.

5 Evaluation

To evaluate our Korean Open IE system introducing cross-lingual annotation projection-based self-supervision, extractions were performed for two types of datasets. One dataset was built by annotating the semantic relationships denoted in a small number of sentences randomly selected from Korean Wikipedia articles. The dataset consists of 250 sentences and 1,434 instances, 308 of which were annotated to be positive instances. To compare with our system, we built a heuristic-based Korean Open IE system considered as a baseline. The baseline model was trained on the corpus automatically obtained from Sejong treebank corpus using a set of heuristics which were utilized for the English Open IE system except language-specific rules. On the test dataset, we measured the performances of three models: heuristic-based model, projection-based model, and the merged model trained on the mixture of both training datasets. Precision, Recall and F-measure were adopted for our evaluation.

Table 1 compares the performances of three models. The baseline model using only language-independent heuristics achieves poor performance, especially in recall. On the other hand, our proposed projection-based model outperforms the baseline model, due to largely increased recall. Moreover, the projected instances helps to improve the performance of the heuristic-based approach by merging the training datasets. The results show that our proposed projection-based method is more effective than the previous approach to build an Open IE system for a new language.

Dependency Parsing Error	461 (34.1%)
Extracting Error	527 (39.0%)

Table 3: Distribution of the errors

The second evaluation was performed on the extractions of our system for the large amount of documents. We used two datasets: one dataset consists of 2,565,487 sentences in 302,276 documents obtained from Korean Newswire Second Edition published by LDC; the other contains 1,342,003 sentences in 123,000 articles from Korean Wikipedia.

The evaluation was performed manually for the extracted results annotated by four relation types {BIRTH_PLACE, WON_AWARD, ACQUISITION, INVENT_OF}. The relation type of each extracted result was determined by manual clustering based on its contextual indicator $r_{i,j}$. Our system output 3,727 extractions with an average precision of 63.7% for four relation types (Table 2).

To investigate the reason for erroneous extractions, a qualitative analysis of 1,352 errors was performed (Table 3). Errors were classified into three categories: chunking errors and dependency parsing errors (both caused by the preprocessors), and extracting errors (caused by the extractor for well-preprocessed instances). About 60% of the errors were caused by preprocessors including base phrase chunking and dependency parsing. Because our system is highly dependent on the result of preprocessors, the performance of the ex-

tractor can be increased by reducing its sensitivity to preprocessor errors; this is a topic for future work.

6 Related Work

Many supervised machine learning approaches have been successfully applied to solve traditional relation extraction tasks (Kambhatla, 2004; Zhou et al., 2005; Zelenko et al., 2003; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Zhang et al., 2006), but these approaches require a large number of training examples to achieve high performance. To reduce the annotation cost, weakly-supervised techniques have been designed (Zhang, 2004; Chen et al., 2006).

Open IE pioneered by TextRunner (Banko et al., 2007) is an alternative weakly-supervised IE paradigm. TextRunner aims to perform relation-independent extraction by introducing the self-supervision approach based on a small set of heuristics about syntactic structural constraints. The performance of TextRunner was further improved using O-CRF and casting the Open IE task as a kind of sequential labeling problem (Banko et al., 2008). Wu and Weld (2010) presented another Open IE system WOE which utilizes an alternative self-supervision approach based on Wikipedia infoboxes. The main difference between our work and previous Open IE approaches is that we did not use language-dependent knowledge or resources for self-supervision, but implemented it using cross-lingual annotation projection techniques.

Early studies of cross-lingual annotation projection considered lexically-based tasks, e.g., part-of-speech tagging (Yarowsky and Ngai, 2001), named-entity tagging (Yarowsky et al., 2001), and verb classification (Merlo et al., 2002). Recently, applications of annotation projection such as dependency parsing (Hwa et al., 2002), mention detection (Zitouni and Florian, 2008), and semantic role labeling (Pado and Lapata, 2009) have been studied. To the best of our knowledge, no work has reported on the Open IE task.

7 Conclusions

This paper presented a novel self-supervision approach for Open IE. Our approach uses cross-lingual annotation projection to automatically obtain training examples for a target language by propagating annotations generated by an existing Open IE system for a source language via a parallel corpus between two languages. The main advantage of our method is that no language-dependent knowledge is required to learn the extractor. Our method can contribute to improving the cross-language portability of the Open IE paradigm.

The feasibility of our approach was demonstrated by our Korean Open IE system. The system was developed using only an English Open IE system and an English-Korean parallel corpus; the system never utilized any language specific knowledge or resources for the target language Korean. Furthermore, the system operated in fully unsupervised manner, because all components including prerequisites do not require hand-labeled annotations or hand-crafted rules for the target task. The system outperformed the baseline system based on the language-independent heuristics. For large amount of documents, the system produced 3,727 extractions with a precision of 63.7% for four relation types.

However, our method can still be improved. Many erroneous extractions were caused by errors committed by preprocessors. To reduce sensitivity to these kinds of errors, we plan to introduce assessment techniques which are not included in this work. Another direction of our future work is to investigate a hybrid approach to self-supervision considering not only cross-lingual projected annotations, but also various external knowledge source such as Wikipedia and WordNet. We expect that this fusion approach can help to improve the quality of extracted results, because the effectiveness of each approach has been demonstrated for IE tasks.

Abstract

This paper analyzes the effect of the structural variation of sentences on parsing performance. We examine the performance of both shallow and deep parsers for two sentence constructions: imperatives and questions. We first prepare an annotated corpus for each of these sentence constructions by extracting sentences from a fiction domain that cover various types of imperatives and questions. The target parsers are then adapted to each of the obtained corpora as well as the existing query-focused corpus. Analysis of the experimental results reveals that the current mainstream parsing technologies and adaptation techniques cannot cope with different sentence constructions even with much in-domain data.

1 Introduction

Parsing is a fundamental natural language processing task and essential to various NLP applications. Recent research on parsing technologies has achieved high parsing accuracy in the same domain as the training data, but once we move to unfamiliar domains, the performance decreases to unignorable levels.

To address this problem, previous work has focused mainly on adapting lexical or syntactic preferences to the target domain, that is, on adding lexical knowledge or adjusting probabilistic models for the target domain using available resources in the target domain (see Section 2). Underlying the previous approaches, there seems to be the assumption that grammatical constructions are not largely different between domains or do not affect parsing systems, and therefore the same parsing system can be applied to a novel domain.

However, there are some cases where we cannot achieve such high parsing accuracy as parsing the Penn Treebank (PTB) merely by re-training or adaptation. For example, the parsing accuracy for the Brown Corpus is significantly lower than that for the Wall Street Journal (WSJ) portion of the Penn Treebank, even when re-training the parser with much more in-domain training data than other successful domains.

This research attempts to identify the cause of these difficulties, and focuses on two types of sentence constructions: imperatives and questions. In these constructions, words in certain syntactic positions disappear or the order of the words changes. Although some recent works have discussed the effect of these sentence constructions on parsing, they have focused mainly on more well-formed or style-restricted constructions such as QA queries, etc. This research broadens the target scope to include various types of imperatives and questions. We analyze how such sentences affect the parsing behavior and then attempt to clarify the difficulties in parsing imperatives and questions. To do so, we first prepare an annotated corpus for each of the two sentence constructions by borrowing sentences from fiction portion of the Brown Corpus.

In the experiments, parsing accuracies of two shallow dependency parsers and a deep parser are examined for imperatives and questions, as well as the accuracy of their part-of-speech (POS) tagger. Since our focus in this paper is not on the development of a new adaptation technique, a conventional supervised adaptation technique was applied to these parsers and the tagger. Our aim is rather to clarify the difficulties in parsing imperatives and questions by analyzing the remaining errors after the adaptation.

2 Related work

Since domain adaptation is an extensive research area in parsing research (Nivre et al., 2007), many ideas have been proposed, including un- or

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 749–757,
Chiang Mai, Thailand, November 8 – 13, 2011.

semi-supervised approaches (Roark and Bacchiani, 2003; Blitzer et al., 2006; Steedman et al., 2003; McClosky et al., 2006; Clegg and Shepherd, 2005; McClosky et al., 2010) and supervised approaches (Titov and Henderson, 2006; Hara et al., 2007). The main focus of these works is on adapting parsing models trained with a specific genre of text (in most cases the Penn Treebank WSJ) to other genres of text, such as biomedical research papers and broadcast news. The major problem tackled in such tasks is the handling of unknown words and domain-specific manners of expression. However, parsing imperatives and questions involves a significantly different problem; even when all words in a sentence are known, the sentence has a very different structure from declarative sentences.

Compared to domain adaptation, structural types of sentences have received little attention to date. A notable exception is the work on QuestionBank (Judge et al., 2006). This work highlighted the low accuracy of state-of-the-art parsers on questions, and proposed a supervised parser adaptation by manually creating a treebank of questions.[1] The question sentences are annotated with phrase structure trees in the Penn Treebank scheme, although function tags and empty categories are omitted. QuestionBank was used for the supervised training of an LFG parser, resulting in a significant improvement in parsing accuracy. Rimell and Clark (2008) also worked on the problem of question parsing in the context of domain adaptation, and proposed a supervised method for the adaptation of the C&C parser (Clark and Curran, 2007). In this work, question sentences were collected from TREC 9-12 competitions and annotated with POS and CCG lexical categories. The authors reported a significant improvement in CCG parsing without phrase structure annotations.

Our work further extends Judge et al. (2006) and Rimell and Clark (2008), while covering a wider range of sentence constructions. Although QuestionBank and the resource of Rimell and Clark (2008) claim to be corpora of questions, they are biased because the sentences come from QA queries. For example, such queries rarely include yes/no questions or tag questions. For our study, sentences were collected from the Brown Corpus, which includes a wider range of types of questions and imperatives. In the experiments, we also used QuestionBank for comparison.

[1] QuestionBank contains a small number of imperative and declarative sentences, details of which are given in Section 4.

3 Target Parsers and POS tagger

We examined the performance of two dependency parsers and a deep parser on the target text sets. All parsers assumed that the input was already POS-tagged. We used the tagger in Tsuruoka et al. (2005).

3.1 MST and Malt parsers

The MST and Malt parsers are dependency parsers that produce non-projective dependency trees, using the spanning tree algorithm (McDonald et al., 2005a; McDonald et al., 2005b)[2] and transition-based algorithm (Nivre et al., 2006)[3], respectively. Although the publicly available implementation of each parser also has the option to restrict the output to a projective dependency tree, we used the non-projective versions because the dependency structures converted from the question sentences in the Brown Corpus included many non-projective dependencies. We used the `pennconverter` (Johansson and Nugues, 2007) [4] to convert a PTB-style treebank into dependency trees [5]. To evaluate the output from each of the parsers, we used the labeled attachment accuracy excluding punctuation.

3.2 HPSG parser

The Enju parser (Ninomiya et al., 2007)[6] is a deep parser based on the HPSG (Head Driven Phrase Structure Grammar) formalism. It produces an analysis of a sentence including the syntactic structure (i.e., parse tree) and the semantic structure represented as a set of predicate-argument dependencies. We used the toolkit distributed with the Enju parser to train the parser with a PTB-style treebank. The toolkit initially converts a PTB-style treebank into an HPSG treebank and then trains the parser on this. The HPSG treebank converted from the test section was used as the gold-standard in the evaluation. As evaluation metrics for the parser, we used labeled and un-

labeled precision/recall/F-score of the predicate-argument dependencies produced by the parser.

4 Preparing treebanks of imperatives and questions

This section explains how we collected the treebanks of imperatives and questions used in the experiments in Section 5.

4.1 Extracting imperatives and questions from Brown Corpus

The Penn Treebank 3 contains treebanks of several genres of texts. Although the WSJ treebank has been used extensively for parsing experiments, we used the treebank of the Brown Corpus in our experiments. As the Brown Corpus portion includes texts of eight different genres of literary works (see the first column in Table 1), it is expected to contain inherently a larger number of imperatives and questions than the WSJ portion.

The Brown Corpus portion of the Penn Treebank 3 is annotated with phrase structure trees as in the Penn Treebank WSJ. Interrogative sentences are annotated with the phrase label *SBARQ* or *SQ*, where *SBARQ* denotes wh-questions, while *SQ* denotes yes/no questions. Imperative sentences are annotated with the phrase label *S-IMP*. All sentences annotated with these labels were extracted. Imperatives and questions appear not only at the top level but also as embedded clauses. We extracted such embedded imperatives and questions as well. However, if these were embedded in another imperative or question, we only extracted the outermost one. Extracted sentences were post-processed to fit the natural sentence form; that is, with first characters capitalized and question marks or periods added as appropriate.

As a result, we extracted 750 imperative sentences and 1,241 question sentences from 24,243 sentences. Examples of extracted sentences are shown in Figure 1. Table 1 gives the statistics of the extracted sentences, which show that each genre contains top-level / embedded imperative and question sentences to some extent.[7]

As described below, we also used QuestionBank in the experiments. The advantage, however, of using the Brown treebank is that it includes annotations of function tags and empty categories, and therefore, we can apply the Penn Treebank-to-HPSG conversion program of Enju (Miyao and Tsujii, 2005), which relies on function tags and empty categories. Hence, we show experimental results for Enju only with the Brown data. It should also be noted that, a constituency-to-dependency converter, `pennconverter` (Johansson and Nugues, 2007), provides a more accurate conversion when function tags and empty categories are available (see footnote 4).

4.2 Extracting questions from QuestionBank

QuestionBank consists of question sentences as well as a small number of imperative and declarative sentences. We extracted 3,859 sentences annotated with *SBARQ* or *SQ*. During the exper-

[7] Although we also applied a similar method to the WSJ portion, we only obtained 115 imperatives and 432 questions. This data was not used in the experiments.

Target	Total	Division
WSJ	43,948	39,832 (Section 02-21) for training / 1,700 (Section 22) for development test / 2,416 (Section 23) for final test
Brown overall	24,243	19,395 for training / 2,424 for development test / 2,424 for final test (randomly divided)
Brown imperatives	750	65×10 for ten-fold cross validation test / 100 for error analysis (chosen evenly from each genre)
Brown questions	1,240	112×10 for ten-fold cross validation test / 141 for error analysis (chosen evenly from each genre)
QuestionBank questions	3,859	1,000 for final test / 2,560 for training / 299 for error analysis (from the top of the corpus)

(# of sentences)

Table 2: Experimental datasets for each domain

iments, we found several annotation errors that caused fatal errors in the treebank conversion. We manually corrected the annotations of twelve sentences.[8] Examples of the annotation errors include brackets enclosing empty words and undefined or empty tags. We also found and corrected obvious inconsistencies in the corpus: character " ' " replaced by "<" (737 sentences), token "?" tagged with "?" instead of "." (2,051 sentences), and phrase labels annotated as the POS (one sentence).

5 Exploring difficulties in parsing imperatives and questions

We examined the performance of the three parsers and the POS tagger with Brown imperatives and questions, and QuestionBank questions. By observing the effect of the parser or tagger adaptation in each domain, we can identify the difficulties in parsing imperative and question sentences. We also examined the portability of sentence construction properties between two similar domains: questions in Brown and in QuestionBank.

5.1 Experimental settings

Table 2 shows the experimental datasets we created for five domains: WSJ, Brown overall, Brown imperatives, Brown questions, and QuestionBank questions. Each of the parsers and the POS tagger was adapted to each target domain as follows:

POS tagger - For Brown overall, we trained the model with the combined training data of Brown overall and WSJ. For Brown imperatives / questions and QuestionBank, we replicated the training data a certain number of times and utilized the concatenated replicas and WSJ training data for training. The number of replicas of training data was determined from among 1, 2, 4, 8, 16, 32, 64, and 128, by testing these numbers on the development test sets in three of the ten datasets for cross validation.

MST and Malt parser - For Brown overall and QuestionBank questions, we trained the model on combined data for the target domain and the original model. For Brown imperatives and questions, we replicated the training data ten times and utilized the concatenated replicas and WSJ training data for training.

Enju parser - We used the adaptation toolkit in the Enju parser (Hara et al., 2007), which is based on the idea of reference distribution (Jelinek, 1998). The parser was trained on the same training data set as the MST and Malt parser for each of the target domains .

[8] We intend making these corrections publicly available.

Target	WSJ tagger	Adapted tagger
WSJ	97.53%	-
Brown overall	96.15%	96.68%
Brown imperatives	92.36%	93.96%
Brown questions	94.69%	95.80%
QuestionBank questions	93.14%	95.69%

Table 3: Accuracy of each POS tagging system for imperatives and questions

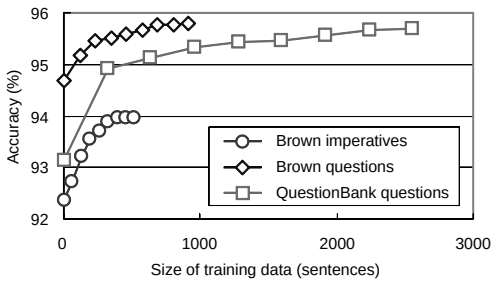

Figure 2: POS tagging accuracy vs. corpus size

5.2 Overview of POS tagging accuracy

Table 3 gives the POS tagging accuracy for the target domains. When we applied the WSJ tagger to other domains, the tagging accuracy basically decreased. For Brown overall, compared with the WSJ, the accuracy did not decrease much. However, for imperatives and questions, the POS tagger accuracy decreased significantly. The table shows that the adaptation improved the tagging accuracy to some extent, but that the improved accuracy for imperatives and questions was still below that of the adapted tagger for Brown overall.

Figure 2 shows the POS tagging accuracy for

Target	Correct → Error	WSJ tagger	Adapted tagger
Brown imperatives	VB → NN / NNP	13	9
	VB → VBP	8	2
	RB → RP	4	2
	UH → RB	3	1
	RB → IN	3	1
	IN → RP	3	3
	NN → NNP	2	3
	RB → DT	2	3
Brown questions	VB → VBP	16	2
	NN → JJ	3	3
	JJ → VBN	3	3
	IN → RB	2	3
QuestionBank questions	WDT → WP	28	0
	NN → NNP	17	12
	JJ → NNP	9	7
	VB → VBP	8	1
	VB → NN / NNP	7	6
	NN → JJ	6	4
			(# of errors)

Table 4: Main tagging errors for each construction

the target domains for varying sizes of the target training data. This graph shows that for both types of sentences, the first 300 training sentences greatly improved the accuracy, but thereafter, the effect of adding training data declined. It indicates the inherent difficultly in parsing imperatives and questions; to match the tagging accuracy of the WSJ tagger for the WSJ (97.53% in Table 3), just using much more training data does not appear to be enough. In particular, the problem is more serious for imperatives.

5.3 Error analysis in POS tagging

Next, we explored the tagging errors in each domain to observe the types of errors from the WSJ tagger and which of these were either solved by the adapted taggers or remain unsolved.

Table 4 shows the most frequent tagging errors given by the WSJ tagger / adapted tagger for Brown questions, Brown imperatives, and QuestionBank questions, respectively. From the results, we found that the main errors of the WSJ tagger for the Brown domains were mistagging of verbs, that is, "VB → ***". We then analyzed why each of these errors had occurred.

For Brown imperatives, the WSJ tagger gave two main tagging errors: "VB → NN(P)" and "VB → VBP". These two types of errors arise from the differences in sentence constructions between Brown imperatives and WSJ. First, the WSJ tagger, trained mainly on declarative sentences, prefers to give noun phrase-derived tags at the beginning of a sentence, whereas an imperative sentence normally begins with a verb phrase. Second, the main verb in an imperative sentence takes a base form, whereas the WSJ tagger trained mainly on tensed sentences prefers to take the verb as a present tense verb.

After adapting the tagger to Brown imperatives, the tagger would have learned that the first word in a sentence tends to be a verb, and that the main verb tends to take the base form. Table 4 shows that the above two types of errors decreased to some extent as expected, although a few mistags of verbs still remained.

By investigating the remaining errors associated with VB, we found that several errors still occurred even in simple imperative sentences such as "VB → NN" for "Charge" in "Charge something for it", and that some errors tended to occur after a to-infinitive phrase or conjunction, such as "VB → NN" for "subtract" in "To find the estimated net farm income, subtract ...". The former type could be solved by increasing the training data, whereas the latter error type cannot easily be solved with a model based on a word N-gram since it cannot recognize the existence of a long advervial phrase, etc. preceding the main verb.

We also analyzed the errors in Brown questions and QuestionBank questions, and again found that many errors were due to the fact that the WSJ tagger was trained on a corpus consisting mainly of declarative sentences. After the adaptation, although some of the errors, such as the special use of wh-words, i.e., "WDT → WP", were corrected, other kinds of errors related to the global change in sentence structure still remained.

To tag words correctly both in imperatives and questions, we may have to consider richer information than only N-gram based features, such as dependency or phrasal structures. Context information may also help; if the tagger knows that a sentence is uttered in a sequence of conversation, the tagger can consider the higher possibility of the sentence being an imperative or question.

5.4 Overview of parsing accuracy

Table 5 gives the parsing accuracy of MST (first order), MST (second order), Malt, and the Enju parser for WSJ, Brown overall, Brown imperatives, Brown questions, and QuestionBank questions. Figure 3 plots the parsing accuracy against the training data size of the four parsers for Brown imperatives, Brown questions, and QuestionBank questions. The bracketed numbers give the accuracy improvements from "WSJ parser + WSJ tagger". Note that, since the training of the MST

Parser	Target	WSJ parser + WSJ tagger	WSJ parser + Adapted tagger	WSJ parser + Gold POS	Adapted parser + WSJ tagger	Adapted parser + Adapted tagger	Adapted parser + Gold POS

(Enju: F-score of predicate-argument relations / MST, Malt: Accuracy of labeled attachments (%))

Table 5: Accuracy of each parsing system for the Brown Corpus and QuestionBank

parser (second order) on Brown overall, Brown questions, and QuestionBank could not be completed in our experimental environment[9], the corresponding parsing accuracies denoted by bracketed hyphens in Table 5 could not be measured, and consequently, we could not plot complete graphs of the second order MST for Brown questions and QuestionBank questions in Figure 3.

After adaptation (see "Adapted parser" columns in Table 5), the parser achieved two to eight percent higher accuracy for each of the Brown domains compared to the WSJ parser. For QuestionBank, 25 to 35 percent improvement in accuracy was observed. Figure 3 shows that the improvement is generally proportional to the size of the training data and that this tendency does not seem to converge, except for the Malt parser for QuestionBank. This would suggest that lower accuracy than that of the WSJ parser for the WSJ could still be as a result of a lack of training data. In Figure 3, the parser accuracy for QuestionBank, for which we could use much more training data than for Brown questions, approaches or even exceeds that of the WSJ parser for WSJ. However, as there is no more training data for Brown imperatives and questions, we need to either prepare more training data or explore approaches that enable the parsers to be adapted with small amounts of training data.

5.5 Error analysis on parsing

To capture an overview of the adaptation effects, we observed the error reduction in the Malt parser.

[9]The reason is a crash of the learning program, presumably caused by huge memory consumption and/or huge intermediate files.

(# of recall errors)

Table 6: Main parsing errors of Malt parser for Brown imperatives and questions

Table 6 gives the recall errors on labeled dependencies, which were observed more than ten times for 100 analysis sentences in each domain. For each dependency shown in the second column, the third and fourth columns show the number of parsing errors by the WSJ parser with gold tags and the adapted parser with gold tags, respectively. Since ROOT dependencies, that is, heads of sentences, are critical to the construction of sentences, we focus mainly on this type of error.

For Brown imperatives and questions, the reduction in ROOT dependency accuracy was prominent. On investigation, we found that the WSJ parser often made mistakes in parsing sentences which began or ended with the name of the person being addressed. For example, in Brown imperatives, for the sentence "See for yourself, Miss Zion.", the WSJ parser mistook the name "Zion" to be ROOT, and the main verb "See" to be a modifier of the name. The adapted parser correctly assigned ROOT to the main verb.

We also found that the WSJ parser often made mistakes in parsing sentences containing quota-

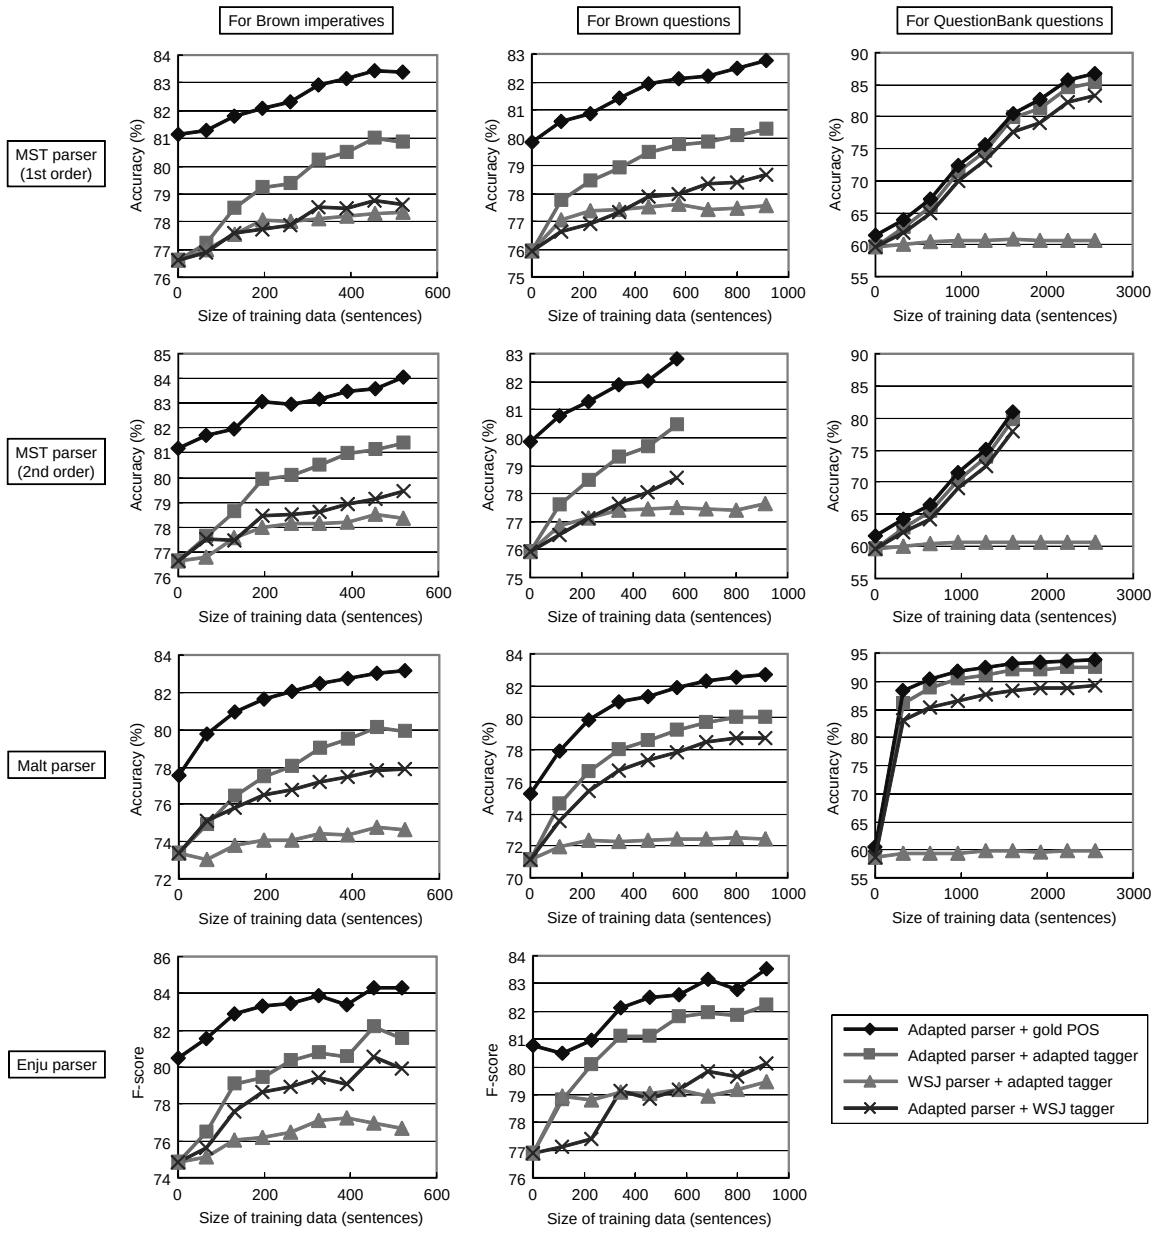

Figure 3: Learning curve of various parsers for Brown Corpus and Question Bank

tion, exclamation, or question marks, such as " "Hang on" !!" " or " "Why did you kill it" ??". For such sentences, the WSJ parser regarded the first "!" or "?" as ROOT, and "Hang" or "did" as the modifier of the punctuation. A possible reason for this type of error could be that the Brown Corpus places exclamation or question marks outside, instead of inside the quotation. The adapted parser could handle this dubious construction and assigned ROOT to the main verbs as the corpus required. [10]

On the other hand, we also observed some unsolved errors, of which we discuss two. First, Brown imperatives and questions, include many colloquial sentences, which have rather flexible constructions, especially imperatives, such as "Lift, don't shove lift!", "Come out, come out in the meadow!", etc. The parsing models based on the plausibility of constructions were not able to capture such sentences.

Second, having different sentence constructions within a single sentence, such as, where a to-infinitive phrase or subordinate clause precedes an imperative or question, often confused the parser. For example, for the imperative sentence, "To find the estimated net farm income, subtract

[10] We may have to correct the corpus.

QuestionBank questions	0	48	31	21

(# of sentences in the analyzed data)

Table 8: Distribution of question types

the estimated annual farming expenditure...", both the WSJ and adapted parsers regarded "find" as ROOT, because the parsers regarded the words following "find" as a that-clause complementing "find", as in "To find [(that) the estimated net farm income, subtract the estimated annual farming ...]". It would be difficult for the parsers to know which is the main clause in such complex sentences. This type of error cannot be solved merely by increasing the training data.

Imperative or question sentences typically consist not only of a pure imperative or question clause, but also of other constructions of phrases or clauses. These complex sentences were parsed without being partitioned into separate constructions, and as a result the parser sometimes became confused.

5.6 QuestionBank vs. Brown questions

Both the Brown questions and QuestionBank are in the question domain. In this section, we examine whether a parser adapted to one domain could be ported to another domain.

QuestionBank does not provide function tags, and therefore in training and evaluation of the parsers, abstracted dependencies were extracted from the corpus. As a result, a parser adapted to one domain could not provide correct dependency labels on functions for the other domain. However, we would expect that sentence constructions are basically common and portable between two domains, which would provide a correct boundary for phrases and therefore, the correct dependencies in phrases would be introduced by the adaptation.

Table 7 gives the parsing or tagging accuracy of each parser and the POS tagger for Brown questions and QuestionBank. These results differ from those in Table 5 in that the parsers and the tagger have been adapted to another question domain. The table shows that the parsers adapted to the Brown questions improved their parsing accuracy with QuestionBank, whereas the parsers adapted to QuestionBank decreased in accuracy. Table 8 could explain this result. Using Brown questions, many wh-questions were learnt, which is what QuestionBank mainly contains. On the other hand, despite yes-no questions constituting more than half the Brown Corpus, these were not learnt using QuestionBank for training.

A question domain contains various types of questions with various sentence constructions. In order to parse questions correctly, we need to capture each of these correctly. This type of problem was not so obvious when we were working mainly with declarative sentences.

6 Conclusion

Through experiments with various parsers we observed that simple supervised adaptation methods are insufficient to achieve parsing accuracy comparable with that of declarative sentences. This observation holds both for POS tagging and parsing, and indicates that the parsers need to be fundamentally improved, such as re-constructing feature designs or changing parsing models.

Following on from this study, future work includes investigating parsing frameworks that are robust for sentences with different constructions, and/or methods that can effectively adapt a parser to different sentence constructions including imperatives and questions, among others.

A Discriminative Approach to Japanese Zero Anaphora Resolution with Large-scale Lexicalized Case Frames

Abstract

We present a discriminative model for Japanese zero anaphora resolution that simultaneously determines an appropriate case frame for a given predicate and its predicate-argument structure. Our model is based on a log linear framework, and exploits lexical features obtained from a large raw corpus, as well as non-lexical features obtained from a relatively small annotated corpus. We report the results of zero anaphora resolution on Web text and demonstrate the effectiveness of our approach. In addition, we also investigate the relative importance of each feature for resolving zero anaphora in Web text.

1 Introduction

Zero anaphora resolution is the task of detecting and identifying the omitted arguments of a predicate. Since arguments are often omitted in Japanese, zero anaphora resolution plays an important role in the analysis of Japanese predicate-argument structures. For example, in the following text:

(i) *Musuko-wa* *itazura-ga* *sukide*
son-TOP mischief-NOM like

watashi-mo *(φ-ni)* *te-wo* *yaiteiru.*
I φ-DAT hands-ACC burn
(have difficulty)

(My son likes mischief, so I have difficulty with φ.)

the dative argument of the predicate '*yaku*[1] (burn)' has been omitted. The omitted element is called a zero pronoun, and in this example it refers to '*musuko* (son).' Although most previous work has focused on zero anaphora in newspaper articles, this paper aims to resolve zero anaphora in Web text, since this involves a wider range of writing styles and is thus considered to be a more practical setting.

Reference resolution systems generally require a variety of information sources ranging from syntactic and discourse preferences to semantic preferences (Ng and Cardie, 2002; Haghighi and Klein, 2010). Since syntactic and discourse preferences are not word-specific, they can be learned from a relatively small annotated corpus. Semantic preferences, on the other hand, represent highly lexicalized knowledge, and hence it is difficult to learn these from a small annotated corpus. In some cases, knowledge of the relations between a predicate and its particular argument is insufficient, particularly for zero anaphora resolution. For example, although the dative argument of the predicate '*yaku* (bake/burn)' is generally filled by a *disk*, such as a CD or DVD, it is often filled by a *person*, such as '*musuko* (son),' if the accusative argument is filled by '*te* (hands)' as in the example (i).[2] Thus, knowledge of relations among a predicate and its multiple arguments is required to take such preferences into account.

Sasano et al. (2008) exploited large-scale case frames that were automatically constructed from 1.6 billion Web sentences as such a lexical resource, and proposed a probabilistic model for Japanese zero anaphora resolution. Their model demonstrated moderate performance, but it could not easily introduce new features, especially overlapping ones, nor take into consideration the importance of each feature, due to the assumption of independence in estimating probability. However, we think a variety of clues can be useful for zero anaphora resolution, where it is important to exploit overlapping features and consider the importance of each feature.

[1] '*Yaku*' is the original form of '*yaiteiru.*'

[2] '*Te-wo yaku*' (literally 'burn hands') is a Japanese idiom, which means 'have difficulty' in English.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 758–766,
Chiang Mai, Thailand, November 8 – 13, 2011.

Therefore, in this paper, we extend Sasano et al. (2008)'s model by incorporating it into a log-linear framework, and introduce overlapping features such as lexical features with different granularities. In addition, we also investigate the relative importance of each feature for resolving zero anaphora in Web text.

2 Related Work

Several approaches to Japanese zero anaphora resolution have been proposed. Seki et al. (2002) proposed a probabilistic model for zero pronoun detection and resolution that used hand-crafted case frames. Kawahara and Kurohashi (2004) introduced wide-coverage case frames that were automatically constructed from a large corpus to alleviate the sparseness of hand-crafted case frames. They used the case frames as selectional restrictions for zero pronoun resolution. Iida et al. (2006) explored a machine learning method using rich syntactic pattern features that represented the syntactic relations between a zero-pronoun and its candidate antecedent.

Since predicate-argument structure analysis and zero anaphora resolution are closely related, several approaches have simultaneously solved these two tasks. Sasano et al. (2008) proposed a lexicalized probabilistic model for zero anaphora resolution, which adopted an entity-mention model and simultaneously resolved predicate-argument structures and zero anaphora. Taira et al. (2008) proposed a model for analyzing predicate-argument structures by using decision lists, which integrated the tasks of semantic role labeling and zero-pronoun identification. Imamura et al. (2009) proposed a discriminative model for analyzing predicate-argument structures that simultaneously conducted zero anaphora resolution.

For languages other than Japanese, Ferrandez and Peral (2000) proposed a hand-engineered rule-based method for both determining anaphoricity and identifying antecedents in Spanish zero pronoun resolution. Zhao and Ng (2007) proposed feature-based methods to Chinese zero anaphora resolution. Kong and Zhou (2010) proposed a tree kernel-based unified framework for Chinese zero anaphora resolution, which dealt with three subtasks: zero anaphora detection, anaphoricity determination, and antecedent identification.

3 Case Frames

3.1 Lexicalized case frames

Our model exploits lexicalized case frames that are automatically constructed from 1.6 billion Web sentences by using Kawahara and Kurohashi (2002)'s method. Case frames are constructed for each predicate like PropBank frames (Palmer et al., 2005), and for each meaning of the predicate like FrameNet frames (Fillmore et al., 2003). However, neither pseudo-semantic role labels such as Arg1 in PropBank nor information about frames defined in FrameNet are included in the case frames. Each case frame describes surface cases that each predicate has and examples that can fill a case slot, which is fully-lexicalized like the subcategorization lexicon VALEX (Korhonen et al., 2006).

Note that case frames offer not only knowledge of the relations between a predicate and its particular case slot, but also knowledge of the relations among a predicate and its multiple case slots. Table 1 shows examples of constructed case frames.[3] A different case frame is constructed for each meaning of '*yaku* (bake/burn),' such as 'bake foods,' 'have difficulty,' and 'burn on a disk.'

3.2 Generalization of examples

The data sparseness problem is alleviated to some extent but not eliminated by using case frames that are automatically constructed from a large corpus. For instance, there are thousands of named entities (NEs) that cannot intrinsically be covered. Sasano et al. (2008) generalized examples of case slots based on 22 common noun categories defined in the Japanese morphological analyzer JUMAN,[4] and 8 NE classes defined by the IREX Committee (1999) to deal with this problem.

In addition, we generalized case slot examples based on automatically acquired multi-word noun clusters. Kazama and Torisawa (2008) proposed the parallelization of EM-based clustering with the aim of enabling large-scale clustering and using the resulting clusters in NE recognition. We used the resulting 2,000 clusters acquired from 1 million unique multi-word nouns.

Table 2 lists examples of the resulting 2,000 clusters.[3] As well as common noun categories and NE classes, we calculated the average of the probabilities that each case slot example belonged to

[3] We use English examples for the sake of readability.

CL:70	CD (0.896), DVD (0.837), CD-ROM (0.603), cassette (0.512), ⋯
CL:291	low heat (0.720), slow fire (0.715), moderate heat (0.681), distant fire (0.678), ⋯
CL:624	dinner (0.926), supper (0.925), lunch (0.882), breakfast (0.868), ⋯
CL:883	Chinese noodles (0.860), noodles (0.801), curry (0.793), cake (0.749), ⋯
CL:887	mother (0.909), parents (0.875), mom (0.838), husband (0.775), father (0.774), ⋯

Table 2: Examples of resulting 2,000 clusters (Kazama and Torisawa, 2008). Nouns that have high probabilities of belonging to target clusters are shown with probabilities.

the target cluster, and added it to the case slot. For example, if examples of a case slot include 'CD:3106,' 'DVD:2066,' and 271 other examples that have no probability of belonging to cluster 70, the average for cluster 70 is calculated as:

$$\frac{0.896 \times 3106 + 0.837 \times 2066}{3106 + 2066 + 271} \approx 0.829.$$

This type of generalized example represents more fine-grained semantic categories compared with examples that are generalized by using common noun categories and NE classes. The generalized examples are also included in Table 1, such as "[CL:70]:0.829" in the dative case slot of '*yaku* (3).' CT, NE, and CL in generalized examples denote common noun **ca**t**e**gory, **n**amed **e**ntity class, and multi-word noun **cl**uster, respectively.

4 A Discriminative Model for Zero Anaphora Resolution

4.1 Overview

Our model basically follows that of Sasano et al. (2008), except for the method of estimating possible combinations of case frames and predicate-argument structures. We also limited the target cases for zero anaphora resolution to '*ga*' (nominative), '*wo*' (accusative), and '*ni*' (dative) cases. The outline of our model is as follows:

1. Parse an input text and recognize NEs.
2. Resolve coreference and link each mention to a discourse entity or create a new entity.
3. From the end of each sentence, analyze the predicate-argument structure for each verb or adjective using the following steps:

1.	$< cf =$'*yaku*'(1), $s =$[NOM:'*watashi*' (I), ACC:'*te*' (hands), DAT:'*musuko*' (son)]>
2.	$< cf =$'*yaku*'(1), $s =$[NOM:'*watashi*' (I), ACC:'*te*' (hands), DAT:NULL']>
3.	$< cf =$'*yaku*'(1), $s =$[NOM:NULL, ACC:'*te*' (hands), DAT:'*watashi*' (I)]>
4.	$< cf =$'*yaku*'(1), $s =$[NOM:'*musuko*' (son), ACC:'*te*' (hands), DAT:NULL>
5.	**$< cf =$'*yaku*'(2), $s =$ [NOM:'*watashi*' (I), ACC:'*te*' (hands), DAT:'*musuko*' (son)]>**
6.	$< cf =$'*yaku*'(2), $s =$[NOM:'*watashi*' (I), ACC:'*te*' (hands), DAT:NULL']>
	⋮

Table 3: Examples of possible combinations of case frame cf and predicate-argument structure s for the predicate '*yaku*' in the example (i) in Section 1. Bold font indicates the proper combination for this example.

(a) Select a case frame temporarily.

(b) List possible predicate-argument structures including omitted arguments.

(c) Estimate possible combinations of case frames and predicate-argument structures, and select the one with the highest estimate.

In 3-(b), we first consider only the overt arguments and prune away improbable structures to reduce the search space. We apply a log-linear framework to estimating a combination of a case frame and a predicate-argument structure to introduce overlapping features and take into consideration the relative importance of each feature.

Note that the estimation is not separately conducted for each argument, but for all arguments including overt and omitted arguments. For examples, when we analyze the predicate '*yaku*' in the example (i) in Section 1, we consider the various combinations as listed in Table 3, and choose the combination with the highest estimate.

4.2 Log-linear model

When text t and target predicate p are given, we choose the combination of case frame cf and predicate-argument structure s with the highest conditional probability,

$$(cf_{best}, s_{best}) = \arg\max_{cf,s} P(cf, s|p, t).$$

We model the conditional probability, using a log-linear framework:

$$P(cf, s|p, t; \Lambda) = \frac{1}{Z(p,t)} \exp\{\Lambda \cdot \boldsymbol{F}(cf, s, p, t)\},$$

$$Z(p,t) = \sum_{\{cf,s\} \in C(p,t)} \exp\{\Lambda \cdot \boldsymbol{F}(cf, s, p, t)\},$$

where $\boldsymbol{F} = (f_1, \ldots, f_K)$ is a feature vector whose elements represent K feature functions, $\Lambda = (\lambda_1, \ldots, \lambda_K)$ denotes a weight vector (parameter vector) for the feature functions, and $C(p,t)$ yields a set of possible combinations of case frame cf and predicate-argument structure s for given predicate p and text t.

4.3 Parameter estimation

We now describe how parameter vector Λ is estimated from a set of training data. When the training set consisting of N instances $\{(s^{(1)}, p^{(1)}, t^{(1)}), (s^{(2)}, p^{(2)}, t^{(2)}), \ldots, (s^{(N)}, p^{(N)}, t^{(N)})\}$ is given, we choose the combination of CF and Λ that maximize the posterior probability:

$$\max_{CF,\Lambda} \left\{ \sum_{n=1}^{N} \log P(cf^{(n)}, s^{(n)}|p^{(n)}, t^{(n)}; \Lambda) - \alpha||\Lambda||^2 \right\},$$

where α is a regularization parameter for the L2 norm, and $CF = (cf^{(1)}, cf^{(2)}, \ldots, cf^{(N)})$ is a combination of possible case frames, i.e. $cf^{(n)}$ is a candidate case frame for the given instance $(s^{(n)}, p^{(n)}, t^{(n)})$. Since the appropriate case frames are not annotated in the training set, we choose an appropriate case frame in estimating parameters with the following algorithm:

1. Initialize parameter Λ to a random value in the range [0,1].

2. For each training instance, update $cf^{(n)}$ that maximizes $P(cf, s|p, t; \Lambda)$ with current parameter Λ:

   $$\hat{cf}^{(n)} = \arg\max_{cf^{(n)}} P(cf^{(n)}, s^{(n)}|p^{(n)}, t^{(n)}; \Lambda)$$

   If $CF = (cf^{(1)}, cf^{(2)}, \ldots, cf^{(N)})$ is not updated, we determine current parameter Λ as the resulting parameter.

3. If CF is updated, we renew parameter Λ that maximizes the posterior probability with N training instances $\{(cf^{(1)}, s^{(1)}, p^{(1)}, t^{(1)}), \ldots, (cf^{(N)}, s^{(N)}, p^{(N)}, t^{(N)})\}$,

$$\mathcal{L}_\Lambda = \sum_{n=1}^{N} \log P(cf^{(n)}, s^{(n)} | p^{(n)}, t^{(n)}; \Lambda) - \alpha ||\Lambda||^2,$$

and go back to step 2. To avoid overfitting, we include an L2-regularization term in the objective.[5] $\mathcal{L}_\Lambda$ is maximized by the Limited memory BFGS (L-BFGS) algorithm (Nocedal, 1980).[6]

In both steps 2 and 3, the log-likelihood increases monotonically, and this algorithm thus always converges to an optimal solution but does not ensure the global maximum parameter will be assigned. That is, we can obtain convergence to different local optima. Therefore, we test several initial values and adopt the resulting parameter that maximizes posterior probability.

5 Features

5.1 Lexical features

We exploit six types of lexical features: word PMI (Pointwise Mutual Information), cluster PMI, category PMI, NE PMI, occupancy of a case slot, and overt argument assignment score. Their values are real values that are calculated by using case frames. Since our model is based on the entity-mention model that assigns zero pronouns not to a certain mention but to an entity, several values can be calculated for a certain lexical feature by taking coreferential mentions into consideration. In such cases, we choose the highest value as a corresponding lexical feature.

Word PMI Each case slot of a case frame has typical words that are often assigned to the slot. We use the PMI features between a slot of a case frame and its antecedent candidate to reflect such preferences:

e.g.

- $\log\{P(child|\text{cf=}yaku(2),\text{case=}ni)/P(child)\}$

As well as most other features, this type of features is distinguished by the case of zero pronouns: '*ga*,' '*wo*,' and '*ni*,' respectively.

Cluster, Category, and NE PMI We also use generalized example versions of word PMI to alleviate the data sparseness problem in word PMI:

e.g.

- $\log\{P([\text{CL:32}]\ |yaku(2), ni)/P([\text{CL:32}])\}$
- $\log\{P([\text{CT:PERSON}]|yaku(2), ni)/P([\text{CT:PERSON}])\}$
- $\log\{P([\text{NE:PERSON}]|yaku(2), ni)/P([\text{NE:PERSON}])\}$

After this, we will generically call these three features **GE PMI**. All the features described above overlap, and only their granularities are different.

Occupancy of case slot We believe that there is a relation between the occupancy of a case slot and its generativity of zero pronouns. For example, since the *ni* (dative) case of '*yaku* (3)' often appears, we assume this slot is just omitted as a zero pronoun even if there is no overt argument. However, since the *ni* (dative) case of '*yaku* (1)' rarely appears, we assume there is no case slot if there is no overt argument.

Therefore, we use the log occupancy of the case slot, whose value is the same as the log of the generative probability of a case slot in Kawahara and Kurohashi (2006)'s model and estimated from case structure analysis of a large raw corpus:

e.g.

- $\log P(A(cs) = 1|\text{cf=}yaku(2),\text{case=}ni)$,

  where $A(cs) = 1$ denotes that the target case slot is occupied by an overt argument.

Overt argument assignment score Our model not only takes into account the correspondence between a case slot and its omitted argument, but also the correspondence between a case slot and its overt argument. The score for overt argument assignment reflects the likelihood of an overt argument assignment, and this is the same as the score for the predicate-argument structure in Kawahara and Kurohashi (2006)'s model, which does not take into consideration zero anaphoric relations.

e.g.

- $\log P(\text{cf=}yaku(2), ga_{ov}\text{:}watashi, wo_{ov}\text{:}te|yaku)$

Only this feature is not separately calculated for each case, but for the whole overt predicate-argument structure. Note that, this feature also includes non-lexical preferences in the analysis of a predicate-argument structure.

5.2 Non-lexical features

We also exploit three types of non-lexical features, which are binary features to reflect syntactic and

[5] We set α to 1.0 in all our experiments.

Table 4: Examples of case/location categories.

discourse preferences. Since Web text slightly adheres to formal grammar and thus rich syntactic preferences are not considered very important for resolution of zero anaphora in Web text, we only introduce simple features as non-lexical features.

Case/location We use case/location features to reflect syntactic, functional, and locational preferences. We considered 85 case/location categories, examples of which are summarized in Table 4. If an antecedent candidate appears in a certain case/location category, the corresponding feature value is 1; otherwise 0. These features are made for each case, respectively, i.e. there are a total of 255 case/location features.

Salience Previous work has reported the usefulness of salience in anaphora resolution (Lappin and Leass, 1994; Mitkov et al., 2002; Sasano et al., 2008). We introduce salience features to take into account the salience of each discourse entity. First, we apply the following simple rules to estimating the salience of each entity, and we then set salience features, whose value is 1 if the salience of an antecedent candidate is no less than 1.0; otherwise 0.

- $+2$: mentioned with topical marker "*wa*."
- $+1$: mentioned without topical marker "*wa*."
- $\times 0.5$: beginning of each sentence.

Case assigned features We introduce case assigned features for each case type. The value is 1 if the corresponding zero pronoun is assigned to an antecedent; otherwise 0.

If the weights for these features become larger, corresponding zero pronouns are assigned to antecedents more often. Thus, the weights for these features are regarded as parameters to control the recall/precision trade-off. Although we mainly evaluate our system by using the F-measure, the algorithm mentioned in Section 4.3 does not select a parameter that maximizes the F-measure. Thus, after parameters are estimated by the algorithm, we adjust the weights for these features to maximize the F-measure by using training or development data.

6 Experiments

6.1 Setting

We used the same data set as described in (Sasano et al., 2009). This data set consisted of 186 Web documents (979 sentences, 19,677 morphemes), in which all predicate-argument relations were manually annotated. There were 2,137 predicates in this corpus, and 683 zero anaphoric relations were annotated. We call this data set a Web Corpus after this. We performed 6-fold cross-validation. We used correct morphemes, named entities, dependency structures, and coreference relations that were manually annotated to concentrate on zero anaphora resolution. We tested 10 initial values as parameter Λ. Since the parameters converged to almost the same value for each initial value, we considered that our model achieved the global maximum parameters in most cases.

We applied two baseline models for comparison. The first was the model proposed by Sasano et al. (2008), which did not use a log-linear framework but exploited almost the same clues. In addition, we also conducted an experiment with merged case frames to verify the usefulness of the

	Recall	Precision	F-measure
Sasano et al. (2008)'s model	0.341 (233/683)	0.306 (233/762)	0.322
Proposed model with merged case frames	0.334 (228/683)	0.412 (228/553)	0.369
Proposed model	0.379 (259/683)	0.403 (259/642)	**0.391**

Table 5: Experimental results of zero anaphora resolution on Web Corpus.

Case	Type	Recall	Precision	F-measure
NOM	Intra-sentential	0.504 (120/238)	0.460 (120/261)	0.481
	Inter-sentential	0.460 (104/226)	0.387 (104/269)	0.420
ACC	Intra-sentential	0.250 (17/68)	0.447 (17/38)	0.321
	Inter-sentential	0.163 (7/43)	0.194 (7/36)	0.177
DAT	Intra-sentential	0.105 (6/57)	0.316 (6/19)	0.158
	Inter-sentential	0.098 (5/51)	0.263 (5/19)	0.143

Table 6: Detailed experimental results for the proposed model on the Web Corpus.

case frames that had been constructed for each meaning of each verb/adjective. We merged all case frames of a certain verb/adjective in this experiment, and thus each predicate only had one case frame. As a result, this model only took into account knowledge of the relations between two terms, i.e. a predicate and its particular argument. For example, while the model with the case frames in Table 1 considers the dative case of '*te-wo yaku*' would be filled by a *person*, the model with the merged case frame considers the case would be filled by a *disk* with high probability.

6.2 Experimental Results

Table 5 summarizes the experimental results of zero anaphora resolution on the Web Corpus. The results indicate that our proposed model outperformed both Sasano et al. (2008)'s model[7] and the model with merged case frames, which demonstrates the effectiveness of the log-linear framework and the usefulness of the case frames that were constructed for each meaning of each verb/adjective.

Table 6 shows the performance of the proposed model for each case and for each of intra- and inter-sentential zero anaphoric relations. Since the Web Corpus consists of relatively short sentences, there are many inter-sentential zero anaphora. Compared with previous work (Taira et al., 2008; Imamura et al., 2009), our model can resolve inter-sentential zero anaphora in the Web Corpus with comparatively good performance.

[7]For the same 20 articles that were used for testing in (Sasano et al., 2008), our model achieved a recall of 0.525 (64/122), a precision of 0.615 (64/104), and an F-measure of 0.566, while they obtained a recall of 0.410 (50/122), a precision of 0.373 (50/134), and an F-measure of 0.391.

Removed feature type	Recall	Precision	F-measure
None (Use all features)	0.379 (259/683)	0.403 (259/642)	**0.391**
(Lexical features)			
− Word PMI	0.363 (248/683)	0.378 (248/656)	*0.370*
− Cluster PMI	0.375 (256/683)	0.401 (256/638)	0.387
− Category PMI	0.367 (251/683)	0.423 (251/593)	**0.393**
− NE PMI	0.381 (260/683)	0.389 (260/668)	0.385
− GW PMI (Clust. + Cat. + NE)	0.350 (239/683)	0.413 (239/579)	*0.379*
− All PMI (Word + GW)	0.325 (222/683)	0.391 (222/567)	*0.355*
− Occupancy of case slot	0.365 (249/683)	0.404 (249/617)	0.383
− Overt argument assignment score	0.411 (281/683)	0.350 (281/804)	*0.378*
(Non-lexical features)			
− Case/location	0.264 (180/683)	0.346 (180/520)	*0.299*
− Salience	0.376 (257/683)	0.411 (257/626)	**0.393**
− All non-lexical (Case/loc. + Salience)	0.250 (171/683)	0.312 (171/545)	*0.279*

Table 7: Performance by removing one feature type at a time from feature sets. Bold font indicates higher F-measures than 0.390 and italics indicate F-measures lower than 0.380.

6.3 Contribution of features

We eliminated feature types one by one to investigate the contribution each made. Table 7 presents the eliminated feature types and the performance without each type. This table indicates the importance of word PMI and case/location features, since we obtained 0.021 and 0.092 lower F-measures without these features, respectively.

On the other hand, generalized example versions of word PMI did not affect performance much. However, when all generalized example PMIs were eliminated, performance worsened. Therefore, we considered that cluster PMI, category PMI, and NE PMI could be clues for zero anaphora resolution, and confirmed that zero anaphora resolution could benefit from overlap-

Feature	Weight		
	ga nominative	*wo* accusative	*ni* dative
Occupancy of case slot	0.292	**0.531**	**0.723**
Word PMI	0.154	**0.299**	0.211
Cluster PMI	0.005	**0.347**	0.058
Category PMI	**0.844**	**0.617**	0.391
NE PMI	**0.563**	-0.119	-0.444

Table 8: Weights of lexical features. The Bold font indicates that value of weight is larger than average of weights in the same row.

Case	Type	Imamura et al. (2009)			Our model		
		R	P	F	R	P	F

	Inter	0.000	0.000	0.000	0.030	0.023	**0.026**

Table 9: Experimental results on the NAIST Text Corpus. R, P, and F denote recall, precision, and F-measure, respectively.

ping features. Salience features did not contribute to performance when using case/location features. We think this is because case/location features involve salience information.

Table 8 lists the weights of the lexical features in the proposed model. Since the variance in each type of feature is different, it is not very meaningful to compare different feature types. However, we can find a tendency for each case type by comparing the weights of the same feature types. In fact, we have obtained several interesting findings.

The weights of the case slot occupancy features, which denote how often the target slot is occupied by an overt argument, are large for the *wo* (accusative) and *ni* (dative) cases, but small for the *ga* (nominative) case. This means that there are tight relations between occupancy of the case slot and the generativity of the slot in the accusative and dative cases, but not in the case of the nominative.

We also found differences between the nominative and the accusative cases in the PMI features. The weights of course-grained lexical knowledge, such as category and NE PMIs, are relatively large in the nominative case. However, the weights of fine-grained lexical knowledge are relatively large in the accusative case. This means that the lexical preference for the nominative is coarser than that for the accusative case.

6.4 Comparison with previous work

We also conducted experiments on the NAIST Text Corpus version 1.4β (Iida et al., 2007) to compare our results with those from previous work. We used articles from January 1st to 11th and editorials from January to August for training, articles on January 12th and 13th and the September editorials for development, and articles from January 14th to 17th and editorials from October to December for testing. While the NAIST Text Corpus has the predicate-argument structure of the original form annotated even for predicates that appear in passive or causative voice, our model outputs the surface predicate-argument structure. Therefore, we excluded such predicates. Table 9 summarizes the performance of our model on the NAIST Text Corpus with the performance of Imamura et al. (2009)'s model. Although these experiments did not use the exact same data, we can see that our model achieved comparable performance even for newspaper articles.

Compared with Iida et al. (2006)'s model, which exploited rich syntactic patterns, our model did not seem to perform as well for the NAIST Text Corpus.[8] We conjectured that this was because the NAIST Text Corpus consisted of newspaper articles that included relatively long sentences with formal grammar, and thus rich syntactic patterns were quite effective. Our model also took into account syntactic clues by using case/location features. However, since we basically focused on the zero anaphora in Web text that only adhered slightly to formal grammar, we did not give priority to exploring effective syntactic patterns.

7 Conclusion

This paper presented a discriminative model for Japanese zero anaphora resolution that can exploit large-scale lexicalized case frames, as well as non-lexical features obtained from a relatively small annotated corpus. Experimental results on a Web text revealed that our model could effectively resolve zero anaphora. We plan to investigate new features for zero anaphora resolution including richer syntactic patterns and global constraints in future work.

[8] Note that, their experiment was conducted on a small and relatively reliable subset of the NAIST Text Corpus, and thus we could not directly compare the results.

Abstract

We compare two types of methods which deal with unknown words in the context of computational grammars. Methods of the first type are based on the idea of *supertagging* and use a tagger to predict lexical descriptions for unknown tokens in a given input. The second type of methods perform *lexical acquisition* (LA) which, in the context of this paper, refers to the automatic acquisition of new lexical entries for the lexicon of a given grammar. The methods are compared based on the effect their application has on the parsing coverage and accuracy of the GG grammar of German (Crysmann, 2003). In particular, we adapt the LA method of Cholakov and van Noord (2010) which was originally developed for the Dutch Alpino system to be used with the GG. Its impact on coverage and accuracy on a test corpus of German newspaper texts is compared to the results reported previously on the same corpus for methods which employed a tagger. Furthermore, in a smaller experiment, we show that the linguistic knowledge this LA method provides can also be used for sentence realisation.

1 Introduction

Computational grammars of natural language which rely on hand-crafted lexicons containing elaborate linguistic descriptions usually have low lexical coverage. This is due to the fact that it is impossible to list every word in a language in the lexicon. If a word is unknown to the grammar, or its description in the lexicon is wrong or incomplete, the grammar might fail to produce a (correct) analysis.

In this paper, we compare two types of approaches for dealing with unknown words. The first type is based on the concept of supertagging while the second one performs LA. Generally, supertagging refers to the process of applying a sequential tagger to assign lexical descriptions associated with each word in an input string, relative to a given grammar. It was introduced as a means to reduce parsing ambiguity of LTAG grammars (Bangalore and Joshi, 1999), and has since been applied within CCG (Clark, 2002; Clark and Curran, 2004) and HPSG (Dridan et al., 2008; Zhang et al., 2010) grammars. Supertagging has also been employed for dealing with unknown words. However, in such methods, the tagger is used to assign lexical descriptions **only** to the unknown tokens in a given sentence. It is important to note here that henceforth, we will use the term *suppertagging* in this narrow sense of tagging unknown words only. Supertagging methods often work *online*. The unknown words are assigned lexical entries when they are encountered in the input during parsing. Therefore, the focus is primarily on improving the parsing coverage and accuracy of the grammar for a particular input. The performance of such methods is usually evaluated in terms of *token accuracy*, that is the proportion of correctly tagged unknown lexical tokens in the input.

LA, on the other hand, aims at learning automatically new lexical entries and thus, at extending the lexicon of a given grammar. The strategy is to improve the parsing coverage and accuracy by improving the quality and the coverage of the lexicon of the grammar. While suppertagging methods are concerned with a particular form of the unknown word within the particular context this form occurs in the input, LA techniques look at various forms and contexts of the unknown word and use more detailed linguistic information to learn a new lexical entry for it. This makes LA methods more complex and time-consuming. That is why, they are often applied *offline*. LA methods are usually

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 767–775,
Chiang Mai, Thailand, November 8 – 13, 2011.

evaluated in terms of *type precision* and *type recall*. For a given LA method, type precision indicates the proportion of correctly predicted lexical entries and type recall indicates how many of the correct lexical entries for a given word are actually found.

Both supertagging and LA have been successfully used. For instance, Blunsom and Baldwin (2006) employ a conditional random field-based tagger to predict lexical entries for large-scale HPSG grammars of English (ERG; (Copestake and Flickinger, 2000)) and Japanese (JACY; (Siegel and Bender, 2002)). Zhang and Kordoni (2006) and Dridan et al. (2008) have developed a maximum entropy-based (ME) tagger and investigate the effect its application has on the parsing performance of the ERG and the GG. Other methods which apply the same tagger to the GG include Nicholson et al. (2008) and Cholakov et al. (2008). The ERG, the GG and JACY are part of the DELPH-IN collaboration[1] and as such, they share the same grammar design and parsing architecture which facilitates the application of the same tagger. Baldwin (2005) presents a LA approach where various secondary resources (POS taggers, chunkers, etc.) are used to create an abstraction of words unknown to the ERG and then binary classifiers are employed to learn lexical entries for those words. However, learning is done based on incomplete information obtained by the various resources used. Further, no evaluation of the effect the method has on the parsing performance of the ERG is provided. Cholakov and van Noord (2010) describe a LA method where a ME-based classifier is used to acquire lexical entries for all forms in the paradigms of words, unknown to the large-scale Dutch Alpino grammar (van Noord, 2006). The paper also shows that the application of LA improves the parsing accuracy of Alpino on open-domain texts.

For our purpose of comparing supertagging and LA, we investigate how methods implementing these strategies affect the parsing coverage and accuracy when applied with the same grammar, namely the GG. Our choice of German and the GG as a platform for comparison is motivated by the fact that German has richer morphology and a more free word order than both English and Dutch which makes unknown word handling more challenging. We adapt the LA method of Cholakov and van Noord (2010) – henceforth C&vN– and applied with the GG. Then, we compare the parsing coverage and accuracy the GG achieves on a German newspaper corpus to those reported for supertagging methods applied previously with the GG on the same corpus. For all techniques, the experiments show that their application leads to an increase in coverage compared to the baseline, that is the standard GG setup. However, the supertagging methods achieved this at the price of having lower accuracy than the baseline. The application of the adapted C&vN method, on the other hand, increases parsing accuracy compared to the baseline. This difference in quality might not always be crucial since less accurate parses produced by the grammar can still be used successfully in many NLP applications. In such cases, the less complex supertagging methods might be the preferred choice. However, through a small sentence realisation experiment, we give an example of an application where high-quality LA is a prerequisite.

Other kinds of LA techniques have also been proposed. Cussens and Pulman (2000) used a symbolic approach employing *inductive logic programming*, while Erbach (1990), Barg and Walther (1998) and Fouvry (2003) followed a unification-based approach. However, it is doubtful if those methods are scalable since they have not been applied to large-scale grammars and no meaningful evaluation has been provided.

The remainder of the paper is organised as follows. Section 2 describes the resources we employ. Section 3 gives an overview of the supertagging methods previously applied with the GG. Section 4 describes the adaptation of the C&vN method to the GG. Section 5 gives details on the training procedure for the ME-based classifier used in the C&vN technique. Section 6 evaluates the parsing coverage and accuracy on the German newspaper corpus when this technique is applied with the GG and compares the results to the results reported previously for the suppertagging methods for this corpus. Section 7 explores the possibility of using newly acquired lexical entries in a small sentence realisation task. Section 8 concludes the paper.

2 Resources

The GG (Crysmann, 2003) is an HPSG grammar based on typed feature structures. The GG types are strictly defined within a type hierarchy. The

[1] http://wiki.delph-in.net/

grammar contains constructional and lexical rules, as well as a lexicon where words are assigned lexical types. Currently, it consists of 5K types, 115 rules and the lexicon contains approximately 55K entries. There are 411 distinct lexical types which words can be mapped onto. Below is an example of a GG lexical entry, namely the entry for the word *Aufgabe* (a task):

```
aufgabe-n := count-noun-le &
 [ MORPH.LIST.FIRST.STEM < "Aufgabe" >,
   SYNSEM.LKEYS [ --SUBJOPT -,
            KEYAGR c-n-f,
            KEYREL "_aufgabe_n_rel",
            KEYSORT abstract,
            MCLASS nclass-9 ] ].
```

The lexical type 'count-noun-le' shows that the word is a countable noun[2]. The STEM type feature specifies the stem of the word. The stem for nouns is the singular nominative noun form, for adjectives– the base noninflected form and for verbs– the root form. Adverbs in German have a single form which is used as the value of the STEM feature in adverb entries. Some nouns (e.g., *Baukosten* (building costs)) do not have all forms typical for German nouns. In such cases, the word itself is set as the value of the STEM feature. The KEYAGR feature indicates case, number and gender. In the example above, case and number are left underspecified while the gender is set to feminine. The value of SUBJOPT shows that this noun is always used with an article and MCLASS indicates its morphological paradigm. The KEYREL and KEYSORT features define the semantics of the word.

Further, we employ the PET system (Callmeier, 2000) to parse with the GG. PET is a system for efficient processing of unification-based grammars. The system comprises a sophisticated preprocessor, a bottom-up chart parser and a grammar compiler. For our purposes, we should note that the parser has a built-in unknown word guesser which, based on some simple heuristics, assigns generic types to the unknown words. Most of the features in these types are left underspecified.

We compare the results of the various methods based on how they affect the parsing coverage and accuracy of the GG on the Frankfurter Rundschau (FR) newspaper corpus. The corpus contains 614K sentences and the articles in it deal with various domains.

[2] *le* stands for lexeme.

3 Suppertagging Methods

Here, we give an overview of supertagging methods applied previously with the GG. Typically, the unknown words are assigned *open-class* lexical types. In the case of the GG, open-class lexical types are those assigned to nouns, adjectives, verbs and adverbs. It is assumed that closed-class words are already handled by the grammar.

Dridan et al. (2008) adopts the method proposed in Zhang and Kordoni (2006) for English and the ERG and applies it to the GG. A ME-based tagger is trained on features extracted from the context of the unknown word– four characters from the beginning and the end of the word, and two words of context (where available) either side of the target word together with their POS tags[3]. The application of the tagger led to an improved parsing coverage on a test corpus containing 700 short German questions from the CLEF competition. No evaluation in terms of accuracy is provided for German. For the same experiment with the ERG, the accuracy achieved with the tagger was below the baseline accuracy (the standard ERG setup).

Nicholson et al. (2008) employs the same ME-based tagger but the paper examines its performance more closely. The tagger is evaluated by performing a 10-fold cross-validation on the treebank associated with the GG. Words which appeared only in the test fold were considered unknown. Since the sentences in the treebank are annotated, the method is able to use the lexical types of the context words as features instead of their POS tags. The achieved token accuracy is 58%. Then, the tagger is used to predict lexical types for unknown words in a random sample of 1000 sentences extracted from the FR corpus. However, since no annotation is available for the test corpus, the tagger is run with the same features as in Dridan et al. (2008) but without the POS tags of the context words.

The results are given in Table 1. Coverage increased by 8% for the test corpus. An estimation of the parsing accuracy is also given. Parsing accuracy is measured as the proportion of sentences for which a correct parse is produced, among the set of parses. 87 sentences were randomly selected and manually examined. The baseline accuracy was 85%. When suppertagging is applied accuracy drops to 84%. This is consistent with the re-

[3] The corpora used had been POS tagged with the TreeTagger (Schmid, 1994).

sults reported in Dridan et al. (2008) for the ERG.

Cholakov et al. (2008) develops further the idea of using lexical types as features in the tagger. The paper presents the same system setup as Nicholson et al. (2008) but with one crucial difference. The tagset used in the experiments consists of more detailed descriptions of the GG lexical types. In this new tagset, the values of some of the morphosyntactic features from the lexical entries are attached to the type definition, thus making the information they carry accessible to the tagger. For example, according to the guidelines given in Cholakov et al. (2008), the lexical type of *Aufgabe* would become *count-noun-le_-_f* after attaching the values of the SUBJOPT and KEYAGR features to the type definition[4]. Having this additional information, the token accuracy of the tagger increases to 73.54%. The effect the method has on the parsing coverage and accuracy is shown in Table 1. The experiment is done on a random sample of 10K sentences from the FR with the corpus POS tagged and the tags of the context words used as features in the tagger instead of lexical types. Parsing accuracy is measured as the proportion of 100 randomly selected sentences with at a correct parse produced. Again, accuracy decreases in comparison to the baseline (the standard GG setup).

It is important to note that the lexical entries created by the aforementioned methods for unknown words are sort of generic due to the inability of those methods to access the values of the type features defined in the entries. In Nicholson et al. (2008) only the type of the word can be specified and the word is set as the value of the STEM feature. Every other feature in the entry is either underspecified or assigned some default value. The technique of Cholakov et al. (2008) can define more features in the created lexical entry due to the detailed tagset used. However, accuracy still decreased.

4 Lexical Acquisition with The GG

In this section, we describe the adaptation of the C&VN LA method to the GG. This adaptation raises the important question about portability of LA. Because of their complexity and dependence on a particular grammar, LA methods have been applied within a single parsing system, in a single framework, and mostly for a single language. So, it is unclear to what extent the various techniques can be used for a different language or parsing architecture. However, the C&VN method is claimed explicitly to be portable to other systems and languages provided some conditions are met. These include: a finite set of labels which unknown words are mapped onto, a syntactic parser, and a morphological component which generates the paradigm(s) of a given unknown word.

Similar to Cholakov et al. (2008), we created a set of labels which consists of more refined definitions of the GG lexical types. Accordingly, we attach the values of some of the type features defined in the relevant lexical entries to the type definitions of those entries. However, for reasons of data sparseness, we choose to exclude some of the features which Cholakov et al. (2008) considered relevant. Experiments with different sets of features have shown that the best results are achieved when only features designating morphosyntactic agreement are considered. For all noun types and predicative adjectives this is the KEYAGR feature and for verb types allowing for prepositional complements– the COMPAGR and the OCOMPAGR features which indicate the case of the the (oblique) complement. For instance, the lexical type of *Aufgabe* will become *count-noun-le_f* after the gender value of the KEYAGR feature is attached.

C&VN propose a method for the generation of the paradigm(s) of a given unknown Dutch word (Cholakov and van Noord, 2009). The type of word form predicted by the paradigm for that word is used as a feature in the ME-based classifier employed in C&VN for learning unknown words. For example, the paradigm of *Aufgabe* will indicate that the word is a singular feminine noun and this information will be passed on to the classifier. Further, unlike the Dutch Alpino grammar, the GG does not have a full form lexicon. All word forms are derived by applying various morphological rules defined in the GG to the word stem. Therefore, we need to add only the correct stem of the unknown word the lexicon. Then, all forms of the word will automatically be recognised by the grammar. That is why, in the case of the GG, we use the generated paradigms to perform the mapping between unknown words and their stems. For instance, if *Aufgaben* (tasks) is an unknown word, we will add *Aufgabe*, the stem

[4]The values for case and number for nouns are almost always left underspecified; that is why only the value of the gender is attached to the type definition.

Method	Coverage (%)		Accuracy (%)	
	Baseline (standard GG)	GG + tagger	Baseline (standard GG)	GG + tagger
Lexical	12	20	85	84
Lexical+POS	8.9	21.1	85	83

Table 1: Coverage and accuracy results for the GG and the FR corpus. *Lexical* refers to Nicholson et al. (2008) where only affixes and context words are used as features. The last row refers to Cholakov et al. (2008) where the POS tags of the context words are also employed.

indicated by its paradigm, to the lexicon.

Due to the GG design, it is not straightforward to use the morphological rules of the grammar for paradigm generation. Following the C&VN technique developed for generating the paradigms of Dutch words, we created a German finite state morphology. The morphology does not have access to any linguistic information and thus, it generates all possible paradigms allowed by the word orthography. Then, the number of search hits Yahoo! returns for each form in a given paradigm is combined with some simple heuristics to disambiguate the output of the morphology and to determine the correct paradigm(s). We also apply heuristics to guess the gender for words with generated noun paradigms and to determine if a word which is assigned a verb paradigm starts with a separable particle.

One could argue that there is a simpler approach for mapping the various forms of the unknown word to its stem. For instance, the TreeTagger provides both POS and stem information with high accuracy. However, the generation of the paradigms allows us to consider contexts in which other forms of a given unknown word occur and thus, to have access to much more and linguistically diverse data. Further, using the paradigms, we are able to determine which of the morphological classes defined within the GG a given unknown word belongs to and specify the value of the MCLASS type feature in the lexical entry generated for this word. We are also able to determine the value of the VCOMPFORM type feature which indicates the separable particle in verb entries. However, those are not crucial for the classification process and they are likely to cause data sparseness. That is why, those type features are assigned their values after the lexical type of a given word has been predicted. The semantic features in the lexical entries for newly acquired words, as well as the other features whose values are not learnt via LA are assigned default values or left underspecified.

We adopted the ME-based classifier[5] and the features used for unknown word prediction as described in C&VN. The probability of a lexical type *t*, given an unknown word and its context *c* is:

$$(1) \qquad p(t|c) = \frac{exp(\sum_i \Theta_i f_i(t,c))}{\sum_{t' \in T} exp(\sum_i \Theta_i f_i(t',c))}$$

where $f_i(t, c)$ may encode arbitrary features from the context and $< \Theta_1, \Theta_2, ... >$ can be evaluated by maximising the pseudo-likelihood on a training corpus (Malouf, 2002).

Table 2 shows the features for *Aufgabe*. Since the stem of the unknown word is added to the lexicon, we also experimented with prefix and suffix features extracted from the stem. We assumed that those could allow for a better generalization of morphological properties but they proved to be less informative for LA.

Features
i) A, Au, Auf, Aufg
ii) e, be, abe, gabe
iii) hyphen_no
iv) noun_feminine #predicted by the paradigm
v) count-noun-le_f, mass-noun-le_f
vi) noun⟨f⟩

Table 2: Features for *Aufgabe* (a task)

Rows **(v)** and **(vi)** show syntactic features obtained from what C&VN refer to as 'parsing with universal types'. In C&VN, each unknown word is assigned all target lexical types, i.e. it is treated as being maximally ambiguous. However, to reduce ambiguity and make the parsing computationally feasible, we use the generated paradigms as a filtering mechanism and assign a given word only those types which belong to the POS of the paradigm(s) generated for this word. That is why, *Aufgabe* is assigned all noun lexical types. Sentences containing morphological forms of *Aufgabe*

[5]The classifier is developed using the TADM tool; `http://tadm.sourceforge.net/`

are then parsed with PET in best-only mode. For each sentence only the best parse selected by the disambiguation model of the parser is preserved. Then, the lexical type that has been assigned to the form of *Aufgabe* occurring in this parse is stored.

We employ the most frequently used type(s), based on an empirical threshold (80% for the GG), as features in the classifier (row **v**). Further, as illustrated in row **(vi)**, each piece of information attached to the type definitions (the part after the underscore) is also taken as a separate feature. By considering these syntactic features, we manage to involve the grammar directly in the prediction process, unlike the methods discussed in the previous section where only lexical features and POS tags were used. Here, the grammar can decide which lexical type(s) are best suited for a given unknown word. This is an effective way to include the syntactic constraints imposed on the unknown word into the prediction process.

5 Training of The Classifier

In order to train the classifier, we need annotated data. That is why, we temporarily remove some words from the GG lexicon and use them for training and tuning the various parameters of the classifier. The lexical entries of the removed words are used as gold standard.

We remove only words belonging to open-class lexical types. Each such type has at least 10 lexical entries in the lexicon mapped onto it and it is assigned to at least 15 distinct words occurring in large corpora parsed with PET and the GG. The parsed corpus we use consists of roughly 2.5M sentences randomly selected from the German part of the Wacky project (Kilgarriff and Grefenstette, 2003). Following these criteria, we have selected 39 open-class types out of the 411 lexical types defined in the GG. The expansion of the type definitions of the 39 types with the values of the relevant type features resulted in the creation of 68 *expanded* types. Table 3 gives more details about the type distribution.

2400 words are removed from the lexicon of the GG. Of these, 2000 are used for training, and 400 words are used as a test set to give an idea about the performance of the classifier. We assume that less frequent words are typically unknown and, in order to simulate their behaviour, all 2400 words have between 40 and 100 occurrences in the parsed corpus. Experiments with a minimum lower than 40 occurrences have shown that this is a reasonable threshold to filter out typos, tokenization errors, etc. The distribution of the parts-of-speech for the 2400 words and the evaluation of the paradigm generation component are shown in Table 4 (some words have more than a single part-of-speech). Accuracy indicates how many of the generated paradigms are correct.

	Original types	Expanded types
Total	39	68
-nouns	5	15
-verbs	28	45
-adjectives	4	6
-adverbs	2	2

Table 3: Distribution of the target lexical types

	overall	nouns	adj	verbs
total	2954	1196	651	694
accuracy(%)	96.45	91.09	100	99.54

Table 4: Paradigm generation results

In the paradigms generated for verbs there were three mistakes. However, the generated verb stems were all correct. Similarly, the stems for all nouns were correct, including the stems of 98 nouns which contained a mistake in their paradigm. In 91 cases the singular genitive form was incorrect, in another 12 cases the predicted gender was wrong. The mapping of the words to their correct stems is correct in all cases.

We allow for multiple types per word to be predicted but we discard the types accounting together for less than 5% of probability mass. Additionally, there are four baseline methods. The ***naive*** one assigns the most frequent expanded type in the lexicon, *count-noun-le_f*, to each unknown word. In the ***naive POS*** baseline each word is given the most frequent expanded type for the POS of each paradigm generated for it. The ***GG*** baseline predicts for the unknown word the target type(s) used as features for this word in the classifier (e.g., for *Aufgabe*, these are the types from row (v) in Table 2). For the ***TnT*** baseline, we used the treebank available for the GG to train the TnT POS tagger (Brants, 2000) with the tagset consisting of all lexical types in the GG. The sentences extracted for each unknown word are then tagged in best-only mode. Similarly to the GG baseline, the unknown word is given the type(s) most fre-

quently assigned to it (80% threshold). The average type precision and type recall for the 400 test words are given in Table 5. Table 6 shows the F-measure per POS for the LA model.

Model	Prec(%)	Rec(%)	F-meas(%)
Naive	21.75	21.07	21.41
Naive POS	58.96	47.65	52.7
GG	55.03	57.12	56.06
TnT	61.21	49.17	54.53
LA with the GG	82.04	86.5	84.21

Table 5: Results on the 400 test words

POS	nouns	adj	verbs	adv
F-meas (%)	92.4	90.93	67.25	75.82

Table 6: F-measures per POS for the LA model

The LA model improves upon the baselines. The F-measure reaches 80% when 300 words are used for training and the learning curve flattens out at 1600 training words. The method performs very similar to the results reported for Dutch and Alpino, which demonstrates that it can be successfully applied outside the environment it was primarily developed for.

Predicting lexical entries for verbs is the hardest task for the LA model. The classifier has a strong bias towards assigning transitive and intransitive verb types. It either fails to predict infrequent frames or it wrongly predicts a transitive type for intransitive verbs and vice versa. Another difficulty for the model is the distinction which the GG makes between ergative and non-ergative verbs. The main issue with adverbs is that many of them can be used as adjectives as well. As a consequence, the classifier has a strong bias towards predicting an adverb type for words for which an adjective type has also been predicted. No pattern in the errors for nouns and adjectives can be identified.

6 Parsing Coverage and Accuracy

Having adapted the C&VN method to be used with the GG, we can now compare it with the supertagging methods by investigating how its application affects parsing coverage and accuracy on the FR corpus. We were not able to obtain the sentence sets used in Nicholson et al. (2008) and Cholakov et al. (2008), so we created a test set of 450 sentences randomly extracted from the FR corpus. All sentences contained at least one unknown word. The average sentence length is 17.16 tokens, with a ratio of 1.09 unknown words per sentence. For this experiment, we parse the 450 sentences with PET, under three conditions. In the first case, the standard configuration of the GG is used where the unknown word guesser assigns generic types to the unknown words. Dridan et al. (2008) report that passing a POS tagged input to the guesser enhances its performance and improves parsing coverage. That is why, in the second case, the 450 sentences were tagged with TnT outputting all POS tags with non-zero probabilities for each word. Then, the tagged sentences are parsed with PET. In the third case, we add to the GG lexicon lexical entries acquired offline by the adapted C&VN method.

The results are given in Table 7. The models employing POS tags and LA have practically the same coverage performance. The *GG+POS* one produced at least one parse for 113 sentences and the LA model produced analyses for those 113 sentences plus 4 more, thus giving a total of 117 parsed sentences. The standard GG model was able to cover 57 sentences. The parsed sentences for all models are manually examined and accuracy is again measured as the percentage of those parsed sentences which had a correct parse produced among the set of parses. There were 99 such sentences for the model which employs LA and 89 and 47 for the *GG+POS* and the *GG-standard* model, respectively. The drop in the accuracy for the *GG+POS* model compared to the standard GG one is consistent with the accuracy results reported in Dridan et al. (2008) for the ERG. We should note, though, that both the LA and *GG+POS* models also produced a correct parse for the 47 sentences for which the standard model delivered a correct analysis.

Model	Cov (%)	Acc (%)	LB Acc (%)
GG-standard	12.67	82.46	92.87
GG + POS	25.11	78.76	92.51
GG + LA	26	84.62	94.71

Table 7: Coverage and accuracy results for FR. *LB Acc* stands for labelled brackets accuracy.

The better accuracy result achieved by the LA model has to do mainly with the fact that the built-in guesser assigns noun types to the vast majority of the unknown words. The underspecified features in those entries create a lot of ambigu-

ity and make it harder for the parser disambiguation model to select the correct analysis. The LA method, on the other hand, supplies the parser with more detailed and linguistically accurate lexical entries which facilitates ambiguity resolution.

The results differ from the ones reported on the FR corpus for the suppertagging methods (Table 1) where the application of the tagger increased coverage but the price was lower accuracy. We attribute this to the bigger amount of features used in the classifier in the C&VN method which enabled the learning of more detailed lexical entries.

However, the estimation used up till now for accuracy is a rather crude one. Another way of looking at accuracy is to measure how close the top ranked parse for a given sentence is to the correct parse produced for this sentence. We selected the 47 sentences for which all three models have produced the correct parse and used them as our gold standard, to be able to report accuracy numbers, for the best parse.[6] Accuracy is measured in terms of labelled brackets. The results given in Table 7 show that not only the LA model produces a correct parse for more sentences but also the top ranked analysis is of better quality.

7 LA for Text Generation

As a further evaluation, we also investigate how the lexical entries acquired with LA affect sentence realisation. While in parsing the ambiguity in such less constrained lexical entries dissolves quickly in its context, there is a potential risk of overgeneration in the reverse process.

We selected 14 words assigned verb types by the tagger in the experiment with the FR corpus. Then, 64 sentences, each of which contains one of those 14 words, are extracted from corpora. We construct manually another sentence set where these words are replaced by verbs from the GG lexicon with a similar lexical type. This comparison set indicates what the performance of the GG would be with fully constrained, but otherwise similar lexical entries.

Realisation with the GG is performed within the LKB grammar engineering platform which provides a chart-based generator with various optimisations for packed parse forest (Carroll and Oepen, 2005). We parsed the two sentence sets and then used the best analysis to generate a realisation for each sentence. There were 3.28 realisations per sentence for the test set versus 3.16 for the comparison one. As for accuracy, a realisation is considered correct if it is an exact match of the original sentence (excluding punctuation). Despite the higher number for realisations per sentence for the test set, the quality of the realisations is the same for both sets– for 60 sentences a correct realisation is produced. Thus, the entries acquired with LA can be employed for both parsing and realisation.

We should note that realisation with the generic lexical entries acquired by the unknown word guesser of the parser is computationally not feasible because of the many underspecified features in those entries. Nicholson et al. (2008) and Cholakov et al. (2008) did not perform any experiments on realisation but we assume that the underspecification in the entries those methods produce would also make sentence realisation practically impossible.

8 Conclusion

Two types of methods for dealing with unknown words were compared. The application of methods, where a tagger was used to predict lexical descriptions for words unknown to the GG grammar of German, led to an increase in parsing coverage on a German newspaper corpus. However, accuracy was below the baseline, that is the accuracy of the standard GG setup. The other type of methods employ LA techniques to extend the lexicon of a grammar with new lexical entries for unknown words. We adapted one such method, namely the one of Cholakov and van Noord (2010), which has been primarily developed for the Dutch Alpino grammar, to be used with the GG. The application of the method led to an increase in both parsing coverage and accuracy on the same newspaper corpus. We attributed the better performance of the C&VN technique to the fact that it had access to more features during prediction, including such which came directly from the grammar, and it was able to assign more linguistically accurate entries to the unknown words. Last, in a smaller experiment, we showed that those entries can be successfully used for sentence realisation.

Abstract

We introduce a maximum spanning tree (MST) dependency parser that can be trained from partially annotated corpora, allowing for effective use of available linguistic resources and reduction of the costs of preparing new training data. This is especially important for domain adaptation in a real-world situation. We use a pointwise approach where each edge in the dependency tree for a sentence is estimated independently. Experiments on Japanese dependency parsing show that this approach allows for rapid training and achieves accuracy comparable to state-of-the-art dependency parsers trained on fully annotated data.

1 Introduction

Parsing is one of the fundamental building blocks of natural language processing, with applications ranging from machine translation (Yamada and Knight, 2001) to information extraction (Miyao et al., 2009). However, while statistical parsers achieve higher and higher accuracies on in-domain text, the creation of data to train these parsers is labor-intensive, which becomes a bottleneck for smaller languages. In addition, it is also a well known fact that accuracy plummets when tested on sentences of a different domain than the training corpus (Gildea, 2001; Petrov et al., 2010), and that in-domain data can be annotated to make up for this weakness.

In this paper, we propose a maximum spanning tree (MST) parser that helps ameliorate these problems by allowing for the efficient development of training data. This is done through a combination of an efficient corpus annotation strategy, and a novel parsing method. For corpus construction, we use partial annotation, which allows an annotator to skip annotation of unnecessary edges, focusing their efforts only on the ones that will provide the maximal gains in accuracy.

While partial annotation has been shown to be an effective annotation strategy for a number of tasks (Tsuboi et al., 2008; Sassano and Kurohashi, 2010; Neubig and Mori, 2010), traditional MST parsers such as that of McDonald et al. (2005) cannot be learned from partially annotated data. The reason for this is that they use structural prediction methods that must be learned from fully annotated sentences. However, a number of recent works (Liang et al., 2008; Neubig et al., 2011) have found that it is possible to ignore structure and still achieve competitive accuracy on tasks such as part-of-speech (POS) tagging.

Similarly, recent work on dependency parsing (Spreyer and Kuhn, 2009; Spreyer et al., 2010) has shown that training constraints can be relaxed to allow MST parsers to be trained from partially annotated sentences, with only a small reduction in parsing accuracy. In this approach the scoring function used to evaluate potential dependency trees is modified so that it does not penalize trees consistent with the partial annotations used for training. Our formulation of an MST parser is based on an even stronger independence assumption, namely that the score of each edge is independent of the other edges in the dependency tree. While this does have the potential to decrease accuracy, it has a number of advantages such as the ability to use partially annotated data, faster speed, and simple implementation.

We perform an evaluation of the proposed method on a Japanese dependency parsing task. First, we compare the proposed method to both a traditional MST parser (McDonald et al., 2005), and a deterministic parser (Nivre and Scholz, 2004). We find that despite the lack of structure in our prediction method, the proposed method is still able to achieve accuracy similar to that of

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 776–784,
Chiang Mai, Thailand, November 8 – 13, 2011.

the traditional MST parser, while training and testing speeds are similar to that of the deterministic parser.

In addition, we perform a case-study of the use of partial annotation in a practical scenario, where we have data that follows a segmentation standard that differs from the one we would like to follow. In Japanese dependency parsing, traditionally phrase segments (*bunsetsu*) have been used instead of words as the minimal unit for parsing (Kudo and Matsumoto, 2002; Sassano and Kurohashi, 2010), but these segments are often too large or unwieldy for applications such as information extraction and machine translation (Nakazawa and Kurohashi, 2008). In our case-study, we demonstrate that a corpus labeled with phrase dependencies can be used as a partially annotated corpus in the development of a word-based parser that is more appropriate for these applications. The use of a phrase-labeled corpus allows us to increase the accuracy of a word-based parser trained on a smaller word-labeled data set by 2.75%.

2 Pointwise estimation for dependency parsing

This work follows the standard setting of recent work on dependency parsing (Buchholz and Marsi, 2006). Given as input a sequence of words, $\boldsymbol{w} = \langle w_1, w_2, \ldots, w_n \rangle$, the goal is to output a dependency tree $\boldsymbol{d} = \langle d_1, d_2, \ldots, d_n \rangle$, where $d_i \equiv j$ when the head of w_i is w_j.[1] We assume that $d_i = 0$ for some word w_i in a sentence, which indicates that w_i is the head of the sentence.

2.1 A Pointwise MST Parser

The parsing model we pursue in this paper is McDonald et al. (2005)'s edge-factored model. A score, $\sigma(d_i)$, is assigned to each edge (i.e. dependency) d_i, and parsing finds a dependency tree, $\hat{\boldsymbol{d}}$, that maximizes the sum of the scores of all the edges.

$$\hat{\boldsymbol{d}} = \mathop{\mathbf{argmax}}_{\boldsymbol{d}} \sum_{d \in \boldsymbol{d}} \sigma(d). \qquad (1)$$

It is known that, given $\sigma(d)$ for all possible dependencies in a sentence, $\hat{\boldsymbol{d}}$ can be computed by the maximum spanning tree algorithm such as Chu-Liu/Edmonds' algorithm.

An important difference from McDonald et al. (2005) is in the estimation of $\sigma(d)$. McDonald et al. (2005) applied a perceptron-like algorithm that optimizes the score of entire dependency trees. However, we stick to pointwise prediction: $\sigma(d_i)$ is estimated for each w_i independently. A variety of machine-learning-based classifiers can be applied to the estimation of $\sigma(d)$, because it is essentially an n-class classification problem.

In the experiments, we estimate a log-linear model (Berger et al., 1996). We calculate the probability of a dependency labeling $p(d_i = j)$ for a word w_i from its context, which is a tuple $x = \langle \boldsymbol{w}, \boldsymbol{t}, i \rangle$, where $\boldsymbol{t} = \langle t_1, t_2, \ldots, t_n \rangle$ is a sequence of POS tags assigned to $\boldsymbol{w}$ by a tagger. The conditional probability $p(j|x)$ is given by the following equation.

$$p(j|x, \boldsymbol{\theta}) = \frac{\exp\left(\boldsymbol{\theta} \cdot \boldsymbol{\phi}(x, j)\right)}{\sum_{j' \in \mathcal{J}} \exp\left(\boldsymbol{\theta} \cdot \boldsymbol{\phi}(x, j')\right)} \qquad (2)$$

The feature vector $\boldsymbol{\phi} = \langle \phi_1, \phi_2, \ldots, \phi_m \rangle$ is a vector of non-negative values calculated from features on pairs (x, j), with corresponding weights given by the parameter vector $\boldsymbol{\theta} = \langle \theta_1, \theta_2, \ldots, \theta_m \rangle$. We estimate $\boldsymbol{\theta}$ from sentences annotated with dependencies. It should be noted that the probability $p(d_i)$ depends only on i, j, and the inputs $\boldsymbol{w}$, $\boldsymbol{t}$, which ensures that it is estimated independently for each w_i. Because parameter estimation does not involve computing $\hat{\boldsymbol{d}}$, we do not apply the maximum spanning tree algorithm in training.

2.2 Features

Our current implementation uses the following features for $\boldsymbol{\phi}$.

- F1: The distance between a dependent word and its candidate head.
- F2: The surface forms of the dependent and head words.
- F3: The parts-of-speech of the dependent and head words.
- F4: The surface forms of up to three words to the left of the dependent and head words.
- F5: The surface forms of up to three words to the right of the dependent and head words.

[1] While we describe unlabeled dependency parsing for simplicity, it is trivial to extend it to labeled dependency parsing.

i	1	2	3	4	5	6	7	8	9
w_i	政府	は	投資	に	つなが	る	と	歓迎	し
Eng.	Gov.	*subj.*	investment	to	leads	*ending*	that	welcomes	do
t_i	noun	part.	noun	part.	verb	infl.	part.	noun	verb
d_i		8							
F1		6							
F2		は						歓迎	
F3		part.						noun	
F4		政府						つなが, る, と	
F5		投資, に, つなが						し	
F6		noun						verb, infl., part.	
F7		noun, part., verb						verb	

The second word, case marker は (*subj.*), has two grammatically possible heads: the verb つなが (leads) and the verb 歓迎 (welcomes). In our framework, only this word needs to be annotated with its head.

Figure 1: An example of a partially annotated sentence and the features for a dependency between case marker は (*subj.*) and the verb 歓迎 (welcomes).

F6: The parts-of-speech of the words selected for F4.

F7: The parts-of-speech of the words selected for F5.

Figure 1 shows the values of these features for a partially annotated example sentence where one word, case marker は (*subj.*), has been annotated with its head, the verb 歓迎 (welcomes).

Pointwise prediction rather than structured prediction has the potential to hurt parsing accuracy. However, our method can enjoy greater flexibility, which allows for training from partially annotated corpora as will be described in Section 3. It also simplifies the implementation and reduces the time necessary for training.

2.3 Solution Search

In the experiments, we target Japanese parsing. Because Japanese is a head-final language, we assume $d_i > i$ for all $i \neq n$ and $d_n = 0$. This assumption reduces the maximum spanning tree algorithm to a simpler algorithm: for each word we select the dependency with the maximum score. As this never creates a loop of dependencies, a recursive process as in Chu-Liu/Edmonds' algorithm is not necessary.

3 Domain Adaptation for MST Parsing

Assuming that the cost of annotation corresponds roughly to the number of annotations performed, out of all possible annotations to have annotators perform for a target domain corpus we want to select the ones which provide the greatest benefit to accuracy when training. The high cost of annotation work is the primary motivation for this approach.

3.1 Partial Annotation for a Parser

In the context of dependency parsing, partial annotation refers to annotating only certain dependencies between words in a sentence. Dependencies which are assumed to have little to no value for training are left unannotated. Figure 1 shows an example of a partially annotated sentence that can be used as training data by our system.

Before text can be annotated with dependencies for use in our system, it must first be tokenized and labeled with POS tags.[2] We assume that the results of this tokenization and POS tagging are accurate enough that we need to manually annotate only the dependencies between the tokenized words.

3.2 Learning Feature Weights from Partial Annotations

As explained in Section 2.1, edge scores, $\sigma(d_i)$, are estimated for each w_i independently. This means that the estimation of $\sigma(d_i)$ requires only a gold dependency of w_i, and the other dependencies in a sentence are not necessary. This allows us to learn weights $\boldsymbol{\theta}$ for features from partially annotated corpora. When training data includes a gold

[2]We take a language-independent approach that does not make any assumptions about the unit of tokenization or the meaning of tags used.

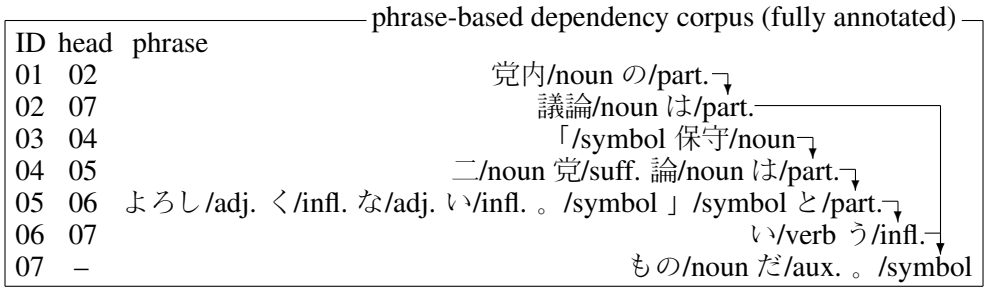

Figure 2: An example of phrase-based dependency annotation for a sentence.

dependency that w_i depends on w_j, a discriminative classifier can be trained by regarding $d_i = j$ as a positive sample and $d_i = j'$ s.t. $j' \neq j$ as negative samples.

In the case of Japanese parsing, because $j > i$ for all $d_i = j$, negative samples are $d_i = j'$ s.t. $j' \neq j \wedge j' > i$. For example, from the partial annotation given in Figure 1, we can create a training instance for w_2, は (*subj.*), where the positive sample is $d_2 = 8$ and the negative samples are $d_2 = 3, 4, \ldots, 7, 9$.

3.3 Domain Adaptation with a Partially Annotated Training Corpus

As a case study, we show how partial annotation can be used as a low-cost method of converting the annotation standard of an existing linguistic resource. As we mentioned in Section 1, traditional frameworks for Japanese dependency parsing are phrase-based. Many existing dependency corpora use phrases as the unit of annotation, and these resources are a valuable potential source of data for mining word dependencies. However, phrase dependencies alone do not provide enough information for an automatic conversion to word dependencies. One of the advantages of our parser is that it can be trained on a partially annotated corpus, so if we can derive even some word dependencies from phrase dependencies we can quickly and easily make use of existing resources.

To take advantage of these linguistic resources, we created a number of rules to derive word-based dependency annotations from phrase-based annotations. Instead of trying to convert all phrase dependencies, we focused on heuristics that provide only reliable word dependencies. The word-based dependency set produced by these rules is a partial annotation of the original corpus.

For the domain adaptation experiments described in Section 4, we used this procedure on the NAIST Text Corpus (NTC) (Iida et al., 2007) to create a small partially-annotated target domain corpus. The NTC consists of newspaper articles from the Mainichi Shimbun.[3] Figure 2 shows an example sentence from this corpus annotated with phrase dependencies.

To aid the construction of conversion rules, we chose three broad categories of words - content words, function words, and punctuation symbols - that provide clues to the structure of a phrase. Before we explain our rules, we will give a short explanation of these three categories.

We defined content words as nouns, verbs, adjectives, interjections, prenominal adjectives, suffixes, and prefixes. Function words are auxiliary verbs, particles, inflections, and conjunctions. In this context, punctuation symbols are both the English and Japanese versions of period and comma characters. These three categories are used to determine phrases which can be mined for relatively accurate word dependencies.

Figure 3 shows an example of how the rules explained below are used to derive word-based dependencies from phrase-based dependencies for the sentence given in Figure 2.

The first two rules are inter-phrase rules, which are concerned with the relationship between words located in different phrases.

1. LAST: Given a dependent phrase and its head phrase in the original annotation, set the head of the last word in the dependent phrase to the last content word in the head phrase. Note, we only apply this rule if the head phrase consists of a content word followed by zero or more function words, followed by an optional punctuation symbol.

[3] In addition to phrase dependency annotations, the NTC also contains predicate-argument and coreference tags that are useful for deriving reliable word dependencies.

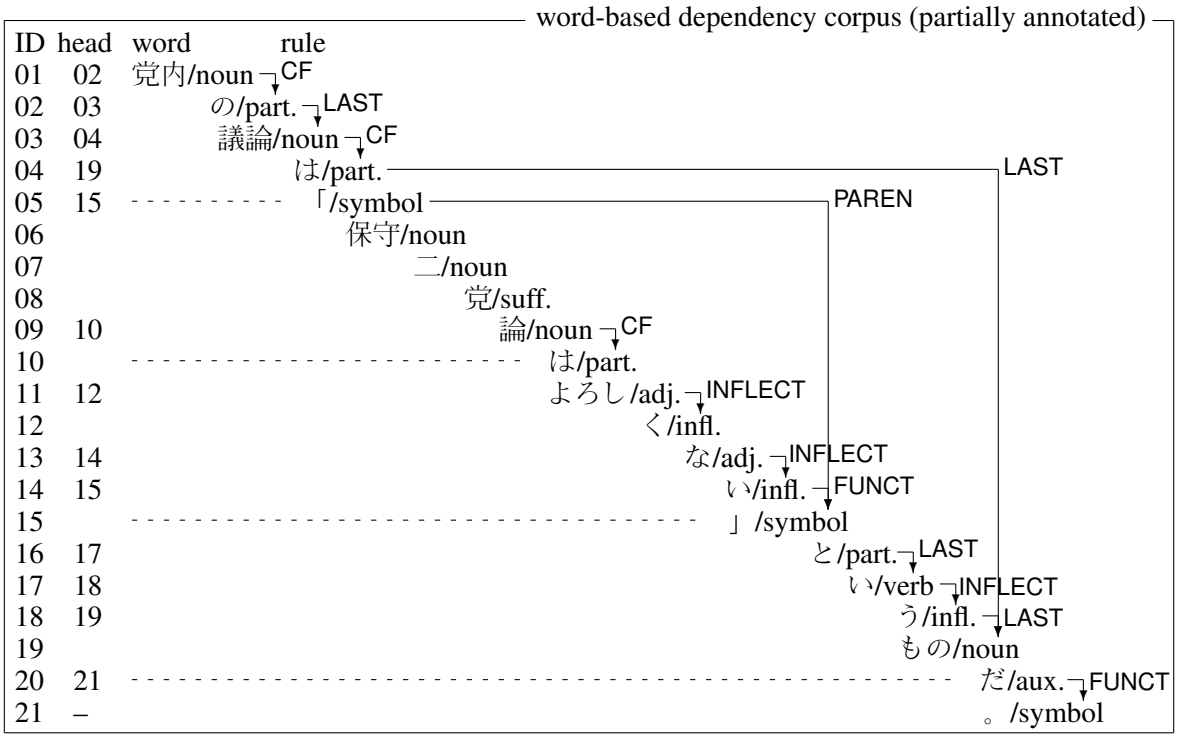

Figure 3: An example of word-based dependencies derived from phrase-based dependencies for a sentence.

2. PAREN: Set the head of a left parenthesis (or left bracket) word to the first right parenthesis (or right bracket) that follows it in the sentence.

The last four rules are intra-phrase rules that are concerned with the dependencies between words in the same phrase. The following rules were found to be effective.

3. FFS: If a phrase consists of zero or more content words, function words, or punctuation symbols followed by a sequence of two function words and a punctuation symbol, then set the head of the first function word in the sequence to the second function word and the head of the second function word to the punctuation symbol.

4. CF: If a phrase consists of zero or more content words followed by a sequence of a content word and a function word, then set the head of the content word to the function word.

5. INFLECT: If a word that is inflected in Japanese (verb, auxiliary verb, or adjective[4]) is followed by an inflection, the first word depends on the inflection.

6. FUNCT: If a function word is followed by a punctuation symbol, set the head of the function word to the punctuation symbol.

[4]In Japanese there are two types of adjectives, *i*-type adjectives and *na*-type adjectives. Both types are inflected.

4 Evaluation

As an evaluation of our parser, we measured parsing accuracies of several systems on test corpora in two domains: one is a general domain in which a corpus fully annotated with word boundary and dependency information is available, and the other is a target domain assuming an adaptation situation in which only a partially annotated corpus is available for quick and low-cost domain adaptation.

4.1 Experimental Settings

In the experiments we used example sentences from a dictionary (Keene et al., 1992) as the general domain data, and newspaper articles as the target domain data. We used business newspaper articles (Nikkei), similar to the Wall Street Journal, for the target domain test set. For the domain adaptation experiments, we used the partially-annotated corpus mentioned in Section 3.3 as a

Table 1: Sizes of Corpora.

ID	source	usage	#sentences	#words	#chars
EHJ-train	example sentences	training	11,700	145,925	197,941
EHJ-test	from a dictionary	test	1,300	16,348	22,207
NTC-train	newspaper articles	training	34,712	1,045,328	1,510,618
NKN-test	newspaper articles	test	1,002	29,038	43,695

NTC-train is a partially annotated corpus derived from phrase-based dependency annotations.

target domain training corpus. This corpus consists of newspaper articles that are similar to the target domain test set.

Usages and specifications of the various corpora are shown in Table 1. All the sentences are segmented into words manually and all the words are annotated with their heads manually. The Japanese data provided by the CoNLL organizers (Buchholz and Marsi, 2006) are the result of an automatic conversion from phrase (*bunsetsu*) dependencies. For a more appropriate evaluation we have prepared a word-based dependency data set.

The dependencies have no labels because almost all nouns are connected to a verb with a case marker and many important labels are obvious. The words are not annotated with POS tags, so we used a Japanese POS tagger, KyTea (Neubig et al., 2011), trained on about 40k sentences from the BCCWJ (Maekawa, 2008).

For the general domain experiments we compared the following systems, using projective parsing algorithms for training because of the assumptions about Japanese parsing outlined in Section 2.1.

1. **Malt**: Nivre et al. (2006)'s MaltParser, using Nivre's arc-eager algorithm and the option for strict root handling.

2. **MST**: McDonald et al. (2005)'s MST Parser, using k-best parse size with k=5.

3. **PW**: Our system, where pointwise estimation is used to estimate dependencies. Stochastic gradient descent training was used to train log-linear models.

4.2 With a Fully Annotated Training Corpus

For the first experiment, we measured the accuracy of each system on an in-domain test set when training on a fully annotated corpus. The results are shown in Table 2. Malt and MST have similar accuracy. PW has slightly higher accuracy than both of these systems, but the difference in accuracy is not statistically significant. We also measured the training time and the parsing speed of each system. Table 3 shows the results. From this table, first we see that MST is much slower than Malt, as is well known. Our method, however, is much faster than MST and the parsing speed is approximately the same as the shift-reduce-based Malt.

Theoretically the training time of our method is proportional to the number of annotated dependencies. In line with Kudo and Matsumoto (2002), we make two assumptions about Japanese dependency parsing. First, because Japanese is a head-final language we assume that every word except the final one in a sentence depends on one of the words located to its right. Second, we assume that all dependencies are projective, in other words that edges in the dependency tree do not cross each other. These assumptions limit the number of candidate heads for a word, reducing the training time.

Because all parsers were trained with projective algorithms, the first assumption is most likely the main reason for the difference in training times between PW and MST. For other languages where possible heads can be located both to the left and right of a word, we expect training times to increase. Our pointwise approach can be extended to handle these languages by changing the constraint on heads from $j > i$ to $j \neq i$ for all $d_i = j$. This is an important direction for future work now that we have confirmed that this approach is effective for Japanese.

We performed a second experiment in the general domain to measure the impact of the training corpus size on parsing accuracy. To make smaller training corpora, we set a fixed number of dependency annotations and then sequentially selected sentences from EHJ-train until the desired number of dependency annotations were collected. The re-

Table 2: Parsing Accuracy on EHJ-test.

method	EHJ-test
Malt	96.63%
MST	96.67%
PW	96.83%

All systems were trained on EHJ-train.

Table 3: Training Time and Parsing Speed.

method	training time	parsing speed
Malt	14[s]	1.3[ms/sent.]
MST	1901[s]	32.7[ms/sent.]
PW	125[s]	2.8[ms/sent.]

All systems were trained on EHJ-train and tested on EHJ-test. The machine used had a 3.33GHz processor and 12GB of RAM.

sults are shown in Figure 4. Though PW achieves the highest accuracy when the full training corpus is used, Malt has higher accuracy than both of the MST-based systems when the training corpus is one-third or less the size of the full training corpus. It can also be shown that both MST-based systems improve at a similar rate for all sizes of training corpora.

4.3 Domain Adaptation with a Partially Annotated Training Corpus

Tasks that make use of parsers, such as machine translation (Yamada and Knight, 2001), often require word-based models. However, because phrase-based approaches have traditionally been used for Japanese dependency parsing (Kudo and Matsumoto, 2002; Sassano and Kurohashi, 2010), word-based linguistic resources for Japanese are scarce. Preparing the fully annotated corpora required by existing word-based parsers such as McDonald et al. (2005)'s MST Parser is an expensive and laborious task.

Our parser attempts to address these problems by introducing a word-based framework for dependency parsing that can use partially annotated training data. Partial annotation is one way to efficiently make use of existing resources in the target domain without incurring high annotation costs.

We used each rule described in Section 3.3 individually to convert the annotations in the NTC-train and produce a pool of word-based dependencies. We then selected 5k of those dependencies to add to EHJ-train, and measured the results on NKN-test. We also used all rules simultaneously to produce word-based dependencies and measured the results in the same way as the individual rules. The total size of the partial annotation pool produced by using all rules was 248,148 dependencies out of 1,010,648 annotation candidates (not counting the last word of sentences, which has no dependency). The baseline case only used the EHJ-train with no partial annotations from the pool. The results are shown in Figure 5.

It can be seen that the LAST rule is the most effective, followed by the PAREN rule. This suggests that the long-distance dependencies provided by these rules are more useful for domain adaptation than the short-distance dependency information that the intra-phrase rules provide.

Combining all of the rules increases the accuracy on NKN-test to 88.44%, an increase of 2.75% over the baseline. This combination of rules results in lower accuracy gains than the sum of the gains from individual rules because different rules may convert the same phrase dependencies. These results show that our pointwise approach allows for effective use of existing target domain resources and increased parsing accuracy in the target domain through partial annotation.

5 Related Work

There has been a significant amount of work on how to utilize in-domain data to improve the accuracy of parsing. The majority of this work has focused on using unlabeled data in combination with self-training (Roark and Bacchiani, 2003; McClosky et al., 2006) or other semi-supervised learning methods (Blitzer et al., 2006; Nivre et al., 2007; Suzuki et al., 2009).

Roark and Bacchiani (2003) also present work on supervised domain adaptation, although this focuses on the utilization of an already-existing in-domain corpus.

There has also been some work on efficient annotation of data for parsing (Tang et al., 2002; Osborne and Baldridge, 2004; Sassano and Kurohashi, 2010). Most previous work focuses on picking efficient sentences to annotate for parsing, but Sassano and Kurohashi (2010) also present a method for using partially annotated data with deterministic dependency parsers, which can be trivially estimated from partially annotated data.

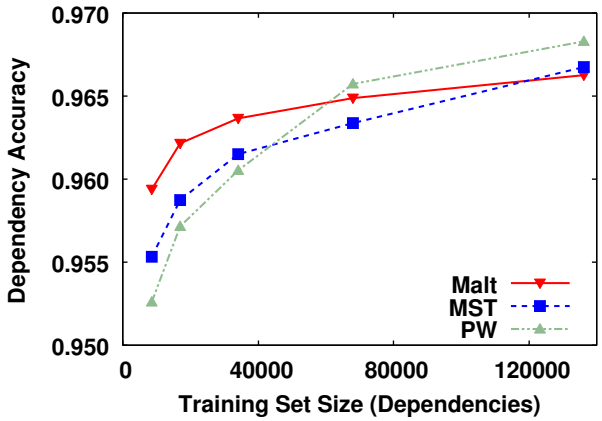

Figure 4: Comparison of parsing accuracy for different parsers.

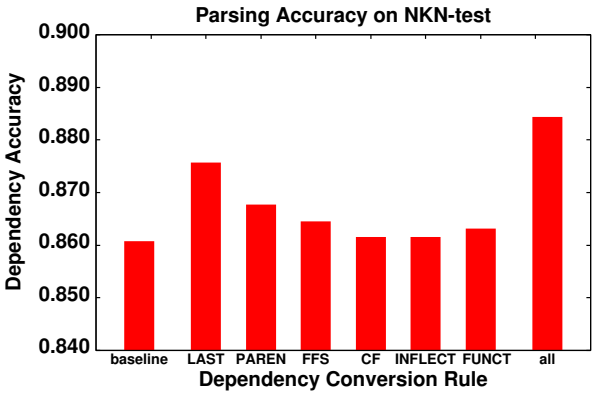

Figure 5: Parsing Accuracy on NKN-test.

Other recent work (Spreyer and Kuhn, 2009; Spreyer et al., 2010) has shown how both Nivre et al. (2006)'s MaltParser and McDonald et al. (2005)'s MST can be adapted to use partially annotated training data.

Traditional MST parsers such as McDonald et al. (2005)'s use structured prediction methods. Wang et al. (2007) showed that local classification methods can be used to train structured predictors. Their approach also uses "dynamic" features, where the predictions for some surrounding edges are used as features when estimating a possible edge between a dependent and head word.

Our parser also makes use of local classification methods for training, but in contrast to Wang et al. (2007) we take a pointwise approach based on the assumption that edge scores can be estimated independently. This work follows in the thread of Liang et al. (2008) and Neubig et al. (2011), who demonstrated that these assumptions can be made without a significant degradation in accuracy for POS tagging. Here we demonstrated that the same approach can be used for MST-based dependency parsing.

6 Conclusion

We introduced an MST parser that evaluates the score for each edge in a dependency tree independently, which allows for the use of partially annotated corpora in training. We demonstrated that target domain data annotated in this way can be combined with available general domain data to increase parsing accuracy in the target domain.

We evaluated state-of-the-art dependency parsers on a Japanese dependency parsing task, and found that our parser achieves accuracy comparable to that of a traditional MST parser. Additionally, the training and parsing speed of our parser is much faster than the traditional one, which allows it to be used for active learning in a real-world domain adaptation situation.

A Breadth-First Representation for Tree Matching in Large Scale Forest-Based Translation

Abstract

Efficient data structures are necessary for searching large translation rule dictionaries in forest-based machine translation. We propose a breadth-first representation of tree structures that allows trees to be stored and accessed efficiently. We describe an algorithm that allows incremental search for trees in a forest and show that its performance is orders of magnitude faster than iterative search. A B-tree index is used to store the rule dictionaries. Prefix-compressed indexes with a large page size are found to provide a balance of fast search and disk space utilisation.

1 Introduction

Statistical machine translation (SMT) uses machine learning and parallel corpora to perform translations automatically. Syntax based SMT systems can be broadly classified into two types based on the input to the system: tree-based and string-based (Mi et al., 2008). In a tree-based system, the input is a parse tree of the source language, whereas in the latter, the input is a sequence of words that is simultaneously parsed and translated. Forest-based translation employs multiple parse trees for each source language sentence.

Forest-based translation can be performed in three main steps. First, the input sentence is parsed into a packed forest, which is then pruned. Next, for each tree in the packed forest, all matching translation rules are found. These translation rules are then combined to form a translation forest. The translation forest is finally decoded to produce a sentence in the target language.

The second step – finding all matching translation rules for each tree in the source sentence forest – is a complex task in itself. It could be performed by enumerating all trees in the forest and then searching for those trees in the translation rule dictionary. Of the enumerated trees, those that are present in the rule dictionary produce the translation forest. However, enumerating all possible trees from a forest incurs an exponential cost and many or most of those generated trees may not exist in the rule dictionary. Hence, a common approach in MT research is to perform the inverse task, and iterate over all the rules to check whether each rule matches anywhere in the source forest. This is a relatively easy task, especially if the rule dictionary is not large. In experimental setups a subset of rules may be used based on the prior knowledge of the rules required for the given test sentences. While that method works for research experiments on translation methods, no prior knowledge is available for online MT systems, and iterating over all rules will not be efficient for large rule dictionaries. Another method used to quicken the search is to limit the depth of the rules. Shallower rule trees are lesser in number. However, the reduction in depth can lower the translation quality.

This paper's contribution is in the second step of forest-based translation. We propose a breadth-first representation of translation rule trees and a sorted index architecture to store and retrieve translation rules efficiently. Together, they allow all translation trees to be discovered at each node in the forest, incrementally. Each node in the forest is expanded to form trees that are present in the rule dictionary. This allows the rule dictionary to contain all rules without any restriction on the depth of the rule or the size of the collection.

Translation rules are stored in the BerkeleyDB (Olson et al., 1999) B-tree index structure. Section 3 describes the breadth-first representation used to store trees in the index. The architecture of the translation system and the method of incremental tree expansion are described in Sec-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 785–793,
Chiang Mai, Thailand, November 8 – 13, 2011.

tion 4. Section 4 also discusses the significance of the breadth-first over a depth-first tree storage approach.

Section 5 describes our experimental setup. The experiments measure the total time to construct a translation forest from a pruned source forest. An iterative search over the rule dictionary is the baseline performance measure. In addition to comparing the indexed search with the baseline, this section also analyses the effect of page size and compression on search performance. Multiple rule indexes are created to test the effect of the database parameter settings. The operating system disk cache and the database cache are cleared to simulate a fresh start before operating on each forest. The experiments are conducted on two rule dictionaries and three forest collections. The first rule dictionary has 11.8M rule trees and the second has 33.1M rules. The rules are extracted from NIST (2010a) data while the forest collections are extracted from NIST (2010a; 2010b) data.

2 Background

In this section we present the fundamentals of packed forests and forest-based translation before briefly describing the B-tree index structure.

2.1 Packed Forest

Packed forests or forests are directed hypergraphs and have been used to model and represent several applications in computer science and discrete mathematics (Klein and Manning, 2001).

Directed hypergraphs can be defined as a pair: $H = (V, E)$ where $V = \{v_1, v_2, \cdots, v_n\}$ is the set of nodes and $E = \{E_1, E_2, \cdots, E_m\}$ is the set of hyperedges. Each hyperedge can be defined as a pair: $E_i = (X_i, Y_i) \mid X_i,\ Y_i \subseteq V,\ i = 1, 2, \cdots, m.$

Packed forests have been used in NLP in the area of sentence parsing (Gallo et al., 1993) where the propositions of a parse analysis correspond to the nodes in the hypergraph and rules are represented as hyperedges. A similar model is used in forest based machine translation, where multiple parses of the input sentence are modelled as a forest. In NLP applications, the head of a hyperedge is usually a single node. This allows a single hyperedge to be semantically equivalent to a tree node with its children.

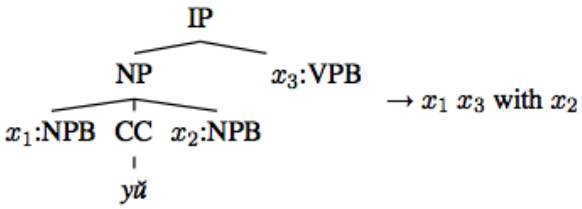

Figure 1: A translation rule reproduced from (Mi and Huang, 2008)

2.2 Forest Based Translation

Forest-based SMT overcomes the limitations of parse errors in tree-based translation and has been shown to be faster than k-best tree-based translation (Mi et al., 2008). For translating a sentence using the forest-based translation technique, we require a parser that can process a source language sentence and produce a packed forest and a translation rule dictionary, or database, which is a collection of *tree-to-string* translation rules (Huang et al., 2006; Liu et al., 2006).

A translation rule is a mapping from a source language tree to a string in the target language. An example translation rule from Chinese to English is shown in Figure 1. The left-hand-side is the source language tree. The Chinese word *yǔ* is translated to *with* in the target side on the right. The x_i variables on the right-hand-side are placeholders for the corresponding elements in the tree. Other numerical parameters associated with each translation rule are not shown here. Note that there may be several rules in the rule dictionary that have identical source language trees but different translations.

Once a source language sentence is parsed into a packed forest and pruned, the next step is to find trees in the forest that have matching rules in the translation rule dictionary. Matching rules are used to produce a translation forest for decoding into a target language string. The forest is a hypergraph made up of hyperedges where each hyperedge has a single source node, while the rules in the rule dictionary are trees.

Recent work by Huang and Mi (2010) has shown that forest expansion can be done in decoders using beam search (Koehn, 2004). However, to the best of our knowledge, no index-based search structures for incrementally finding trees have been proposed to date.

2.3 Indexing Methods

Data structures for indexing can be broadly classified into either memory based or disk based. Memory based indexes are not considered here since an online SMT system with a large translation rule dictionary requires disk based storage.

B-trees are balanced search trees that are designed to work efficiently from the disk. They minimise disk I/O and provide an insert and delete time complexity of $O(\log n)$, where n is the number of objects in the database. The keys in a B-tree are always in sorted order, therefore providing a guarantee of proximity for comparable keys.

The B-tree implementation in BerkeleyDB is used in our experiments. Since the keys are sorted, consecutive keys often share a common prefix. BerkeleyDB allows the compression of keys in a database via user-defined compress and decompress functions. If no such functions are supplied, it performs prefix compression. Our experiments test the performance of search with page size and compression of keys. Other settings such as the minimum number of keys for each leaf page and cache size allow us to fine tune the performance of the system, but we do not report experiments on those for lack of space.

3 Breadth-first Representation

The storage and efficient retrieval of the left-hand-side of translation rules is closely linked to the format in which they are stored. This section describes the format we use to represent trees both in queries and for rules in the index.

Trees can be represented linearly in several ways. As mentioned in Section 2.2, although a forest is a hypergraph made up of hyperedges, the left-hand-sides of rules in the rule dictionary are actually trees. Each node in a forest can have zero or more outgoing hyperedges. A hyperedge is be treated as a tree node with its children. Source sentence trees are constructed by recursively expanding nodes in the forest.

Figure 2a shows a tree constructed with three hyperedges, having head nodes A, B and F. Figure 2b shows the typical string representation of the tree where a node's descendants are scoped by an open and close bracket. The bracketed format, although visually intuitive, is not efficient for storage and processing. There has been much research on succinct representation of tree structures. Succinct representations encode trees in the most compact fashion by either using a balanced bracket representation or depth first unary degree sequences (Jansson et al., 2007). Such methods often represent the open and close brackets of a tree in bit notations. However, braces can only be matched when the trees are stored in a depth-first format and it cannot be applied to breadth-first representations.

Figure 2c represents the tree as a sequence of label and integer pairs. The labels represent node labels in the tree in a depth first format and the integers that follow each node label give the number of children at that node. Figure 2d shows a similar encoding scheme, but with the tree traversed in a breadth-first format. Finally, Figure 2e shows the format used in this paper. In our format, we separate the node labels and the integers representing the number of child nodes. When using this representation in the index, each node label is represented by a unique integer, which occupies four bytes, whereas the integer representing the number of child nodes is restricted to a maximum value of 255, and can therefore be represented in one byte.

Separating the node labels from integers representing the number of child nodes gives us a greater prefix overlap between consecutive expansions. For example, if we were to use the interleaved expansion method shown in Figure 2d on the hyperedge with head A and then expand the hyperedge with head B, the breadth-first representation of the trees would be A3B0E0F0 and A3B2E0F0C0D0. We can see that the expansion of the node B has resulted in its number of children being updated to 2 from 0. Since, each label is encoded using 4 bytes and the child count using 1

byte, the overlap between the expanded sequences is 9 bytes. With the separated breadth-first format (Figure 2e) the two trees are ABEF3000 and ABEFCD320000, an overlap of 4 node labels or 16 bytes. The separated form helps in increasing the prefix overlap of expanded tree structures.

If, instead, the depth-first notation is used, then the second tree is represented as A3B2C0D0E0F0. Then, even if the integers are separated, the prefix shared by the two queries is only 9 bytes.

To generalise the breadth-first representation and the prefix overlap, consider a tree T containing k nodes, denoted here as an ordered sequence $N = (n_1, n_2, \cdots, n_k)$ in breadth-first order. Each node is either fully expanded or is collapsed, therefore, if k is greater than 1, then the first node, being the root, must be fully expanded. Let the labels of nodes in N be a sequence $L = (l_1, l_2, \cdots, l_k)$ and let $C = (c_1, c_2, \cdots, c_k)$ denote the sequence of the number of children of each node in N. The separated breadth-first representation of T, which is used in this paper, is the sequence $B = (l_1, l_2, \cdots, l_k, c_1, c_2, \cdots, c_k)$. In a tree T, the number of nodes that can be expanded is equal to the number of leaves p, where $p \leq k$. Each expansion of a leaf node in T produces a new tree. Let $S = \{T_i \mid i \in \{1, 2, \cdots, k\}\}$ be the set of all trees produced as a result of the expansion, where $|S| = p$ and each tree, T_i, is an expansion of node n_i in T and its separated breadth-first representation is B_i. Let $N'_i = \{n_j \mid depth(n_j) \leq depth(n_i)\}$ be a set of all nodes of depth less than or equal to node n_i's depth in T. Then, B_i shares a prefix of at least $4\,|N'_i|$bytes with B.

Now, each node n_i has been considered to have either no child or one ordered set of children. While this is true in a tree, a forest is different. Each node in a forest can have multiple expansions, or hyperedges. The algorithm discussed in the next section therefore iterates over all possible hyperedges at a node.

4 Index Architecture

This section explains the structure of the index and the incremental search algorithm. To present a broader picture of where the index and search components fit within a larger online MT system, a representative block diagram of a complete forest-based MT system is provided in Figure 3. We focus only on the the incremental search algorithm

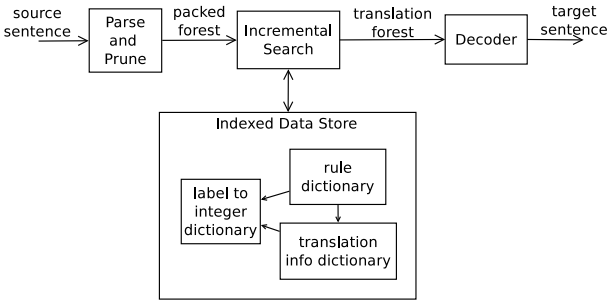

Figure 3: Architecture for an online forest-based translation system

and the rule dictionary in this section. The function of other components in the indexed data store is only briefly explained as they are not critical to the operation of the search algorithm.

The indexed data store is composed of three dictionaries. The first is a label to integer mapper. It assigns an integer identifier to all unique labels in the system. All tree node labels, including words, that appear on both sides of translation rules are indexed within this dictionary. The integer id for a label can be looked up using the label string as the key while encoding a tree query or while creating the other two dictionaries. A reverse mapping from the integer id to the label is used while constructing the translation forest from encoded rule trees. Any key-value data-structure could be used for the label mapper. It could even be a memory based hash table if it fits in memory.

The other two dictionaries, the rule dictionary and the translation info dictionary, contain the information about translation rules. The rule dictionary or database is a collection of left-hand-sides of translation rule trees accessible by a tree as the key. Each tree in the rule database has a unique integer id as its value. The integer id is the reference to a position in the translation info dictionary. Each rule tree may have one or more target language translations. Hence, each entry in the translation info database is a list of translations. Each element in the list is a tuple of the target language strings and the parameters defining the statistics of that translation. The target language strings are stored as a sequence of integer ids and the parameters are stored in a pre-defined binary format. The translation info database uses a simple record list structure from the BerkeleyDB library.

A large rule dictionary, requires a disk-resident index to support efficient access. The B-tree data-structure is used as the rule database because of

its scaling capabilities and its sorted key storage property which is critical to the operation of the incremental search algorithm.

4.1 Incremental Forest Exploration

The incremental search algorithm finds trees within a forest that are also present in the rule dictionary. Nodes are expanded incrementally to ensure that expansions occur only where there is a possibility of a translation rule when expanded. This section also explains the significance of the breadth-first representation to the working of the algorithm and the reason why depth-first encoding will not work.

The algorithm works on a given source language forest where each node has one or more hyperedges. The function Process_Node in Pseudocode 1 iterates over each node in a forest in order to find the trees originating at that node. The incremental search itself is detailed in function Find_Tree_Increment in Pseudocode 1. The increment finding function is now explained here by assuming that a tree is being processed. It can be extended to work with forests as shown in the pseudocode.

Consider the tree T with k nodes, of which p nodes are leaves, as described in Section 3. The separated breadth-first representation of T, B, is essentially made up of two halves. The first half of B contains node label identifiers while the latter half contains child counts. This is true when the elements of B are considered as integers only, but the ratio is different in the binary form of B where the first half is represented using 4 bytes and the second half uses only 1 byte each. Nevertheless, both halves represent the information of nodes in sequence N, where N is in breadth-first order. To find a tree T in the rule dictionary, the tree has to be translated to the binary encoding of B to be searched in the index. Then, the tree would need to be expanded at p nodes to check if there are any possible rules that match when expanded. The process of finding any expansions of a tree is performed recursively in the function Find_Tree_Increment of Pseudocode 1.

When expanding trees, the data-structure needs to be an efficient one to operate on, since this is a recursive task. The algorithm should also facilitate a simple way of tracking the position in the tree where the expansion is taking place. This can be performed very easily because of a prop-

Pseudocode 1 Incremental search for trees

```
proc Get_Translation_Forest sourceForest
  RuleDB points to the translation rule database
  for node in sourceForest do

    if query is found in RuleDB then
      add query to translation forest
    end if
    if query is found or (query is not found but prefix of
    query is found) then
      call Find_Tree_Increment with query
    end if
  end for

proc Find_Tree_Increment sbfArray
  labels ← first half of sbfArray
  childCounts ← second half of sbfArray
  lastNd ← node corresponding to labels' last element
  startNd ← node imm. after node corresponding to
  childCounts's last non-zero entry
  # startNd contains the node after the last expanded node
  # in breadth-first order
  for node from startNd to lastNd do
    if node doesn't have hyperedges then
      word ← child of node
      appLabel ← labels + [word's label]
      appChild ← childCounts + [0]
      appChild[node] ← the number of children of node
      query ← appLabel + appChild
      if query is present in RuleDB then
        add query to translation forest
      end if
      continue
    end if
    hyperedges ← all hyperedges at node
    for hyperedge in hyperedges do
      numTails ← number of hyperedge's tail nodes
      appLabel ← labels + [hyperedge's tail labels]
      arrayOfZeroes ← [0] * numTails
      appChild ← childCounts + arrayOfZeroes
      appChild[node] ← numTails
      query ← appLabel + appChild
      if query is found in RuleDB then
        add query to translation forest
      end if
      if query is found or (query is not found but prefix of
      query is found) then
        call Find_Tree_Increment with query
      end if
    end for
  end for

proc Separated_Breadth_First tree
  return the separated breadth first representation of tree
```

erty of the breadth-first representation. The property is that, when we expand node n_i in a tree T, and the $depth(n_i) = depth(T)$ or $depth(n_i) = depth(T) - 1$ and $\nexists\ n_j$ where $j > i$ and n_j is expanded, then, the child nodes of node n_i can simply be appended to N. In the function Find_Tree_Increment, the $startNd$ and $lastNd$ variables point to the start and end of expandable nodes in the tree represented by $sbfArray$. The $startNd$ node is located by finding the node immediately after the last expanded node when traversing the sequence N from k to 1. A node n_i is expanded if c_i is greater than 0. Hence, since this pattern exists, the recursive function treats its input parameter as a list and ignores the fact that it's operating on a tree.

A depth-first representation does not support such a property that allows expansions of nodes to be appended at the end of the list. This is because the tree expansion for searching rules is such that when a node is expanded, all its children have to be included at once, due to which expansions of trees in the depth-first method will almost always have child nodes appear in-between the original sequence of nodes. The only exception is when the very last node in the depth-first sequence is expanded. Having successive expansions differ from one another reduces their proximity in the index.

5 Experiments

5.1 Data

We use two rule collections in our experiments. The rules are extracted from 1.5M word-aligned sentence pairs of Chinese and English from the NIST (2010a) machine translation corpus. The first rule collection contains 11.8M Chinese translation rules, of which about 7.8M are for unique trees. All trees are limited to a depth of five levels. The second rule collection contains 33.1M rules, of which 23.9M are unique. The rules in the second collection are binarized but not limited by depth. The rule collections are 285MB and 2.5GB on disk, respectively, when gzipped.

In total, we use three forest collections. The first forest collection contains 254 forests from NIST (2010a) data. The second forest collection contains 288 forests, also obtained by parsing NIST (2010a) data, but they are binarized to work with the second rule collection. The third forest collection contains 348 binarized forests obtained by parsing NIST (2010b) data.

rule set	page size	regular	compressed
1	4K	1001MB	569MB
1	8K	947MB	537MB
1	16K	960MB	525MB
1	32K	954MB	496MB
2	4K	3.1GB	1.6GB
2	8K	3.0GB	1.5GB
2	16K	3.0GB	1.3GB
2	32K	3.0GB	1.2GB

Table 1: Size of B-tree indexes

5.2 Setup

The experiments are run on an Intel Core2Duo processor (2.4GHz; 4MB cache) desktop machine with 2GB of RAM. The operating system is Ubuntu desktop edition version 10.04.2. The index and program are installed on two different hard disks, both having a disk speed of 5400 rpm. The disk on which the code is installed has a page size of 4KB while the index disk has a page size of 8KB.

The index is created using B-tree index structures in the BerkeleyDB (version 5.1) library. The search algorithm is coded in Python and is open sourced[1]. Database accesses from the python program are through a python wrapper for BerkeleyDB called bsddb3[2]. The B-tree indexes are created with and without prefix compression. We also create indexes with four different page sizes (4K, 8K, 16K, and 32K) to analyse the effect of page size on performance. The sizes of the B-tree rule dictionaries are shown in Table 1.

Caching has a significant impact on performance measurements for disk-based searching. There are a minimum of 2 levels of caching while performing the tests. One cache is handled by the database while the other is a disk level cache managed by the operating system. We clear the database cache by choosing an in-memory cache and re-starting the database process when required. The commands *sync;* followed by *echo 3 > /proc/sys/vm/drop_caches;* are used to clear the operating system cache.

Search time is measured using the *datetime* package in Python version 2.6 and cache performance of the database is measured using BerkeleyDB tools. Every test is run three times and the average time is reported. The exact search process

rule set	forest set	baseline	breadth-first
1	1	$\sim$ 23min	1.55sec
2	2	$\sim$ 80min	15.71sec
2	3	$\sim$ 80min	11.49sec

Table 2: Average time to search a forest

is explained in the specific experiment's sections.

5.3 Incremental Tree Matching

Experiment 1: Comparison with baseline

This experiment compares the performance of the baseline system with the breadth-first index based approach. The baseline checks if each rule in the rule dictionary is found in the forest being translated. If found, the rule is added to the translation forest. Almost one-third of the rules in the full rule collection have a common left-hand side. Also, rules with the same left-hand-side have been found to be consecutive in the collection. Therefore, the outcome of previous rule's check is reused if the current rule is same as the previous one.

The average forest search time with the baseline setup is compared with the best breadth-first index based search method in Table 2. The times reported for the incremental breadth-first search are obtained when using a regular 32K page size index. The average time is the ratio of the total time required to search all forests in a forest set, and the number of forests in the set.

Experiment 2: Page size and compression

This experiment compares the effects of page size and compression on the search time in a breadth-first index. For each forest in a forest collection, the time to search the forest is measured. An average of those times across all forests in the collection is shown in Table 3 for indexes of various page sizes, with and without compression.

Experiment 3: Cache utilisation

In order to measure the cache utilisation of the indexes, the forests are searched sequentially without closing the database or clearing the disk cache. A BerkeleyDB utility is then used to obtain the memory usage statistics which displays the cache hit ratio. The cache usage will depend on the order in which the forests are searched and also on the content of the forests. However, the forests are searched in the same order across all indexes, therefore, their relative cache performances can be meaningfully compared.

rule set	forest set	page size	regular (s)	compressed (s)
1	1	4K	2.35	2.09
1	1	8K	2.01	1.93
1	1	16K	1.69	1.86
1	1	32K	1.55	2.01
2	2	4K	20.86	22.90
2	2	8K	25.42	18.52
2	2	16K	17.73	18.69
2	2	32K	15.71	19.62
2	3	4K	14.13	15.03
2	3	8K	17.86	12.78
2	3	16K	12.63	13.16
2	3	32K	11.49	14.03

Table 3: Average time for breadth-first search

5.4 Analysis

From Table 2, it is clear that the baseline method is more than an order of magnitude slower. It can also be observed that forest sets 2 and 3 take about the same amount of time on average over rule set 2. It is therefore clear that the search time for the baseline method is primarily determined by the size of the rule set and not on the size of the forest. Table 3 shows that the best performance in B-tree indexes is always obtained in the uncompressed, or regular, index and when using the 32K page size. However, the performance of the compressed index seems to stabilise and not deteriorate much beyond the 8K page size. Considering that the compressed indexes are almost half the size of the regular index – or even smaller than half in the case of rule set 2 with 16K and 32K page sizes – they might be the better option to consider for very large collections.

The average run times on a collection of forests depend on the properties of individual forests in the collection. A histogram of the number of forests searched in time intervals shows us that when searching a compressed index the search operates faster on already fast searches and slower on the initially-slow searches. Figure 4 and Figure 5 show the histograms for the third set of forests searched using a compressed and an uncompressed index, respectively, each with a page size of 8K. From the figures, it is evident that the number of forests translated in less than 5s – the first stick in the figures – increase in the compressed index, while the slower forests which take about 200s on a regular index take about 250s or

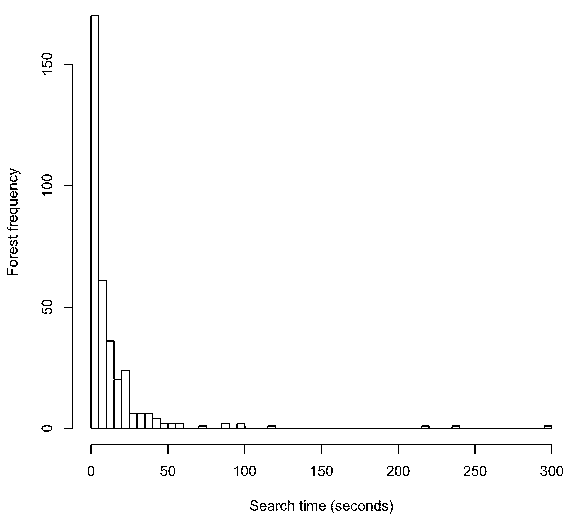

Figure 4: Distribution of forests searched in an 8K compressed index

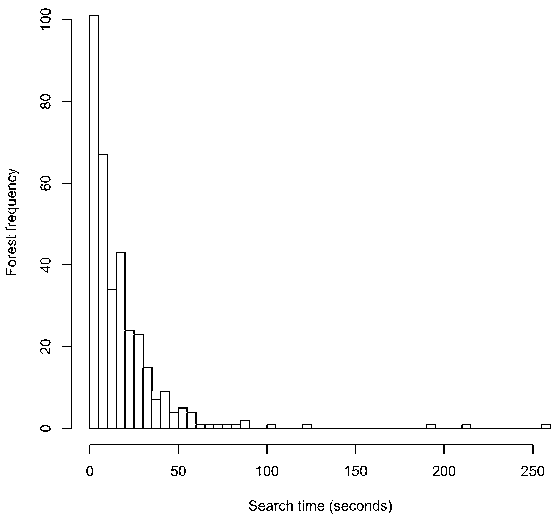

Figure 5: Distribution of forests searched in an 8K uncompressed index

longer on the compressed index. This is true even in other page sizes. Histograms for the 32K page size index – omitted here for lack of space – look similar to Figure 4 and Figure 5, but the compressed index shows a very marginal increase in the number of faster forests and a clear increase in the time for the slower forests. But, even without compression, the 32K index has about the same number of forests translated in less than 5s as the faster 8K compressed index.

Cache utilisation is found to be very high in all cases. The number of pages retrieved from a compressed index is always lower than that for an uncompressed one. Cache misses are clearly not the cause for the slowdown in the compressed indexes. The decompress operation is the most likely reason. However, with compression, more queries, or keys, would fit in one page which may causes a speedup when fewer queries are required while searching a forest.

Another observation is that although rule set 2 is about 3 times as large as rule set 1– both in the number of rules and in the size of the index – the search times do not show a 3-fold increase. This could be the result of various factors. One, the rule set 1 might have more pages cached than rule set 2, because it's a smaller index. Two, the depth of the rules in rule set 1 are limited to 5 whereas the depth is not limited in set 2. We feel that the most likely reason in this case is the first one. However, to verify we would have to test with a larger dataset which is limited in depth.

6 Conclusion and Future Work

We propose a breadth first representation for trees and use that representation in an algorithm to incrementally find all trees in a forest that are also present in a rule dictionary. We compare the performance of the algorithm on two different rule sets and three forest collections. We find our method to outperform an exhaustive search baseline by more than an order of magnitude. We find that the a compressed index provides a balance of fast search and less disk space, but uncompressed indexes are faster with large B-tree page sizes.

In the future, we would like to explore the properties of forests that influence their search time. We would also like to perform more experiments with depth limitation to ascertain if a depth limit improves performance.

Abstract

Word sequential alignment models work well for similar language pairs, but they are quite inadequate for distant language pairs. It is difficult to align words or phrases of distant languages with high accuracy without structural information of the sentences. In this paper, we pro- pose a Bayesian subtree alignment model that incorporates dependency relations be- tween subtrees in dependency tree struc- tures on both sides. The dependency re- lation model is a kind of tree-based re- ordering model, and can handle non-local reorderings, which sequential word-based models often cannot handle properly. The model is also capable of handling multi-level structures, making it possible to find many-to-many correspondences automatically without any heuristic rules. The size of the structures is controlled by non-parametric Bayesian priors. Experimental alignment results show that our model achieves 3.5 points better alignment error rate for English-Japanese than the word sequential alignment model, thereby verifying that the use of dependency information is effective for structurally different language pairs.

1 Introduction

Alignment accuracy is crucial for providing high quality corpus-based machine translation systems because translation knowledge is acquired from an aligned training corpus. For similar language pairs, alignment accuracy is high, and the state-of-the-art word alignment tool GIZA++ has a smaller than 10% alignment error rate (AER) for French-English. GIZA++ is an implementation of the alignment models called the IBM models (Brown et al., 1993), which handle sentences as sequences of words, usually followed by some heuristic symmetrization rules to combine the alignment results in both directions. Since the accuracy is to some extent good for some language pairs, many researchers focus not on alignment, but on translation with more linguistic information incorporated in the models. Phrase-based SMT (Koehn et al., 2003) uses units larger than words, whereas Hiero (Chiang, 2005) used a kind of sentence structure. Various other studies tried incorporating additional linguistic knowledge such as syntactic trees (Chiang, 2010), dependency trees (Menezes and Quirk, 2008), or packed-forests (Tu et al., 2010) in their translation models. Note that all these works are based on the word sequential alignment models.

However, for distant language pairs such as English-Japanese or Chinese-Japanese, the word sequential model is quite inadequate (about 20 to 30 % AER), and therefore it is important to improve the alignment accuracy itself. The differences between languages can be seen in Figure 1, which shows an example of English-Japanese. The word or phrase order is quite different for these languages. Another important point is that there are often many-to-one or many-to-many correspondences. For example, the Japanese noun phrase "受 光 素子" is composed of three words, whereas the corresponding English phrase consists of only one word "photodetector", and the English function word "for" corresponds to two Japanese function words "に は". In addition, there are basically no counterparts for the English articles (a, an, the). Figure 2 shows the alignment results from bi-directional GIZA++ together with a combination heuristic called grow-diag-final-and[1] for the same sentence pair given in Figure 1. The system failed to align some words in the Japanese noun

[1]This is trained on the same corpus used in Section 4.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 794–802,
Chiang Mai, Thailand, November 8 – 13, 2011.

phrase, and incorrectly aligned "the ↔ は ". The word sequential model is prone to many such errors even for short simple sentences of a distant language pair.

Even if the word order differs greatly between languages, phrase dependencies tend to hold between languages. This is also true in Figure 1. Therefore, incorporating dependency analysis into the alignment model is useful for distant language pairs. Cherry and Lin (2003) proposed a model that uses a source side dependency tree structure and constructs a discriminative model. However, the drawback is that the alignment unit is the word, and thus, it can only find one-to-one alignments. The capability of generating many-to-many correspondences is also important because one or more words often correspond to more than one word on the other side.

Nakazawa and Kurohashi (2009) also proposed a model focusing on dependency relations. They modeled phrase dependency relations in dependency trees on both sides. The model is also capable of estimating many-to-many correspondences automatically without any heuristics through maximum likelihood estimation. One serious drawback of their model is that it tends to acquire incorrect larger subtrees. For models that can handle multiple levels (or sizes) of structures, larger structures always defeat smaller ones in maximum likelihood estimation, and the best solution is to align one sentence as a structure with the other for all sentence pairs. Although Denero et al. (2008) solved this degeneracy by placing a Dirichlet process prior over the parameters that can control the size of phrases properly, their Bayesian model again only handles sentences as sequences of words. In this paper, we take advantage of the two studies by Nakazawa et al. and Denero et al., and propose a Bayesian subtree alignment model based on dependency trees to improve alignment accuracy for distant language pairs.

2 Dependency Tree-based Alignment Model

Our model is an extension of the one proposed by Denero et al. (2008). Two main drawbacks of the previous model are the lack of structural information and a naive distortion model. For similar language pairs such as French-English (Marcu and Wong, 2002) or Spanish-English (DeNero et al., 2008), even a simple model that handles sentences as a sequence of words works adequately. This does not hold for distant language pairs such as English-Japanese or Chinese-Japanese, in which word orders differ greatly. We incorporate dependency relations of words into the alignment model and define the reorderings on the word dependency trees. Figure 1 shows an example of the dependency trees for Japanese and English.

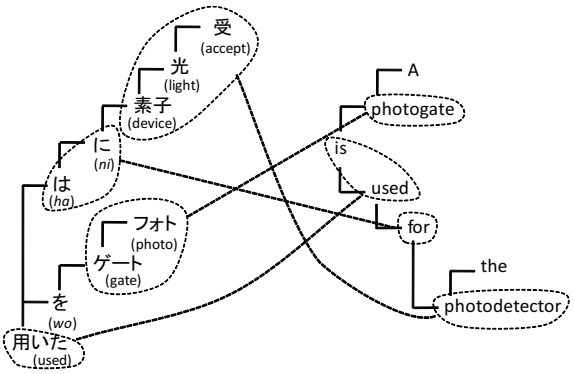

Figure 1: Example of dependency trees and alignment of subtrees. The root of the tree is placed at the extreme left and words are placed from top to bottom.

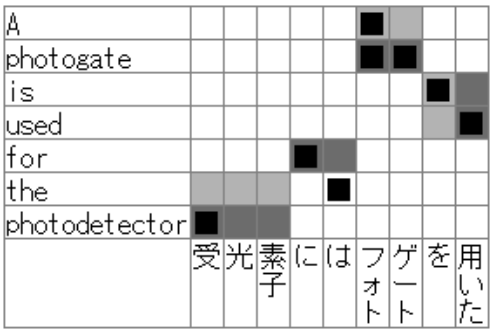

Figure 2: Alignment results from bi-directional GIZA++. Black boxes depict the system output, while dark (Sure) and light (Possible) gray cells denote gold-standard alignments.

2.1 Generative Story Description

Similar to the previous works (Marcu and Wong, 2002; DeNero et al., 2008), we first describe the generative story for the joint alignment model.

1. Generate ℓ concepts from which subtree pairs are generated independently.

2. Combine the subtrees in each language so as to create parallel sentences.

Here, subtrees are equivalent to phrases in the previous works. One subtree in a concept can be NULL, which represents an unaligned subtree. We restrict the unaligned subtrees to be composed of exactly one word, because of our model simplicity (NULL-alignment restriction).

The number of concepts ℓ is parameterized using a geometric distribution:

$$P(\ell) = p_c \cdot (1 - p_c)^{\ell - 1}. \quad (1)$$

Each concept c_i generates a subtree pair $\langle e_i, f_i \rangle$ from an unknown distribution θ_T, and then they are combined in each language. We denote the combinations of subtrees in English as $D_E = \{(j \rightarrow k)\}$, where $(j \rightarrow k)$ denotes that subtree e_j depends on subtree e_k, and in the foreign language as D_F. D refers to D_E and D_F as a whole.

With these notations, the joint probability for a sentence pair is defined as:

$$P(\{\langle e, f \rangle\}, D) = P(\ell) \cdot P(D|\{\langle e, f \rangle\}) \cdot \prod_{\langle e, f \rangle} \theta_T(\langle e, f \rangle). \quad (2)$$

2.2 Subtree Generation

When generating subtrees, we first decide whether to generate an unaligned subtree (with probability p_ϕ) or an aligned subtree pair (with probability $1 - p_\phi$). DeNero et al. (2008) used $p_\phi = 10^{-10}$ to strongly discourage NULL alignment, but this is not reasonable for some language pairs. Taking Japanese and English as an example, English determiners (a, an, the) and Japanese case markers (*ha*, *ga*, *wo*, etc.) rarely have counterparts. In addition, if the corpus is less clean and sentence pairs often contain a different amount of information, the strict restriction may lead to alignment errors. Therefore, we use $p_\phi = 0.33$.

Aligned subtree pairs are generated from an unknown probability distribution θ_A, which obeys the Dirichlet process (DP):

$$\theta_A(\langle e, f \rangle) \sim DP(M_A, \alpha_A), \quad (3)$$

where M_A is the base distribution and α_A is a concentration parameter. The base distribution is defined as:

$$\begin{aligned} M_A(\langle e, f \rangle) &= [P_f(f) P_{WA}(e|f) \cdot P_e(e) P_{WA}(f|e)]^{\frac{1}{2}} \\ P_f(f) &= p_t \cdot (1 - p_t)^{|f|-1} \cdot \left(\tfrac{1}{n_f}\right)^{|f|} \\ P_e(e) &= p_t \cdot (1 - p_t)^{|e|-1} \cdot \left(\tfrac{1}{n_e}\right)^{|e|}, \end{aligned} \quad (4)$$

where P_{WA} is the IBM model1 likelihood (Brown et al., 1993), and n_f and n_e are the numbers of word types in each language. θ_A gives a non-zero weight to aligned subtree pairs only.

Unaligned subtrees are generated from another unknown probability distribution θ_N:

$$\begin{aligned} \theta_N(\langle e, f \rangle) &\sim DP(M_N, \alpha_N) \\ M_N(\langle e, f \rangle) &= \begin{cases} P_{WA}(e|\text{NULL}) & \text{if } f = \text{NULL} \\ P_{WA}(f|\text{NULL}) & \text{if } e = \text{NULL} \end{cases}. \end{aligned} \quad (5)$$

θ_N gives a non-zero weight to unaligned subtrees only. Note that unaligned subtrees are always composed of only one word in our model. Finally, θ_T can be decomposed as:

$$\theta_T(\langle e, f \rangle) = p_\phi \theta_N(\langle e, f \rangle) + (1 - p_\phi) \theta_A(\langle e, f \rangle). \quad (6)$$

2.3 Dependency Relation Probability

Instead of the naive reordering model in the previous work, our model considers dependency relations between subtrees and assigns a weight to each relation. Suppose subtree f_j depends on subtree f_k (parent subtree), which means $(j \rightarrow k) \in D_F$, and both f_j and f_k are aligned subtrees. Their counterparts, e_j and e_k respectively, are somewhere on the dependency tree of the other side. We can assume that e_j tends to depend on e_k because the dependencies between concepts hold across languages. The dependency relation probability reflects this tendency.

Formally, we extract a tuple $(N(f_j), rel(f_j, f_{j'}))$ for subtree f_j, and assign the dependency relation probability to that tuple. For unaligned subtrees, the dependency relation probability is not taken into consideration. If the parent subtree is an unaligned subtree, we ascend the dependency tree to the root node until an aligned subtree is found. We call the nearest aligned subtree a *pseudo parent*. The pseudo parent for subtree f_j is denoted as $f_{j'}$, and the number of unaligned subtrees from f_j to $f_{j'}$ is denoted as $N(f_j)$. We consider an imaginary root node as a pseudo parent for the root subtree. For example, the parent subtree of "フォト ゲート (photogate)" is "を (accusative)" which is unaligned in Figure 1. The pseudo parent is "用いた (used)" and the number of unaligned subtrees $N = 1$. Japanese function words are often unaligned, similar to this example, but the dependency relations between subtrees stepping over the function words are assumed to hold on

the other side. Therefore we introduce a pseudo parent to capture the relations.

Function $rel(f_j, f_{j'}))$ returns a dependency relation between the counterparts of the two arguments. Note that the counterparts of f_j and $f_{j'}$ are e_j and $e_{j'}$, respectively. We express a dependency relation as the shortest path from one subtree to another. For simplicity, we indicate the path with a pair of non-negative integers, where the first is the number of steps going up (Up) the dependency tree and the other is the number going down ($Down$). It also requires one additional step for going through unaligned subtrees. For example, in Figure 1, traveling from "A photogate" to "photodetector" requires 1 step going up (to reach "is used") and 2 steps going down (via "for"), so the dependency relation is $(Up, Down) = (1, 2)$. Consequently, the tuple is represented as a triplet of non-negative integers $R_f = (N, Up, Down)$.

The dependency relation probabilities for the foreign language side are drawn from an unknown probability distribution θ_{fe} and for the English side from θ_{ef}, with both obeying the DP:

$$\begin{aligned} \theta_{fe}(R_f) &\sim DP(M_{fe}, \alpha_{fe}) \\ M_{fe}(R_f) &= p_{fe} \cdot (1 - p_{fe})^{N+Up+Down-1} \\ \theta_{ef}(R_e) &\sim DP(M_{ef}, \alpha_{ef}) \\ M_{ef}(R_e) &= p_{ef} \cdot (1 - p_{ef})^{N+Up+Down-1}. \end{aligned} \quad (7)$$

Using the notations and definitions above, the dependency tree-based reordering model $P(D|\{\langle e, f\rangle\})$ is decomposed as:

$$P(D|\{\langle e, f\rangle\}) = \prod_{\langle e,f\rangle} \theta_{fe}(R_f) \cdot \theta_{ef}(R_e). \quad (8)$$

3 Model Training

We train the model by means of a collapsed Gibbs sampling, which has been used in some recent NLP works (DeNero et al., 2008). In a Gibbs sampling, we first need to initialize the states of the training data, such as the boundaries between subtrees and their alignments, and also initialize the latent variables according to the initial states of the data. Starting with the initial state, we generate many samples in order from the last state by changing a small local point. Normalizing the counts in the samples yields the parameter estimations.

3.1 Initialization

We initialize the states of the training data by heuristically merging bi-directional alignment results of the standard word alignment tool GIZA++. Many machine translation studies use heuristics to combine the two alignment results, one of which is called grow-diag-final-and (Koehn et al., 2007). Our heuristic is similar to this, but the difference is that we combine the two results based on dependency trees, and not on word sequences. The initialization is carried out by the following steps:

1. Take the intersection of the two results.
2. Add alignment points connected to at least one accepted point in terms of the dependency tree (corresponds to grow-diag).
3. Add alignment points between two unaligned words (corresponds to final-and).

Initial boundaries of subtrees and their alignments, and also the counts of subtree pairs and dependency relations are thus acquired.

3.2 Sampling Operators

Our sampler uses three operators repeatedly to generate samples. The operators are illustrated in Figure 3. A solid circle represents a single word, while a subtree is depicted as the part surrounded by a dotted line. Alignment links between subtrees are represented by broken lines.

Each application of an operator generates one new sample, and of course we could use all the generated samples. However, successive samples are almost the same, except for one local part. It is no use keeping all the samples, so we keep only one sample, which is the final outcome after applying all the operators to all the possible points in all the sentence pairs in the training corpus.

SWAP

The SWAP operator exchanges the counterparts of two subtrees with each other. Boundaries between subtrees and the number of aligned subtrees in the sentence pair are fixed. There are two cases for SWAP:

1. Both of the subtrees are aligned (SWAP-1).
2. One of the two subtrees is unaligned and the other is composed of only one word (SWAP-2).

An illustration of the result of the SWAP operator is shown at the top of Figure 3.

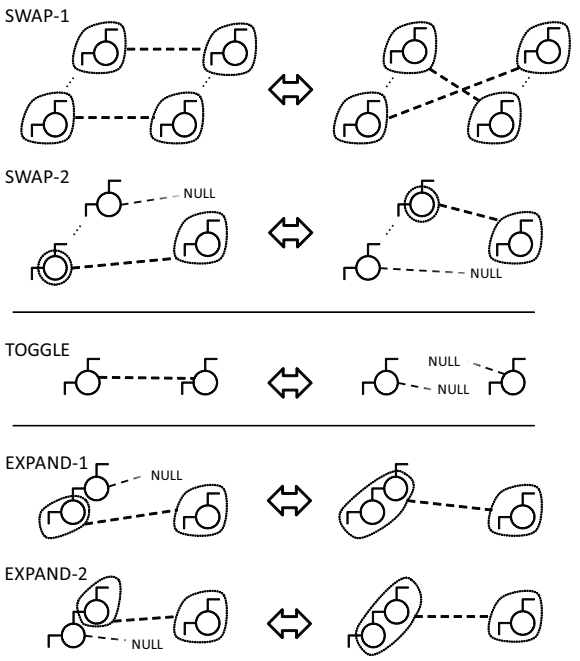

Figure 3: Illustration of the operators.

TOGGLE

The TOGGLE operator adds or removes an alignment. If f_j and e_k are both unaligned subtrees, TOGGLE links these two subtrees. Alternatively, if f_j and e_j are aligned, TOGGLE cuts the link and makes each of the subtrees unaligned. Because of the NULL-alignment restriction, TOGGLE does nothing if f_j or e_j is composed of more than one word. Boundaries between subtrees are fixed. An illustration of the TOGGLE operation is shown in the middle of Figure 3.

EXPAND

The EXPAND operator expands or contracts an aligned subtree. If an unaligned subtree is next to an aligned one, EXPAND tries to merge the unaligned and aligned subtrees. It also tries to exclude a marginal node from a subtree, and to make the excluded node unaligned. There are two cases for EXPAND:

1. A node is added to a subtree as a new leaf node, or a leaf node of a subtree is excluded (EXPAND-1).

2. A node is added to a subtree as the new root node, or the root node of a subtree is excluded (EXPAND-2).

EXPAND-1 does not have any restrictions on its operation. However, for EXPAND-2, if the root node has more than one child node inside the subtree, it cannot exclude the root node, because the subtree will be divided into two subtrees by the exclusion, and it is impossible to return to the previous state. Operators in a Gibbs sampler must be able to return the same status by immediately reapplying the same operator to the same point. An illustration of the EXPAND operation is shown in Figure 3.

3.3 Computational Complexity and Parallel Sampling

The distortion model of the previous work does not consider any relations to neighboring phrases, so any operation does not affect the distortions of neighboring phrases. On the contrary, our proposed model considers the relations, and this leads to an increase in the computational complexity for one operation. For example, swapping two aligned subtree pairs requires re-calculation of the dependency relation probabilities for not only the four focused subtrees, but also subtrees whose pseudo parent is one of the focused subtrees. This is the same for the TOGGLE operation.

To make matters worse, the EXPAND operator requires much more. All the subtrees that traverse the locally changed subtree, 1) in finding a pseudo parent, and 2) in finding the dependency relations, need re-calculation of the dependency relation probabilities, because the number of steps (N, Up and $Down$) will change.

This increase in computational complexity makes the training time much longer, so that it is impossible to train using a single CPU. To alleviate this problem somewhat, we divide the training data into several parts and execute sampling in parallel. The overall flow of model training is summarized as follows:

1. Initialize the training corpus and current counts of subtree pairs and dependency relations, and divide the corpus into several sections.

2. Start sampling in parallel using the same current counts, and generate one sample from each section. A sample is the final state of the section.

3. Gather samples and update the current counts by counting subtree pairs and dependency relations in the samples.

4. Go back to step 2.

4 Alignment Experiments

We conducted alignment experiments on English-Japanese and Chinese-Japanese corpora to show the effectiveness of the proposed model.

4.1 Settings

For English-Japanese, the JST[2] paper abstract corpus was used. This corpus was created by NICT[3] from JST's 2M English-Japanese paper abstract corpus using the method of Utiyama and Isahara (2007). For Chinese-Japanese, we used the paper abstract corpus provided by JST and NICT. This corpus was developed during a project in Japan called the "Development and Research of Chinese-Japanese Natural Language Processing Technology". The statistics of these corpora are shown in Table 4.1. Unfortunately, these two corpora are not freely available now, but they will become available to everyone in near future.

As gold-standard data, we used 479 sentence pairs of English-Japanese and 510 sentence pairs of Chinese-Japanese. These were annotated by hand using two types of annotations: sure (S) alignments and possible (P) alignments (Och and Ney, 2003). The unit of evaluation was the word for all the languages. We used precision, recall, and alignment error rate (AER) as evaluation criteria. All the experiments were run on the original forms of words. The hyper parameters for our model used in the experiments are summarized in Table 4.1.

Japanese sentences were converted into dependency structures using the morphological analyzer JUMAN (Kurohashi et al., 1994), and the dependency analyzer KNP (Kawahara and Kurohashi, 2006). For English sentences, Charniak's nlparser was used to convert them into phrase structures (Charniak and Johnson, 2005), and then they were transformed into dependency structures by rules defining head words for phrases. Chinese sentences were converted into dependency trees using the word segmentation and POS-tagging tool by Canasai et al. (2009) and the dependency analyzer CNP (Chen et al., 2008).

For comparison, we used GIZA++ (Och and Ney, 2003) which implements the prominent sequential word-based statistical alignment model

of the IBM Models. We conducted word alignment bidirectionally with the default parameters and merged them using the grow-diag-final-and heuristic (Koehn et al., 2003). Furthermore, we used the BerkeleyAligner[4] (DeNero and Klein, 2007) with default settings for unsupervised training. Experimental results for English-Japanese are shown in Table 4.1, and those for Chinese-Japanese are shown in Table 4.1. The alignment accuracy of the initialization described in Section 3.1 is indicated as "Initialization", while the accuracy after conducting Gibbs sampling is indicated as "Proposed".

4.2 Discussion

For English-Japanese, our proposed model achieved reasonably high alignment accuracy compared with that of GIZA++ and the BerkeleyAligner. Using tree structures combined with the bi-directional alignment results leads to better accuracy than the original sequential heuristic (indicated as Initialization). We also give the alignment accuracy obtained by Nakazawa and Kurohashi (2009) (indicated as Nakazawa+ in Table 4.1, and applicable only to the English-Japanese corpus)[5]. Their model suffered from a degeneracy in acquiring larger phrases caused by maximum likelihood estimation, and this led to low precision and high recall. Compared with their model, our proposed model overcomes the degeneracy and outperforms in terms of both precision and recall. Figure 4 shows an example of the improvement in alignment. GIZA++ aligned function words incorrectly because of the lack of structural information. For example, GIZA++ aligned the English "of" and the Japanese "の"

[4]http://code.google.com/p/berkeleyaligner/

[5]They used 475 sentence pairs instead of 479 sentence pairs of ours. The difference comes from the inconsistency of word segmentations of Japanese, but it is negligibly small.

in the third word. This was incorrectly derived from the combination heuristic: English posterior word "other" and Japanese prior word "その他" are aligned by intersection, and thus, "of ↔ の" is also aligned through the grow-diag heuristic. This could be avoided by introducing dependency trees: the English words "of" and "other" are not contiguous in the dependency tree. In addition, there is no correspondence between "に ついて の ↔ of". This is a rare translation for "of", which is most frequently translated as "の", so GIZA++ aligned "の ↔ of" only. A nonparametric Bayesian model is capable of finding the correct alignment with the support of occurrences of the subtree pair elsewhere in the training corpus.

The reasons for recall being significantly lower than precision in all the models are summarized in the two points. One is the separation between gold-standard criteria and system output. In Figure 4, "are described" and "を 取りまとめた" are aligned in their entirety, but the system found one-to-one alignments, which are also acceptable. The other is that it is sometimes hard to align part of a sentence in a smaller unit for distant language pairs, because the expressions are quite different. In such cases, the system is obliged to align expressions enmasse, which leads to low recall.

For Chinese-Japanese, we failed to improve alignment accuracy greatly. A major cause of this undesirable result could be the accuracy of the Chinese parser. Both the English and Japanese parsers used in the experiments can analyze sentences with over 90% accuracy, whereas the accuracy of the Chinese parser is less than 80% despite it being state-of-the-art in the world (Chen et al., 2008). The parsing accuracy reported in this paper was obtained from an experiment using gold-standard word segmentation and POS-tags. Starting with raw sentences results in about 77.4% accuracy. This information was obtained from communication with the authors. Fundamental NLP technologies in each language must be improved in the long term, and sophisticated models, which use deeper analysis of sentences like our model, should become effective in the near future. One possible short-term solution for the parsing problem is to use the n-best parsing results in the model. Another kind of solution was proposed by Burkett et al. (2010), who described a joint parsing and alignment model that can exchange useful information between the parser and aligner.

However, even in the case of Chinese-Japanese alignment, we achieved higher precision than GIZA++. For translation, precision is more im-

portant than recall. The BerkeleyAligner showed much higher precision than GIZA++ and, in Chinese-Japanese alignment, than our model as well. However, recall was quite low compared with all the other models. Lower recall results in a large translation table because the phrase extraction heuristics 'grow' over each unaligned word.

5 Translation Experiments

We conducted Japanese-to-English translation experiments on the same corpus used in the alignment experiment. We translated 500 paper abstract sentences from the JST corpus. Note that these sentences were not included in the training corpus. We used the state-of-the-art phrase-based SMT toolkit Moses(Koehn et al., 2007) with default options, except for the distortion limit ($6 \rightarrow 20$). It was tuned by MERT using another 500 development sentence pairs.

Table 5 shows the BLEU scores for the translations. Although the difference in alignment accuracy between grow-diag-final-and and Initialization is small, the BLEU score was improved by 0.74 point. This is because syntactic information reduced incorrect alignment points and the quality of translation table becomes better. This result provided evidence that syntactic knowledge is useful for distant language pairs. However, the BLEU score decreased after iterations of our alignment model. The main reason is that the alignment result of our model is not compatible with Phrase-based SMT. Our model often output sequentially discontiguous alignments which are harmful for PSMT to create fine-grained phrase table. We need to use other decoders which is compatible with our alignment model (Nakazawa and Kurohashi, 2010), and we believe that our model leads to better translation quality.

6 Conclusion

In this paper, we proposed a linguistically-motivated nonparametric Bayesian subtree alignment model based on dependency tree structures for distant language pairs. The model incorporates the tree-based reordering model. It also solves the degeneracy of the maximum likelihood estimation for models capable of handling multiple levels of structures by placing a Dirichlet process prior over parameters. Experimental results show that a word sequential model does not work well for distant language pairs, but that this can be addressed by using syntactic information. Our proposed model achieved a lower AER by about 3.5 points compared with GIZA++.

To support allegation that syntactic information is important for distant language pairs, it is necessary to compare our model with the original word sequential study (DeNero et al., 2008), which was consulted often. It is also important to apply our model not only to other distant language pairs, but also to similar language pairs, and to investigate the results. We are planning to use standard data set such as NIST or IWSLT. Also, we could use the n-best parsing results in our model to alleviate the error propagation from parsing, especially for Chinese.

Abstract

This paper proposes a novel method to resolve the coverage problem of SMT system. The method generates paraphrases for source-side sentences of the bilingual parallel data, which are then paired with the target-side sentences to generate new parallel data. Within a statistical paraphrase generation framework, we employ an object function, named Sentence Novelty, to select paraphrases which having the most novel information to the bilingual training corpus of the SMT model. Meanwhile, the context is considered via a language model in the source language to ensure the fluency and accuracy of paraphrase substitution. Compared to a state-of-the-art phrase based SMT system (Moses), our method achieves an improvement of 1.66 points in terms of BLEU on a small training corpus which simulates a resource-poor environment, and 1.06 points on a training corpus of medium size.

1 Introduction

Current statistical machine translation (SMT) systems learn how to translate by analyzing bilingual parallel corpora. Generally speaking, high-quality translations can be produced when ample training data is available. Previous studies have indicated that the translation quality can be improved by 2 points of BLEU (Papineni et al., 2002) when the size of the parallel data is doubled (Koehn et al., 2003). However, for the so called *low density* language pairs that do not have large-scale parallel corpora, limited amount of training data usually leads to a problem of low coverage in that many phrases encountered at run-time have not been observed in the training data. According to Callison-Burch et al. (2006), for a training corpus containing 10,000 words, translations will have been learned for only 10% of the unigrams in the test set. For a training corpus containing 100,000 words this increases to 30%. This problem becomes more serious for higher-order n-grams, and for morphologically richer languages.

To overcome the coverage problem of SMT, besides the efforts of mining larger parallel corpora from various resources, some researchers have investigated to use paraphrasing approaches. The studies can be classified into two categories by the target of paraphrasing: (1) paraphrasing the input source sentences; (2) paraphrasing the training corpus. In the first category, the proposed approaches mainly focus on handling n-grams that are unknown to the SMT model. Callison-Burch et al. (2006) and Marton et al. (2009) paraphrase unknown terms in the input sentences using phrasal paraphrases extracted from bilingual and monolingual corpora. Mirkin et al. (2009) rewrite unknown terms with entailments and paraphrases acquired from WordNet. Onishi et al. (2010) and Du et al. (2010) build paraphrase lattices for input sentences and select the best translations using a lattice-based SMT decoder. In the second category of paraphrasing training corpus, Bond et al. (2008) and Nakov (2008) paraphrase the source side of training corpus using hand-crafted rules.

In this paper, we propose a method that enriches SMT training data using a statistical paraphrase generating (SPG) model. The method generates paraphrases for the source-side sen-

tences of the bilingual parallel data, which are then paired with the target-side sentences to generate new parallel data. The procedure is illustrated in Figure 1. The SPG framework can be considered as an application-specific source-to-source translating procedure (Zhao et al. 2009) which is similar to phrase based statistical machine translation. We employ an object function, named *Sentence Novelty*, to select paraphrases that introduce the most novel information to the bilingual training corpus. In our approach, the context of paraphrasing substitution is considered during generating paraphrasing sentences, which yields paraphrases with higher precision. Experimental results show that the performance of a state-of-the-art phrase based SMT system (Moses in this work) can be improved from 17.91 to 19.57 in terms of BLEU on a small training set, and from 25.46 to 26.52 on a training corpus of medium size. Results also indicate that our method gains a significant improvement over the method of Callison-Burch et al. (2006).

The rest of this paper is structured as follows. We review related work on improving SMT through paraphrasing in Section 2. The proposed statistical paraphrase generation model is described in Section 3. Section 4 presents our method of enlarging training data via paraphrasing. Section 5 and 6 present the experiments and results. We discuss our work in Section 7 and conclude the paper in Section 8.

2 Related Work

Previous studies on improving SMT through paraphrasing input sentences mainly focus on finding translations for unknown terms using phrasal paraphrases. In these methods, an unknown term can be paraphrased to a known term which has translations in the phrase table. Callison-Burch et al. (2006) acquire phrasal paraphrases from bilingual parallel corpora based on a pivot approach. The main idea is that phrases aligned with the same foreign phrase in a bilingual corpus may be paraphrases. The learned paraphrases are applied in a SMT system in the following manner. Suppose e_1 is an unknown source phrase, e_2 is a paraphrase of e_1, which can be translated as f in the phrase table, the method simply takes f as e_1's translation. A new phrase pair (e_1, f) is added to the phrase table with an additional feature $h(f, e_1)$ to distinguish the original phrase pairs and the newly generated ones, which is defined as:

$$h(f, e_1) = \begin{cases} p(e_2|e_1) & \text{If phrase table entry } (f, e_1) \text{ is generated from } (f, e_2) \\ 1 & \text{Otherwise} \end{cases}$$

where $p(e_2|e_1)$ denotes the paraphrase probability.

Marton et al. (2009) propose a method similar to that of Callison-Burch et al. (2006). The only difference is that the paraphrases are extracted from monolingual corpora based on distributional hypothesis. Compared with bilingual corpora, it is easier to acquire monolingual corpora, especially for resource-poor languages.

Mirkin et al. (2009) utilize paraphrases and entailment rules, namely the synonyms and hyponyms from WordNet, to substitute unknown terms in source sentences. Some context models are also used for ranking and filtering the paraph-

rases and entailments before feeding them to the SMT engine.

Onishi et al. (2010) and Du et al. (2010) build paraphrase lattices for the input sentences. In this scenario, paraphrases are in fact competing with each other. All possible paraphrases are kept and finally selected by the SMT decoder.

Experimental results in these works have proved that the methods that paraphrase input sentences indeed improve SMT results by increasing coverage, especially on small training sets. However, the approaches have two problems. The first one is efficiency. All of the methods that improve SMT through paraphrasing input sentences can be considered as a two-stage procedure, i.e., collecting paraphrases for unknown terms and then translating. Obviously, low efficiency is the bottleneck for this kind of method, since it goes through decoding twice, one for paraphrasing and one for translating. The other problem is that the context is not considered during phrasal paraphrase substitution, which causes a low paraphrasing accuracy. Notice that many paraphrase substitutions are acceptable only in specific contexts. For example, *bank* and *shore* are paraphrases, but we can only substitute *bank* with *shore* in a context related to rivers. Without considering the paraphrase's context, the paraphrasing substitution has a relatively low accuracy, which limits the effect of these methods. The only exception is the work of Mirkin et al. (2009), which uses context models for ranking paraphrases. However, the generated paraphrases without paraphrasing probabilities are difficult to be incorporated with a statistical context model. As described in Mirkin et al. (2009), the main contribution of context models was to reduce the number of paraphrase candidates and improve the efficiency of the system. In contrast, in our method, all the work that enriches SMT with paraphrases is conducted in the training step, which avoids affecting the decoding procedure. Meanwhile, the context of paraphrase substitution is considered using a source language model in our method.

Other researches directly enlarge SMT training corpora based on paraphrase techniques. Nakov (2008) employs six rules for paraphrasing the training corpus. Here we list two rules as examples:

1. $[_{NP}$ **NP**$_1$ ***of*** **NP**$_2$] → $[_{NP}$ **NP**$_2$ **gen NP**$_1$]
the lifting of the beef import ban → the beef import ban's lifting
2. **NP**$_{gen}$ → **NP**
Commissioner's statement→Commissioner statement

where: gen is a genitive marker: ' or 's; NP$_{gen}$ is an NP with an internal genitive marker.

Bond et al. (2008) use grammars to paraphrase the source side of training data, covering aspects like word order and minor lexical variations (tenses etc.) but not content words. The paraphrases are added to the source side of the corpus and the corresponding target sentences are duplicated.

The above-mentioned methods that expand training data via paraphrasing have two disadvantages: (1) hand-crafted paraphrasing rules are language-dependent; (2) to ensure the paraphrase accuracy, only some simple paraphrase rules are used. Our work should be classified into this category. But a clear difference is that our paraphrase generation method is a statistical one without any language specific feature, which (1) utilizes paraphrase resources extracted from large-scale corpora; (2) balances the accuracy and variation rate of paraphrases with a decoding algorithm that searches for the optimal path among all the paraphrasing candidates.

3 Paraphrase Generation

3.1 Paraphrasing Framework

We employ an application-driven statistical paraphrase generation framework which is proposed by Zhao et al. (2009). The framework is based on a log-linear model in which three sub-models are defined, namely, a paraphrase model, a language model and a usability model, which control the adequacy, fluency and usability of the paraphrases, respectively.

Paraphrase generation is a decoding process similar to SMT. The input sentence S is first segmented into a sequence of I units $\bar{s}_1^I$, which are then paraphrased to a sequence of units $\bar{t}_1^I$. Let $(\bar{s}_i, \bar{t}_i)$ be a pair of paraphrase units, their paraphrase likelihood is computed using a score function $\varphi_{pm}(\bar{s}_i, \bar{t}_i)$. Thus the paraphrase score $p_{pm}(\bar{s}_1^I, \bar{t}_1^I)$ between S and T is decomposed into:

$$p_{pm}(\bar{s}_1^I, \bar{t}_1^I) = \prod_{i=1}^{I} \varphi_{pm}(\bar{s}_i, \bar{t}_i)^{\lambda_{pm}}$$

where λ_{pm} is the weight of the paraphrase model.

A four-gram language model is employed to ensure the fluency and eliminate the ambiguity of paraphrase. The language model based score for the paraphrase T is computed as:

$$p_{lm}(T) = \prod_{j=1}^{J} p(t_j \mid t_{j-3} t_{j-2} t_{j-1})^{\lambda_{lm}}$$

where J is the length of T, t_j is the j-th word of T, and λ_{lm} is the weight for the language model.

The usability model prefers paraphrase units that are more suitable for the application. The usability of T depends on paraphrase units it contains. We propose a specific usability model to enrich SMT training corpus, which is described in chapter 3.2.

3.2 Sentence Novelty Model

In this paper, we do not limit our method to handling unknown terms. Instead, our goal is to grub knowledge from paraphrases and enrich the translation corpora. Therefore, within the application-driven paraphrase generation framework, we propose a specific paraphrasing usability model, *sentence novelty*, for selecting paraphrases which contain the most novel n-grams to the translation model. Given a paraphrased sentence T, which consists of J words, the novelty function $Novel(TM,T,n,j)$ judges whether the occurrence of t_j generates a new n-gram to the translation model (TM) according to the prior n-1 words of t_j. Formally, the novel function for position j can be defined as:

$$Novel(TM,T,n,j) \begin{cases} 1 & \text{If } t_{j-n+1}\ldots t_j \text{ is a new n-gram to } TM \\ 0 & \text{otherwise} \end{cases}$$

Thus the novelty model for a paraphrased sentence T, considering the novelty of 1-gram to N-gram (N=4 in this work), is computed as:

$$p_{nm}(t) = \exp\Big(\sum_{j=1}^{J}\sum_{n=1}^{N} Novel(TM,t,n,j)\Big)^{\lambda_{nm}}$$

where λ_{nm} is the weight for the novelty model,

Now we can describe the complete formula of the SPG framework as:

$$p(T \mid S) = \lambda_{pm}\sum_{i=1}^{I}\log\varphi_{pm}(\bar{s}_i,\bar{t}_i) + \lambda_{lm}\sum_{j=1}^{J}\log p(t_j \mid t_{j-3}t_{j-2}t_{j-1}) + \lambda_{nm}\sum_{j=1}^{J}\sum_{n=1}^{N} Novel(TM,T,n,j)$$

4 Expanding SMT Training Corpus

4.1 Corpus Expansion

We enhance the SMT model by expanding the training corpus using paraphrases. Firstly, the sentence-level paraphrases are generated on the source side (English in our experiments) of the training bi-texts. Then the paraphrased sentences and the corresponding translations on the target side (Chinese in this work) which align with the original sentences compose new bilingual sentence pairs.

To grub knowledge from paraphrases as much as possible, we exploit two different strategies for paraphrase generation in the experiments: (1) generating 1-best paraphrase for every source sentence in the training corpus, and (2) generating k-best paraphrases for a source sentence and selecting m sentences from them which have the most novel n-grams. Thus we get two paraphrased bilingual corpora besides the original corpus. Sentence pairs generated by the two strategies are shown in Table 1. From the table, it can be seen that on the source side the 1-best paraphrase sentence has a relatively high quality, while the sentences selected from k-best paraphrase results have lower accuracy but higher coverage. On the target side, the original Chinese sentence is just copied to align with the generated paraphrase sentences.

4.2 Paraphrase Selecting Strategy

As mentioned above, in strategy (2) we selected m paraphrases in the generated top-k results, which have the most different n-grams. The reason of not using all the k-best results for improving SMT is that the top-k paraphrases generated for a sentence are generally very similar, if we train the SMT model on all these sentences, it would be quite time-consuming and much of the computation is vain. Therefore we propose an algorithm to select a subset from all the paraphrase sentences, which can cover most of the newly introduced information while dramatically reduce the numbers of paraphrases. The algorithm is described in Figure 2.

```
1:procedure SENTENCE_SELECTION
2:input: m, set S {k-best paraphrase sentences:S1,…,Sk}
3:todo: select m sentences from set S
4:  M := {S1}, remove S1 from S
5:  while (|M| < m)
6:    MAX_DISTANCE := 0
7:    i-max := 0
8:    for Si := each sentences in S
9:       Ai := AVERAGE_EDIT_DISTANCE(Si,M)
10:      if Ai > MAX_DISTANCE
11:        MAX_DISTANCE := Ai
11:        i-max = i
12:   M := M ∪ {Si-max}, remove Si-max from S
13: return M
```

Figure 2: The algorithm for paraphrase selection.

Table 1: Examples of generated sentence pairs.

At the beginning of the algorithm, the selected sentence set M is empty. In each iteration, we select a sentence $S_{i\text{-}max}$ from the k-best paraphrase sentence set S and add it to M. In the selection of $S_{i\text{-}max}$, we calculate the average Edit Distance (ED) between each candidate sentence S_i and all sentences in M by the function of AVERAGE_EDIT_DISTANCE(S_i,M). The sentence most different (with the largest average ED) from the already selected sentences in M is selected. In the algorithm, the edit distance among the sentences in M has been considered as the optimization objective function, which ensures the sentences with most novel n-grams are selected.

4.3 Model Integrating

After corpus expansion, we get three bilingual corpora for SMT training: (1) the original corpus, (2) corpus of 1-best paraphrases on the source side and original translations on the target side, (3) corpus of selected m paraphrases on the source side and original translations on the target side. Notice that the reliability of the three corpora is in a descending order. The original corpus which is produced by human can be considered as golden standard corpus. The quality of corpus consisting of 1-best paraphrases (*1-PARA* corpus in the following context) is lower than the original corpus. The corpus of m paraphrase sentences which were selected from the k-best paraphrase results by the algorithm described in 4.2 (namely, *M-PARA* corpus) may be the most noisy.

Considering the different reliabilities of these corpora, simply merging them into a new corpus and train a translation model is not the optimal solution. Therefore, within a phrase-based SMT framework, we train three phrase tables from these corpora, and then integrate these phrase tables with different weights. The integration is a procedure of linear interpolation which can be described in the following formula:

$$PT = \sum_{i=1}^{n} \lambda_i PT_i$$

where λ_n is weight of PT_n, which is set up empirically.

We first merge the phrase tables trained from the original corpus and *1-PARA* corpus, and get a new phrase table (Original + *1-PARA*). Then we integrate the Original + *1-PARA* phrase table with the phrase table trained from the *M-PARA* corpus and get another phrase table (Original + *1-PARA* + *M-PARA)*. The effectiveness of these enriched phrase tables is tested in the experimental section.

5 Experimental Setup

5.1 Paraphrase Resources

The paraphrase generating framework we used is not limited to a certain type of paraphrase resource. Any paraphrase resources with paraphrasing probability can be integrated into the framework. We simply choose phrasal paraphrases acquired from the Europarl corpus using Callison-Burch's paraphrase extracting toolkit[1]. The toolkit supports extraction of both phrasal paraphrases and syntactically constrained paraphrases. In this paper, we only use the phrasal paraphrase extracting part of the toolkit which extracts paraphrases from bilingual corpus using

[1] http://cs.jhu.edu/~ccb/howto-extract-paraphrases.html

pivot method (Colin Bannard and Chris Callison-Burch. 2005).

We extract phrasal paraphrases for all n-grams ($n \leq 6$) in the source sentences in the training data. Some operations are performed on the extracted phrasal paraphrases to ensure the accuracy: (1) paraphrases with score < .03 are filtered out, (2) paraphrases consisting of nothing but stop-words are removed.

5.2 SMT Data

For the baseline system, we trained on the Sinorama and FBIS corpora (LDC2005T10 and LDC2003E14). After tokenization and filtering, this bilingual corpus contained 319,694 lines (7.9M tokens on Chinese side and 9.2M tokens on English side). We trained a 4-gram language model on the Chinese side of the bi-text. Then we randomly selected 29,000 lines form the bi-text, and constructed a reduced training corpus to simulate a resource-poor language. We tested the system using the English-Chinese NIST MT 2008 evaluation set. The test set contains 1859 English sentences, each of which has four human references for automatic evaluation. For development, we used the Chinese-English NIST MT 2005 evaluation set, taking one of the English references as source, and the Chinese source as a single reference translation. All the Chinese sentences in the training corpora were segmented with the word segmentation tool from Language Technology Platform (LTP)[2]. We used two metrics, BLEU[3] and TER[4] (Snover et al., 2005), for automatic evaluation. Following the evaluation standard of NIST, the system translations and references were split into Chinese characters in automatic evaluation.

5.3 Translation Model

We used Moses, a state-of-the-art phrase-based SMT model (Koehn et al., 2007), in decoding. In Moses, the generated translation hypotheses are scored mainly based on a translation model, a language model, and a reordering model. These components are deemed as features and combined within a log-linear framework:

$$e^* = aug \max_e \{\sum_{i=1}^{n} \lambda_i h_i(e, f)\}$$

where $h_i(e, f)$ is a feature function with λ_i as the weight. The feature weights can be trained with Minimum Error Rate Training (MERT) (Och, 2003) on the development set using BLEU as the objective function.

Table 4: Coverage rate of phrase tables trained from 29k training set.

6 Results and Analysis

After corpus expansion and model integrating, the size of the original phrase table is increased. The number of phrase pairs in the original PT and the merged PTs which are extracted from 29k and full corpora are shown in Table 2.

As can be seen, the number of phrase pairs is significantly increased after corpus expansion. Specifically, the sizes of the augmented phrase tables are increased by 56% and 171% for the 29k set, 25% and 132% for the full set, which prove that our sentence novelty model has made considerable contributions to the enrichment of phrase tables.

We evaluated the effectiveness of the enriched phrase tables in translation. In order to conduct a direct comparison with the existing techniques, we took Moses trained with the original bi-text

1	Source sentence	cyber experts said the investigations in india will take time
	Baseline result	**网络**版**专家说，在印度将**把**时间调查。**
	Our result	**网络**版**专家说，在 印度的调查需要 时间。**
2	Source sentence	it happens again and again .
	Baseline result	它再**次**与再**次发生。**
	Our result	**发生这 一次 又一次。**
3	Source sentence	people just talk about cars and stuff .
	Baseline result	**人们只谈车和材料。**
	Our result	**人只谈**公园**和材料。**

Table 5: Translation examples on 29k-bitext systems. The n-grams that match the references are highlighted in bold. Here *our result* refers to the system of Original+1-PARA+M-PARA.

as a baseline. We also developed another comparison system by re-implementing the method proposed by Callison-Burch et al. (2006) (CB for short hereafter), which used the same paraphrase resource as described above to paraphrase unknown phrases (up to 6-gram) of the test sentences. The feature weights for the model of Callison-Burch et al. (2006) were trained with MERT on the development set.

The evaluation results are shown in Table 3. We can see that our method outperforms both the baseline and CB models under both evaluation metrics. On the 29k subset, the improved model using only 1-best paraphrases has a significant 1.35 BLEU points gain over its baseline, and the model integrated with both 1-best and m-best paraphrases has a further improvement of 1.66 points. On the full set, the model augmented by 1-best paraphrases achieves the best performance, which gained 1.06 BLEU points over the baseline; the model augmented by 1-best and m-best selected paraphrases got an improvement of 0.87 points. A possible reason is that for small training data, the increment of coverage is more important for improving the translation model; while on a larger training corpus, the accuracy of paraphrases plays a more important role.

Notice that the training set, test set and development set in this work are the same as (Marton et al. 2009), which reported a negative result on the full training set. In contrast, our method outperformed the baseline on both small and full training sets.

We further compared the coverage rate of different models on the test set. The result of 29k training set is shown in Table 4. It can be seen that the coverage of 1-gram, 2-grams, 3-grams and 4-grams on the test set is increased by our Ori.+1-PARA. And the method Ori.+1-PARA+ M-PARA has further improved the coverage. It is not surprising that the phrase table of Callison-Burch (CB) has the best coverage on the test set among all the compared models, since their method targets on paraphrasing unknown terms of the test set at run-time. While our method does not target on unknown terms, our goal is enriching the knowledge of SMT system using paraphrases with novel information. Therefore given a specific test set, the unknown terms covered by our method are just a subset of CB's method. However, on such a subset, our method gains significant improvement in translation quality over CB's approach. A possible reason that can explain this is that CB's method only considers the paraphrase probability which controls the adequacy, while in our method, the adequacy, fluency and novelty of the generated paraphrase sentences are well balanced by the SPG framework which can produce paraphrases of better quality.

7 Discussion

We have shown that the SPG framework with an object function of sentence novelty can improve the performance of SMT on both training corpus of small and medium size. Although the experiments are performed on a resource-rich language pair, i.e. English-to-Chinese, the method is portable to other language pairs because our approach is language-independent. No language-specific features are used in the SPG framework. Our proposed method has another advantage of not relying on certain paraphrase resources, and therefore can use any type of training data for paraphrasing. This advantage is important for those resource-poor language pairs.

We further examine the translation results of the baseline and our method. Some examples are shown in Table 5. In row 1 and row 2, the baseline results are improved by our method mainly in the translation of *will take time* and *again and*

again. The phrases can only be translated word by word in the baseline model. But in our augmented model, the phrases can match complete translation phrases which are extracted from the paraphrase-expanded training data. The paraphrase quality remains an issue with this method. A negative example is shown in row 3, which is caused by a wrong paraphrase substitution *cars* → *park*.

8 Conclusions and Future Work

This paper proposes a novel method for enriching SMT training data by paraphrasing the source-side sentences of the bilingual parallel data through a statistical paraphrase generation framework. Within the framework, a paraphrase model and a language model in the source language are employed to ensure the accuracy of paraphrase. And a proposed object function, named sentence novelty, is used to select paraphrases which have the most novel information for SMT system. Experimental results demonstrate that our method significantly improves the baseline by 1.66 and 1.06 on small and medium size training corpora in terms of BLEU. We have also proved in experiments that our method significantly outperforms the model proposed by Callison-Burch et al. (2006). In the future work, we will plan to test the effectiveness of our method on a large-scale corpus.

Abstract

Recent research on multilingual statistical machine translation focuses on the usage of *pivot languages* in order to overcome resource limitations for certain language pairs. This paper provides new insights into what factors make a good pivot language and investigates the impact of these factors on the overall pivot translation performance. Pivot-based SMT experiments translating between 22 Indo-European and Asian languages were used to analyze the impact of eight factors (*language family*, *vocabulary*, *sentence length*, *language perplexity*, *translation model entropy*, *reordering*, *monotonicity*, *engine performance*) on pivot translation performance. The results showed that 81% of system performance variations can be explained by these factors.

1 Introduction

The translation quality of statistical machine translation (SMT) approaches heavily depends on the amount and coverage of bilingual language resources available to train the statistical models. There exist several data collection initiatives[1] amassing and distributing large amounts of textual data. For frequently used language pairs like *French-English*, large text data sets are readily available. However, for less frequently used language pairs only a limited amount of bilingual resources are available, if any at all.

In order to overcome language resource limitations, recent research on SMT focuses on the usage of *pivot languages* (de Gispert and Marino, 2006; Utiyama and Isahara, 2007; Wu and Wang, 2007; Bertoldi et al., 2008). Instead of a direct translation between two languages where only a limited amount of bilingual resources is available, the *pivot translation* approach makes use of a third language that is more appropriate due to the availability of more bilingual corpora and/or its relatedness towards either the source or the target language. For most recent research efforts, *English* is the pivot language of choice due to the richness of available language resources. However, recent research on pivot translation has shown that the usage of non-English pivot languages can improve translation quality for certain language pairs (Paul et al., 2009; Leusch et al., 2010).

Concerning the contribution of aspects of different language pairs on the quality of machine translation, (Birch et al., 2008) identified three features (*morphological complexity*, *amount of reordering*, *historical relatedness*) for predicting success of MT in translations between the official languages of the European Union. Moreover, (Koehn et al., 2009) investigated an additional feature (*translation model complexity*) using the JRC-Aquis corpus covering not only Indo-European languages, but also one semitic and three Finno-Ugric languages.

This paper differs from previous research in the following aspects: we focus on the framework of *pivot translation*, where a target language translation of a source language input is obtained through an intermediate (*pivot*) language, investigate what factors make a good pivot language and what impact these factors have on the overall translation quality of language pairs not only including Indo-Euopean languages, but also a large variety of Asian languages. In Section 2, we report on pivot-based SMT experiments translating between 22 Indo-European as well as Asian languages in order to provide new insights into how much language diversity affects the translation performance of pivot translation approaches. In Section 3, eight factors (*language family*, *vocabulary*, *sentence length*, *language perplexity*,

translation model entropy, *reordering*, *monotonicity*, *engine performance*) are investigated to determine the significance of each factor in predicting translation quality using linear regression analysis.

2 Pivot Translation

Pivot translation is a translation from a source language (SRC) to a target language (TRG) through an intermediate *pivot* (or *bridging*) *language* (PVT). Within the SMT framework, various coupling strategies like *cascading*, *phrase-table composition*, and *pseudo-corpus generation* have been proposed. For the experiments reported in this paper, we utilized the *cascading* approach because it is computational less expensive, but still performs comparably well compared to the other, more sophisticated pivot translation approaches. Pivot translation using the *cascading* approach requires two translation engines where the first engine translates the source language input into the pivot language and the second engine takes the obtained pivot language output as its input and translates it into the target language. Given *N* languages, a total of *2*N*(N-1)* SMT engines have to be built in order to cover all *N*(N-1)*(N-2)* SRC-PVT-TRG language pair combinations.

The importance of translation quality factors in pivot translation are investigated using the multilingual *Basic Travel Expressions Corpus* (BTEC), which is a collection of sentences that bilingual travel experts consider useful for people going to or coming from another country (Kikui et al., 2006). The sentence-aligned corpus consists of 160k sentences pairs covering 22 Indo-European and Asian languages which belong to a variety of language families including *Germanic* (da,de,en,nl), *Romance* (es,fr,it,pt,ptb), *Slavic* (pl,ru), *Indo-Iranian* (hi), *Semitic* (ar), *Austronesian* (id,ms,tl), *Tai* (th), *Mon-khmer* (vi), and *Sinitic* (zh,zht) languages. The corpus statistics are summarized in Table 1, where *Voc* specifies the vocabulary size and *Len* the average sentence length of the respective data sets. These languages differ largely in word order (*Order*: subject-object-verb (*SOV*), subject-verb-object (SVO), verb-subject-object (*VSO*)), segmentation unit (*Unit*: phrase, word, none), and degree of inflection (*Inflection*: high, moderate, light). Very similar characteristics can be seen for *Indo-European* languages and for certain subsets of *Asian languages* (*ja*, *ko*; *id*, *ms*). In addition, *Indo-European* languages have, in general, a higher degree of inflection compared to Asian languages. Concerning word segmentation, the corpora were preprocessed using language-specific word-segmentation tools for languages that do not use white-space to separate word/phrase tokens (ja,ko,th,zh,zht). For all other languages, simple tokenization tools were applied. All data sets were case-sensitive with punctuation marks preserved.

Table 1: Language Resources

(European Languages)

Language		Voc	Len	Order	Unit	Inflection

Chinese	zh	13.3k	6.8	SVO	none	light
Taiwanese	zht	39.5k	5.9	SVO	none	light

The language resources were randomly split into three subsets for the evaluation of translation quality (*eval*, 1000 sentences), the tuning of the SMT model weights (*dev*, 1000 sentences) and the training of the statistical models (*train*). However, in a real-world application, identical language resources covering three or more languages are not necessarily to be expected. In order to avoid a trilingual scenario for the pivot translation experiments, the *train* corpus was randomly split into two subsets of 80k sentences each, whereby the first set of sentence pairs was used to train the SRC-PVT translation models and the second subset of sentence pairs was used to train the PVT-TRG translation models. In total, 924 SMT translation engines were built to cover all 9,240 language pair combinations.

For the training of the SMT models, standard

word alignment (Och and Ney, 2003) and language modeling (Stolcke, 2002) tools were used. Minimum error rate training (MERT) was used to tune the decoder's parameters, and was performed on the *dev* set using the technique proposed in (Och and Ney, 2003). For the translation, an in-house multi-stack phrase-based decoder was used. For the evaluation of translation quality, we applied the standard automatic evaluation metric BLEU which calculates the geometric mean of n-gram precision by the system output with respect to reference translations multiplied by a brevity penalty to prevent very short candidates from receiving too high a score. Scores range between 0 (worst) and 1 (best) (Papineni et al., 2002). For our experiments, single translation references were used.

Table 2 summarizes the BLEU score ranges of all pivot translation experiments obtained for a given pivot language. The results show a large variation in BLEU scores for all pivot languages indicating that the best pivot choice largely depends on the respective source and target language. For European pivot languages, the best language combination scores are in general much higher than the ones obtained for Asian pivot languages.

Table 3 lists the highest BLEU scores of the pivot translation experiments obtained for all language pair combinations. The pivot language achieving

the highest scores (*oracle pivot*) for translating the source (S) language into the target (T) language are given in parantheses. Non-English oracle pivot languages are highlighted in boldface. The figures show that the *English* pivot approach still achieves the highest scores for the majority of the examined language pairs. However, in 49.8% (230 out of 462) of the cases, a non-English pivot language, mainly *Portuguese*, *Brazilian Portuguese*, *Malay*, *Indonesian*, *Japanese*, *Korean*, is preferable. For languages that are closely related like Portuguese vs. Brazilian Portuguese and Malay vs. Indonesian, the related language should be chosen as the pivot language when either translating from or into the respective language for 88.7% (71 out of 80) and 85.0% (68 out of 80) of the privot translation experiments, respectively. Moreover, *Japanese* is the dominant pivot language when translating from Korean into an other language (95.0%, 19 out of 20) , but not for the translation into Korean (30.0%, 6 out of 20). These results suggest that in general pivot languages closely related to the source language have a larger impact on the overal pivot translation quality than pivot languages related to the target language.

Interestingly, for European-only language pairs, only European languages are the oracle pivot language, the majority of which is English. In addition, Spanish is the pivot language of choice when translating from English into another European language and the Dutch pivot achieved the highest BLEU scores for Germanic-only language pairs. On the other hand, when translating between Asian languages, 65.6% (59 out of 90) of the oracle pivot languages are Asian languages. The Spanish (Chinese) oracle pivot languages for translations between Portuguese and Brazilian Portuguese (Japanese and Korean) also stresses the importance of language relatedness.

In order to investigate the dependency of pivot language selection and language families further, Table 4 summarizes the BLEU scores of pivot translations between only (a) non-English European and (b) Asian language pairs. The results of the European-only language pairs in the table on the left confirm the findings of Table 3. *Portuguese* and *Brazilian Portuguese* are still the dominant pivot languages for non-English European language pairs. An increase of Spanish/Dutch oracle pivot language pairs can be seen for the translation between only Romance/Germanic languages, respectively. Similarly, Malay and Indonesian are the dominant pivot languages, followed by Japanese and Korean, for Asian-only language pairs, most of which achieve BLEU scores that are only slightly lower than the ones for the English oracle pivot language experiments reported in Table 3.

Table 5 summarizes the percentages for the language pairs where the respective pivot language achieved the highest automatic evaluation score for the pivot translation experiments summarized in Table 3 (all language pairs) and Table 4 (non-English European language pairs, Asian language pairs). The results show that English is indeed the pivot language of choice for the majority of the investigated translation directions, but for almost half of the language pairs a non-English pivot language is preferable.

In order to investigate how much improvement

in pivot translation performance can be achieved by using non-English pivot languages instead of an English pivot, we calculated the difference in BLEU scores for all 188 non-English language pairs where the non-English pivot language improved translation quality. Table 6 summarizes the average, minimal and maximal gains in BLEU scores for the respective pivot language translation experiments. The pivot languages are sorted according to the highest average increase in translation performance and the amount of improved language pairs are given in parantheses. In total, an average gain of 2.2 BLEU points were obtained for the investigated language pairs. The highest gains (13.4/11.4 BLEU points) were achieved for the Japanese/Korean pivots when translating Korean/Japanese into Chinese, respectively.

3 Indicators of Pivot Translation Quality

The diversity of the pivot language selection reported in the last section rises the question of what makes a language a good pivot language for a given language pair.

We investigated the following eight factors (comprised of a total of 45 distinct features) based on the language resources and SMT engines (SRC-PVT, PVT-TRG) used for the pivot translation experiments described in Section 2 where the total number of features of each factor is given in brackets. For SMT-engine-related features, both translation directions (SRC-PVT, PVT-TRG) are taken into account.

- *language family* [2]: a binary feature verifying whether the source and target languages of the SMT engines belong to the same family or not.
- *vocabulary* [15]: the training data vocabulary size of source and target languages, the ratio of source and target vocabulary sizes, and the overlap between source and target vocabulary.
- *sentence length* [12]: the average sentence length of source and target training sets and the ratio of source and target sentence length.
- *reordering* [6]: the amount and span of word order differences (reordering) in the training data and the *Reordering Quantity* score as proposed in (Birch et al., 2008).
- *language perplexity* [4]: perplexity of the utilized language models measured on the *dev*/*eval* data sets.
- *translation model entropy* [2]: amount of uncertainty involved in choosing candidate translation phrases as proposed in (Koehn et al., 2009).
- *engine performance* [2]: the BLEU scores of the respective SMT engine used for the pivot translation experiments.
- *monotonicity* [2]: the BLEU score difference of a given SMT engine for decoding with and without a reordering model.

The impact of the above factors in isolation on the translation performance is measured using linear regression which models the relationship between a response variable and one or more explanatory variables. Data sets are modeled using linear functions and unknown model parameters are estimated from the data. In this paper, the response variable is defined by the BLEU metric (measuring the pivot translation performance) and the explanatory variables are given by the feature values obtained for each of the respective language pair combinations. Figure 1 gives an example for a simple linear regression using the *reordering quantity* feature as the explanatory variable for (a) all language pairs, (b) European languages only, and (c) Asian languages only. The “goodness of

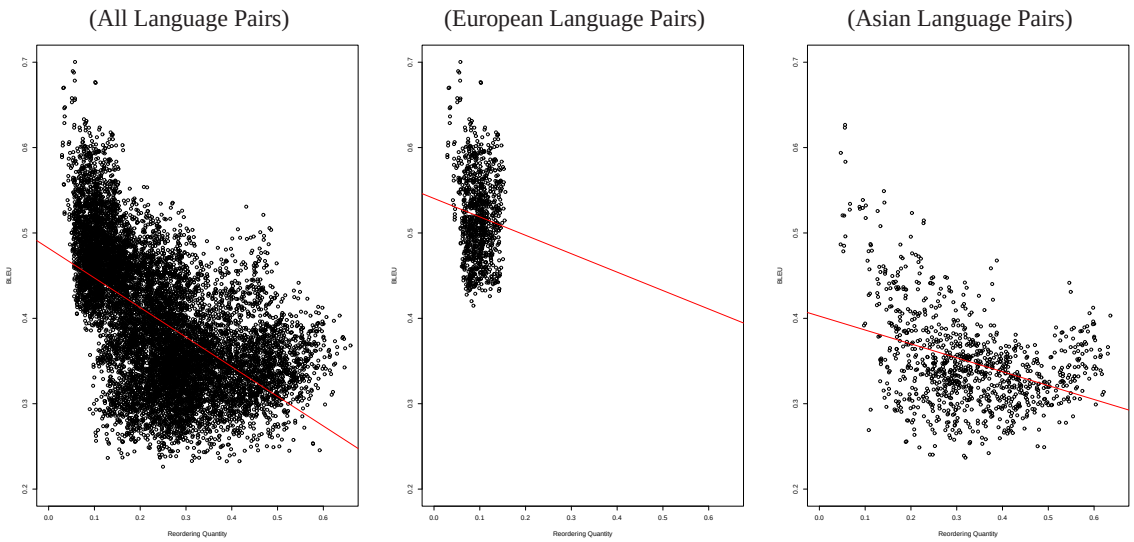

Figure 1: Linear Regression Example (*Reordering Quantity*)

fit" of the explanatory variable(s) is calculated using the R^2 coefficient of determination, which is a statistical measure of how well the regression line approximates the real data points. An R^2 of 1.0 indicates that the regression line perfectly fits the data. For the *translation model entropy* factor, for example, we obtain an R^2 of 0.4604 for all language pairs, which indicates that 46.04% of the differences in translation performance can be explained by this factor.

3.1 Predictive Power of Single Factors

Table 7 summarizes the R^2 scores of the multiple linear regression analysis of the respective investigated factors, i.e. all features of a given factor are combined and treated as multiple explanatory variables. In total, 81% of the system performance variations can be explained when all investigated factors are taken into account. For European language pairs, the impact is even larger (91%). However, for Asian language pairs, the investigated factors have much less correlation (R^2 of 0.5888) with the overall pivot translation translation quality, indicating the difficulty of selecting an appropriate pivot language for translation tasks including Asian languages.

The impact of each factor on the translation performance is also given in Table 7. The results show that *engine performance* is the most correlated factor, followed by *translation model entropy* and *reordering* when all language combinations are taken into account. *Language family* and *language perplexity* seems to have the least impact on translation performance. However, when applying linear regression on language subsets (only European vs. only Asian languages), the impact of factors largely differs. Similar to all language pairs, the *engine performance* factor is most relevant for both European and Asian language subsets.

Table 7: Impact on Translation Performance

Explanatory Variable	R^2 All	R^2 European	R^2 Asian
all factors	0.8102	0.9106	0.5880
engine performance	0.7438	0.7906	0.5151
translation model entropy	0.4604	0.3669	0.1661
reordering	0.4383	0.4593	0.1806
vocabulary	0.3112	0.3867	0.2389
monotonicity	0.2682	0.0149	0.1323
sentence length	0.1717	0.6052	0.0724
language family	0.1204	0.1280	0.0982
language perplexity	0.0826	0.1100	0.0337

For pivot translations between European languages, *sentence length*, *reordering* and *vocabulary* are more predictive than the *translation model entropy* factor. Moreover, the *monotonicity* factor obtains the lowest R^2 score indicating that word order differences between European languages occur mainly on the phrase-level (*local reordering*) and that only minor gains can be achieved when reordering successive phrases. The high R^2 score for *sentence length* also suggests that the ratio of sentence length is an important feature when selecting an appropriate pivot language for closely related languages.

On the other hand, looking at the Asian language pair regression results, the lower R^2 scores underline the large diversity between the Asian languages. Relatively high R^2 scores for *reordering* and *monotonicity* are obtained for Asian lan-

Table 8: Factor Contribution

Explanatory Variable	R^2 All	European	Asian
all factors	0.8102	0.9106	0.5880
w/o engine performance	0.5621	0.8755	0.3683
w/o language perplexity	0.7734	0.8895	0.5488
w/o sentence length	0.7856	0.8989	0.5501
w/o reordering	0.7958	0.8999	0.5712
w/o vocabulary	0.7961	0.8766	0.5669
w/o translation model entropy	0.8004	0.9024	0.5748
w/o monotonicity	0.8026	0.9024	0.5768
w/o language family	0.8035	0.9022	0.5793

guages, indicating that structural differences between the pivot language and the source/target language largely affects the overal pivot translation quality.

3.2 Contribution of Single Factors

Besides the predictive power of each factor, we calculated the R^2 scores of all the factors besides one (*leave-one-out*) in order to investigate the contribution of each factor to the multiple linear regression analysis. In general, the smaller the R^2 score after omitting a given factor, the larger the contribution of this factor on the explanation of the overall translation performance is supposed to be.

The results summarized in Table 8 show that the largest contribution for all language pairs is obtained for the *engine performance* factor, followed by *language perplexity* and *sentence length*. Interestingly, the *vocabulary* factor contributes as much as the *engine performance* factor for European languages, but not for Asian languages. This confirms that morphological similarities between highly inflected languages are important to identify an appropriate pivot language. Moreover, for European-only and Asian-only language pairs, the omission of any of these factors led to lower R^2 scores, but the difference towards the complete factor set is much smaller. This shows the importance of all the investigated features for the task of pivot language selection, especially if languages of large diversity are to be taken into account.

3.3 Translation Direction Dependency

In order to investigate whether the selection of a pivot language depends more on its relationship towards the source language or the target language, we carried out a linear regression analysis based on all factors using (a) only source-language-related features (*SRC-PVT only*) and (b) only target-language-related features (*PVT-TRG only*). The results are summarized in Table 9.

Table 9: Source vs. Target Language Dependency

Explanatory Variable	R^2 All	European	Asian
all factors	0.8102	0.9106	0.5880
SRC-PVT only	0.4923	0.3125	0.2805
PVT-TRG only	0.4732	0.6505	0.2986

In order to distinguish between languages of large diversity, the source language features seem to be more predictive than the target language features. However, for more coherent language pairs, like in the case of European languages, the impact on how much language diversity affects pivot translation performance shifts towards target-language-related features. However, the restriction to either the source or the target features leads to a large decrease in the R^2 scores for all language data sets, underlining the importance of both source-language-related and target-language-related feature sets to identify an appropriate pivot language for a given language pair.

4 Conclusion

We investigated the impact of eight translation quality indicators for the task of pivot translation between 22 languages covering a large diversity of language characteristics. A linear regression analysis showed that 81% of the variation in translation performance differences can be explained by the combination of these factors. The most informative factor in identifying the best pivot language is *engine performance*, i.e., the translation quality of the SMT engines used to translate (a) the source input into the intermediate language and (b) the intermediate language MT output into the target language. In addition, the highest correlation of the investigated factors towards pivot translation performance was obtained when both source-language-related and target-language-related features were combined. The importance of source vs. target language features largely depends on the diversity of the investigated language pairs, i.e., source language features are preferable for heterogenous language pairs whereas the focus shifts towards target-language-related features for more coherent language pairs. In addition, the differentiation between European and Asian languages revealed that the task of identifying a pivot lan-

guage for new language pairs largely depends on the availability of structurally similar languages.

As future work, we are planning to investigate the importance of the factors analyzed in Section 3 in the selection of pivot languages for new language pairs by applying a machine learning algorithm like *Support Vector Machines* (SVM) to train discriminative models for the task of predicting a pivot language that achieves the highest translation performance for a given translation task.

Abstract

The unavailability of parallel training corpora in resource-poor languages is a major bottleneck in cost-effective and rapid deployment of statistical machine translation (SMT) technology. This has spurred significant interest in active learning for SMT to select the most informative samples from a large candidate pool. This is especially challenging when irrelevant outliers dominate the pool. We propose two supervised sample selection methods, viz. greedy selection and integer linear programming (ILP), based on a novel measure of benefit derived from error analysis. These methods support the selection of diverse and high-impact, yet relevant batches of source sentences. Comparative experiments on multiple test sets across two resource-poor language pairs (English-Pashto and English-Dari) reveal that the proposed approaches achieve BLEU scores comparable to the full system using a very small fraction of all available training data (ca. 6% for E-P and 13% for E-D). We further demonstrate that the ILP method supports global constraints of significant practical value.

1 Introduction

The laborious and time-consuming nature of producing parallel training corpora for the development of high-quality SMT systems cannot be overstated. Barring a few mainstream languages, the vast majority of language pairs can be classified as "resource-poor" as far as availability of a usable SMT system is concerned. Active learning can reduce human labor, turn-around time and monetary cost of developing SMT systems with little or no loss in translation accuracy.

In its simplest form, active learning for building parallel corpora involves selecting "high-value" samples from a large monolingual corpus of source sentences (the *candidate pool*) for translation by a bilingual human expert. The notion of "value" depends on the selection method, and can be derived using unsupervised, semi-supervised, or supervised techniques. For instance, Eck et al. (2005) define high-value source sentences as those that contain a large number of previously unseen n-grams. While it aims to increase coverage of the training set, the main deficiency of this approach is its tendency to pick irrelevant outliers if the candidate pool contains data from unrelated regimes.

Haffari et al. (2009) propose a number of features, such as similarity to the seed corpus, translation probability, n-gram and phrase coverage as unsupervised measures of the value of candidate samples. Additionally, a linear combination of these features is proposed as a supervised measure of value for ranking candidate sentences. The parameters of this model are optimized on two separate held-out bilingual development sets. The disadvantage of this approach is that it relies on the candidate pool having the same distributional characteristics as the development sets used for parameter estimation. Haffari and Sarkar (2009) explore active learning in a multilingual setting (different source languages f_d to be translated to a single target language e) using disagreement between target hypotheses generated by each of the SMT systems. For single language active learn-

ing, they use OOV phrases, i.e. source n-grams without translation choices.

Ananthakrishnan et al. (2010) propose an error-driven approach that identifies translation errors on a held-out development set, and uses this to train a discriminative pairwise comparator function that preferentially selects candidate sentences with constructs that are incorrectly translated in the development set. The chosen sentences provide maximum potential reduction in translation error. The advantage of this method over other unsupervised and semi-supervised selection strategies is that it favors domain-relevant sentences that are difficult to translate. However, its granularity is low, because it considers errors only at the sentence level. Further, the diversity constraint is implemented in a non-optimal, ad-hoc manner by deleting feature functions from the pairwise classification model.

Bloodgood and Callison-Burch (2010) explored active learning to augment training data for *high resource* language pairs. They experimented with random, shortest, and longest sentence selection, as well as a technique they refer to as *Vocab-Growth*. The latter prefers a candidate sentence that contains the most frequent n-gram not seen in the labeled training data. Again, this approach is unsuitable if the pool contains a lot of irrelevant sentences. Moreover, their system is based entirely on source language statistics, and does not use any feedback from the SMT system. As one of their examples indicates, this makes it susceptible to selecting sentences containing n-grams that were already correctly translatable.

This paper introduces a novel, fine-grained, error-driven measure of value for candidate sentences obtained by translation error analysis on a domain-relevant held-out development set. Errors identified in translation hypotheses are projected back on to the corresponding source sentences through phrase derivations from the SMT decoder. This projected error is used to obtain a "benefit value" for each source n-gram that serves as a measure of its translation difficulty. Sentence selection is posed as the problem of choosing K sentences from the candidate pool that maximize the sum of the benefit values of n-grams covered by the choice. This is a generalization of the set-covering problem, known to be NP-Complete. We present two approximate solutions: (a) an efficient greedy algorithm and (b) an integer linear programming (ILP) formulation. We compare these two methods and demonstrate their superiority to numerous competing selection strategies described in the literature.

2 Translation Error Projection

The principal advantage of error-driven sample selection (Cohn et al., 1996; Meng and Lee, 2008) over traditional unsupervised or semi-supervised active learning (Hwa, 2004; Tang et al., 2002; Shen et al., 2004) is its ability to choose instances, which, when annotated, potentially maximize error reduction of the learner on a reference set.

We assume the following data configuration for error-driven sample selection for SMT. A seed parallel corpus $\mathbf{S}$ is required to bootstrap an initial translation system. However, we do not require that this corpus be drawn from the same distribution as the testing condition. This relaxed assumption is particularly useful for developing SMT systems for resource-poor language pairs for which in-domain parallel training data may not be readily available, but a (low quality) translation system may be built using data from other domains, genres or dialects. We also assume a phrase-based SMT architecture (Koehn et al., 2003).

A held-out development (tuning) set $\mathbf{D}$ is used for optimizing the parameters of the SMT system using MERT (Och, 2003), as well as for error-analysis in guiding the proposed sample selection algorithms. System performance is evaluated on a fair test set $\mathbf{T}$. We assume that the tuning set is derived from the same distribution as the test set. The selection algorithms operate on a large pool of monolingual source sentences $\mathbf{P}$ to extract high-value samples for translation by a human expert. The candidate pool may contain any mixture of relevant and irrelevant sentences, and may also possess significant redundancy.

2.1 Error Analysis

The SMT system is bootstrapped using the seed training corpus $\mathbf{S}$. The held-out set $\mathbf{D}$ is decoded by the SMT to obtain 1-best translation hypotheses. Translation edit rate (TER) analysis (Snover et al., 2006) is used to identify errors in the hypotheses by aligning them to the target references. The TER alignment identifies a set of insertions, substitutions, deletions, and shifts that is required to transform a hypothesis to its corresponding reference. Large values of TER indicate greater dis-

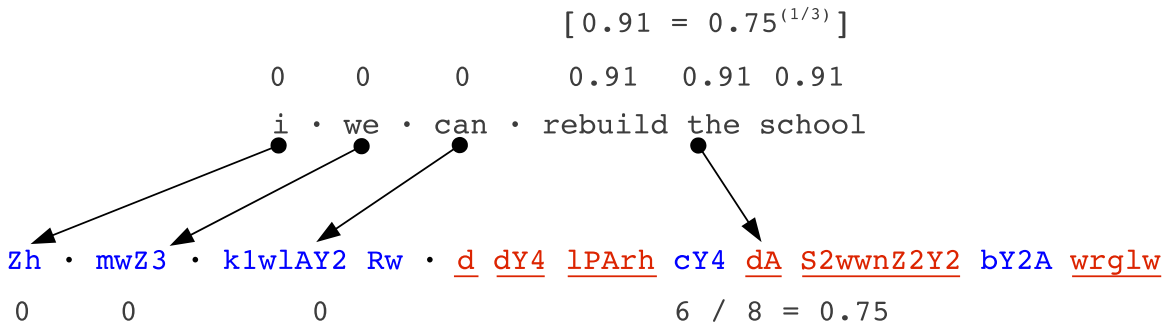

Figure 1: Example illustrating evaluation of back-projected error for a source sentence given phrase derivations and error analysis of its translation hypothesis (English-Pashto). Incorrectly hypothesized words are underlined in red.

similarity between hypotheses and references, corresponding to poor translations.

An individual target word in the hypothesis is deemed "correct" if it aligns to itself in the TER alignment. Conversely, hypothesized words corresponding to substitution or insertion errors are considered "incorrect" translations, while deletion errors are ignored. Thus, each hypothesized word can be labeled "correct" or "incorrect" based on the TER alignment, providing a fine-grained view of translation difficulty on the held-out set.

2.2 Benefit/Objective Function

TER analysis enables us to label errors at the word level for each SMT hypothesis. However, it is the knowledge of which *source words* were translated incorrectly that is useful for sample selection. Assuming there is a way to attach a label (or real value) to each source word in the held-out set $\mathbf{D}$ indicating whether it was correctly translated (or to what degree it was translated), we can compute a *benefit value* over each source n-gram. The sum of benefit values over all source n-grams can be used as an objective function that must be maximized by selecting suitable samples from the candidate pool.

The SMT decoder produces *phrase derivations* specifying the origin of each target phrase in a hypothesis, providing a convenient mechanism for approximate projection of target error labels back on to the source words. We refer to this as error back-projection. We compute, for each target phrase in the phrase derivations, the *target phrase error* as a ratio of the number of words labeled "incorrect" to the total number of words within that phrase. This quantity is then equally distributed among constituent source words using the geometric mean with respect to the number of words in the containing source phrase (obtained from the phrase derivation), to give us a back-projected error at the level of individual source words. Since the phrase derivations form a mutually exclusive partition over the source sentence, we can compute an unambiguous back-projected error value for each source word in the held-out set $\mathbf{D}$. Figure 1 illustrates this procedure with an example.

We then compute a benefit value for each source n-gram as the sum of back-projected error of the constituent source words. The set of source phrases in the SMT decoder derivations is typically a very small subset of the set of all possible n-grams of equal length. By distributing back-projected phrase error over individual target words, we are able to compute benefit values for n-grams not covered by the phrase table inventory. Finally, we sum the benefit values of source n-grams that occur multiple times in $\mathbf{D}$ to generate a table of benefit values hashed by the corresponding n-grams.

3 Sentence Selection Problem

Given a set of n-grams $\mathcal{N} = \{n_i\}_{i=1}^{m}$ from source sentences in $\mathbf{D}$ and associated benefit values $b_i \geq 0$ computed by error back-projection, the goal of sample selection is to choose a batch of K sentences that maximizes the cumulative benefit value of n-grams covered by the chosen sentences. The contribution of each sentence towards the objective function is equal to the sum of benefit values of all unique n-grams it contains.

The sentence selection problem is closely related to the classical set covering problem, one of 21 NP-complete problems described in Karp's

seminal paper on reducibility (Karp, 1972). The decision version of set covering is as follows: given a set of elements T and a set of subsets within T, say $\mathcal{T} = \{T_j \subseteq T\}$, is it possible to select k subsets such that their union is the superset T? This problem is known to be NP-Complete.

To visualize the similarity of set covering to the sentence selection problem, note that the elements of T are akin to n-grams, and the subsets T_j's correspond to sentences. It is easy to show that the set covering problem can be reduced to the sentence selection problem. Thus, there does not exist a polynomial time algorithm for optimal sentence selection unless $P = NP$.

There is a standard greedy approximation algorithm for the minimum set covering problem (Cormen et al., 2001): at each iteration, choose the subset T_j that has the largest number of as yet uncovered elements of T. The procedure is repeated until all elements in T are covered. We next present a variant of this algorithm for the sentence selection problem. Our algorithm address two differences between sentence selection and set covering: (a) each n-gram provides a distinct benefit value on covering, and (b) we must select only K sentences and maximize the cumulative benefit.

4 Greedy Sample Selection

The greedy solution constructs batches iteratively by choosing, at each step, the sentence whose total current benefit is the largest. Each sentence in the candidate pool is decomposed into its constituent n-grams, and the sum of benefit values of these n-grams is computed. The sentence that scores highest on this criterion is chosen. Resetting the benefit values of n-grams in previously chosen sentences ensures diversity. The greedy selection technique is illustrated in Algorithm 1. Each iteration of the master loop selects one sentence based on the local maximum of the objective function. The indicator function $\mathcal{I}_i(\cdot)$ returns unity if n-gram n_i is present in the argument sentence, and zero otherwise.

The greedy algorithm provides a highly-scalable approximation to the solution and can be applied to systems with millions of n-grams and candidate sentences. It is, however, sub-optimal in general; potentially better solutions can be obtained by casting it in an integer linear programming (ILP) framework, as discussed below.

Algorithm 1 Greedy Sample Selection

$\mathbf{B} \leftarrow ()$
for $k = 1$ to K **do**
  $p^* \leftarrow \arg\max_{p \in \mathbf{P}} \sum_{i=1}^{m} b_i \mathcal{I}_i(p)$
  $B(k) \leftarrow p^*$
  $\mathbf{P} \leftarrow \mathbf{P} - \{p^*\}$
  $b_i \leftarrow 0 \ \forall \{i \mid \mathcal{I}_i(p^*) = 1\}$
end for
return $\mathbf{B}$

5 Integer Linear Programming (ILP)

We define a set of indicator variables, x_j, for the sentences, $x_j = 1$ if sentences p_j is selected and 0 otherwise. Similarly, there are a set of indicator variables, y_i, for the n-grams, $y_i = 1$ if n-gram n_i is covered by some selected sentence and 0 otherwise. Sentence selection can be expressed as the following integer linear program (ILP):

$$\begin{aligned} \max: \ & \sum_i b_i y_i \\ \text{subj. to.}: \ & y_i \leq \sum_{j \mid \mathcal{I}_i(p_j)=1} x_j \ \ \forall\, i \\ & \sum_j x_j \leq K \\ & 0 \leq y_i \leq 1 \ \ \forall\, i \ \ , \ \ x_j \in \{0,1\} \ \ \forall\, j \end{aligned} \tag{1}$$

Notice that since $b_i \geq 0$, in order to maximize the optimization function each y_i will be set to 1 whenever at least one of the sentence covering its n-gram is selected, $x_j = 1$.

In general, exact optimization of ILP is NP-Hard. However, there are several publicly available solvers for ILPs with thousands of variables. For instance, the open-source *lp-solve* program uses the Branch-and-Bound technique to solve ILPs and in our experiments handles systems with thousands of sentences.

5.1 Including Application Constraints

Unlike greedy selection, ILP allows us to impose additional application or domain specific global constraints within the optimization framework. One example is to bound the total number of words in the selected sentences rather than number of chosen sentences. This is useful because when the number of sentences is constrained, the system is biased to choose longer sentences as they would cover more n-grams. Assuming manual translation cost to be linear in the number of words, we

can put a bound on the total length of the chosen sentences. Let l_j be the length of sentence p_j. We can put a bound $\sum_j l_j x_j \leq L$. Imposing such a bound is similar to the Knapsack problem, a standard NP-Complete problem (Cormen et al., 2001). We can also incorporate prior information on the goodness of sentences by including sentence costs (e.g. syntactic well-formedness, length, etc.), c_j's, within the optimization function: $\sum_i b_i y_i + \sum_j c_j x_j$. In contrast to the greedy algorithm, ILP provides a natural framework to perform *joint* optimization over multiple types of constraints.

5.2 Solving the ILP for Practical Problems

Even moderate size SMT applications involve tens of thousands of n-grams and sentences, e.g., one of our test conditions has approximately $79,000$ n-grams and $100,000$ sentences. Each sentence would result in an integer variable in the ILP. State-of-the-art solvers have difficulty handling such large problems, e.g., *lp-solve* was unable to solve the ILP for a system with $100,000$ sentences. We propose a two-step solution to achieve scalability. If k sentences must be selected in a given active learning iteration, we use the greedy algorithm to prune the problem by choosing $k' > k$ sentences from the corpus, and subsequently construct the ILP on this smaller problem to select the required k sentences. While ILP is optimal, greedily pruning the problem for ILP may result in sub-optimality.

We observed the run time and optimization value computed by ILP for different k', keeping k constant at 16. We chose smaller (k', k) for these simulations to allow ILP to run to completion. Figure 2 summarizes our findings. Note that the optimum improves with larger prune size and requires more iterations. Larger prune sizes allow the ILP to choose from a larger pool of sentences, and are therefore likely to improve the optimum. However, these typically require more iterations. In this paper, we used the greedy algorithm to prune the problem to $K' = 1000$ sentences, and then select $K = 400$ sentences using ILP (we restricted ILP run-time to 20 minutes per batch).

6 Experimental Results

We demonstrate the effectiveness of greedy and ILP-based sample selection by conducting simulation experiments on two resource-poor language pairs commissioned under the DARPA Transtac speech-to-speech translation initiative, viz. English-Pashto (E2P) and English-Dari (E2D). In both cases, only a small fraction of the available training data is pertinent to the translation task. This simulates a condition where a large source language corpus (e.g. English) is harvested from the Web, of which only a small fraction is relevant to the target SMT system.

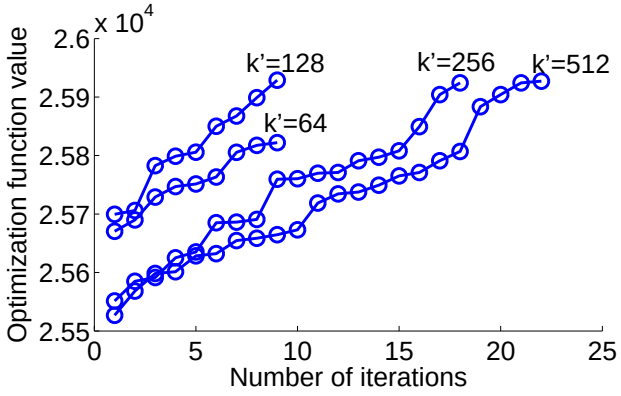

Figure 2: Optimization function value for different iterations of ILP branch-and-bound, for different sizes of pruned problems ($k' = 64, 128, 256, 512$) for constant choice cardinality, $k = 16$.

We simulate low-resource conditions by sequestering the majority of available parallel training data. A seed translation model is bootstrapped with a very small subset of the training corpus; source sentences of the remainder constitute the candidate pool. Because obtaining monolingual text in the target language is usually not a constraint, we train the target language model (LM) from all available target language sentences in the training corpus.

We then apply the proposed selection algorithms to choose fixed-size batches from the pool. Translations for the selected sentences are obtained from the sequestered parallel corpus (thus simulating a human oracle). The chosen batch and its translation is appended to the seed corpus $\mathbf{S}$ for retraining the SMT. At each iteration, we independently decode the test set and evaluate translation accuracy in order to compare the trajectory of BLEU for these and other competing selection strategies:

- *Random*: Source sentences are uniformly sampled from the candidate pool $\mathbf{P}$.
- *Dissimilarity*: Select sentences from $\mathbf{P}$ with the largest number of n-grams not seen in $\mathbf{S}$

(Eck et al., 2005; Haffari et al., 2009).

- *Longest*: Pick the longest sentences from the candidate pool $\mathbf{P}$.
- *Discriminative*: Choose sentences that potentially minimize translation error using a maximum-entropy pairwise comparator (Ananthakrishnan et al., 2010).
- *Greedy*: Simple greedy selection with proposed error-projection benefit objective.
- *ILP*: Integer linear programming optimization with error-projection benefit objective.

English-to-Pashto Simulation: The E2P data originates from a two-way collection of spoken dialogues, and consists of two parallel sub-corpora: a directional E2P corpus and a directional Pashto-English (P2E) corpus. Each sub-corpus has its own independent training, development, and test partitions. The directional E2P training, development, and test sets consist of 33.9k, 2.4k, and 1.1k sentence pairs, respectively. The directional P2E training set consists of 76.5k sentence pairs. In addition, DARPA has made available to all Transtac participants an open 564-sentence E2P test set with four target references for each input.

We trained a baseline E2P SMT system from all available E2P and reversed P2E data. The full-system BLEU scores on the single-reference internal test set and on the multi-reference DARPA evaluation test set were 10.8 and 24.4, respectively. We set up active learning simulation by randomly sampling 1,000 sentence pairs from the directional E2P training partition to obtain the seed training corpus. The remainder of this set, and the entire reversed P2E training partition were combined to create the pool. The reversed directional P2E data is considered irrelevant as far as the E2P test sets are concerned. The pool thus consists of 30% in-domain and 70% irrelevant sentence pairs. We simulated 35 iterations with batches of 400 sentences each; the seed corpus grows to 15,000 sentence pairs at the end of the simulation.

English-to-Dari Simulation: The E2D data is also derived from a two-way collection of spoken dialogues. The directional E2D training, development, and test sets consist of 11.6k, 3.2k, and 2.8k sentence pairs, respectively. The directional D2E training set consists of 52.9k sentence pairs. The full-system BLEU on the E2D test set was 15.1.

As with E2P, the seed training corpus was obtained by randomly sampling 1,000 sentence pairs from the directional E2D training partition. All remaining parallel training data were designated as the candidate pool. Thus, only about 17% of the candidate pool is considered relevant with respect to the E2D test set. Again, we simulated 35 iterations with batches of 400 sentences each.

BLEU Trajectories: The trajectories of BLEU scores for the E2P and E2D test sets are shown in Figures 3(a), 3(b), and 3(c), respectively. The horizontal line near the top of each plot represents the corresponding full-system BLEU score. The following observations are noteworthy:

- BLEU scores using the proposed greedy and ILP-based selection methods ramp up very quickly to the full-system level using a small fraction of available training data. On the E2P single-reference test set, the top-line BLEU score of 10.8 is attained after just 12 iterations (5.8k sentence pairs), as against 100k sentence pairs for the full system (**6%** of the corpus). Likewise for E2D, the full-system BLEU score of 15.1 is attained after only 18 iterations (8.2k sentence pairs), as opposed to 65k sentence pairs for the full system (**13%** of the corpus).
- In some cases, BLEU scores with training corpora constructed using active learning exceed those obtained with the full system. This is because our selection algorithms are biased to choose relevant, in-domain sentences from the candidate pool. Initially, the training corpus is kept free of outliers that cause performance degradation in the full system. With more iterations of selection, the latter eventually find their way into the training set, causing translation performance to settle around the top-line BLEU scores.
- Under identical initial conditions at the first iteration of active learning, the ILP benefit optimum exceeds the greedy optimum by 444.5 units for E2P, and by 420.3 units for E2D. This confirms the theoretical superiority of ILP over greedy selection.

We computed total area under the BLEU curves for the various selection techniques as a single figure of merit. Summarized in Table 1, the BLEU-Iteration product shows source error-projection with the ILP selection algorithm outperforming all competing techniques, including discriminative sample selection (Ananthakrishnan et al., 2010).

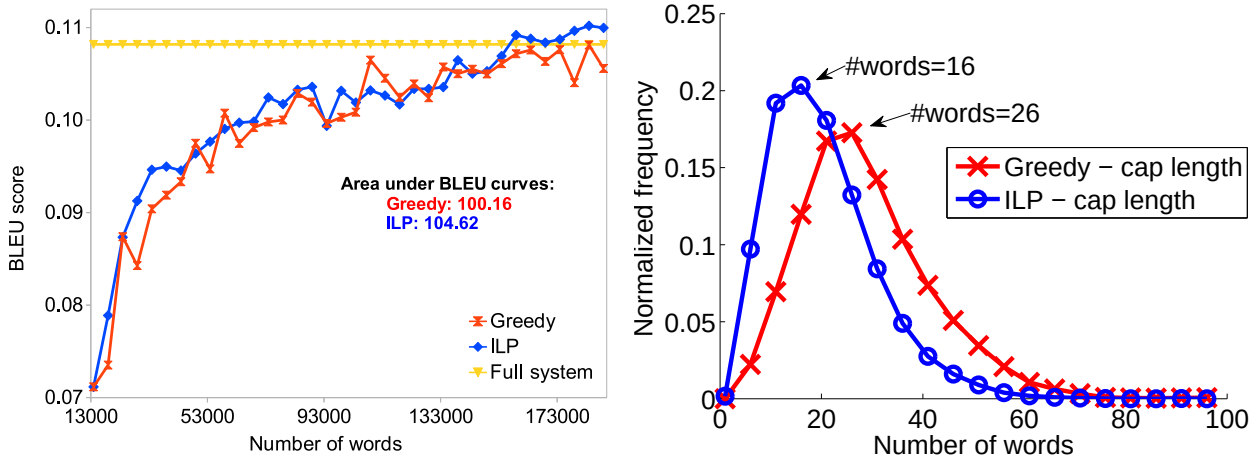
tions choose a fixed number of sentences at each iteration. However, the ILP optimization framework also permits the integration of global constraints, such as the number of words in a batch. This is an important practical benefit, as most professional translators charge by word rather than by sentence. Other selection methods can only support such constraints in an ad-hoc fashion. To evaluate this feature of ILP selection, we implemented a variant of the greedy algorithm where the stopping criterion is number of words selected. We then imposed a global length constraint for ILP as described in Section 5.1, and compared BLEU scores across 35 simulation iterations for E2P with a limit of 5,000 words per batch (Figure 4(a)). The trend in BLEU indicates that ILP provides a better framework for integration of such constraints.



(a) Length-capped BLEU trajectory (E2P-SingleRef). Full system training data contains 1.46M source words.

(b) Normalized histogram of sentence length

Figure 4: Comparison of greedy and ILP with global length constraint of 5,000 words per batch.

Moreover, the overall sentence length distribution shown in Figure 4(b) indicates that the greedy algorithm prefers a smaller number of very long sentences, whereas ILP prefers a larger number of shorter sentences. The latter is an important practical benefit for applications such as crowdsourcing, because annotators often find it difficult to translate long sentences. Secondly, automatic word alignment quality for long sentence pairs is often poor. Finally, larger number of sentences in the training pool is likely to increase diversity.

7 Discussion and Future Work

Active learning provides a useful framework for alleviating the significant costs associated with developing SMT systems for resource-poor language pairs. In this paper, we introduced a novel criterion for active sample selection, viz. back-projected translation error. Candidate instances that score well on this criterion are chosen for translation by a bilingual human expert. We showed that the problem of maximizing the error-projection objective function is closely related to the set-covering problem, known to be NP-complete.

We used a simple greedy selection algorithm as a first approximation to the solution. BLEU trajectories from simulation experiments demonstrated the superiority of this scheme to competing active learning algorithms. We then proposed an optimization framework to maximize the objective function for sample selection, and provided a solution via ILP. The ILP-based selection algorithm also supports global constraints on the optimization problem, e.g. overall corpus size in words, which neither greedy selection nor other competing strategies can implement in a principled fashion. We also showed that ILP was superior to the greedy approach when constraining selected batches by total number of words, rather than by number of sentences.

The proposed approach is shown to outperform competing active learning strategies when the candidate pool contains a small number of high-impact samples buried within a large corpus of mostly irrelevant text. Guided by an in-domain development set, our approach always selects relevant samples that are likely to provide maximal benefit to the SMT system. Pilot experiments suggest that this approach may not be as effective when the candidate pool is completely task-relevant. Another weakness of our technique is the reliance on a relatively small development set to guide selection. Performance may saturate once all sentences in the development set can be translated accurately. Generally, a large, rich development set will tend to give better results. In the future, we plan to experiment with random sampling to vary the development set at each active learning iteration.

We have shown the effectiveness of our approach in the context of phrase-based SMT systems. The same principles can be extended to hierarchical or syntax-based SMT architectures with minimal effort.

Abstract

We propose a Named Entity (NE) recognition method in which word chunks are repeatedly decomposed and concatenated. We can obtain features from word chunks, such as the first word of a word chunk and the last word of a word chunk, which cannot be obtained in word-sequence-based recognition methods. However, each word chunk may include a part of an NE or multiple NEs. To solve this problem, we use the following operators: SHIFT for separating the first word from a word chunk, POP for separating the last word from a word chunk, JOIN for concatenating two word chunks, and REDUCE for assigning an NE label to a word chunk. We evaluate our method on a Japanese NE recognition data set that includes about 200,000 annotations of 191 types of NEs from over 8,500 news articles. The experimental results show that the training and processing speeds of our method are faster than those of a linear-chain structured perceptron and a semi-Markov perceptron while high accuracy is maintained.

1 Introduction

Named Entity (NE) recognition is a process by which the names of particular classes and numeric expressions are recognized in text. NEs include person names, locations, organizations, dates, times, and so on. NE recognition is one of the basic technologies used in text processing, including Information Extraction (IE), Question Answering (QA), and Information Retrieval (IR).

Supervised learning algorithms have been applied successfully to create NE recognizers. In the early stages, algorithms for training classifiers, including Maximum Entropy Models (Uchimoto et al., 2000), AdaBoost (Carreras et al., 2002), and Support Vector Machines (Yamada, 2007) were widely used. Recently, learning algorithms for structured prediction, such as linear-chain Conditional Random Fields (CRFs) (Lafferty et al., 2001), linear-chain structured perceptron (Collins, 2002a), semi-Markov perceptron (Cohen and Sarawagi, 2004), and semi-Markov Conditional Random Fields (Sarawagi and Cohen, 2004), have been widely used because of their good performances in terms of accuracy.

However, the computational cost of using these algorithms for structured prediction can become problematic when we handle a large number of types of NE classes. The computational cost of learning first-order-Markov models with linear-chain CRFs or structured perceptron is $O(K^2N)$, where K is the number of types of classes and N is the length of the sentence. Semi-Markov-based algorithms, such as semi-Markov perceptron and semi-Markov CRFs, enumerate NE candidates represented by word chunks in advance for capturing features such as the first word of a chunk and the last word of a chunk. Therefore, the computational cost of a semi-Markov perceptron is $O(KLN)$, where L is the upper bound length of the entities.

The computational cost might not be a big problem, when we use these learning algorithms to recognize a small number of types of NEs, such as the seven types in MUC (Grishman and Sundheim, 1996), the eight types in IREX (Committee, 1999), and the four types in the CoNLL shared task (Tjong Kim Sang and De Meulder, 2003). However, the computational cost will be higher than ever, when we recognize a large types of classes like Sekine's extended NE hierarchy that includes about 200 types of NEs for covering several types of needs of IE, QA, and IR (Sekine et al., 2002).

This paper proposes a word-chunk-based NE recognition method for creating fast NE recog-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 828–836,
Chiang Mai, Thailand, November 8 – 13, 2011.

nizers while high accuracy is maintained by capturing rich features extracted from word chunks. Our method recognizes NEs from word-chunk sequences identified by a base chunker. When we use a base chunker with a computational cost of $O(KN)$ or lower than it, we can maintain the computational cost of our method as $O(KN)$. This is because the length of the word-chunk sequences is less than or equal to the sentence length N. In addition, our method can use features extracted from word chunks that cannot be obtained in word-based NE recognitions.

However, each word chunk may include a part of an NE or multiple NEs. To solve this problem, we use the following operators: SHIFT for separating the first word from a word chunk, POP for separating the last word from a word chunk, JOIN for concatenating two word chunks, and REDUCE for assigning an NE class label to a word chunk. Therefore, we call our method SHIFT-POP-JOIN-REDUCE parser (SPJR for short).

We demonstrate experimentally that the training and processing speeds of SPJR-based NE recognizers can be considerably faster than those of a linear-chain-perceptron and a semi-Markov-perceptron, while high accuracy is maintained.

2 SHIFT-POP-JOIN-REDUCE Parser

This section describes our method that recognizes NEs from word chunk sequences. We assume word chunk sequences are given by a base chunker which is described in Section 3.4.

2.1 Operators for Word Chunks

To recognize NEs from word chunks, we use SHIFT and POP for decomposing word chunks, JOIN for concatenating two word chunks, and REDUCE for assigning one of the defined NE class labels. In the following, $C = \langle C_1, ..., C_{|C|} \rangle$ denotes a word chunk sequence. cbw_j is the first word of C_j, and cew_j is the last word of C_j.

- REDUCE: This operator assigns one of the NE labels to a word chunk.
- POP: This operator separates the last word from a word chunk, and the separated word is treated as a new word chunk. POP is only applied to a word chunk consisting of more than one word. When POP is applied to C_j, the last word cew_j is separated from C_j. Indices of the following word chunks C_k ($j+1 \leq k \leq |C|$) are incremented by 1, and the separated word cew_j becomes new C_{j+1}. There is one exceptional procedure for POP to use as much initial chunk information as possible. If POP is successively applied to the j-th chunk, the separated words are concatenated and regarded as the $(j+1)$-th chunk. For example, if C_j consists of words "w x y z" and POP is applied to both y and z, then the C_{j+1} will be considered to be "y z".
- SHIFT: This operator separates the first word from a word chunk, and the separated word is treated as a new word chunk. SHIFT is only applied to a word chunk consisting of more than one word. When SHIFT is applied to C_j, the first word cbw_j is separated from C_j. Indices of the word chunks C_k ($j \leq k \leq |C|$) are incremented by 1, and the separated word cbw_j becomes new C_j.
- JOIN: This operator concatenates two adjacent word chunks. When JOIN is applied to C_j and C_{j+1}, C_j and C_{j+1} are concatenated for creating new C_j. Indices of the word chunks C_k ($j+2 \leq k \leq |C|$) are decremented by 1. To avoid an endless loop by generating previously processed word chunks, we forbid JOIN from occurring immediately after POP or SHIFT.

2.2 Training an NE Recognizer

The input to our training procedure is the word chunks of a base chunker along with the NE labels on those correct word chunks. To train an NE recognizer, we first generate training samples, and then run a machine-learning algorithm over the training samples. Figure 1 shows a pseudo-code of the procedure for generating training samples from the i-th input. $\{T_1, ... T_M\}$ is a set of training data consisting of M sentences.

$T_i = \langle T_{i,1}, ..., T_{i,M_i} \rangle$ ($1 \leq i \leq M$) is the i-th training input. $T_{i,j}$ ($1 \leq j \leq M_i$) is the j-th chunk of T_i, and $l(T_{i,j})$ is the NE label of $T_{i,j}$. If $T_{i,j}$ is not an NE, $l(T_{i,j})$ is O. The procedure runs as follows:

- (S0) We generate initial word chunks C from the word-sequence consisting of T_i with the given base chunker. We start to check the following steps from (S1) to (S5) for generating samples. The following process continues until all word chunks in T_i are processed.

```
# T_i = {T_{i,1}, ... T_{i,M_i}}: an input
# T_{i,j} (1 ≤ j ≤ M_i): a word chunk
# l(T_{i,j}): T_{i,j}'s NE label
# W_i: words in T_i
# C = {C_1, ... C_{|C|}}: word chunks
# l(cbw_j): the NE label of the last word of C_j
# l(cew_j): the NE label of the first word of C_j
# gen(C_j, OP): generate a training sample
#       for OPERATOR (OP) applied to C_i
# (S0) to (S5) correspond to those of Sec. 2.2.
GenerateTrainingSample(T_i)
# (S0) Generate a word chunk-sequence
# with a base chunker.
C = Chunking(W_i); j = 1;
while j ≤ M_i do
  if C_j == T_{i,j} then # (S1)
    gen(C_j, REDUCE = l(T_{i,j})); j++;
  else if l(cew_j) == O then # (S2)
    gen(C_j, POP); C = POP(C, j);
  else if l(cbw_j) == O then # (S3)
    gen(C_j, SHIFT); C = SHIFT(C, j);
  else if ( a word or words included in C_j
    are not the constituents of T_j) then # (S4)
    gen(C_j, POP); C = POP(C, j);
  else # (S5)
    gen(C_j, JOIN); C = JOIN(C, j);
  end if
end while
```

Figure 1: A pseudo code of the generation of training samples.

- (S1) If the current chunk C_j is equivalent to the correct chunk $T_{i,j}$, we generate a training sample for REDUCE=$l(T_{i,j})$. This means REDUCE for annotating a word chunk with $l(T_{i,j})$. Then we move to the next word chunk. ($j++$)

- (S2) If the label of the last word of the current chunk cew_j is "O", a training sample for applying POP to C_j is generated. Then POP is applied to C_j.

- (S3) If the label of the first word of the current chunk cbw_j is "O", a training sample for applying SHIFT to C_j is generated. Then SHIFT is applied to C_j.

- (S4) If a word or words included in C_j are not the constituents of $T_{i,j}$, a training sample for applying POP to C_j is generated.

- (S5) If all the above steps are not executed, the correct NE exists across more than one chunk. Therefore, we generate a sample of current word chunk for JOIN.

After generating training samples for all the inputs, we train a model from the training samples with a machine-learning algorithm.

2.3 An Example of Training

Consider the following training data T_i.

- [Mr.]$_O$ [Ken Ono]$_{PER}$ [went]$_O$ [skiing]$_O$

We first identify base chunks, and the result is as follows:

- [Mr. Ken] [Ono went] [skiing]

We denote this base chunking result as C. Word chunks are indicated by bracketing, and a current chunk is underlined.

We first compare $T_{i,1}$ and C_1. C_1 is not equivalent to $T_{i,1}$, and the NE label of the first word of C_1, "Mr.", is "O". Therefore, we generate a training sample for applying SHIFT to C_1 by (S3), and apply SHIFT to C_1. The current C would be the following.

- [Mr.] [Ken] [Ono went] [skiing]

We compare C_1 and $T_{i,1}$ again, and C_1 is equivalent to $T_{i,1}$. Therefore, we generate a training sample for applying REDUCE=O to C_1 by (S1), and move to the next word chunk.

- [Mr.] [Ken] [Ono went] [skiing]

C_2 is not equivalent to $T_{i,2}$, and C_2 does not satisfy (S1) to (S4). We generate a training sample of JOIN for C_2 by (S5), and apply JOIN to C_2 and C_3.

- [Mr.] [Ken Ono went] [skiing]

C_2 is still not equivalent to $T_{i,2}$, and the NE label of the last word "went" is "O". Therefore, we generate a training sample for applying POP to C_2 by (S2), and apply POP to C_2.

- [Mr.] [Ken Ono] [went] [skiing]

C_2 is equivalent to $T_{i,2}$, and a training sample for REDUCE=PER is generated. The remaining C_3 and C_4 are also equivalent to $T_{i,3}$ and $T_{i,4}$, respectively. Thus, two training samples for REDUCE=O are generated.

2.4 NE Recognition

Figure 2 shows a pseudo-code of our NE recognition method. When recognizing NEs from a given word sequence, we first identify an initial word

```
# W: an input word-sequence
# C = {C_1, ... C_|C|}: word chunks
# L = {L_1, ... L_|C|}: NE class labels of word chunks
# Model : a trained model
NERecognition(W, Model)
# Generate a word chunk-sequence
# with a base chunker. j is for C.
C = Chunking(W); j = 1;
while j ≤ |C| do
  # Select an operation. If REDUCE is
  # selected, selectOP returns an NE label l.
  (op, l) = selectOP(C_j,Model);
  if op == REDUCE then
    L_j = l # keep C_j's NE label
    j++ # Move to the next word chunk
  else if op == POP then
    C = POP(C, j);
  else if op == SHIFT then
    C = SHIFT(C, j);
  else if op == JOIN then
    C = JOIN(C, j);
  end if
end while
return C and L
```

Figure 2: A pseudo code of NE recognition.

chunk sequence of the input with a base chunker as in the training.

Then we process each word chunk from the beginning of the sentence to the end of the sentence. An operator to use on the current word chunk is decided upon with a trained model, and each word chunk is processed according to the selected operator. If all the word chunks are processed, we return word chunks with their NE labels.

2.5 An Example of Recognition

Consider the following input data:

```
-Mr.  Jim Ji goes to U.K
```

We identify base chunks of the input as follows.

```
-[Mr.  Jim Ji] [goes] [to] [U.K]
```

We denote this base NE chunking result as C. An operator for each word chunk in C is selected with a trained model $Model$. Here, we assume SHIFT is selected and apply SHIFT to C_1. After applying SHIFT to C_1, C_1 becomes [Mr.], and C_2 becomes [Jim Ji].

```
-[Mr.] [Jim Ji] [goes] [to] [U.K]
```

We start to select an operator for the new C_1, and REDUCE=O is selected. We keep O as the NE class of C_1, and move to the next chunk C_2.

```
-[Mr.]  [Jim Ji] [goes] [to]
[U.K]
```

Next, we select an operator for the C_2, and REDUCE=PER is selected. We keep PER as the NE class of C_2, and move to the next chunk C_3. We continue this NE recognition process for the remaining word chunks. When we process all the word chunks, we return C with their NE labels.

3 Experimental Settings

3.1 Data Set and Evaluation Metrics

We used an extended NE corpus for our evaluation (Hashimoto et al., 2008). This Japanese corpus consists of about 8,500 articles from 2005 Mainichi newspaper. NE tags on this corpus is based on the extended NE hierarchy introduced by Sekine et al (Sekine et al., 2002). The corpus includes 240,337 tags for 191 types of NEs. To segment words from Japanese sentences, we used ChaSen.[1] We created the following sets for this experiment.

- training data: news articles from January to October 2005 in the corpus. The training data includes 1,806,772 words and 205,876 NEs.
- development data: news articles from November 2005 in the corpus. The development data includes 145,635 words and 15,405 NEs.
- test data: news articles from December 2005 in the corpus. The test data includes 177,159 words and 19,056 NEs.

Recall, precision, and F-measure are our evaluation metrics. Recall is defined to be the number of correctly recognized NEs divided by the number of all NEs. Precision is defined to be the number of correctly recognized NEs divided by the number of all recognized NEs. F-measure (FM) is defined as follows:

FM = 2 × recall × precision / (recall + precision).

[1] We use ChaSen-2.4.2 with Ipadic-2.7.0. ChaSen's web page is http://chasen-legacy.sourceforge.jp/. Words may include partial NEs because words segmented with ChaSen do not always correspond with NE boundaries. If such problems occur when we segment the training data, we annotated a word chunk with the type of the NE included in the word chunk. We did not deal with the difference between NE boundaries and word boundaries in this experiment.

3.2 Algorithms to be Compared

The following algorithms are compared with our method.

- Linear-chain structured perceptron (**Linear-Chain**, for short) (Collins, 2002a): This is a perceptron-based algorithm for labeling tags to word-sequences. In this algorithm, features are only generated from each word and its surrounding words.

- Semi-Markov perceptron (**Semi-Markov**, for short) (Cohen and Sarawagi, 2004): This algorithm is based on sequentially classifying chunks of several adjacent words, rather than single words. Ideally, all the possible word chunks of each input should be considered for this algorithm. However, the training of this algorithm requires a great deal of memory. Therefore, we limit the maximum length of the word-chunks. We use word chunks consisting of up to five or ten words. [2]

- NE Chunking and Classification (**NECC**, for short) (Carreras et al., 2002): This method consists of two parts. The first part is a base NE recognition as in our method. The second part is NE classification. Unlike in our method, this method just classifies given word chunks without decomposing and concatenating them. This method was used in the best system of the shared task of CoNLL 2002 (Tjong Kim Sang, 2002).

- Shift-Reduce Parser for NE Recognition (**SR**, for short) (Yamada, 2007): This algorithm is based on shift-reduce parsing for word-sequences. It uses two operators. The first one is shift which concatenates a word and its following word chunk. The other is reduce for annotating an NE label to current word chunk.[3] The algorithm is different from ours in that the initial inputs of their method are word sequences. Thus, each word chunk is constructed little by little. Therefore, the algorithm cannot use features obtained from word chunks at the early stage.

We use the multiclass perceptron algorithm for NECC, SR and SPJR. Thus all of the algorithms are based on perceptron (Rosenblatt, 1958). We apply the averaged perceptron (Collins, 2002a) for all the training algorithms. All the learners and NE recognizers were implemented with $C++$. We used perceptron-based algorithms because perceptron-based algorithms usually show the faster training speed and lower usage of memory than training algorithms, such as MEMM (McCallum et al., 2000), CRFs (Lafferty et al., 2001), and so on. Actually, when we applied a CRFs implementation based on LBFGS (Liu and Nocedal, 1989) to the training data, the implementation consumed 72GB memory which is our machine memory size.

We select the number of the iteration that shows the highest F-measure in the development data for each NE recognizer. We set the maximum iteration number at 50.

3.3 Features

The features used in our experiment are shown in Table 1. As features for Linear-Chain perceptron, we used the following. Here, k denotes the current word position. w_k is the k-th word, and p_k is the Part-Of-Speech (POS) tag of k-th word. We used the word and the POS of the k-th word and the words in 2-word windows before and after the k-th word with the current NE-tag t_k and the NE tag t_{k-1} of the previous word. Each NE tag is represented as IOB1 (Ramshaw and Marcus, 1995). This representation uses three tags I, O and B, to represent the inside, outside and beginning of a chunk. B is only used at the beginning of a chunk which immediately follows another chunk that NE class is the same. Each tag is expressed with NE classes, like I-CL, B-CL, where CL is an NE class.[4] To realize a fast training speed for Linear-Chain, we only used the valid combination of t_k and t_{k-1} in terms of the chunk representation.

[2] This is because when we ran Semi-Markov without the chunk length constraint, it used 72GB memory, which is our machine memory size, and 1 GB swap region on its hard disc.

[3] To compare the performance under the same conditions, we did not use the operator to separate characters from words to recognize partial NEs in words.

[4] We compared five types of chunk representation: IOB1 , IOB2, IOE1, IOE2 (Tjong Kim Sang and Veenstra, 1999) and Start/End (SE) (Uchimoto et al., 2000) in terms of the number of the NE tags. The number of the NE tags for each representation is as follows; IOB1 is 202, IOB2 is 377, IOE1 is 202, IOE2 is 377, and SE is 730. This experiment uses IOB1 because IOB1 has one of the lowest number of NE tags. The number of NE tags is related to the training speed of Linear-Chain. Actually, Linear-Chain using IOB1-based training data was about 2.4 times faster than Linear-Chain using SE-based training data in our pilot study with small training data.

Table 1: Features. k denotes a word positions for Linear-Chain. w_k is the k-th word surface, and p_k is the POS tag of the k-th word. t_k is the tag of the k-th word. TT_k is t_k or the combination of t_k and t_{k-1}. bp is the position of the first word of the current chunk. ep indicates the position of the last word of the current chunk. ip is the position of words inside the current chunk. ($bp < ip < ep$). If the length of the current chunk is 2, we use features that indicate there is no inside word as the features of ip-th words. t_j is the NE class label of j-th chunk. CL_j is the length of the current chunk, whether it be 1, 2, 3, 4, or longer than 4. WB_j indicates word bigrams, and PB_j indicates POS bigrams inside the current chunk.

$[t_j, p_{bp-2}, p_{bp-1}, p_{bp}]$, $[t_j, p_{ep}, p_{ep+1}, p_{ep+2}]$

Semi-Markov, NECC, SR, and SPJR, using word chunks, used features extracted from words in a word chunk and the words in two-word windows before and after the word chunk. The features extracted from chunks differ from those of Linear-Chain.

3.4 Base Chunkers

NECC and SPJR require a base chunker. To compare performances obtained with different base chunkers, we used a rule-based chunker and a machine-learning-based chunker.

We used a chunker that concatenates successive words with noun or unknown POS tags, or words existing in brackets, for the rule based chunker (**RC**, for short). This identification is fast because the chunker only checks POS tags.

Our machine-learning-based base chunker is the SR-based chunker trained to distinguish just two chunks: NE and non-NE. To train a machine-learning-based chunker, we first converted the given training data into a training data for base chunkers. There are only two classes for the training data used for base chunking: NE or not.

For example, the following labeled input,
`Dr. [Toru Tanaka]`$_{PER}$ `goes to [Kyoto]`$_{LOC}$
is converted as follows.
`[Dr.]`$_O$ `[Toru Tanaka]`$_{BNE}$ `[goes]`$_O$ `[to]`$_O$ `[Kyoto]`$_{BNE}$
BNE indicates that the word chunk becomes NE, and O indicates non-NE.

The converted training data are used for training a base NE chunker that identifies base NEs and non-NEs. Words identified as non-NEs are treated as word chunks consisting of a word.

Then we split the converted training data into five portions. To obtain a training set for recognizing NEs, we repeated the following process for all the five portions. We trained a base NE chunker with four out of five the portions of the converted training data. The base NE chunker identified base NEs from the remaining portion. After all the portions were processed, we trained the SPJR- or NECC-based NE recognizer from the five portions along with the NE labels on those correct word chunks.

For recognizing NEs in the test phase, we used a base NE chunker trained with all the given training data converted by the method. To examine whether we can attain high accuracy while maintaining fast training and processing speed, we used SR, the fastest algorithm among our compared algorithms, for training base NE chunkers.

4 Experimental Results

Table 2 shows the experimental results.[5] The NE recognizers based on our method showed good performance. SPJR with RC is the second, and SPJR with SR is the fourth best F-measure on test data. The best and the third systems are Semi-Markov-based ones. These results indicate that features extracted from word chunks contributed to improved accuracy.

To compare the results of SPJR (RC) with the others, we employed a McNemar paired test on the labeling disagreements as was done in (Sha and

[5]We used a machine with Intel(R) Xeon(R) CPU X5680 @ 3.33GHz and 72 GB memory.

Table 2: Experimental results. FM, RE, and PR indicate F-measure Recall, and Precision, obtained with each algorithm, respectively. The dev. and test indicate the results for the development data, and the results for the test data. MEM. indicates the amount of memory size (GB) for the training of each algorithm. TRAIN. indicates the training time for each algorithm (in hours). PROC. indicates the processing speed of the development data for each algorithm (in seconds). (SR) and (RC) indicate NECC or SPJR that uses a SR-based chunker or RC, respectively. The numbers after L= indicate the maximum length of the word-chunks for Semi-Markov perceptron.

Algorithm	FM (RE,PR) for dev.	FM (RE,PR) for test	MEM.	TRAIN.	PROC.
Linear-Chain	78.95 (75.53, 82.68)	80.62 (77.36, 84.18)	12.9	23.54	81.27
Semi-Markov (L=5)	79.46 (76.78, 82.34)	80.90 (78.39, 83.58)	9.8	0.97	41.06
Semi-Markov (L=10)	80.54 (77.46, 83.86)	81.95 (79.04, 85.08)	18.3	1.98	62.96
SR	78.66 (74.53, 83.28)	79.89 (75.84, 84.39)	0.78	0.12	3.54
NECC (SR)	78.81 (72.02, 87.01)	80.61 (73.98, 88.55)	0.76	0.26	5.75
NECC (RC)	51.56 (36.73, 86.49)	50.00 (35.09, 86.93)	0.73	0.08	2.98
SPJR (SR)	79.30 (76.06, 82.82)	80.83 (77.85, 84.05)	0.76	0.29	5.86
SPJR (RC)	79.48 (76.05, 83.23)	81.09 (77.76, 84.71)	3.05	0.27	3.02

Pereira, 2003). We compared results on test data by character units because the ends or beginnings of Japanese NEs do not always correspond with word boundaries. All the results except for Semi-Markov (L=10) indicate that there is a significant difference ($p < 0.01$). This result shows that SPJR (RC) showed high accuracy.

Our method also showed faster training and processing speeds than those of Linear-Chain and Semi-Markov. Specifically, our proposed method with RC showed about a 87 times faster training speed and about a 27 times faster processing speed than those of Linear-Chain. Our method showed about a 7 times faster training speed and about a 21 times faster processing speed than those of Semi-Markov (L=10). In addition, our algorithm requires a lower maximum memory size than Linear-Chain and Semi-Markov.

5 Discussion

5.1 Comparison with Linear-Chain

Our algorithm showed much faster speed than Linear-Chain. This is because the difference of computational procedure. Linear-Chain-based ones run Viterbi algorithm to select the best labeled sequence in terms of the scores assigned by a trained model for each input in both training and testing. When running Viterbi algorithm, Linear-Chain-based ones have to check the connections of class labels. The number of connections is up to K^2, where K is the number of types of class labels. On the other hand, SPJR-based ones greedily recognize NEs.

5.2 Comparison with Semi-Markov

Since the maximum length of the word-chunks affects the performance of Semi-Markov, we evaluated Semi-Markov using two types of the maximum lengths of the word-chunks. Semi-Markov (L=5) showed faster training and processing speed than Semi-Markov (L=10). However, SPJR-based ones still showed much faster training and processing speed than Semi-Markov (L=5). In addition, compared with Semi-Markov (L=5), SPJR (RC) showed higher accuracy and SPJR (SR) showed competitive accuracy. This result indicates that SPJR-based ones show faster speed than Semi-Markov giving up accuracy for improving speed.

5.3 Comparison with SR

SR showed faster training and processing speeds than those of SPJR and NECC using the SR-based base NE chunker. Specifically, SR showed about a 2.4 times faster training speed and about a 1.6 times faster processing speed than those of SPJR. This is because SPJR and NECC require training for the SR-based NE chunker and base NE recognition. However, SPJR showed better accuracy than SR. In addition, SPJR with RC showed faster processing speed than SR. These results indicate that our method using an appropriate base chunker realizes fast processing speed while maintaining accuracy.

5.4 Comparison with NECC

SPJR with RC showed much higher accuracy than NECC with RC. This is because the accuracy of RC-based NEs recognition is low. The SR-based base NE chunker identifies 86.56% of word chunks that become NEs in development data. However, RC identified only 50.75%. NECC can only identify correct NEs from correct chunks. Therefore, NECC with RC showed low accuracy. These results indicate our method based on decomposition and concatenation of word chunks contributed to improving accuracy.

However, SPJR (RC) showed more memory usage than SPJR (SR) and NECC-based ones. This is also related to the accuracy of each base chunker. To correctly recognize NEs from word chunks wrongly identified by the rule-based chunker, more training samples for decomposition or concatenation were generated. NECC showed slightly faster training and processing speeds than SPJR. This may be because NECC identifies the NE class of each word chunk without decomposition or concatenation.

5.5 Computational Efficiency

Our algorithm showed faster training and processing speeds than Linear-Chain and Semi-Markov. Formally, the computational cost of Semi-Markov is $O(KLN)$, where L is the upper bound length of word chunks, N is the length of the sentence and K is the size of the label set. As for Semi-Markov, L is 10 and K is 191 in this experiment. And that of the first order Linear-Chain perceptron is $O(K^2N)$, and K is 202 in this experiment. In contrast, the computational cost of NECC, SR, and SPJR is $O(KN)$ and K is 191.

Semi-Markov required more memory usage than the other algorithms. The number of word chunks of each sentence in Semi-Markov is roughly LN. In contrast, the number of word chunks or words of each sentence for Linear-Chain, NECC, SR, and SPJR are up to N. This indicates that Semi-Markov handles about L times larger space than the other algorithms in terms of the number of nodes. Therefore, it requires more memory usage than the others.

6 Related Work

There have been methods proposed to improve the training speed for semi-Markov-based models and perceptron-based methods. With regard to reducing the space of lattices built into the Semi-Markov-based algorithms, a method was proposed to filter nodes in the lattices with a naive Bayes classifier (Okanohara et al., 2006). To improve training speed of the structured perceptron, distributed training strategies and convergence bounds for a particular mode of distributed the structured perceptron training are provided in (McDonald et al., 2010).

While the formulation is different, SPJR shares similar idea with transformation based learning (Brill, 1995). For example, a transformation-based POS tagging alters the POS tag of each word with an ordered list of transformations. These transformations alter the POS tag of each word based on contextual cues.

Methods using rich information other than semi-Markov-based algorithms are proposed as well. Previous works use N-best outputs to obtain rich features. For example, a boosting-based algorithm and a perceptron-based algorithm for reranking N-best outputs were proposed (Collins, 2002b). Another approach uses feature forests generated from N-best outputs (Huang, 2008). This method merges N-best outputs into a single lattice. In contrast with these methods, which require a computational cost for processing N-best outputs, our method only handles an output.

Our proposed method showed good performance in this experiment, however, there is a drawback due to our recognizing strategy. Since NE recognizers based on our proposed method recognizes NEs greedily, only a mistake may affect later recognition process. In the future, we consider methods to incorporate techniques used in shift-reduce parsing (Huang and Sagae, 2010), like beam search or dynamic programming, into our recognition method for solving the problem.

7 Conclusion

We proposed a method for recognizing NEs from word chunk sequences. Our method uses operators for decomposing and concatenating word chunks. Experimental results showed training and processing speeds of our method are faster than those of linear-chain structured perceptron and semi-Markov perceptron while high accuracy is maintained. In the future we would like to evaluate our method with other tasks, such as NP chunking, and Text Chunking. We would also like to evaluate our method with different base chunkers.

Abstract

The representative method of using morphological evidence for Chinese unknown word (UW) extraction is Chinese word segmentation (CWS) model, and the method of using distributional evidence for UW extraction is accessor variety (AV) criterion. However, neither of these methods has been verified on large-scale corpus. In this paper, we propose extensions to remedy the drawbacks of these two methods to handle large-scale corpus: (1) for CWS, we propose a generalized definition of word to improve the recall; and (2) for AV, we propose a restricted version to decrease noise. We carry out experiments on a Chinese Web corpus with approximate 200 billion Chinese characters. Experimental results show that our methods outperform the baselines, and the combination of the two evidences can further improve the performance. Moreover, our methods can also efficiently segment the corpus on the fly, which is especially valuable for processing large-scale corpus.

1 Introduction

A Chinese word is constructed with one or more Chinese characters. Chinese characters can ambiguously combine to form Chinese words, and there are no explicit delimiters in the text to indicate word boundaries. It is thus crucial for most Chinese natural language processing tasks to maintain a large word list. Given that Chinese language has several productive word creation mechanisms, identification and extraction of UW is an important task for or Chinese NLP tasks.

Chinese unknown word (UW) extraction aims to extract UWs from a given corpus and enrich the word list. Two types of information can be used to determine whether a string of characters in question is a Chinese UW or not, namely the characters that construct the string in question, and the neighbors that this string of characters appears with. The first type of information can be regarded as the morphological evidence, while the second can be viewed as the distributional evidence.

The representative method of using morphological evidence is Chinese word segmentation (CWS) model. CWS is to identify every word token in a given sentence. Using the CWS model, we can define the word-string ratio (WSR) to extract UWs. The representative method of using distributional evidence is the accessor variety (AV) criterion (Feng et al., 2004a).

WSR is directly derived from the CWS method based on character tagging (Xue, 2003). This CWS method is based on the morphological information of the strings in question and their context. Strings with high WSR are considered as words, for high WSR indicates that the corresponding string is segmented as a word by this CWS method with high probability. Though the performance of the CWS method is relatively high, it leaves a number of UWs unrecognized or incorrectly recognized due to erroneous segmentation.

The AV criterion (Feng et al., 2004a) is based on the distributional information. Strings that have various contexts can be considered as words. It is shown that this method works well even for UWs with frequency of about 10. But both words and non-words with high frequency tend to have high AV. This brings noise for UW extraction in a large-scale corpus.

However, neither of these methods has been verified on large-scale Web corpus. In fact, as we observe, they both show certain deficiencies when dealing with large-scale corpus.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 837–845,
Chiang Mai, Thailand, November 8 – 13, 2011.

The emergence of online documents that contain various UWs poses challenges to UW extraction and other Chinese NLP tasks, but also provides a rich resource to make the UW extraction more meaningful.

Taking the two methods above as baselines, we propose two new methods, namely, generalized word string ratio (GWSR), and restricted accessor variety (RAV), by extending the current methods respectively, in order to overcome the relevant problems for large-scale corpus.

For GWSR, we propose a sophisticated way to generalize the definition of word in the CWS model. This method can extract more UWs that cannot be correctly segmented as words. For RAV, as opposed to AV, we restricted the accessors to be a small set of word pairs $(\mathbf{w}_l, \mathbf{w}_r)$ such that $\mathbf{w}_l$ appears right before the string in question and, at the same time, $\mathbf{w}_r$ appears right after the string in question. RAV is especially suitable for a large-scale corpus in which UWs occur with relatively high frequency.

We carry out experiments on a Chinese Web corpus with approximate 200 billion Chinese characters. Experiment results show that our methods outperform the corresponding baselines, and the combination of our methods can further improve the performance. Some examples are shown in the experiments section.

We further investigate the effect of corpus size to UW extraction. The numbers of Chinese characters in corpora range from 20 million to 200 billion. Moreover, our methods can also efficiently segment the corpus on the fly, which is practical for processing large-scale corpus.

The contribution of this paper is twofold. First, we proposed two UW extraction methods which outperform the baselines based on morphological and distributional evidence. Second, our experiments were conducted on corpora with up to 200 billion Chinese characters and provided insights about the effect of corpus size on UW extraction.

2 Background

2.1 CWS as Character Tagging

CWS aims to segment Chinese sentences into words. A practical CWS model needs to handle UWs, which are also named as out-of-vocabulary (OOV) words. If a corpus is perfectly segmented, the UW extraction task is also accomplished.

Xue (2003) proposed a character sequence tagging framework for CWS. Comparing to other methods, it has better performance on dealing with the UWs (Ling et al., 2003; Peng et al., 2004). The sequence tagging framework is also used for named entity identification in English (McCallum and Li, 2003), which is related to Chinese UW extraction.

In this framework, the input is a raw Chinese sentence $\mathbf{s}$, denoted as a sequence of characters c_i:

$$\mathbf{s} = \overline{c_1 \dots c_n} \tag{1}$$

The output of the character sequence tagging is a sequence $\mathbf{t}$ of tags t_i corresponding to the input characters:

$$\mathbf{t} = \overline{t_1 \dots t_n} \tag{2}$$

where $t_i \in \{\mathrm{B}, \mathrm{M}, \mathrm{E}, \mathrm{S}\}$. The tags B / M / E indicate that the corresponding character is at the beginning / middle / end position of a multi-character word. The tag S indicates that the corresponding character is a single character word. The segmentation result of this sentence can thus be determined by the tag sequence.

Given an input sentence $\mathbf{s}$, the output sequence of tags $\mathbf{t}$ is calculated as

$$\mathbf{t} = \arg\max_{\mathbf{t}'} W^T \Phi(\mathbf{s}, \mathbf{t}') \tag{3}$$

where Φ returns a feature vector of the pair $(\mathbf{s}, \mathbf{t}')$, and W is a vector of feature weights. The decoding is to find a $\mathbf{t}$ that maximizes the objective function.

Machine learning methods such as maximum entropy (Ng and Low, 2004), conditional random field model (Peng et al., 2004) and perceptron (Jiang et al., 2009) have been used for this framework.

The features in this framework are mainly composed by character unigrams, character bigrams and tag bigrams. In Chinese, a character is usually a morpheme. Therefore the CWS model based on the character tagging framework can be regarded as a UW extraction method using morphological information.

However, in contrast to CWS, UW extraction focuses on identifying substrings in a corpus that are potential words independent of the environments where they may occur. Though the performance of the CWS method is relatively high, the poor recall of UWs 'is still the Achilles heel of segmentation systems' (Emerson, 2005). The

CWS methods also fails to capture distributional information of the strings in question.

2.2 UW Extraction and the Accessor Variety Criterion

There are methods proposed for UW extraction based on morphological evidence, distributional evidence, or both (Chen and Ma, 2002; Ma and Chen, 2003; Feng et al., 2004a; Hong et al., 2009).

Some methods can be used for both UW extraction and CWS (Sun et al., 1998; Feng et al., 2004b; Jin and Tanaka-Ishii, 2006; Zhao and Kit, 2008). But for CWS, these methods are not comparable with the character tagging based CWS methods (Zhao and Kit, 2008), because the character tagging based CWS methods can better capture the morphological information.

We focus on a UW extraction method based on the distributional information, namely the accessor variety (AV) criterion (Feng et al., 2004a).

Assuming that a string is likely a meaningful unit if it occurs in different linguistic environments (Feng et al., 2004a), AV is defined as:

$$\mathrm{AV}(\mathbf{v}) = \min\{\mathrm{L_{av}}(\mathbf{v}), \mathrm{R_{av}}(\mathbf{v})\} \tag{4}$$

The $\mathrm{L_{av}}(\mathbf{v})$ is defined as the number of distinct Chinese characters that precede $\mathbf{v}$ plus the number of times that $\mathbf{v}$ appears at the beginning of a sentence. The $\mathrm{R_{av}}(\mathbf{v})$ is defined as the number of distinct Chinese characters that succeed $\mathbf{v}$ plus the number of times that $\mathbf{v}$ appears at the end of a sentence. The larger the $\mathrm{AV}(\mathbf{v})$ is, the more likely $\mathbf{v}$ is a word.

In order to fulfill this method, an extra dictionary is needed. And three ad hoc rules are used to discard strings which contain adhesive characters and cannot be words. The details can be found in (Feng et al., 2004a).

This method works well even for strings with low frequency because any distinct character is regarded as an accessor. However, when applying the method to a large-scale corpus in which strings in question are of high frequency, the noise increases considerably due to the lenient definition of the accessor.

3 Our Model

In this section, first we will introduce two UW extraction methods based on a character tagging based CWS model. Then we propose a UW extraction method called restricted accessor variety based on the distributional evidence. Finally, we discuss the combination of these methods.

3.1 Morphological Evidence

3.1.1 Word-string Ratio

A character tagging based CWS model, which is based on the morphological evidence, can be directly used to extract UWs in a corpus. The Word-string ratio (WSR) provides a straightforward way to determine whether a string in question is a word or not. Strings with high WSR are regarded as UWs.

WSR is defined as the ratio of the frequency of $\mathbf{v}$ that is segmented as a word to the frequency $\mathbf{v}$ that occurs as a string in the corresponding corpus:

$$\mathrm{WSR}(\mathbf{v}) = \frac{\mathrm{WF}(\mathbf{v})}{\mathrm{SF}(\mathbf{v})} \tag{5}$$

where word frequency $\mathrm{WF}(\mathbf{v})$ is the number of times that string $\mathbf{v}$ is segmented by the CWS model as a word in the corpus, and string frequency $\mathrm{SF}(\mathbf{v})$ is the number of times that string $\mathbf{v}$ appears in the corpus.

Now we discuss how to define the words in the CWS model. Since the tag sequence $\mathbf{t}$ in the character tagging framework may contain conflicts (e.g., the tag sequence "B B" means that two immediately connected characters are both at the beginning of multi-character words, which is impossible), we use an alternative way to define the words in the output. This new definition is also a preparation for the definition of the generalized word that we will propose.

Recall the decoding process of the CWS model in the character tagging framework described in Equation 3. Given a sentence $\mathbf{s} = \overline{c_1 \dots c_n}$, we define $\mathrm{Conf}(m)$ as the confidence that there is a word boundary after the m-th character c_m ($t_m \in \{\mathrm{E}, \mathrm{S}\}$):

$$\begin{aligned}\mathrm{Conf}(m) = &\max_{t_m \in \{\mathrm{E,S}\}} W^T \Phi(\mathbf{s}, \mathbf{t}) - \\ &\max_{t_m \in \{\mathrm{B,M}\}} W^T \Phi(\mathbf{s}, \mathbf{t})\end{aligned} \tag{6}$$

Obviously, $\mathrm{Conf}(m) > 0$ indicates that there is more likely a word boundary after the m-th character, while $\mathrm{Conf}(m) < 0$ indicates that there is less likely a word boundary after the m-th character.

If the string in question $\overline{c_i \cdots c_j}$ in $\mathbf{s}$ is a word, two confidences of the string boundaries $\mathrm{Conf}(i -$

1) and $\text{Conf}(j)$ should be positive and the confidences inside the string $\text{Conf}(k)$ should be negative for $k = i, \cdots, j-1$. In other words, the string $\overline{c_i \cdots c_j}$ is regarded as a word if and only if:

$$\text{Conf}_{\text{o}}(\overline{c_i \cdots c_j}) > 0 > \text{Conf}_{\text{i}}(\overline{c_i \cdots c_j}) \quad (7)$$

where $\text{Conf}_{\text{o}}(\overline{c_i \cdots c_j})$ and $\text{Conf}_{\text{i}}(\overline{c_i \cdots c_j})$ are defined as:

$$\text{Conf}_{\text{o}}(\overline{c_i \cdots c_j}) = \min\{\text{Conf}(i-1), \text{Conf}(j)\} \quad (8)$$

$$\text{Conf}_{\text{i}}(\overline{c_i \cdots c_j}) = \max_{k=i,\cdots,j-1} \text{Conf}(k) \quad (9)$$

Roughly speaking, words defined according to tag sequence $\overline{t_i \cdots t_j}$ and words defined according to the definition above are identical. In a test set of 107 thousand words, there are only 6 sentences of which the results are not identical.

3.1.2 Generalized Word-String Ratio

Although the CWS model can achieve relatively high performance. It fails to segment many instances of UWs correctly. This makes them hard to be extracted based on WSR.

In order to address this deficiency, we define a notion of generalized word, and we use the Generalized Word-String Ratio (GWSR) to extract UWs as a modified version of WSR. This idea is derived from Liu et al. (2008) and Zhang et al. (2010). For convenience, the term "word" in the rest part of this subsection always refers to a string that is segmented as a word by CWS model.

We define a cost function of string $\mathbf{v} = \overline{c_i \cdots c_j}$ based on the confidence function:

$$\text{Cost}(\mathbf{v}) = \max\{0 - \text{Conf}_{\text{o}}, \text{Conf}_{\text{i}} - 0\} \quad (10)$$

If a string $\mathbf{v}$ is segmented as a single word, the cost function returns a non-positive value; otherwise, it returns a positive value. The larger this value is, the less likely this string can be regarded as a word.

Now we can define GWSR of string $\mathbf{v}$:

$$\text{GWSR}_{\text{th\_LW}}(\mathbf{v}) = \frac{\text{GWF}_{\text{th\_LW}}(\mathbf{v})}{\text{SF}(\mathbf{v})} \quad (11)$$

where the generalized word frequency $\text{GWF}_{\text{th\_LW}}(\mathbf{v})$ is the number of times that string $\mathbf{v}$ appears with $\text{Conf}_{\text{o}}(\mathbf{v}) > \text{Conf}_{\text{i}}(\mathbf{v})$ and $\text{Cost}(\mathbf{v}) \leq$ th_LW in a certain sentence. Here th_LW is a threshold. The inequality $\text{Conf}_{\text{o}}(\mathbf{v}) > \text{Conf}_{\text{i}}(\mathbf{v})$ should be always satisfied. Otherwise it will bring in noise.

Note that $\text{WF}(\mathbf{v}) = \text{GWF}_0(\mathbf{v})$ means that when th_LW $= 0$ only words are regarded as generalized words.

The GWSR provides a way to allow UWs which are incorrectly segmented by the CWS model to be extracted. As a side effect, more noise may be brought in.

3.2 Distributional Evidence

The AV criterion is a method to extract UWs based on the distributional evidence. Here we propose a new version of the distribution-based criterion called restricted accessor variety (RAV) which is more suitable for the extraction from a large-scale corpus. We will describe this method and then discuss the difference between RAV and AV.

The RAV method can be divided into two steps. First, we identify the restricted contexts that words tend to appear in. Second, we count the number of distinct restricted contexts that the string in question appears in.

We define a restricted accessor pair as a pair of words that has the ability to match the majority of words. First, we define the matching between a pair of words $(\mathbf{w}_l, \mathbf{w}_r)$ and a string $\mathbf{v}$. We say that $(\mathbf{w}_l, \mathbf{w}_r)$ and $\mathbf{v}$ match if:

$$\frac{t(\mathbf{w}_l, \mathbf{v}, \mathbf{w}_r)}{f(\mathbf{v})} > \text{th\_RAV} \quad (12)$$

where th_RAV is a threshold. $f(\mathbf{v})$ is the number of times that $\mathbf{v}$ appears as a word or a sequence of words in the corpus segmented by our CWS model. $t(\mathbf{w}_l, \mathbf{v}, \mathbf{w}_r)$ is the number of times that the string $\mathbf{v}$ appears right after $\mathbf{w}_l$ and before $\mathbf{w}_r$ where $\mathbf{w}_l$ and $\mathbf{w}_r$ are also segmented as words.

Given a dictionary, we can find m word pairs which are most likely to match words in the dictionary. These pairs construct a set of restricted accessor pairs $\mathbf{R}$.

The RAV of a string v is defined as the number of restricted accessor pairs that match this string:

$$\text{RAV}(\mathbf{v}) = \sum_{(\mathbf{w}_l, \mathbf{w}_r) \in \mathbf{R}} 1_{[\text{th\_RAV}, \infty)} \left(\frac{t(\mathbf{w}_l, \mathbf{v}, \mathbf{w}_r)}{f(\mathbf{v})} \right) \quad (13)$$

where $1_{[\text{th\_RAV}, \infty)}$ is an indicator function to indicate whether $(\mathbf{w}_l, \mathbf{w}_r)$ and $\mathbf{v}$ match:

$$1_{[\text{th\_RAV}, \infty)}(x) = \begin{cases} 1 & x \in [\text{th\_RAV}, \infty) \\ 0 & \text{otherwise.} \end{cases} \quad (14)$$

The more restricted accessor pairs a string matches, the more likely it is a word.

Notice that the distribution-based method is usually used to measure the semantic distance between words. In our approach, by setting m (the number of restricted accessor pairs) to a relatively small number, the restricted accessor pairs can match any UW, no matter what meaning the word has or what word category it belongs to. Examples of the restricted accessor pairs will be shown in Section 4.3.

RAV is different from AV in at least four ways.

First, RAV is normalized. This prevents RAV from possible noise in the large-scale corpus. In such a corpus, a high frequency string tends to have more accessors which will bring noise to the AV criterion. In contrast, noise may be filtered out by a threshold in Eq. 13.

Second, RAV only considers restricted accessor pairs rather than any characters that precede or succeed the strings. This is also designed to further decrease the noise from a large-scale corpus.

Third, RAV does not need an ad hoc procedure to discard strings with adhesive characters, which prevents RAV from improperly discarding UWs. These adhesive characters in Chinese may also have the ability to be as a morpheme in a word. For example, "地" can be used as a function mark following an adverb, while it can also be a morpheme with the meaning "ground/territory" to form many UWs like "飞地" (enclave, literally "flying territory").

Last but not least, as RAV only concerns with a small number of restricted accessor pairs, RAV is more effective and efficient than AV in a large-scale corpus.

3.3 Combine Morphological and Distribu-tional Evidences

The morphological evidence and the distributional evidence represent the properties of different aspects of the "wordhood". The morphology-based method concerns with the possible character sequence that forms the string in question, and treats each occurrence of the string independently. The distribution-based method is not concerned with how a string is made up by characters, but with the context the string is in.

Evidence shows that these two methods are complementary; we expect to get a better performance by combining them. In this paper we only propose a simple way of linear combination.

4 Experiments

4.1 Dataset and Evaluation Method

A dictionary is needed to distinguish unknown words from known words. We used the same dictionary that Feng et al. (2004a) used. Totally 119,803 words in this downloaded dictionary are used as the known words.

SogouT corpus is an open and free large-scale Web corpus . This Web corpus was also used by Li and Sun (2009) in their semi-supervised CWS model. After certain process to remove non-text content such as the HTML tags, we obtained 119 million web pages consisting of 203 billion Chinese characters.

The whole corpus is denoted as LARGE. We sampled about one percent of these pages as a smaller corpus called MIDDLE, and further sampled about one percent of these pages in MIDDLE as SMALL. Corpora with different sizes are used to investigate how the size of the corpus influences the performances of different UW extraction methods.

It is difficult to evaluate the performance of UW extraction directly on such a large corpus. We used a partial evaluation method similar to the method used by Feng et al. (2004a). We sampled 2000 sentences from a balanced corpus (YUWEI corpus) consisting of news articles, academic articles, textbook articles, novels and other types of texts. Various UWs appear in these sentences. Since Chinese words commonly consist of 2, 3 or 4 characters (Chang and Su, 1997), only strings with length of 2, 3 or 4 in these sentences are considered as the UW candi-dates (strings in question). After filtering the strings that already appear in the dictionary, the remaining 111,536 strings are used as the test set.

In order to annotate these strings in the test set, we used the record of a Chinese input method software as an auxiliary data . We selected strings that are frequently inputted by users and manually annotated 1,630 of them as UWs. The annotation may have bias because the low frequency words tend to be ignored for the manually annotation. But the annotation is still independent of these UW extraction methods we use. Some of the UWs are 小诸葛 (nickname of a Chinese general Bai Chongxi), 二氯甲烷 (methylene chloride), 冬修 (to build in the winter by peasants in their slack

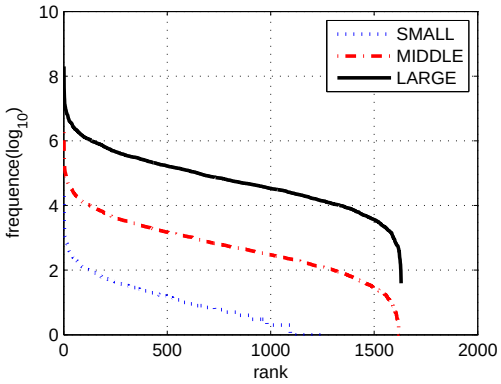

Figure 1: The frequencies of UWs in three corpora

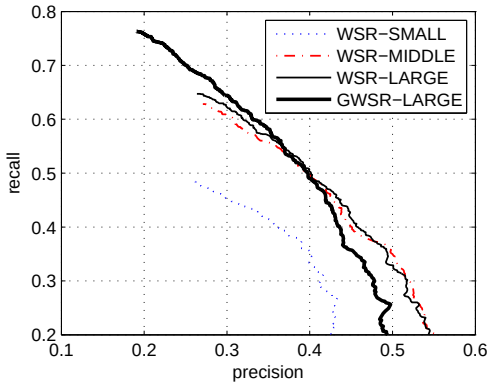

Figure 2: The precision-recall curves for WSR and GWSR on three corpora. The curves of GWSR on the SMALL and MIDDLE corpora are not showed due to the limitation of space.

season) and 官印 (official seal).

Figure 1 is an overview of the frequencies of the UWs in the corpora we used. We can observe the differences between these corpora. A number of UWs even do not appear in the SMALL corpus, while most of the UWs appear with a frequency higher than 10,000 in the LARGE corpus.

We use precision and recall as the evaluation measures:

$$\text{precision} = \frac{\text{\# of retrieved unknown words}}{\text{\# of retrieved words}} \quad (15)$$

$$\text{recall} = \frac{\text{\# of retrieved unknown words}}{\text{\# of annotated unknown words}} \quad (16)$$

The precision-recall curves of every method are drawn for the comparison. For each of these methods, a single threshold can be used to control the number of strings that are extracted. The precision-recall curves are drawn according to these thresholds.

Notice that in the evaluation, all the known words (words that are already in the dictionary) are not counted.

4.2 Morphological Evidence: WSR and GWSR

In this subsection we describe the implementation of our character tagging based CWS model, and the experiment results of the WSR and GWSR methods.

Template
$c_{i-1}t_i$, c_it_i, $c_{i+1}t_i$
$c_{i-2}c_{i-1}t_i$, $c_{i-1}c_it_i$, $c_ic_{i+1}t_i$, $c_{i+1}c_{i+2}t_i$
$t_{i-1}t_i$

Table 1: The feature templates for the CWS model

The CWS model we use is based on the averaged perceptron (Collins, 2002). The features templates are listed in Table 1, which are similar to the templates used for a CRF-based model (Tseng et al., 2005).

The training set provided by Microsoft Research in SIGHAN bake-off 2005 (Emerson, 2005) is used to train our CWS model. The F-measure on the test set was 0.963. This is comparable with the reported best 0.964, which is from a CRF-based model (Tseng et al., 2005).

Additional techniques were used to speed up the decoding of our CWS model. A modified double-array trie (Aoe et al., 1992) data structure was implemented to store and retrieve the feature values. Fix-point numbers (integer) rather than floating point numbers are used for the calculation without losing accuracy. With some other minor improvements, the decoding speed of one process is up to 2 million characters per second. This makes it possible to segment the large-scale Web corpus on the fly.[1]

Since the WSR and GWSR for strings with low string frequency are not precise enough, we discard strings with low string frequency using the thresholds 0, 15 and 1,500 for the SMALL, MIDDLE and LARGE corpora, respectively. The threshold th_LW discussed in Section 3 for GWSR is set to 2.

Figure 2 shows the precision-recall curves for WSR and GWSR on three corpora.

On the SMALL corpus, the performance of

[1]The modified version is available at http://code.google.com/p/perminusminus/

WSR is poor, for the majority of UWs appear with a low frequency or even do not appear in this corpus. On the MIDDLE corpus, the performance is better than the one on the SMALL corpus. But on the LARGE corpus, the performance improvement is not observable comparing to the performance on the MIDDLE corpus. The GWSR behaves similarly to WSR when we enlarge the corpus. This phenomenon indicates that the methods based on the morphological evidence cannot benefit from a larger corpus if the frequencies of corresponding strings are high enough.

Consider this with Figure 1, we find that a frequency of about 100 is enough for WSR and GWSR to determine whether the corresponding string is a word or not.

Now we compare GWSR with WSR on the LARGE corpus in Figure 2. GWSR has a better performance in the left part of the precision-recall curve but a poorer performance in the right part of this curve. We can say that GWSR has a better recall but a poorer precision, which is consistent with our discussion in Section 3.1. Comparing to WSR, the GWSR can extract more UWs, while it brings in more noise as a side effect. The advantage of simply using GWSR instead of WSR is not obvious.

4.3 Distributional Evidence: AV and RAV

The words used to induce the restricted accessor pairs set are all the known words that appear in the 2,000 sentences we sampled from YUWEI corpus. We induce a restricted accessor pairs set of 50 word pairs, which are most likely to match these words. Some of the pairs are (#,#), (#, 和), (到, 的) and (没有,#). # is used as a special word to denote the beginning and the end of a sentence.

Among these 50 word pairs, only 3 pairs contain words with 2 characters. Other words are all single character words. Nearly all the words are function words. 和 (and), 到 (to), 的 (a particle) and 没有 ('no' or 'do not') which are in the pairs we showed are all frequently used function words.

We found that the word with the highest frequency in these pairs is "#", which is consistent with the claim by Li and Sun (2009) that punctuation marks are useful for CWS.

All these pairs have the ability to match a majority of words in different word categories or with different meanings. This result also benefits from the fact that Chinese words do not have inflection

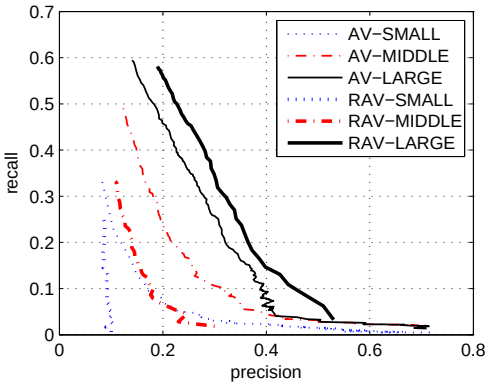

Figure 3: precision-recall curves for AV and RAV on three corpora

and agglutination. For example, an adjective like 幸福 (happy) can be used as a noun (happiness), a verb (be happy) or an adverb (happily) without changing the form.

We calculated AV and RAV for the strings in the test set on these three corpora. We found that RAV is more efficient than AV. According to the formulas, RAV only needs to assign a vector of 50 integers (we use 50 restricted accessor pairs in the experiments) for each string, while AV needs to assign a hash table for each string. Plus, the additional process for AV to discard strings with adhesive characters is also implemented according to the instruction in (Feng et al., 2004a).

Results are shown in Figure 3. Notice that the precision and recall for AV are lower than those reported by Feng et al. (2004a), for in our experiments the known words are not counted. Counting known words, the precision and recall are comparable with those reported by them.

We see that for both methods, larger size of the corpus improves the performances. We can even expect that more data can further enhance these methods.

AV and RAV behave differently when we enlarge the corpus. On both the SMALL and MIDDLE corpus, the AV method is better than the RAV method, whereas on the LARGE corpus, RAV outperforms AV. The reason is that the RAV method strongly depends on the size of corpus. Even 1000 occurrences may not be enough for a relatively accurate RAV of a string. This characteristic is also quite different from the WSR and LWSR methods.

Thus RAV is more suitable than AV when we have a large-scale corpus. Plus RAV does not need an ad hoc process to discard strings with adhesive

characters.

4.4 Combine Morphological and Distribu-tional Evidences

In this subsection we first show the differences of the errors made by the methods based on morphological and distributional evidences, respectively. Then we combine these two kinds of methods and show that the performance will be further improved.

(G)WSR and RAV are based on different evidences. The errors of these methods are thus quite different.

Non-words	GWSR	RAV
逍遥法 (part of "逍遥法外")	0.879	6
脱但 (off but)	0.817	2
一书里 (in a book of)	0.671	10
一个女孩 (a girl)	0	50
实验结果 (experiment result)	0	49
严格把关 (to strictly check)	0	43

Table 2: Some false positive examples for GWSR and RAV in the LARGE corpus

Table 2 shows some non-words that are incorrectly regarded as UWs by GWSR or RAV. Some non-words sun as 逍遥法 have high GWSR values, for they tend to be segmented as words by the CWS models. But they may have low RAV values for they are hard to be used as single syntactic units. Multi-word compounds such as 一个女孩 have high RAV for they have similar distribution as words. But they may have low GWSR because the CWS model tends to segment them into smaller parts with high confidence.

We linearly combine the scores of the morphological and distributional evidences. WSR and GWSR are used as the morphological evidence, respectively. For the AV method contains a filtering process, we cannot assign a value for every string. Only the RAV is used as the distributional evidence.

WSR and GWSR range from 0 to 1, while RAV ranges from 0 to 50. In our experiments, the weights for the morphological and distributional evidences are 50 and 0.8, respectively.

Two thick lines in Figure 4 show the performances of the combinations of the evidences. The precision of combing WSR and RAV (dashed thick line) is increased comparing to WSR. If we replace WSR by GWSR in the combined method

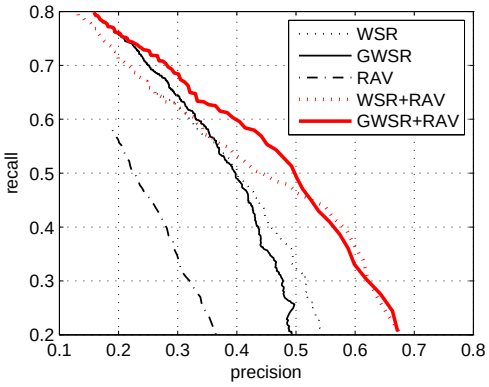

Figure 4: The combination of the morphological evidence and the distributional evidence on the LARGE corpus

(solid thick line), the recall is further increased without observably losing the precision. So the combination of GWSR and RAV outperforms the combination of WSR and RAV.

5 Conclusion

We discussed two UW extraction methods, namely morphology based and distribution based methods. The WSR based on morphological evidence has a relative high performance, while it does not benefit from the use of a large-scale corpus. The performance of the accessor variety (AV) based on distributional evidence improves gradually as we enlarge the corpus. We also proposed two extended methods. The method based on generalized word-string ratio (GWSR) has higher recall comparing to WSR. The restricted accessor variety (RAV) is specially designed for the large-scale web corpus in which the UWs are with high frequency.

Our methods outperformed the baselines, and the combination of the two methods can further improve the performance.

In the future, we will explore how to optimize the combination of GWSR and RAV to further improve UW extraction and the performance of the CWS models in general.

Abstract

Entity linking (EL) is the task of linking a textual named entity mention to a knowledge base entry. It is a difficult task involving many challenges, but the most crucial problem is entity ambiguity. Traditional EL approaches usually employ different constraints and filtering techniques to improve performance. However, these constraints are executed in several different stages and cannot be used interactively. In this paper, we propose several disambiguation formulae/features and employ a Markov logic network to model interweaved constraints found in one type of EL, gene mention linking. To assess our systems effectiveness in different applications, we adopt two evaluation schemes: article-wide and instance-based precision/recall/F-measure. Experimental results show that our system outperforms the baseline systems and state-of-the-art systems under both evaluation schemes.

1 Introduction

Entity linking (EL) is the task of linking a textual named entity mention to a knowledge base (KB) entry, such as linking a person/organization mention to its Wikipedia entry (Kulkarni, Singh et al. 2009; McNamee and Dang 2009). This task has broad applications and is important in information extraction (IE) and text mining.

EL involves many challenges, but the most crucial problem in EL is *entity ambiguity*. Take the name John A. Smith for example. It might appear in KB as John Alexander Smith, John Blair Smith, John D. Smith, etc. Entity disambiguation determines which of all the possible John Smith KB entries a given "John Smith" refers to. Several disambiguation approaches have been proposed to address the entity ambiguity problem. For example, Dredze et al. (2010) formulated the disambiguation task as a ranking problem and developed features to link entities to Wikipedia entries. Zhang et al. (2010) used an automatically generated corpus to train a binary classifier to reduce ambiguities. Dai et al. (2010) collected external knowledge for each entity and calculated likelihoods stating the similarity of the current text with the knowledge to improve the disambiguation performance.

In addition to the entity ambiguity problem, the EL task in Text Analysis Conference (TAC) 2009 introduce the absence issue (McNamee and Dang 2009): for entities that have no corresponding entry in the KB a NIL should be returned. To deal with the absence issue, Bunescu and Pasca (2006) filtered out linked mentions whose scores are less than a fixed threshold. Li et al. (2009) trained a separate binary classifier to validate linked mentions. Dredze et al. (2010) treated the NIL as another KB entry candidate to train their EL ranking model.

Most previous works employed separate stages to execute NIL-filtering and disambiguation. However, a separate-stage approach ignores possible dependencies between NIL-filtering and disambiguation can result in error propagation. Figure 1 illustrates the problem. It shows a biomedical abstract, which discusses the relationship of the gene "CD59" to

TITLE: Structure of the **CD59**-encoding gene: further evidence of a relationship to ***murine*** lymphocyte antigen Ly-6 protein
ABSTRACT: The gene for **CD59** [**membrane inhibitor of reactive lysis** (**MIRL**), **protectin**], a phosphatidylinositol-linked surface glycoprotein that regulates the formation of the polymeric **C9 complex** of complement and that is deficient on the abnormal hematopoietic cells of ***patients*** with paroxysmal nocturnal hemoglobinuria, consists of four exons spanning 20 kilobases. …
PMID [1381503]

Figure 1: An Example of Entity Linking.

other lymphocyte antigens. An EL system must link the human gene entity "CD59" and all its instances in the body of the abstract (including "membrane inhibitor of reactive lysis", "protectin", and "MIRL", in the first sentence) to the EntrezGene database entry ID:966. However, the same name "CD59" in the title refers to a murine gene and, therefore, must be linked to ID:12509 instead. A separate-stage approach is likely to run into trouble with this example. In the EL stage, "MIRL" can be unambiguously linked to ID:996 with high confidence, because a search for the name in EntrezGene returns only one match. Linking the other mentions (e.g. "CD59" and "protectin") to ID:996 is not as easy. For example, "CD59" alone has 18 candidate entries. However, because we know that these names are synonyms of MIRL, we can then link them more easily. Unfortunately, a separate NIL-filtering stage may filter out the entity mention "MIRL" because it is listed as an abbreviation of organization names, such as Mineral Industry Research Laboratory. With a joint inference process we can carry out both tasks simultaneously to avoid this type of error propagation (Poon and Domingos 2007).

Joint inference has become popular recently, because they make it possible for features and constraints to be shared among tasks. For example, Che and Liu (2010) created a joint model for word sense disambiguation (WSD) and semantic role labeling, and Finkel and Manning (2009) integrated parsing and named entity recognition in a joint model. In this paper, we use the Markov Logic Network (MLN) (Richardson and Domingos 2006), a joint model which combines first order logic (FOL) and Markov networks, to unify the NIL-filtering and entity disambiguation stages. The model captures the contextual information of the recognized entities for entity disambiguation as well as the constraints when linking an entity mention to a KB entry—for example, an entity mention can only be linked to a database entry when the mention has not been recognized as an NIL.

Another advantage of employing MLN in our EL disambiguation model is that it is easy to model arbitrary longer range dependencies among entities. For example, the saliency of a given entity in a given discourse is one property that can be modeled with MLN. This property was defined by Gale et al. (1992) in WSD, but has not been applied to EL disambiguation. It states that in a given discourse, there is precisely one entity that is the center of attention. This entity is mentioned over and over again, makes it more salient than others. We can utilize this phenomenon to improve the disambiguation confidence. Continuing with the example shown in Figure 1, ID:996 is a candidate KB entry for the entity "CD59" and all its instances, including "membrane inhibitor of reactive lysis", "protectin", and "MIRL" in the first sentence, we can then assume that ID:996 is more salient than other candidate KB entries. As described in the previous paragraph, we can link the entity "MIRL" to ID:996 with high confidence. Therefore, we are more likely to be able to link all the other entities to ID:996 as well.

Finally, existing EL approaches in biomedical domain assess system performance in terms of the effectiveness of database curation (Morgan, Wellner et al. 2007). In addition, we evaluate our system at a fine-grained resolution, entity by entity. Such an evaluation is more relevant to IE tasks such as the bio-molecular event extraction.

2 Markov Logic

In FOL, formulae are constructed using four types of symbols: constants, variables, functions, and predicates. *Constants* represent objects in a domain of discourse (e.g. people: **Ann**, **John**, etc., or database entries). *Variables* (e.g., x, y) range over the objects. *Predicates* represent the relations among objects (e.g. $correlates$), or attributes of objects (e.g. $hasTitle$). Variables and constants may be typed. An *atom* is a predicate symbol applied to a list of arguments, which may be variables or constants (e.g. $hasTitle(\mathbf{John}, x)$). A *ground atom* is an atom all of whose arguments are constants (e.g. $hasTitle(\mathbf{John}, \mathbf{Mr.})$). A *world* is an assignment of truth values to all possible ground atoms. A KB is a partial specification of a world; each atom in it is true, false or (implicitly) unknown.

A Markov network represents the joint distribution of a set of variables $X = (X_1, \ldots, X_n) \in \mathcal{X}$ as a product of factors: $\mathrm{P}(\mathbf{X} = \mathbf{x}) = \frac{1}{Z}\prod_k f_k(\mathbf{x}_k)$, where each factor f_k is a non-negative function of a subset of the variables $\mathbf{x}_k$, and Z is a normalization constant. As long as $\mathrm{P}(\mathbf{X} = \mathbf{x}) > 0$ for all $\mathbf{x}$, the distribution can be equivalently represented as a log-linear model: $\mathrm{P}(\mathbf{X} = \mathbf{x}) = \frac{1}{Z}\exp(\sum_i w_i g_i(\mathbf{x}))$, where the features $g_i(\mathbf{x})$ are arbitrary functions of (a subset of) the variables' state.

An MLN L is a set of pairs (F_i, w_i), where F_i is a formula in FOL and w_i is a real number represented a weight. Together with a finite set of constants C, it defines a Markov network $M_{L,C}$, where $M_{L,C}$ contains one node for each possible grounding of each predicate appearing in L. The value of the node is 1 if the ground predicate is true, and 0 otherwise. The probability distribution over possible worlds x is given by $\mathrm{P}(\boldsymbol{X} = x) = \frac{1}{Z}\exp\left(\sum_{i\in F}\sum_{j\in G_i} w_i g_j(x)\right)$ where Z is the partition function, F is the set of all first-order formulae in the MLN, g_j is the set of groundings of the ith first-order formula, and $g_j(x) = 1$ if the jth ground formula is true and $g_j(x) = 0$ otherwise. General algorithms for inference and learning in Markov logic are discussed in Richardson and Domingos (2006). We employ thebeast toolkit (downloaded from http://code.google.com/p/thebeast/) to implement our MLN model. It uses 1-best MIRA online learning method for learning weights and employs cutting plane inference (Riedel 2008) with integer linear programming as its base solver for inference at test time and the MIRA online learning process.

3 Methods

In this paper, we tackle one type of EL, gene mention linking, which links each gene entity mention to one EntrezGene ID. EntrezGene (Maglott, Ostell et al. 2006) is the most popular large scale gene database. Generally speaking, the EL task can be separated into four steps: (1) identifying entities in a given article, (2) filtering NIL entity mentions, (3) finding candidate KB entries (or database IDs) for the remaining entity mentions, and (4) picking one KB entry for each entity mention. To concentrate on EL's major challenge, our MLN-based system only focuses on steps 2 and 4. In the following section, we define the main formulae used in our MLN-based EL system.

3.1 Linking Constraints Formulae

First, we illustrate a basic formula for the assumption that if an entity is mapped to only one KB entry, it should be linked to the entry:

Formula L.1

$$\exists!\, id.\, hasCandidate(i, id) \Longrightarrow isLinkedTo(i, id)$$

where $hasCandidate(i, id)$ represents that the ith entity mention has a candidate entry id; and $isLinkedTo(i, id)$ represents that i is linked to id.

Note that we refer to an entity by its order in the article (e.g., the ith entity) for several reasons. One, not all names can be found in the training data. Secondly, even if two entities have the same surface string, they may link to different KB entries. Lastly, this allows us to model the order information and dependency among all entities.

Because the objective of the EL task is to discover a unique KB entry for each entity, we must define a formula to ensure that the constraint is satisfied. We use the following formula to prevent an entity associating with more than two entries.

Formula L.2 $isLinkedTo(i, id_1) \wedge id_1 \neq id_2 \Longrightarrow \neg isLinkedTo(i, id_2)$

Formula L.2 is a hard constraint that must always hold whereas the others are soft and can be violated.

3.2 Saliency Formula

The saliency property can be written as follows:

Formula S.1: Saliency:

$$i < j \wedge isLinkedTo(i, id) \wedge hasCandidate(j, id) \Longrightarrow isLinkedTo(j, id)$$

In other words, if the KB entry id is linked to an entity i that precedes the current mention j, and id is a candidate KB entry of j, then the current entity j should also be linked to id.

3.3 Disambiguation Formulae

As shown in Table 1, there are numerous observed predicates defined for the disambiguation process. Before diving into the details of all the formulae, we summarize the basic idea and describe how one could apply it to other EL tasks.

In our disambiguation approach, we rely on background knowledge k, such as an entity's inhabited location, or an entity's skill or functionality. k describes various aspects of the entity i's ambiguous KB entry, id. Whenever the entity is discussed, some of these aspects will be mentioned as well. Using k, we can write formulae like the following for disambiguation:

hasCandidate(*i*, *id*)	
hasChromosomeInfo(*i*, *id*, *sd*) *hasWord*(*w*): the abstract contain a word *w*. *PPIKeyword*(*w*), *isPPIPartner*(id_1, id_2) *hasPPIPartnerRank* (*i*, *id*, *r*), *hasGOTermRank*(*i*, *id*, *r*), *hasTissueTermRank*(*i*, *id* ,*r*) *hasPrecedingWord*(*i*, *w*, *l*), *hasFollowingWord*(*i*, *w*, *l*) *hasUnigramBetween*(*i*, *j*, *w*)	
Variable Type	*i*: an integer, which refers to the *i*th gene mention in the given article (similarly *j* refers to the *j*th mention) *id*: an EntrezGene ID, which refers to a linked KB entry. *sd*: an integer, which refers to the sentence distance. *w*: a word. *r*: an integer, which refers to the rank of the matching. *l*: an integer, which refers to a context window length.

Table 1: Main Predicates for Disambiguation.

$Content\_Knowledge(i, id, k) \Rightarrow isLinkedTo(i, id)$

The formula shows that if the context of the entity i, which has a linking candidate KB entry id, contains the background knowledge information k, the entity i should be linked to id.

In this paper, we define four predicates to capture the recognized genes' background information, including chromosome location, protein-protein interaction (PPI), tissue type and gene ontology. For example, the predicate $hasChromosomeInfo(i, id, sd)$ indicates that the chromosome location information of the i th entity, which has the KB entry id as its linked candidate entry, can be found in the surrounding text in the range sd. Applying this predicate to the sentence: "The human **UBQLN3** gene was mapped to the *11p15* region of chromosome 11," the entity mention UBQLN3 must be linked to the KB entry ID:50613 because 50613's chromosome location, *11p15*, is found in the same sentence. The formula describing the relation of $hasChromosomeInfo$ and $isLinkedTo$ is defined as follows:

$$hasChromosomeInfo(i, id, +sd) \Rightarrow isLinkedTo(i, id)$$

Here, we can see that there is an additional parameter $(+sd)$ in $hasChromosomeInfo$. sd indicates where the chromosome information corresponding to id locates. The "+" notation in the above formula indicates that we must learn a separate weight for each grounded variable (sd). For example, $hasChromosomeInfo(i, id, 0)$ and $hasChromosomeInfo(i, id, 1)$ are given two different weights in our MLN model after training.

Correlation information, such as "KB entry id_1 usually interacts with an entry id_2", can be used in disambiguating an entity i as follows. The PPI information recorded in the database can provide the correlation information. Based on the correlation information as well as the candidate KB entry distribution in the current context, the id that correlated with the most unambiguous entries is the most likely id to be linked to i. We define the predicate $hasPPIPartnerRank(i, id, r)$ to represent this concept. The formula defining the relationship between $hasPPIPartnerRank$ and $isLinkedTo$ is:

$$\exists! id.\, hasPPIPartnerRank(i, id, 1) \wedge \exists w.\, hasWord(w) \wedge PPIKeyword(w) \Rightarrow isLinkedTo(i, id)$$

One can see that there are two predicates, $hasWord$ and $PPIKeyword$, in this formula that check if the article contains PPI keywords. Two similar predicates, $hasGOTermRank$ and $hasTissueTermRank$, represent the concept that i should be linked to the id with the largest number of corresponding gene ontology terms (entity's function) or tissue terms (entity's location) found in the context.

For the correlation information, we further define the following formula to capture the dependency that an entity j should be linked to id_2 if another entity i has been linked to id_1, and id_1 forms a correlation with id_2:

Formula D.1

$$\exists w.\, hasWord(w) \wedge PPIKeyword(w) \wedge isLinkedTo(i, id_1) \wedge hasCandidate(j, id_2) \wedge isPPIPartner(id_1, id_2) \Rightarrow isLinkedTo(j, id_2)$$

This formula shows another long range dependency among entities used in our MLN model (The first long dependency formula is S.1).

Finally, an entity mention j may sometimes be followed by its variant i (abbreviation or full name). Usually, the variant i is put in parentheses. If i can be uniquely linked to id, it is very likely that j is also linked to id. An example formula is shown as follows:

$$hasPrecedingWord(i, "(", 1) \wedge hasFollowingWord(i, ")", 1) \wedge \exists! u.\, hasUnigramBetween(i, j, u) \wedge \exists! id.\, hasCandidate(i, id) \wedge u = "(" \Rightarrow isLinkedTo(j, id)$$

3.4 NIL-filtering Formulae

We approach the absence issue by filtering the following mention type: those belonging to classes that are not in the database curation target; called NILs. In linking gene mentions to KB entries, NILs appear when the gene mentions are protein families or complexes, or in a specific organism that is not considered. For example, in Figure 1, an EL system must return NIL for "C9

hasName(*i*, *n*) *hasFirstWord*(*i*, *w*), *hasLastWord*(*i*, *w*), *isBlacklisted*(*w*): the word sequence *w* is blacklisted, *containsMoreSpecificMentions*(*i*): the *i*-th gene mention collocates with more specific gene mentions in the current context. *SpeciesTerm*(*w*), *AllUpperCase*(*i*), *hasPartOfSpeech*(*i*, *k*, *p*)	
Variable Type	*n*: a word or a sequence of words that refer to the surface name of a gene mention. *ch*: characters. *d*: an integer. *k*: the *k*th index of the gene mention. *p*: a part-of-speech

Table 2: Main Predicates for NIL-filtering.

complex" in the first sentence, because the mention is a protein complex that is not EntrezGene's curation target. The predicate $isSuitableForLinking$ describes this concept.

We then employ the following formula to ensure that, whenever the ith entity is linked to a KB entry id, it must be an entity suitable for linking.

$$isLinkedTo(i, id) \Rightarrow isSuitableForLinking(i)$$

The formula models the stage decisions determined by traditional EL systems. The KB entry *id* does not have to be linked to the entity i proposed by the entity recognition/classification stage; however, the *id* cannot be assigned to the ith gene mention that has not been proposed as a potential entity. The formula is a hard constraint.

The initial formula containing $isSuitableForLinking$ treats any entity i with surface name n as a potential entity:

$$hasName(i, +n) \Rightarrow isSuitableForLinking(i)$$

Again, the "+" notation in the above formula indicates that the MLN must learn a separate weight for each entity name n.

In person name EL, for example, one could define $hasTitle$ to indicate that a title, such as Mr. or Mrs., appears in the ith entity's context and apply the formula for the $isSuitableForLinking$ predicate:

$$hasTitle(i, +t) \Rightarrow isSuitableForLinking(i).$$

In our work, we construct our formulae by using the observed predicates defined in Tables 1 and 2 to determine whether or not i is a NIL by checking i's context. For example:

$$hasFirstWord(i, +w) \wedge SpeciesTerm(+w) \Rightarrow isSuitableForLinking(i)$$

implies that a certain gene mention i's suitability for linking depends on whether or not i's first word is a certain species keyword w.

4 Results

4.1 Evaluation Metrics

We use two metrics to evaluate our approach and compare it with other EL disambiguation methods. Both use the standard precision, recall, and F-measure metrics (PRF) at two resolutions (article and instance).

Article-wide evaluation is based on the standard used in the BioCreative challenge (Morgan, Lu et al. 2008), which was designed to determine an EL system's performance as an aid for the curation of biological databases. The EL system outputs a list of EntrezGene IDs for a given article. The list is then compared to the gold standard IDs list for the article. The PRF scores are calculated based on the sums of true/false positives/negatives (TP, TN, FP, FN).

Instance-based evaluation measures the EL performance at a fine-grained IE resolution, which can support the development of advanced IE tasks. In contrast to the first metric, the PRF scores are calculated based on the sums of TP, TN, FP and FN for all instances in the test dataset; we further consider whether the boundary matches that of the linked KB entry's mention. Therefore, under this criterion, an FP could link a true entity to the wrong KB entry or link a false entity to any KB entry; while an FN could link a true entity to the wrong KB entry or fail to recognize a true entity. In cases where a true entity is linked to the wrong KB entry, both the FN and FP are increased by 1.

For TP/FP/FN, we need to determine when the predicted boundary matches that of the gold standard. Most entity recognition tasks use "exact-matching" as the primary criterion. Under this criterion, a candidate entity can only be counted as a TP if both its left and right boundaries fully coincide with the gold answer. However, in a real scenario, a gene mention can be tagged in several ways (e.g., "… between serum <entity>LH</entity>" and "… between <entity>serum LH</entity>" are both correct). Furthermore, for the EL task, the correctness of the linked KB entry is more important than its boundaries. Therefore, we use approximate-matching (Subramaniam, Mukherjea et al. 2003) to determine the boundary criterion. For example, a TP is counted when a machine-linked gene mention is a substring of the gold standard-linked gene mention or vice versa, and the linked KB entry is equal to the gold entry.

4.2 Dataset

In the experiments we used the training and test sets released by the BioCreative II gene normalization (GN) task (Morgan, Lu et al. 2008). The dataset provides a list of human gene EntrezGene database entries (IDs) that appear in each abstract. Although the gold standard answers contain each EntrezGene database entry's surface name shown in the abstract, they do not give the exact location of the corresponding entity mention in the abstract. So the original BioCreative II dataset can only be used to evaluate article-wide EL performance.

To obtain instance-based evaluation results, we need to expand the original annotation of the dataset. Our in-lab biologists annotated the exact locations and boundaries of the KB entries' gene mentions in a semi-automated manner. The automated annotation process used the entry's surface name provided by the gold standard to tag the entire corpus. Human annotators then corrected the recognized entities and linked results based on the context.

To compile the EL training corpus for our EL models, we employed a state-of-the-art gene mention linking system released by Lai et al. (2009) to recognize all gene mentions and generate candidate KB entries for each entity. For each mention *m* in a sentence *s* recognized by Lai's system and the set of KB entry candidates for *m* output by Lai's system, we searched *s* for the first human annotated mention *n* overlapping with *m* and set *n*'s KB entry as *m*'s true KB entry. Other candidates were set as *m*'s incorrect KB entries.

For the NIL-filtering corpus (NIL corpus), again, for each mention *m* in a sentence *s* recognized by Lai's system, we checked whether or not the boundary of the mention *m* match with the human annotated boundary. All matched mentions are regarded as true positives while the others are negative instances.

4.3 Model Configurations

For our experiments, we constructed four MLN-based configurations. In addition, separate-stage models for NIL-filtering and disambiguation were also constructed.

$\mathbf{MLN_{LINK}}$: To assess baseline performance without disambiguation and NIL-filtering, we constructed an MLN-based configuration, MLN_{LINK}, only employing formulae related to linking constraints (refer to section 3.1). We compared its performance with that of a modified version of Lai's system, for which all mentions with only one KB entry were directly treated as answers, and entities with more than one candidate KB entry were discarded. This system is referred to as **$\mathbf{Lai_{NO\_DIS}}$**.

$\mathbf{MLN_{SAL}}$: To assess the performance gain from the saliency property, we constructed a second MLN-based configuration, MLN_{SAL}, by adding the formula corresponding to the saliency property (Formula S.1) to the MLN_{LINK} configuration.

$\mathbf{MLN_{DIS}}$: This configuration uses the constraints defined in Section 3.1, the saliency property in Section 3.2, and the disambiguation formulae defined in Section 3.3. We compared it with two other previous approaches: Lai et al.'s rule-based approach and Crim et al.'s (2005) supervised learning approach, which treated the EL disambiguation task as a classification problem and solved by employing the maximum entropy (ME) model. For Lai et al.'s approach, denoted as **$\mathbf{Lai_{DIS}}$**, we directly employed Lai et al.'s original system, which had been well-tuned on the BioCreative II GN dataset. One can refer to their work (Lai, Bow et al. 2009) for more details. For the supervised learning approach, denotes as **$\mathbf{ME_{DIS}}$**, we transformed the formulae described in Section 3.3 to binary feature functions in ME.

$\mathbf{MLN_{JOINT}}$: The final MLN-based configuration (MLN_{JOINT}) was constructed by adding the NIL-filtering formulae to MLN_{DIS}. That is, all formulae introduced in Section 3 were employed.

$\mathbf{ME_{NF}}$ for separate NIL-filtering: To simulate and compare the separate-stage NIL-filtering and EL disambiguation approach with MLN_{JOINT}, we developed a separate NIL-filtering model for Lai_{DIS} and ME_{DIS}, denoted as **$\mathbf{ME_{NF}}$**. The ME_{NF} model was executed before the disambiguation step. We formulated the NIL-filtering task as a classification problem and used the features equivalent to the formulae described in Section 3.4 to train a ME-based classifier.

We employed the greedy backward sequential selection algorithm (Aha and Bankert 1995) to select the optimized feature sets for ME_{NF} with ten-fold cross validation on the training dataset. The algorithm starts from all features transformed from NIL-filtering formulae and repeatedly removes a feature whose removal yields the maximal performance improvement in the overall EL task. Note that the feature selection procedure is designed for optimizing

the performance of EL not NIL-filtering. We will discuss this in Section 5.3.

In the next sub-section, we discuss the instance-based IE results. Then, we derive BioCreative's evaluation results by merging the linked KB entries in all indexes and removing duplicated entries.

4.4 Experiment Results

Table 3 shows the instance-based and article-wide results evaluated on the test set. The first three columns show each system's PRF. The last column shows the relative advantage of F-score over the rule-based baseline (Lai_{NO_DIS}).

In the second row, we can see that MLN_{LINK} achieves exactly the same performance as Lai_{NO_DIS}, indicating that the MLN-based system can simulate Lai_{NO_DIS} by only employing the linking constraints. In the third row, we can observe that, by adding S.1, the recall rate is improved by 2.7% which results in an improved F-score. This shows that the saliency property is effective in instance-based evaluation. However, MLN_{SAL} performs slightly worse than MLN_{LINK} in the article-wide evaluation, the reason for which is explained in Section 5.1.

From the fourth to the sixth row, we can see that MLN outperforms the other two models. Adding disambiguation formulae also further boost the EL performance in both instance-based and article-wide evaluations by an apparent large margin (3.6% and 13.7%).

Finally, in the last configuration set (7th, 8th, and 9th row), we can see that MLN_{JOINT} does better than the compared separate-stage methods under both evaluation metrics. MLN_{JOINT} also achieves the best performance among all MLN-based models under both instance-based and article-wide evaluations.

Metrics	Instance-based (%)				Article-wide (%)			
Config.	P	R	F	Adv	P	R	F	Adv
Lai_{NO_DIS}	80.7	56.3	66.3	-	77.3	71.5	74.3	-
MLN_{LINK}	80.7	56.3	66.3	-	77.3	71.5	74.3	-
MLN_{SAL}	79.5	59.0	67.7	+2.1	77.2	71.3	74.1	-0.2
Lai_{DIS}	72.9	63.9	68.1	+2.7	82.6	83.4	83.0	+11.7
ME_{DIS}	79.2	58.2	67.1	+1.2	88.8	79.0	83.6	+12.5
MLN_{DIS}	73.8	64.3	68.7	+3.6	86.1	83.0	84.5	+13.7
ME_{NF}+Lai_{DIS}	73.7	64.2	68.7	+3.6	84.1	83.7	83.9	+12.9
ME_{NF}+ME_{DIS}	80.2	58.4	67.6	+2.0	90.2	79.0	84.3	+13.4
MLN_{JOINT}	77.5	63.7	70.0	+5.6	87.7	83.8	85.7	+15.3

Table 3: Instance-/Article-wide Results on the BioCreative Test Set.

5 Discussion

5.1 Model Long-range Dependencies

One advantage of employing MLN in our EL modeling is that it is easy to model arbitrary longer range dependencies, as expressed by the formula S.1 and D.1. It is difficult to model such dependencies using ME. As shown in Table 3 (MLN_{SAL}), adding the S.1 dependency improves instance-based EL performance without any domain knowledge. A similar result is achieved by adding D.1 with PPI—instance-based performance can be improved by 1.1%/0.6% on the training/test set, respectively. We also observe that adding Linking formulae with S.1 reduces the recall rate in the article-wide evaluation. According to our analysis, S.1 improves the recall in the instance-based evaluation. In contrast, for article-wide, S.1 slightly reduces the recall. This is because after adding S.1, mentions tend to be linked to "salient" KB entries. In instance-based evaluation, the salient KB entries have higher frequency; therefore, the improvement of linking salient entries can cover the losses caused by disregarding the un-salient entries. However, in the article-wide evaluation, all entries in an article are counted equally; therefore, the improvement of instance-based evaluation does not transfer to article-wide evaluation.

5.2 Linking to Multiple KB Entries

Another advantage of our model is its flexibility. The EL task is usually defined as linking an entity to a unique KB entry. However, in some cases, there are entities that cannot be uniquely linked. For example, the "ABCB9 protein" in the sentence "**ABCB9 protein** appears to be most highly expressed in the Sertoli cells of the seminiferous tubules in *mouse and rat testes*."

The EL system cannot link each of the gene mentions in the above sentences to just one EntrezGene KB entry. Our model can deal with the issue easily by modifying the constraint in L.2 with a larger cardinality, or introducing additional formulae to determine the cardinal constraint dynamically.

5.3 Joint Model vs. Separate-stage Models

Compared with the two separate-stage approaches, MLN_{JOINT} has the following two advantages: (1) it performs several functions using one model, and (2) it finds the optimal solution for the integrated stages. The first advantage has been illustrated by Meza-Ruiz et al. (2009). This is to be contrasted with separate-stage systems where several components need to be trained and integrated by different strategies.

The second advantage is based on our observation on the training set, employing all features transformed from NIL-filtering formulae in the ME_{NF} model might be able to achieve the best NIL-filtering performance, but it does not guarantee that the final integrated EL performance can also be the best. This is the reason why we need to employ the backward feature selection algorithm to optimize EL performance for the separate-stage systems as described in Section 4.3.

5.4 Boundary Issue in EL

Our experiment results raise an interesting question: What causes absolute score differences between the instance-based and article-wide evaluations. Several works have studied the boundary issue in entity recognition (Finkel, Dingare et al. 2005; Tsai, Wu et al. 2006). We observe that the issue also has a significant effect on the performance of EL. For example, consider the following sentence in the training set (PMID: 9346890): "<entity id=3083>Hepatocyte growth factor (HGF) activator</entity> is a serine protease responsible for proteolytic activation of <entity id=3082>HGF</entity> in response to tissue injury"

We found that Lai et al.'s system and the three publically available gene mention recognition systems[1] all separate the first gene mention (ID:3083) into at least one mention, ("hepatocyte growth factor" or "HGF"). The incorrect boundary leads to errors in EL, and could result in the extraction of an incorrect self-activation event: <entity id=3082>HGF</entity> activates <entity id=3082>HGF</entity>. An experiment conducted on the test set shows that our MLN model can achieve an F-score 79.4% in instance-based evaluation if we replaced the predicted mentions' boundaries with their corresponding overlapping gold boundaries.

5.5 Related Works

The EL problem comes up in many fields of research. Among database researchers, this problem is described as data de-duplication (Sarawagi and Bhamidipaty 2002). In the AI community, the same EL problem is described as entity resolution (Singla and Domingos 2006; Bhattacharya and Getoor 2007). In the biomedical field, term identification (Krauthammer and Nenadic 2004) or normalization (Hirschman, Colosimo et al. 2005) are used to refer to the same concepts.

Several approaches had been proposed to deal with EL tasks. The following four points explain the distinctiveness of our work. The first is that, as the names of different database entries might be identical, techniques based purely on character/token-based similarity metrics do not work well. The second is that, in our task, all KB entries in the database are unique while it is not true in the tasks tackled by previous works. Third, in our EL task, measuring the similarity between a KB entry and an entity mention requires comparing their related information (fields). The former's can be acquired from the KB while the latter's should be extracted from its context. The latter's is hard to extract because the context is written in natural language, which is unstructured and some information may not appear in the context. This phenomena is against the assumption most previous EL approaches (Fellegi and Sunter 1969; Elmagarmid, Ipeirotis et al. 2007) based on: entities should have the same set of fields. Finally, as described in Section 1, our work needs to consider the absence issue to filter out NIL entities, which are not considered in the most previous EL approaches.

6 Conclusion

In this paper, we present a novel approach that employs MLN to model the constraints and decisions in the EL task. The contribution of this paper is threefold. First, we propose several features for EL disambiguation and NIL-filtering and demonstrate a feasible approach for modeling them by using an MLN. Second, unlike existing EL disambiguation approaches, which do not model the dependencies among entities, the proposed approach learns to model the dependencies, including the saliency and interaction among KB entries, and the performance improvement is promising. Third, we describe a new evaluation scheme that use the BioCreative corpus to analyze EL tasks from an additional perspective, instance-based evaluation, which have not yet been applied in the EL field thus far.

Abstract

News comment is a new text genre in the Web 2.0 era. Many people often write comments to express their opinions about recent news events or topics after they read news articles. Because news comments are freely written without checking, they are very different from formal news texts. In particular, named entities in news comments are usually composed of some wrongly written words, informal abbreviations or aliases, which brings great difficulties for machine detection and understanding. This paper addresses the task of named entity recognition in Chinese news comments on the Web. We propose to leverage the entity information in the referred news article to improve named entity recognition in the news comments. Three different schemes are investigated to find useful entities in the news article for new feature generation in the CRFs model. Finally, a dictionary-based correction step is employed to further improve the results. We manually labelled a benchmark dataset with 60 pieces of news and 6000 comments downloaded from a popular Chinese news portal – www.sina.com.cn. The experimental results on the dataset show that our method is effective for this special task.

1 Introduction

Named entity recognition (NER) is one of the fundamental tasks in the field of natural language processing. It has been widely used in the areas of information retrieval, machine translation, question answering, and so on. In most literatures, named entities are defined as entity names (person names, location names and organization names). With the advent of MUC, CONLL, ACE and SIGHAN evaluations, NER has received much attention of the researchers and hence achieved great development.

News comment is a new text genre in the Web 2.0 era, and many people often write and post comments to express their opinions on recent news events or topics after they read news articles. As the roles which people play on the internet have gradually changed from acquirers to suppliers, news comments have become one of the most valuable information resources. For example, on one of the popular Chinese news portals – sina.com.cn, every piece of hot news is associated with over 500 comments. Named entity recognition is the basis of many other news comments understanding and mining applications, including entity relation extraction, opinion holder and target extraction in news comments, and so on.

Because news comments are freely written by different persons with different education backgrounds and writing styles, they are very different from formal news texts. In particular, Chinese news comments have the following properties:

1) The texts in news comments are very informal and noisy, especially for entity names. There are always many noisy pieces of texts in the comments because the comments are written by various users, e.g., wrongly written words, extra spaces, meaningless characters, or informal names, etc. For example, "汇源/Huiyuan" may be wrongly written to the word "汇圆/Huiyuan".

2) News comments are written with various styles. Since the comments are written by different users with different backgrounds, each one has its own writing style. Different users may use different words and phrases to express the same entities. For example, "八一队/Bayi Team" may be written as "81 队".

3) The texts in news comments are usually very short and concise. The average length of each comment is about 20~25 characters in our dataset. Many entity names in news comments are abbreviated in various ways. For example, "信息科学技术学院/School of Electronics En-

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 856–864,
Chiang Mai, Thailand, November 8 – 13, 2011.

gineering and Computer Science" may be abbreviated as "信院", "信科" or "信息".

4) Most news comments are relevant to the news topics in the referred news article. There is usually a strong relationship between news comments and the news article. Most news comments are focusing on the entities or events introduced in the news article, or related entities and events. For example, given an news article about "姚明/Yao Ming", some news comments may talk about the players and teams explicitly mentioned in the news article, such as"姚明/Yao Ming" or "休斯敦火箭队/Houston Rockets", and other news comments may talk about related players and teams in NBA, such as "奥尼尔/O'Neal" and "菲尼克斯太阳队/Phoenix Suns".

The first three properties bring great challenges for named entity recognition from Chinese news comments. But the fourth property brings very useful knowledge for the task. In this study, we focus on the task of named entity recognition in Chinese news comments on the web, which has not been investigated yet. Considering the close relationships between named entities in the referred news article and named entities in the news comments, we propose to leverage the entity information in the news article to improve named entity recognition in the news comments. Three schemes are exploited for collecting useful entities from the news article, and then the entity information is incorporated into the CRF-based algorithm for recognizing named entities in the news comments. Finally, an additional correction step is used to further improve the performance.

We manually labeled an evaluation dataset with 60 pieces of news and 6000 news comments from a popular Chinese news portal (www.sina.com.cn). Experimental results on the dataset show that our proposed approach is effective for the task of NER in news comments. The use of focused entities and related entities in the referred news article is very beneficial for the task.

The rest of this paper is organized as follows. Section 2 introduces related work. Section 3 presents our proposed approach. Section 4 shows the experimental setup and results. Finally, Section 5 summarizes the conclusions.

2 Related Work

Traditional named entity recognition systems use linguistic grammar-based techniques as well as statistical models. The techniques can be categorized into rule-based (Sekine and Nobata, 2004; Chiticariu et al., 2010), machine learning-based (including unsupervised, supervised and semi-supervised methods) (Bikel et al., 1999; Mayfield et al., 2003; McCallum and Li, 2003; Bender and Ney, 2003; Florian et al., 2003; McCallum and Li, 2003; Etzioni et al., 2005; Klementiev and Roth, 2006; Okanohara et al., 2006; Finkel and Manning, 2009; Singh et al., 2010) and hybrid models (Srihari et al., 2001). The most popular statistical models for named entity recognition include Support Vector Machine, Hidden Markov Model, Maximum Entropy Model, Conditional Random Fields, and so on. Background knowledge derived from Wikipedia and WordNet has been used for improving the NER task (Kazama and Torisawa, 2007; Richman and Schone, 2008; Pennacchiotti and Pantel, 2009). Most previous works have investigated the NER task over formal text such as news articles. These kinds of texts are written by professional writers, and thus they are well organized and well-structured, and they have seldom grammatical and spelling errors and noises.

Recently, a few works have investigated the task over informal English texts such as emails and blogs. Huang et al. (2001) address the problem of extracting identity and phone number of the caller from voicemail messages, and they present three typical information extraction methods: hand-crafted rule-based method, maximum entropy models, and probabilistic transducer induction. Jansche and Abney (2002) present a two-phase procedure consisting of a hand-crafted component and a classifier for information extraction from voicemail. Minkov et al. (2005) propose to use email-specific structural features and a recall-enhancing method for improving person name recognition from email. Gruhl et al. (2009) explore the application of restricted relationship graphs and statistical techniques to improve named entity annotation in on-line forum texts discussing popular music.

Generally speaking, the Chinese NER task is harder because Chinese texts have no explicit word segmentation information, and Chinese named entities lacks the capitalization information that plays an important role in signaling named entities, and moreover, the structures of Chinese named entities are more complicated, especially for entity abbreviations. Most Chinese NER systems adopt statistical models or hybrid solutions. Sun et al. (2002) consider the problem of Chinese named entity identification using statistical language model, and they integrate word

segmentation and NE identification into a unified framework that consists of several class-based language models. Fang and Sheng (2002) present a hybrid approach, which combines a machine learning method and a rule based method, to improve the Chinese NE system's efficiency. Zhu et al. (2003) adopt the source-channel model framework for the single character named entity recognition. Gao et al. (2005) propose a pragmatic mathematical framework in which segmenting known words and detecting unknown words of different types can be performed simultaneously in a unified way. Wu et al. (2005) present a statistical model with human knowledge which treats NER as a probabilistic tagging problem. Fu and Luke (2005) present a lexicalized HMM-based approach to Chinese NER. Yu et al. (2008) use a Markov Logic Network to combine various types of domain knowledge to correct the output of the Conditional Random Fields model. Zhao and Kit (2008) propose a supervised learning model which combines the unsupervised segmentation results to improve performance. Most of the researches in this field are restricted to formal text corpus, such as newswire articles. To our knowledge, our work is the first attempt to investigate the named entity recognition task over the informal Chinese news comments.

3 Our Proposed Approach

3.1 Overview

As mentioned earlier, named entities in Chinese news comments are more difficult to recognize than those in formal text corpus because of the informal written style of the comments. Given a Chinese news article and its associated comments, our task aims to recognize all named entities (person names, location names and organization names) in the comments.

The basic idea of our proposed approach is to leverage the close relationships between named entities in the news comments and named entities in the news article. We first find a few useful named entities in the news article and then incorporate the entity information into the basic NER tagging algorithm. Finally, we use an additional correction step to further improve the performance. Our approach adopts the CRF-based algorithm for named entity recognition, and we focus on how to find useful entity information from the news article for improving NER in the news comments. Figure 1 shows the framework of our proposed approach. The three key components will be presented in next sections, respectively.

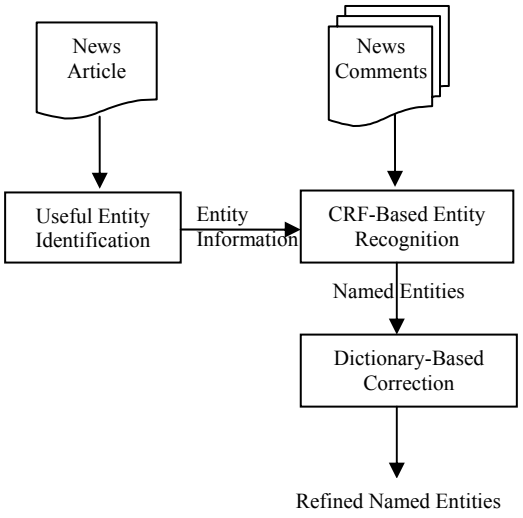

Figure 1: The framework of our proposed approach

3.2 The CRF-Based Entity Recognition Algorithm

The Conditional Random Fields (Lafferty et al., 2001) model is a probabilistic framework to segment and label sequence data, and it has been successfully used in many NLP tasks, including word segmentation, POS tagging, named entity recognition, and so on. The CRFs model defines the conditional distribution $p(Y|X)$ of the labels Y given the observations X with the following formula:

$$P_\lambda(Y \mid X) = \frac{1}{Z(X)} exp(\sum_{c \in C} \sum_{k} \lambda_k f_k(Y_c, X, c))$$

Y is the label sequence; X is the observation sequence; $Z(X)$ is a normalization term; f_k is a feature function; λ_k is the weight of feature function f_k; C is the set of cliques in the undirected graphic model. Given the training data with a set of sentences (characters with their corresponding tags), the parameters of the model are trained by maximizing the conditional log-likelihood. In the testing phase, given a test sentence x, the tagging sequence y is given by $Argmax_y P(y|x)$.

CRFs has been shown to perform well on the task of Chinese named entity recognition (Zhou et al, 2006, Chen et al, 2006, Yu et al, 2008). We treat the Chinese NER task as a character-based sequence labeling problem and use the CRFs model for learning and inference. In this study, we use the linear-chain CRFs model imple-

mented in the CRF++ toolkit[1]. We use four tags (B - beginning of an entity, I - inside of an entity, E – end of an entity, S – a single character entity) for tagging each type of named entity, and thus we have totally 13 tags (including the tag O- outside of any entity). Standard features used in our basic method are listed in Table 1. The segmentation features and POS features are given by our in-house Chinese word segmentation and POS tagging tools. The segmentation features indicate the positions of the Chinese characters in the corresponding Chinese words after word segmentation, and the position of each Chinese character is represented by three types: the first character in a word, the last character in a word, and the middle character in a word. For the POS features, the POS tag of each Chinese character is the same with that of the Chinese word which the character belongs to.

Character features	C_n, $n \in$ [-3,3]
	C_nC_{n+1}, $n \in$ [-3,2]
Segmentation features	S_n, $n \in$ [-2,2]
	S_nS_{n+1}, $n \in$ [-2,1]
POS features	P_n, $n \in$ [-2,2]
	P_nP_{n+1}, $n \in$ [-2,1]

Table 1: Standard features used in the baseline method

Entity features	F_n, $n \in$ [-2,2]
	F_nF_{n+1}, $n \in$ [-2,1]

Table 2: Entity-based features used in our proposed method

The basic method using the above standard features does not work well because the standard features rely only on the news comments, while the named entities in the news comments may appear in different informal or erroneous forms. Since the comments have a very close relationship with the corresponding news article, how to effectively use the named entities' information in the news article is the primary problem in our proposed method. After we extract a few useful entities from the news article, we propose to generate new entity features and add them to the CRFs model.

For each entity type, we collect one prefix list and one suffix list by extracting the prefixes and suffixes from the useful entities. Based on these lists, we assign additional tags to the characters in the news comments to indicate whether the characters are included in a particular list. For instance, the character "刘" \ "Liu" in a person name "刘翔" \ "LiuXiang" is extracted as a prefix of the person name. When a character in a comment is included in a person prefix list, we assign a tag of "Per_Prefix_1", otherwise, we assign a tag of "Per_Prefix_0". The new entity features are listed in Table 2.

The key issue in this study is how to find useful entities from the news article, and we propose three schemes for addressing this problem in next sections.

3.3 Useful Entity Identification

In this section, we propose three schemes for finding useful entities in the news article. The first scheme aims to recognize and use all named entities in the news article. The second scheme aims to extract and use only focused named entities in the news article. The third scheme aims to expand the focused named entities by using web search results.

3.3.1 All NE Recognition

This scheme is the simplest scheme based on the assumption that all the named entities in the news article are useful clues for the NER task in the associated news comments. In this study, we use our in-house Chinese NER tool to tag all named entities in the news article and use all the named entities as useful entities for new feature generation, as mentioned in Section 3.2. Our in-house Chinese NER tool is based on the CRFs model. The F-measure values of the tool over the MSR NER news corpus are 94.14% for person entities, 87.03% for location entities and 84.97% for organization entities.

3.3.2 Focused NE Extraction

This scheme advances the first scheme by finding only a few important named entities in the news article. There are usually many named entities in the news article, and the named entities are unequally important. The associated comments usually focus on discussing a few important entities, which are called focused named entities. The use of all the named entities may introduce some noises, and instead we use only the focused named entities in this scheme.

Focused entities refer to the named entities which are most relevant to the main topic of a news article. Similar to Zhang et al. (2004), we consider the task of focused named entity extraction as a binary classification problem. Given a named entity in the news article, we use a classi-

[1] http://crfpp.sourceforge.net/

fication model to classify it as focused entity or not. For a named entity *A*, the features used in our classification model are listed in Table 3.

Feature Name	Feature Value	Feature Description
Entity Type	Integer (0,1,2)	Entity type of *A*
Entity Frequency	Positive Integer	Occurrence number of *A* in news article
In Title or Not	Boolean (T, F)	Whether *A* appears in the title or not
Entity Document Frequency	Positive Integer	Number of news articles contain A
Entity Distribution	Positive Float	The distribution of *A* in news article

Table 3: Features used for focused NE extraction

In Table 3, the first four features are easy to understand. The entity distribution feature measures how evenly an entity is distributed in a document. The motivation is that if a named entity occurs in many different parts of a document, it is more likely to be an important entity. We use the entropy of the probability distribution to measure it. Considering a document which is divided into *m* sections with equal length, a named entity's probability distribution is represented by $\{p_1, p_2, ..., p_i, \ldots, p_m\}$, where

$$p_i = \frac{occurrence number in the\ i\text{-}th\ section}{total\ occurrence\ number\ in\ the document}$$

The entity distribution feature value is then computed by $entropy = -\sum_{i=1}^{m} p_i \log p_i$. In our experiments, we simply set $m = 5$.

In the experiments, we used the SVMLight toolkit for classification. We collected 1000 news articles from a popular Chinese news portal - news.sohu.com. Each news article was manually annotated with its focused named entities, and there were totally 1447 focused entities (i.e. 1.4 focused entities per article). We performed 5-fold cross-validation on the dataset and the mean F-measure was 81%.

After we use the classification model to classify all the named entities in the news article into focused entities or not, we do not directly use the classified focused entities, because the number of focused entities is very small. Instead, in order to leverage more useful entities for feature generation, we select the top *K* percent named entities, which are the most confidently classified focused entities in the news article, as useful name entities. *K* is a parameter in our study. We use the output value of the SVM classification model to indicate the classification confidence level.

3.3.3 Related NE Expansion

The above two schemes find useful entities only from the particular news article. However, according to our observation, some named entities in the news comments do not appear in the particular news article at all, but they are closely related to some entities in the news article. This phenomenon is called "topic shifting". For example, when a news article is talking about "中国联通"\"China Unicom", related entities such as "中国移动"\"China Mobile", "中国电信"\"China Telecom", which do not appear in the news article, may be talked about in the associated comments. There related entities are also very useful clues and thus we develop a related NE expansion tool to discover the related entities by using web mining techniques. We use the focused name entities extracted from each news article in Section 3.3.2 as seeds and use our tool to discover related entities for each focused entity. Finally, we use these entities as useful entities for feature generation.

There have been a few researches (Ohshima et al., 2006; Wang and Cohen, 2007, Vyas and Pantel, 2009) related to named entity expansion. One of the most famous online services is *Google Sets*[2]. Motivated by these related researches, our tool consists of the following two key steps for NE expansion of each single focused entity.

1) Given a focused entity *e*, we first submit four queries ["*e* 和"] / ["e and"], ["和 *e*"] / ["and e"], ["*e* 比"] / ["e than"] and ["比 *e*"] / ["than e"] to the Google web search engine and get the top 100 results for each query[3]. Then we split the snippets in the search result into sentences. The character sequences that occur both immediately before the two queries (["和 *e*"] and ["比 *e*"]) and immediately after the two queries (["*e* 和"] and ["*e* 比"]) are extracted as initial candidates, and they are ranked by the geometric mean of the times each one appears immediately before the two queries (["和 *e*"] and ["比 *e*"]) and the times each one appears immediately after the two queries (["*e* 和"] and ["*e* 比"]). The top five candidates with high ranks are selected as the initial expansion results. In this step, we emphasize more on the precision of the candidates by using

[2] http://labs.google.com/sets

[3] The string in [ ] is the complete query string. Note that quotation marks ("") are used in each query string to guarantee that the query characters appear consecutively in the results.

only two strong indicator words “和” / “and” and “比” / “than”.

2) For each candidate *e′* obtained in step 1), we submit a query [“*e*” *“e′”*] to the Google search engine and obtain the top 100 results and the corresponding whole web pages[4]. Similar to Wang and Cohen (2007), in each semi-structured web page, we find the common HTML contexts of the two entities *e* and *e′* as wrappers and use these wrappers to extract more candidates from the page. A graph $G = <V, E>$ is built, where V includes all wrappers and candidates and $E = \{(w, c)|$ if candidate c is extracted by wrapper $w\}$. The weight for each edge in E was set to 1. A random graph walk with restart (RWR) is then applied to the graph to score the candidates. Finally, the top ranked candidates whose normalized scores are greater than 0.05 are selected as the expansion results. The precision value can reach 75% based on analysis of the expansion results for five focused entities.

The example expansion results by using our tool and *Google Sets* are shown in Table 4 when the seed entity is “休斯顿火箭”\“Houston Rocket”.

Query: 休斯顿火箭(Houston Rocket)	
Google Sets	Our tool
火箭季后赛 (Rockets Playoffs) 火箭 vs (Rockets vs) 火箭迷来踩 (Rockets fans come to see) 火箭的 (Rockets’) 仓储管理 (Storage Management) 迈阿密热火 (Miami Heat) ……	洛杉矶湖人 (LA Lakers) 圣安东尼奥马刺 (San Antonio Spurs) 达拉斯小牛 (Dallas Mavericks) 波士顿凯尔特人 (Boston Celtics) 底特律活塞 (Detroit Pistons) 丹佛掘金 (Denver Nuggets) 芝加哥公牛 (Chicago Bulls) 菲尼克斯太阳 (Phoenix Suns) 奥兰多魔术 (Orlando Magic) 波特兰开拓者 (Portland Trail Blazers) 金州勇士 (Golden State Warriors) 犹他爵士 (Utah Jazz) ……

Table 4: Related NE expansion results

3.4 Dictionary-based Correction

In this section, we present a dictionary-based correction step to address the following two issues:

1) As compared with named entities in news articles, a few named entities in news comments may have different spellings with the same or similar pronunciations, e.g., “谢亚龙” / “Xieyalong” in a news article and “谢鸭龙” / “Xieyalong” in a news comment, “刘翔” / “Liuxiang” in a news article and “刘降” / “Liuxiang” in a news comment.

2) As compared with named entities in news articles, a few named entities in news comments may be replaced with some concise English expressions, e.g., “易趣” / “Yiqu” in a news article and “ebay” in a news comment, “周杰伦” / “Zhoujielun” in a news article and “JAY” in a news comment.

For addressing the first case, we use a Chinese Pinyin dictionary to correct the results. If a Chinese character sequence in a news comment has the same pronunciation as some named entity in the news article, the character sequence is tagged as a named entity with the same type. For example, the character sequence “谢鸭龙” / “Xieyalong” in a news comment has the same pronunciation as the person name “谢亚龙” / “Xieyalong” in the news article, and thus we tag “谢鸭龙” / “Xieyalong” as a person name in our correction step.

For addressing the second case, we use an online English-Chinese bilingual dictionary (http://dict.youdao.com) for correction. The online dictionary can return the translations for most new words, such as “Jay”, “ebay”, and such translations can not be found in traditional dictionaries. For each sequence of continuous non-Chinese characters, we submit the string to the online dictionary, and a list of Chinese translations is returned. We then compare the translations and the entities in the news article, and if a match is found, the correction is performed.

4 Experiment and Analysis

4.1 Experiment Setup

There are no public benchmark datasets for evaluation of named entity recognition in Chinese news comments. Therefore, we manually labeled our dataset for evaluation. We downloaded 60 pieces of news and their associated comments from a popular Chinese news portal − www.sina.com.cn in October, 2008. They belonged to five different domains: politics, economics, sports, entertainment and technology. For each piece of news, we selected the first 100 comments. We then manually annotated the named entities (person name, location name and organization name) in the comments. Two annotators were employed and the conflicting annotations were resolved by discussion. Figure 2 gives

[4] Note that quotation marks (“”) are used for each entity (*e*, *e′*), but not for the whole query string.

two examples in our dataset and Table 5 shows the entity distribution in our dataset. The dataset will be freely downloaded from our website.

Figure 2: Two examples in our dataset

	Per	Loc	Org	Total
Number	3295	3758	2780	9833

Table 5: Entity distribution in our dataset

In the experiments, we use 5-fold cross validation for evaluation. In each fold, 80% is used for training and the remaining 20% is used for testing. We use the standard F-measure for evaluation.

Finally, the performance values are averaged over the five folds.

4.2 Results and Discussions

Table 6 shows the comparison results for baselines and our proposed methods with different settings. Baseline1 directly uses a public available Chinese NER tool – S-MSRSeg[5] developed by MSR to tag the comments, and it is based on the linear mixture model framework. Baseline2 directly uses our in-house NER tool to tag the comments. Baseline3 uses only the standard features in the CRFs model, which is trained on the comments data via cross-validation, and it does not make use of any entity information in the news article. Different settings are investigated in our proposed method when K is simply set to 50.

We can see that Baseline1 and Baseline2 do not perform well, because the two baselines are developed for NER in formal news texts. Though Baseline3 does not use complex features, it performs much better than the first two baselines, which demonstrates the big difference between news texts and news comments.

The use of the entity information in the referred news article can much improve the performance, especially for person names and organization names. All the three schemes for finding useful entities in the news article are helpful to the task. In particular, the use of focused entities in the news article (Baseline3 + FocusedNE) can much outperform Baseline3 and the method using all named entities (Baseline3 + All NE) for person name recognition and organization name recognition. The results show that not all the named entities in the news article can provide important clues for NER in the news comments, and using all entities' information may cause some noises. We give an example in the news of "SPORTS_12" in our dataset. "SPORTS_12" talks about Liu Xiang withdrawing from the Olympics. There are totally five different named entities in the news article. Our focused NE extraction model marks "刘翔" / "Liuxiang" and "北京" / "Beijing" as focused NEs when the parameter K = 50. In the associated comments, there are totally 216 NEs. Among them, 112 NEs refer to the two focused NEs, and less than 10 NEs in the comments refer to the other three NEs in the news article. Using these three NEs' information for NER in comments may cause some noises.

Furthermore, the use of related named entities (Baseline3 + FocusedNE + RelatedNE) can further improve the performance. The F-measure for organization name recognition receives an improvement of 2.3%, while the F-measures for person and location recognition do not change significantly. This is because our related NE expansion tool works very well with an organization name as input. But when the input entity is a person or location name, a few of the expansion results are not named entities, which may introduce many noises to the CRFs model.

Lastly, we can see that the correction step can improve the performance for person name recognition and organization name recognition. Overall, the use of focused entities and related entities as useful entities, together with the correction step, can achieve the best performance in our experiments. The performance for location name recognition cannot be improved very much because the number of location name variants in the news comments is very limited.

[5] The tool can be downloaded from http://research.microsoft.com/en-us/um/people/jfgao/

	Per (%)	Loc (%)	Org (%)
Baseline1 (S-MSRSeg)	60.93	86.13	26.26
Baseline2 (Our In-house NER Tool)	73.61	80.75	37.28
Baseline3 (CRF with Standard Features)	73.73	88.92	59.63
Baseline3 + All NE	74.78	89.40	61.18
Baseline3 + Focused NE	80.53	90.12	65.02
Baseline3 + Focused NE + Related NE	80.80	90.15	67.31
Baseline3 + Focused NE + Correction	82.83	90.30	68.77
Baseline3 + Focused NE + Related NE + Correction	**83.06**	**90.32**	**70.87**

Table 6: Experimental results (F-measure)

In order to better understand the contribution of the focused named entity extraction step, we show the experiment results for the overall method (Baseline3 + FocusedNE + RelatedNE + Correction) with different values for the parameter *K* in Table 7. *K* is varying from 0 to 100 with a step size of 25. *K*=0 means that no name entity information in the news article is used, and *K* = 100 means that all the name entities in the news article are considered. We can see that in our dataset when *K* is set to a number around 50 (between 25 and 75), the overall performance does not change much. Using no entities (*K*=0) and using all entities (*K*=100) will much lower the overall performance, which demonstrates that it is important to leverage appropriate named entities for feature generation in our proposed method.

K	Per (%)	Loc (%)	Org (%)
K = 0	76.71	89.16	65.37
K = 25	81.57	90.21	71.38
K = 50	83.06	90.32	70.87
K = 75	81.16	89.85	69.53
K =100	77.31	89.56	67.59

Table 7: Overall results (F-measure) vs. *K*

5 Conclusion and Future Work

In this paper, we propose to leverage the entity information in the referred news article to improve named entity recognition in the news comments. Three schemes for finding useful entities are presented. Experimental results demonstrate the effectiveness of each component in our proposed method.

In future work, we will explore new features based on the relationships between news article and news comments, and the relationships between news comments. We will also address the co-reference resolution task in news comments.

Clustering Semantically Equivalent Words into Cognate Sets in Multilingual Lists

Abstract

Word lists have become available for most of the world's languages, but only a small fraction of such lists contain cognate information. We present a machine-learning approach that automatically clusters words in multilingual word lists into cognate sets. Our method incorporates a number of diverse word similarity measures and features that encode the degree of affinity between pairs of languages. The output of the classification algorithm is then used to generate cognate groups. The results of the experiments on word lists representing several language families demonstrate the utility of the proposed approach.

1 Introduction

Cognates are words with a shared linguistic origin, such as English *father* and French *père*. Identification of cognates is essential in historical linguistics, and cognate information has been successfully applied to natural language processing tasks, such as sentence alignment in bitexts (Simard et al., 1993), and statistical machine translation (Kondrak et al., 2003). The problem of automatically identifying pairs of cognates has been addressed previously (Frunza and Inkpen, 2009; Kondrak, 2009). The process of identification is usually based on the combination of the following three types of evidence: phonetic similarity, semantic similarity, and recurrent sound correspondences. The input data include dictionaries, multilingual word lists, and bitexts. The objective can be finding pairs of cognates among two related languages, or finding groups of cognates among multiple languages.

In this paper, we focus on the task of identifying cognate groups (clusters) in word lists on the basis of word similarity and language relationships. Word lists are now available for most of the world's languages (Wichmann et al., 2011). However, only a fraction of such lists contain cognate information. Methods proposed for pairwise cognate identification are of limited utility for such data because they fail to consider the transitivity property of the cognation relationship. Cognate groups are also more useful than cognate pairs as the input to algorithms for reconstructing phylogenetic trees (Bouchard-Côté et al., 2007).

A number of word similarity measures have been applied to the problem of cognate identification (Frunza et al., 2005). Kondrak and Dorr (2004) report that a simple average of various measures outperforms any individual measure of phonetic similarity. We propose to combine measures using a machine-learning approach based on support vector machines (SVMs). The SVMs are trained on both positive and negative examples, and allow for a seamless combination of a number of diverse similarity measures.

In addition to word similarity features, we include a set of language-pair features that incorporate information regarding the degree of relatedness between languages. We develop a way to self-train these features in the absence of preexisting cognate information. We also present a novel clustering algorithm for defining cognate groups, which utilizes the classification decisions generated by the SVM classifier. We evaluate our method on two sets of word lists representing several language families. The results demonstrate the utility of the proposed techniques.

This paper is structured as follows. In Section 2, we define the task that we address in this work. In Section 3, we discuss relevant previous work. In Section 4, we describe our method of clustering cognates. Section 5 explains our evaluation methodology. Sections 6 and 7 report the results of our experiments. We conclude with a discussion of our work, its implications, and the potential for further research.

Chiang Mai, Thailand, November 8 – 13, 2011.

2 Problem definition

There are over five thousand languages in the world, which are grouped into dozens of language families (Lewis, 2009). Some language families, such as Indo-European and Austronesian, are very well documented. There are many languages, however, for which the only available data are relatively short vocabulary lists. For example, most languages in the Automated Similarity Judgement Program database (Wichmann et al., 2011) are represented by word list composed of only 40 meanings. Other lists of the most stable meanings range from 15 to 200 (Dyen et al., 1992).

	ALL	AND	ANIMAL	...
Irish	uile	agus	ainhme	...
Welsh	pob	a	anifail	...
Breton	holl	hag	aneval	...
Rumanian	toti	iar	animal	...
Italian	tutto	ed	animale	...
...	...	...	...	...

Table 1: A sample of the Indo-European Database used in our experiments.

Table 1 visualizes a small part of the typical dataset as a two-dimensional $m \times n$ table, in which rows represent n individual languages and columns represent m distinct meanings. The meanings are limited to the basic vocabulary that is relatively resistant to lexical replacement, and present in most of the world's languages (Swadesh, 1952). The task that we address in this paper is the identification of cognate groups (clusters) within each column. The number of clusters can range between 1 and n. Since many datasets contain either orthographic forms or use an approximate phonetic encoding, we do not require the words to be fully phonetically transcribed. If the data contains multiple words per language/meaning slot, we randomly pick one of the forms and discard the others. We will evaluate our methods by comparing the generated clusters to cognate judgements made by linguists that are experts in language families represented by the datasets.

3 Previous work

Frunza et al. (2005) experiment with several Weka classifiers (Hall et al., 2009) that combine various orthographic similarity measures for the pairwise identification of cognates and false friends[1] as aids to second-language learners. Datasets were extracted from various sources: a manually aligned bitext, lists of cognates and false friends, and exercises for language learners. No single classifier is reported as the most accurate on all tasks. Our approach differs in the focus on identifying cognate groups for the purpose of classifying related languages.

Mulloni (2007) applies the SVMTool tagger (Giménez and Màrquez, 2004) to automatically generate words in one language from their cognates in a related language. He reports a 30-35% accuracy on an English-German cognate list. A relatively large list of cognates (1683 entries) was used for training the SVMTool. This underlines the inherent problem with the proposed methods: in order to identify or generate cognates between languages, a substantial number of cognates must have already been identified. We are interested in a more realistic scenario where *no* cognate pairs are available.

Bouchard-Côté et al. (2007) present a unified stochastic model of diachronic phonology aimed at the automatic reconstruction of proto-forms and deriving phylogenetic trees. They assume the cognate groups to be the input to their model. In the actual experiments on four closely-related Romance languages they filtered out non-cognates by thresholding the normalized edit distance scores. They consider the joint modelling of phonology with the determination of cognates as "an interesting direction for future work." We include edit distance as one of the features in our SVM model.

Hall and Klein (2010) point out the limitations of pairwise cognate identification, and present a generative phylogenetic model for determining cognate groups from unaligned word lists. However, their method requires the language family tree to be known beforehand. This is a difficult prerequisite to satisfy as phylogenetic trees are rarely uncontroversial even in the case of well-studied families. In their experiments, they also disregard the semantic information, instead applying their method to randomly scrambled cognate groups from three closely related Romance languages. In contrast, our experimental setup emulates a much more realistic scenario.

[1] False friends are words that are orthographically similar but historically unrelated, such as English *dinner* and Spanish *dinero*.

4 Clustering cognates

We propose a discriminative approach to clustering cognates. We start by formulating cognate identification as a binary classification task on pairs of words that have the same meaning in different languages. Our model is trained on annotated data from a subset of the dataset, and applied to a different, disjoint subset. The classification results are then used to cluster words into cognate sets. In this section we discuss various features used for training the binary classifier, as well as the details of our clustering approach.

The principal idea for cognate identification follows from the observation that, on average, cognate pairs display higher word similarity that non-cognates. Since no single word similarity measure may be sufficient, we want to utilize a combination of measures. We opt for a feature-based approach because it is more principled and flexible than a simple average or a linear combination of scores. It also allows us to seamlessly incorporate a set of language-pair features that provide additional context for the classification.

We considered various software packages, including Weka (Hall et al., 2009), SVM-light (Joachims, 1999), Liblinear (Fan et al., 2008), and LibSVM (Chang and Lin, 2011). We ultimately selected LibSVM for our experiments due to its higher overall performance in development.

4.1 Word similarity features

We selected the following word similarity features on the basis of the results of our preliminary development experiments:

- minimum edit distance
- the longest common prefix length
- number of common bigrams
- the length of each word (2 separate features)
- the difference in length between the longer and the shorter word

During development, we also experimented with other features, but decided not to include them in the final system for various reasons. The longest common subsequence length was considered redundant with edit distance; longest common substring length and the number of common trigrams were mostly subsumed by bigrams; and shared first letter was generalized by the prefix length.

We decided to exclude features based on phonetic similarity in order to ensure the applicability to datasets that contain only orthographic forms.

4.2 Language-pair features

A limitation of the word similarity features is their strictly local application to pairs of words. However, it is useful to consider not only the words, but also the languages they come from. Intuitively, if we observe that two language lists contain a large number of similar word pairs, we would expect the languages to be closely related, and therefore share many cognates. Conversely, if there is little overall similarity, we may suspect that that cognates will be rare or non-existent.

As an example, consider the average value of the normalized minimum edit distance computed between semantically equivalent words across pairs of word lists. For French and Italian, which are closely related Romance languages, the value is 0.44. In contrast, for French and German, which are more remotely related, the value is only 0.18. Indeed, among 199 word pairs each, there are 155 cognate pairs between French and Italian, and only 48 between French and German. The similarity between cognates is also expected to be greater between strongly related languages, as there would, on average, have been less divergence due to the more recent linguistic split. Once again, our example supports this idea: the average similarity between French/Italian cognates is 0.52, while the average similarity between French/German cognates is 0.22. We would like our classifier to take advantage of this tendency.

Our solution is to introduce a set of binary language pair features, one for each pair of languages in the data. For example, any instance consisting of a German word and an English word has a feature corresponding to that language pair set to '1', and all other language-pair features set to '0'. The language-pair features elevate the learned classification model from a local model to a global one, allowing it to make connections between languages, rather than words alone. For example, if relatively many training instances that have the German-English feature set to '1' are cognate, this information is expected to increase cognate recognition accuracy for this language pair at test time.

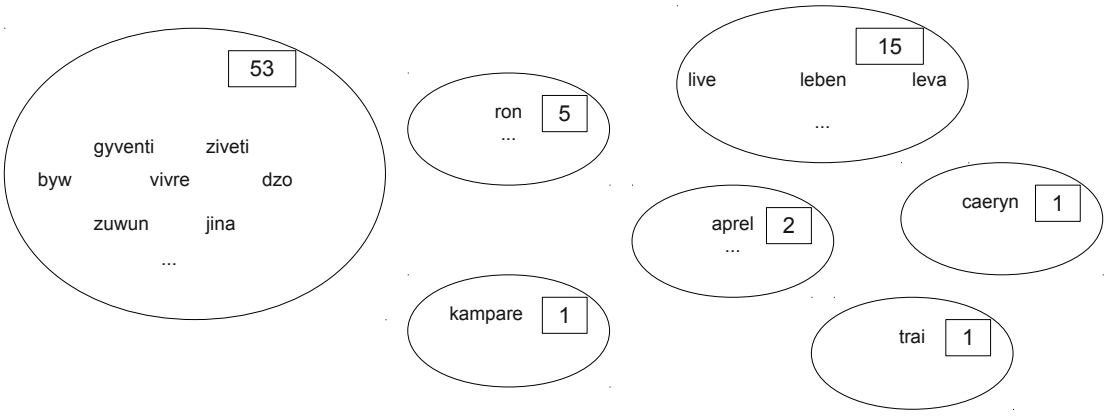

Figure 1: A cognate clustering of of the words with the meaning "to live". The boxed numbers are the total number of words in that cluster.

4.3 Self-training the language-pair features

As with any features, the weights for language-pair features must be derived from annotated training data. For example, in order to derive a useful weight for the German-English feature, we need training instances consisting of English and German words, which are annotated either as cognates or as non-cognates. However, in a realistic scenario of our approach being applied to a previously unanalyzed family of languages, no cognate information may be available. Thus we are faced with a circular problem: language-pair features are likely to improve cognate identification accuracy, but we need to have at least some cognates already identified in order to train the language-pair features.

Our proposed solution to the problem is to train the weights of the language-pair features on our own classifications. We adopt a two-pass approach. We first train a model and classify the data without the language-pair features; language information from the training data is not used in any way. These initial classifications of the test data are then treated as correct, thus providing a 'best guess' at what the cognate classifications would be, were they available. Next, we re-train the model using the initial classification, but this time utilizing the language-pair features. The second and final classification is obtained with the new model, which is expected to be more accurate. This method allows the language-pair features to be used to good effect on any set of languages, using only information locally available in the data to be classified.

4.4 Clustering

After the pairwise cognate classification is completed, the final task is the formation of cognate groups, or clusters. An example of such a clustering is shown in Figure 1, wherein words from various languages for the meaning "to live" have been correctly placed in cognate groups. Each ellipse is a cluster; two words are cognate if and only if they are in the same cluster. Obtaining clusterings such as these for arbitrary data is one objective of our research.

Because of the transitivity property of cognates, there is often no clustering that is completely consistent with the pairwise classification decisions. Each triple of words x, y, and z involves three binary classification instances: $x - y$, $y - z$, and $x - z$. The contradiction arises if two instances are classified as positive, and the remaining one is classified as negative. Consider, for example, the words *beva*, *bivi*, and *vivir*, all of which mean "to live" in Breton, Sardinian, and Spanish, respectively. It is reasonable to expect that *beva* and *bivi* will be identified as cognate, as will *bivi* and *vivir*, due to the similarity between these two pairs. The remaining pair, *beva* and *vivir*, have much lower similarity, and could reasonably be identified as non-cognate. In fact, all three of these words are cognate with each other. A clustering approach would first put two of the words into a single cluster; the remaining word would be added due to its similarity with one of the first two words. Thus, even though the cognate relationship between *beva* and *vivir* may not be found directly,

the links *beva-bivi* and *bivi-vivir* are enough; our clustering method finds a cognate pair that would otherwise have been overlooked.

In order to come up with a clustering, we typically need to override some of the binary classifications. Blindly following the transitivity property is likely to result in clusters that are excessively large, since some positive classifications are caused by accidental similarities between non-cognate words. Consider another pair of words with the meaning "to live": Breton *beva* and Swedish *leva*. While obviously similar (differing by only a single letter substitution), they are, in fact, not cognate. This presents a challenge: finding a proper additional condition that should be satisfied before merging clusters, in order to avoid such accidental merges.

The solution employed by our clustering method is based on the notion of *average similarity* between clusters. Initially, each word corresponding to a particular meaning is placed in its own cluster. We then consider each word pair that has been classified as cognate, and for each pair decide whether the corresponding clusters should be merged. We compute the average value of cognate judgements between the two clusters, which is a measure of how similar the two clusters are. If this value is less than a certain threshold (optimized during development), the merge is aborted, and clustering continues as it would had the two words been judged non-cognate. Otherwise, the clusters containing each word are merged.

5 Evaluation of clustering quality

Pairwise classification is typically evaluated by some combination of the following four well-known measures: accuracy (correct classifications divided by all classifications), precision (true positives divided by all positive classifications), recall (true positives divided by actual positives), and F-score (the harmonic average of precision and recall). However, evaluating clustering is a more complex problem than evaluating pairwise classifications. Pairwise metrics have significant weaknesses when applied to clustering, where a word is proposed to be cognate with all words in its cluster. Incorrectly assigning a word to a large cluster will generate a large number of false positives, while incorrectly assigning a word to a smaller cluster would generate fewer false positives. On the other hand, incorrectly positing two clusters instead of one is penalized proportionally to the square of the size of the cluster. In short, the number of false positives and false negatives an error creates may not be balanced or consistent.

We considered a number of alternative metrics, eventually deciding on the B-Cubed measure. B-Cubed metrics assign a precision and recall to each item in a set of clusters — in our case, to each word. The item precision is the ratio of the number of its cognates in its cluster to the number of items in its cluster. The item recall is the ratio of the number of cognates in its cluster to the total number of its cognates. A B-Cubed F-score is computed from the B-Cubed precision and recall, analogously to pairwise F-score. Amigó et al. (2009) show that B-Cubed metrics satisfy four constraints deemed critical to a valid clustering evaluation metric, while all other metrics investigated, including pairwise metrics, fail at least one of these criteria.

For an illustrative example, consider again the words shown in Figure 1. The gold standard indicates one large cluster (53 words), one medium sized cluster (15 words), and several smaller clusters. In this case, incorrectly assigning (or failing to assign) a single word to the large cluster produces many false positives (or false negatives), while exchanging a word between two smaller clusters has a minimal effect. In order to verify the inconsistency of pairwise metrics on clustering, we analyzed two different clusterings of these words; one was an excessively aggressive clustering, in which the medium-sized cluster was almost entirely subsumed into the larger cluster. The other was a more conservative clustering which formed the medium-sized cluster comparatively well, and generally better recovered the overall structure of the actual clusters. The pairwise metrics reported the more aggressive clustering to be significantly better than the more conservative result; the B-Cubed metrics did not display this anomalous behavior.

The above example demonstrates that pairwise metrics can, under realistic conditions, report a much worse clustering to be significantly better, demonstrating their intrinsic volatility: a single error can have dramatic, unpredictable effects that depend more on chance similarities than on the quality of the clustering or classification process. B-Cubed metrics do not have this problem; being an average of item-based measurements, er-

rors will have consistent effects, balanced against the resulting quality of the clusters. We therefore adopt B-Cubed metrics as the preferred measure of clustering performance.

6 The Indo-European experiments

Our first experiment involves an extremely well-studied family, for which we also have access to relatively long and complete lists of basic words. We divide the data into training and test sets along different sets of meanings. The same languages appear in both sets.

6.1 Data

The publicly-available Comparative Indo-European Database (Dyen et al., 1992) contains words for 200 different meanings in 95 languages of the Indo-European family. The words in each meaning are grouped in cognate sets. We used a pre-processed version of the data which places each meaning in an individual file, for a total of 200 files. Each word is labelled with the number of the cognate set that it belongs to.[2] We randomly selected 20 out of 200 meanings data as a development set. We also created a separate held-out test set of 20 meanings, roughly 10% of the data. We performed two tests: one with a small 20-meaning training set, and the other with a large 180-meaning training set, which also included the development set. In both cases, the test set was the same. We made sure that the sets of meanings in the training and test data were disjoint.

6.2 Classification methods

We tested three methods of classification, each making different use of language-pair features (LPF):

- NO LPF: a strictly "local" method that considers only the pair of words in question, and utilizes no language-pair features.
- SUPERVISED LPF: the weights of language-pair features are trained on the annotated instances in the training set.
- SELF-TRAINED LPF: the two-pass approach described in section 4.3. No cognate information for the language pairs in the test set is assumed to be in the training set.

[2]This processed data is available on request.

Method	Size of Training Set	
	20	180
Baseline	0.623	0.623
NO LPF	0.642	0.687
SELF-TRAINED LPF	0.656	0.687
SUPERVISED LPF	0.677	0.677

Table 2: Average B-Cubed F-Scores for the Indo-European data.

For the baseline, we adopt a simple but surprisingly effective method of grouping words according to their first letter or phoneme. Two cognates maintaining their common initial sound are assigned to the same cluster by this baseline. However, unrelated words that accidentally share the same first letter are also marked as cognate. In the example shown in Figure 1, the baseline correctly identifies the middle-sized cluster of words from 15 Germanic languages, but splits the largest cluster into several smaller ones, containing words starting with b, d, g, j, and z, respectively.

6.3 Results

Table 2 shows the results in terms of average B-Cubed F-score. Our methods consistently outperform the first-letter baseline regardless of the size of the training set. When the 20 meaning training subset was used, the results rank the SELF-TRAINED LPF method between the SUPERVISED LPF and NO LPF methods. When the 180 meaning training set was used, the NO LPF and SELF-TRAINED LPF models achieved substantial improvement voer the baseline; however, somewhat surprisingly, the SUPERVISED LPF model obtained a smaller improvement. This suggests that the SUPERVISED LPF model may have issues with overspecialization, or may not be able to make use of data past a certain point. The improvement exhibited by the SELF-TRAINED LPF model suggest that the two-pass method makes greater use of additional training data, and is capable of producing even better clusters than the SUPERVISED LPF model.

7 The ASJP experiments

This set of experiments involved some of the relatively short lists from a comprehensive database that contains most of the world's languages. This time, we divided the data into the training and test sets by languages, rather than by meanings.

Baseline	0.653
NO LPF	0.662
SELF-TRAINED LPF	0.714
SUPERVISED LPF	0.703

Table 3: Average B-Cubed F-Scores for ASJP data, with languages grouped by family.

Baseline	0.660
NO LPF	0.724
SELF-TRAINED LPF	0.701
SUPERVISED LPF	0.665

Table 4: Average B-Cubed F-Scores for ASJP data, with languages ordered alphabetically.

7.1 Data

Our second dataset consists of word lists from the Automated Similarity Judgement Program (ASJP) project, which represent 92 languages belonging to 5 language families: Austro-Asiatic, Hmong-Mien, Mixe-Zoque, Sino-Tibetan, and Tai-Kadai. Each list contains 40 basic meanings transcribed in a phonetic notation devised for the ASJP.

We performed two experiments on this data. In each experiment, the first 46 languages were used for training, and the other 46 were used for testing. For the first experiments, the languages were grouped according to language families, ensuring that most families appeared exclusively either in the training or the test set (one group was split between the two sets). For the second test, we sorted the languages alphabetically, essentially shuffling different language families. One of our objectives was to determine how the distribution of the languages affects the results. The first experiment adopts natural divisions between language families, emulating a realistic scenario where a model is trained on well-studied families and applied to the data representing less-studied families. The second experiment represents the situation where we have annotation for some of the languages in a family, and aim to discover cognates among other languages in the same family. The alphabetic ordering is akin to random shuffling of languages, but has the advantage of being easy to replicate.

7.2 Results on the data grouped by family

In this experiment, languages were naturally arranged into language families. That is, all languages in the same language family, such as Sino-Tibetan and Tai-Kadai, are adjacent in the data. This provides a realistic testing environment, wherein one set of language families (with known cognate data) is used to obtain cognate information for another set of language families.

Table 3 shows that the SELF-TRAINED LPF model obtains the best results in this experiment. The model appears able to generalize well, though it is not trained on any of the language pairs it is tested on. The NO LPF method and the baseline method are less effective. The SUPERVISED LPF method is again less effective that the SELF-TRAINED LPF method. This is likely caused by the lack of training data that contains the information for the language pairs that it encounters in the test set.

7.3 Results on the data sorted alphabetically

This experiment is based on the same ASJP dataset, with the exception that the languages are sorted alphabetically. This strengthens the relationship between the training and test sets (as languages from all families can be found in each), while reducing the similarities within them.

The results of this test are presented in Table 4. The NO LPF approach was a surprise winner this time. It appears that the presence of more linguistic relationships between the training and testing sets was the deciding factor. We conjecture that the relationship between the training and test sets was sufficiently strong for a locally trained model to provide very good results.

On the other hand, the SUPERVISED LPF approach performed much worse, only barely exceeding the baseline results. This likely occurs for the same reason that the NO LPF method does better — there are not enough similarities between the training and the test data to use global features accurately.

Notably, the SELF-TRAINED LPF approach still does quite well, even with fewer similarities to use. This demonstrates high reliability, as all other methods do poorly on at least one test; only the SELF-TRAINED LPF method provides high quality clusterings throughout all experiments.[3]

8 Discussion

Based on our results, we are able to conclude that our methods can consistently and accurately

[3]We also considered training on the Indo-European data and testing on ASJP data, but unfortunately the two datasets use entirely different notations: Romanized orthography versus specialized phonetic encoding. No simple method exists for converting between the two.

identify and cluster cognates, exceeding the performance of a strong baseline method. We have shown how SVMs can produce accurate cognate classifications; we have also shown how these classifications can be systematically used to create cognate groups. Evaluated with the B-Cubed metrics, these clusters are demonstrated to be of high quality compared to known cognate groups.

Language pairs appear to be most useful as binary features in a supervised SVM model if the data to be classified are from a small number of language families. In cases where there are fewer similarities in the data, fewer connections between languages can be learned. Relying on the cognate annotations substantially lowers the quality of the results in such situations, as the data it requires is not available. We thus find the SUPERVISED LPF method not only impractical, but also rather unreliable.

In contrast, our SELF-TRAINED LPF approach has been demonstrated to be a reliable, high-performing method, which produces good classifications in all of our experiments, throughout which the size of the training data and the distribution of the languages to be classified varies significantly. While not always yielding the best clusters overall, the SELF-TRAINED LPF method has been shown to consistently yield very good results across all tests. It functions well under realistic conditions, as it does not require cognate information on the languages to be classified. Furthermore, it can find global connections between languages that do not have cognate information available. We thus take our results as a recommendation for the use of the SELF-TRAINED LPF approach, and for the further investigation of language-pair features in cognate identification in general.

9 Conclusion

We have proposed an effective new method of identifying cognates that can make useful global connections from local data. Our demonstration that SVMs can make use of language information to improve cognate classifications lays a foundation for the use of cognate judgements in language classification and provides insight into how machine learning methods can be used successfully for the purposes of cognate identification.

Further work in this area might process language pairs directly using a method similar to our own, developing a machine learning, cognate based method for language classification. Brown et al. (2008) notes that cognate judgements could be used to compare and classify languages, but that this is yet to be done. Our use of relationships between language pairs to assist in classification sets a strong precedent for cognate-based language classification. In addition, other machine learning algorithms, such as Bayesian classifiers, as well as sophisticated phonetic similarity measures, may produce more accurate cognate classifications and clusters, and could be tested in future studies.

Abstract

This paper proposes a method for extending WordNet with terms in Wikipedia. Our method identifies a WordNet synset by integrating evidence derived from the structure of an article in Wikipedia and distributional similarity of terms. Unlike previous methods, utilizing the hypernym and siblings of the target term acquired from Wikipedia, the proposed method can deal with terms other than Wikipedia article titles and can work well even when reliable distributional similarity of a target term is unavailable. Experiments show that the proposed method can identify synsets for 2,039,417 inputs at precision rate of 84%. Furthermore, it is estimated from the experimental results that there should be 328,572 terms among all the inputs whose synset our method can correctly identify, while previous methods relying only on distributional similarity and lexico-syntactic patterns cannot.

1 Introduction

As a comprehensive repository of word senses, WordNet (Fellbaum, 1998) has played an important role in many natural-language-processing (NLP) tasks. Hand-crafted semantic knowledge, however, has low coverage of named entities and domain-specific knowledge. To address this issue, many researchers have proposed methods for extending WordNet by mapping new terms to a WordNet "synset."[1]

In this paper, we propose a novel method that extends WordNet by integrating the *Wikipedia article structure* and *distributional similarity*. With this method, an appropriate synset for a term in Wikipedia is identified by using the distributional similarity of the term and that of the term's hypernym and siblings, which are automatically acquired from Wikipedia. (Hereafter, **trg** is used for a target term for which we identify the appropriate synset, **hyper** is used for the hypernym of **trg** and **sib** is used for the sibling of **trg**.)

The reason for using **hyper** and **sib** can be explained as follows. In general, when an unknown term is encountered, its context helps in interpreting the term. Especially, if the unknown term's hypernym and/or its semantically similar terms (its **sib**s) were somehow learned as context, it would often be possible to successfully guess its meaning. In WordNet expansion, **trg** may correspond to terms for which reliable distributional similarity is unavailable. In such cases, the distributional similarity of **hyper** and **sib** can help. Even when the distributional similarity of **trg** is available, that of **hyper** and **sib** can boost the performance of synset identification by providing additional sources of information.

In this study, **trg**, **hyper** and **sib** are derived from hyponymy relation instances acquired from Wikipedia. Acquisition of hyponymy relations from Wikipedia is based on the internal structure of Wikipedia articles. For example, the Wikipedia article "Jack Black" is composed of the article title "Jack Black", section titles "Career" and "Films", and an itemized list under the "films" section as shown in Fig. 1. Hyponymy relation instances like (films, *Kung Fu Panda*), (films, *Airborne*) and (films, *Johnny Skidmarks*) can be acquired from this structure (Sumida et al., 2008). Most hyponyms in these hyponymy relation instances are not in WordNet and thus should be added to WordNet.

Trg, **hyper** and **sib** obtained from Wikipedia are the inputs ($\mathcal{I}$s. See Section 3) to candidate generation of appropriate synset for **Trg**, whose outputs, in turn, become the inputs to candidate selection (Figure 2). The candidate generation relies on multiple *synset identification modules*.

[1] A synset is a set of cognitive synonyms, each expressing a distinct concept.

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 874–882,
Chiang Mai, Thailand, November 8 – 13, 2011.

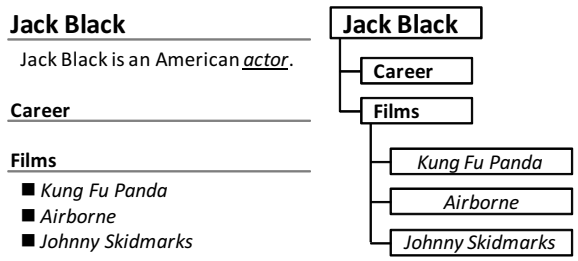

Figure 1: Internal structure of Wikipedia article "Jack Black".

Each module uses a different combination of information sources for generating appropriate synset candidates. This difference between the modules makes it possible to generate diverse synset candidates from the different viewpoint of each module. The most appropriate synset is selected by the candidate selection using a classifier that can discriminate better synset candidates from worse ones among outputs of the multiple synset identification modules. The candidate selection is expected to improve the precision of synset identification.

Experiments show that the proposed method can identify synsets for 2,039,417 $\mathcal{I}$s with 84% precision rate. In contrast, our implementation of Yamada et al. (2009), which uses the distributional similarity of **trg** only, has a precision rate of only 50.3% and covers less than half of the whole input from Wikipedia. Furthermore, it is estimated from the experimental results that there should be 328,572 terms among all the 1,231,172 unique **trg**s in the 2,039,417 $\mathcal{I}$s whose synset can be correctly identified by our method, but not by previous methods relying only on distributional similarity and lexico-syntactic patterns (Snow et al., 2006; Yamada et al., 2009).

2 Related Work

As a resource for extending WordNet, Wikipedia has recently received growing interest (Ruiz-Casado et al., 2005; Suchanek et al., 2007; Toral et al., 2008; Wu and Weld, 2008; Toral et al., 2009; Ponzetto and Navigli, 2009). These studies link a Wikipedia article title to a WordNet synset by using the Wikipedia category system, Wikipedia infoboxes, or similarity between Wikipedia article contents as evidence. However, these methods cannot handle terms that are not Wikipedia-article titles, and thus their coverage is limited.

On the other hand, distributional similarity between terms has been used in extending an existing taxonomy like WordNet (Snow et al., 2006; Yamada et al., 2009). Snow et al. (2006) identified a hypernym for a target term by using lexico-syntactic patterns and distributionally similar terms of the target term. Then the target term is linked to a WordNet synset by using its hypernym and distributionally similar terms as evidence. Yamada et al. (2009) linked a target term to its hypernym in a given taxonomy by using distributional similarity between the target term and terms in the taxonomy.

However, it is often the case that we cannot obtain reliable distributional similarity of a term and we cannot acquire hypernyms of a term co-occurring with lexico-syntactic patterns, especially when the term is infrequent in a corpus. As a result, we can hardly expect that the previous methods (Snow et al., 2006; Yamada et al., 2009) work well for this infrequent term. Nonetheless, we believe that it is important to deal with such infrequent terms, since they constitute the long-tail of the Web. Our method exploits not only the distributional similarity of a target term but also that of hypernym and siblings of the target term. Accordingly, as indicated by the experimental results in Section 4, our method achieves a higher precision and a broader coverage.

Many researchers have proposed methods for hyponymy relation acquisition from texts (Hearst, 1992; Shinzato and Torisawa, 2004; Sumida and Torisawa, 2008; Sumida et al., 2008; Oh et al., 2009; Oh et al., 2010). Recently, Wikipedia has gained attention as a source for hyponymy relations (Sumida and Torisawa, 2008; Sumida et al., 2008; Oh et al., 2009; Oh et al., 2010). Hyponymy relation instances acquired from Wikipedia are relevant to hypernyms and siblings of a term in our proposed method and the method of Sumida and Torisawa (2008) is used for preprocessing in the proposed method.

3 Proposed Method

The proposed method is overviewed in Figure 2. In the preprocessing stage (Section 3.1), hyponymy relation instances are acquired by using a method of acquiring hyponymy relations (proposed by Sumida et al. (2008)) from Wikipedia articles. From these relations, **trg**, **hyper** and **sib**, which are denoted as $\mathcal{I}$ $=<$ target term, hypernym, siblings $>$ or $\mathcal{I}$ $=<$ $trg, hyp, N_{sib}(trg)$ $>$ in short, are obtained. In

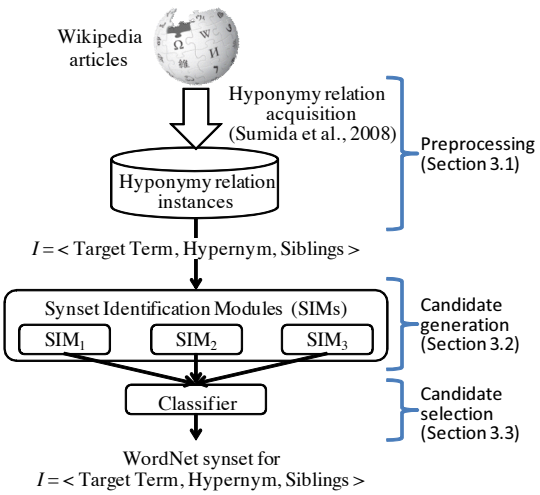

Figure 2: Overview of proposed method.

the candidate-generation stage (Section 3.2), three synset identification modules (SIMs) generate candidates of appropriate synsets for a given $\mathcal{I}$. Finally, in the candidate-selection stage (Section 3.3), a classifier produces the final output by selecting the best one among the output of the three SIMs. In our task, "one sense per one hyponymy relation instance" is assumed. For example, *Airborne* in Fig. 1 represents the meaning of "film", while the term itself has several other meanings.

3.1 Acquisition of Hypernyms (hyper) and Siblings (sibs)

A set of hyponymy relation instances are acquired by using "A tool for hyponymy relation acquisition from Wikipedia"[2] (Sumida et al., 2008). This tool extracts hyponymy-relation candidates from a Wikipedia article structure and then applies SVM to select the correct hyponymy relation instances from the candidates. Among the resulting hyponymy relation instances, reliable ones are selected by using a threshold value for a SVMs score with 90% precision [3]. Furthermore, hyponymy relation instances are restricted to ones whose hyponym comes from leaf nodes in the hierarchical layout of Wikipedia articles (i.e., *Kung Fu Panda* in Fig. 1). By means of this restriction, terms that are not named entities are filtered out. The method used for acquisition of hyponymy relations is explained in detail in Sumida et al. (2008).

[2]Available at `http://alaginrc.nict.go.jp/hyponymy/index.html`

[3]To ensure the results had 90% precision, an SVM score (distance from hyperplane) of 0.49 was used as the threshold value.

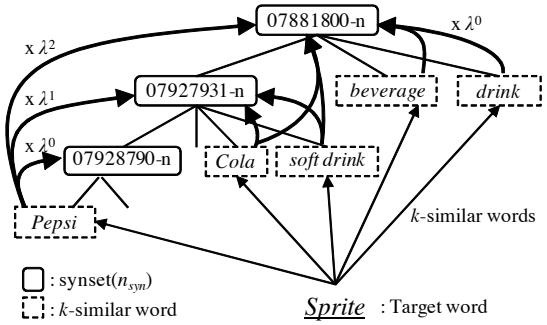

Figure 3: Example of score propagation by **trg** *Sprite* and its **sib** *Coke*.

Some **hyper**s in hyponymy relations extracted from Wikipedia are often very long noun sequences like *wild south-China tiger*. Consequently, their reliable distributional similarity is unavailable owing to their low-frequency or their absence in corpora. This problem is addressed by applying a longest-suffix match against frequently-appearing terms in a corpus for which reliable distributional similarity is measured (Section 3.2.2) under the assumption that the longest suffix can be regarded as the superordinate concept of **hyper**. For example, *south-China tiger* is the longest-suffix match result for *wild south China tiger*. If the longest suffix for **hyper** cannot be found, the hyponymy relation instances containing **hyper** are ignored.

Sibs are extracted from a Wikipedia article structure under the condition that their **hyper**s are the same.

3.2 Synset Identification Modules

Each synset identification module (SIM) generates synset candidates for a given $\mathcal{I} =< trg, hyp, N_{sib}(trg) >$. The candidates are determined by a *score propagation method*. A WordNet synset gets a higher score if it is considered to be the appropriate synset for trg.

3.2.1 Scoring by Propagation

The score for input $\mathcal{I} =< trg, hyp, N_{sib}(trg) >$ and WordNet synset syn is defined as $PS(\mathcal{I}, syn)$ in Eq. (1), which represents the weighted sum of the sub-scores for target term trg, its hypernym hyp, and a set of siblings, $N_{sib}(trg)$. Each sub-score, $S(n, syn)$ (Eq. (2)), is computed by score propagation through the hierarchical structure of WordNet synsets, where n is either **trg**, **hyper** or **sib**. Figure 3 illustrates the score propagation. It is assumed that "*Sprite*" is a **trg** and "07881800-

$$PS(\mathcal{I}, syn) = \alpha \times S(trg, syn) + \beta \times S(hyp, syn) + \gamma \times \sum_{sib \in N_{sib}(trg)} \frac{S(sib, syn)}{|N_{sib}(trg)|} \quad (1)$$

$$S(n, syn) = \sum_{n_k \in TopK(n)} \sum_{syn_k \in SYN(n_k)} \lambda^{d(syn, syn_k)} \times sim(n, n_k) \quad (2)$$

n" is a synset for which the sub-score $S(n, syn)$ is computed. First, a set of k terms in the Japanese WordNet that is the most similar to **trg** is obtained. This set is extracted by using the distributional similarity measure mentioned in Section 3.2.2 and is denoted by $TopK(n)$ in Eq. (2). Second, the synset *receives* the penalized distributional similarity from the k terms ($n_k \in TopK(n)$ in Eq. (2)). The score propagation is controlled by $\lambda^{d(syn, syn_k)}$, where $0 < \lambda < 1$, $d(syn, syn_k)$ is the distance between two synsets syn and syn_k in the WordNet hierarchy, and syn_k is a synset to which $n_k \in TopK(n)$ belongs. More precisely, $d(syn, syn_k)$ is the minimum length of any ancestral path between syn and syn_k, and $d(syn, syn_k) = 0$ if $syn = syn_k$.

Note that as distance $d(syn, syn_k)$ increases, $\lambda^{d(syn, syn_k)}$ becomes smaller and $sim(n, n_k)$ therefore makes less contribution to $S(n, syn)$. On the other hand, $S(n, syn)$ tends to *recieve* a penalized similarity from more synsets distant from syn than those close to syn. The score therefore has the largest value when these two tendencies are balanced.

The score propagation for **trg** and **sib**, in Figure 3, is done only in the direction to ancestors in the Wordnet hierarchy. On the contrary, the score propagation for **hyper** is done in a slightly different way. That is, the penalized distributional similarity is propagated to not only the ancestors but also the descendants.

The final score value, $PS(\mathcal{I}, syn)$, is the sum of sub-score values S for **trg**, **hyper**, and **sib** weighted by constants α, β, and γ, where $\alpha + \beta + \gamma = 1$. These constants are optimized in the experiment, which is described in Section 4.1. This score-propagation scheme is an extension of Yamada et al. (2009).

3.2.2 Measuring Distributional Similarity

The distributional similarity between two terms (n_1 and n_2) is defined as

$$sim(n_1, n_2) = 1 - D_{JS}(P(a|n_1) \| P(a|n_2)) \quad (3)$$

where a denotes a class to which the term belongs, and $D_{JS}(P(a|n_1) \| P(a|n_2))$ is the Jensen-Shannon divergence between two probability distributions, $P(a|n_1)$ and $P(a|n_2)$.

To calculate probability distribution $P(a|n)$, Torisawa (2001) conducted noun clustering using the triple $< v, p, n >$ obtained from a parsed corpus, where v, n, and p represent a verb, a noun, and a postposition that attaches to the noun. The noun and the postposition constitute a phrase that depends on the verb. The probability of occurrence of the triple $< v, p, n >$ is defined as

$$P(< v, p, n >) \quad (4)$$
$$=_{def} \sum_{a \in A} P(< v, p > |a) P(n|a) P(a)$$

where a denotes a class of $< v, p >$ and n. $P(< v, p > |a)$, $P(n|a)$, and $P(a)$ are estimated by the EM-based clustering method, which estimates these probabilities by using a given corpus. In the E-step, probability $P(a| < v, p >)$ is calculated. In the M-step, probabilities $P(< v, p > |a)$, $P(n|a)$, and $P(a)$ are updated to arrive at the maximum likelihood using the results of the E-step. From the results of estimation by this EM-based clustering method, probabilities $P(< v, p > |a)$, $P(n|a)$, and $P(a)$ for $< v, p >$, n, and a are obtained. $P(a|n)$ is then calculated by the following equation:

$$P(a|n) = \frac{P(n|a)P(a)}{\sum_{a \in A} P(n|a)P(a)} \quad (5)$$

With the aim of enabling large-scale clustering and using the resulting clusters in named entity recognition, Kazama and Torisawa (2008) proposed parallelization of this EM-based clustering method. Kazama et al. (2009) then reported the calculation of distributional similarity by using the clustering results. We applied their method to the TSUBAKI corpus (Shinzato et al., 2008), a collection of 100-million Japanese Web pages containing 6×10^9 sentences. We prepared

about 1,000,000 terms for calculating the distributional similarity. These one million terms consist of the following three sets of terms: (1) sets of hyponymy relation instances extracted from Wikipedia, (2) sets in WordNet, and (3) sets from the TSUBAKI corpus that are neither (1) nor (2). Terms in sets (1) or (2) were required to syntactically depend on 10 different $< v, p >$ in the TSUBAKI corpus for reliably calculating the distributional similarities. Terms in set (3) have been chosen from those that have the largest number of dependency relations in the corpus, so the total number of terms is one million.

3.2.3 Definition of SIMs

Three synset identification modules (SIMs), namely, SIM_1, SIM_2, and SIM_3, were developed. These three modules make it possible to generate diverse candidates of an appropriate synset by using different evidence derived from **trg**, **hyper**, and **sib**. Table 1 summarizes the information that each SIM uses as a trigger for score propagation. SIM_1 relies on $PS(\mathcal{I}, syn)$, whose β and γ are zero, while SIM_2 is defined by $PS(\mathcal{I}, syn)$, whose γ is zero.

Information sources	SIM_1	SIM_2	SIM_3
Target term (**trg**)	✓	✓	✓
Hypernym (**hyper**)		✓	✓
Sibling (**sib**)			✓

Table 1: Information sources used in each module.

Basically, each SIM generates top-n synsets that maximize $PS(\mathcal{I}, syn)$ over all WordNet synsets. Here, one heuristics is used for SIM_2 and SIM_3 when **hyper** is available. When **hyper** belongs to WordNet synsets, one of the synsets is usually the appropriate synset of the **trg**. According to this observation, the top-n synsets among the synsets that contain **hyper** are generated. However, if the hyponymy relation is wrong (like *musician* as a hypernym of *acoustic guitars*), this heuristics will have a negative effect on the performance of synset identification.

To avoid this effect, the following additional condition is set: At least one of the synsets to which **hyper** belongs has score $PS(\mathcal{I}, syn) > 0$. Under this condition, the synset which contains the **hyp** but is not supported by the **trg** and its **sib**s is not preferred in generating candidates of an appropriate synset.

3.3 Selecting Appropriate Synset among Outputs of Multiple SIMs

Once SIMs generate WordNet synset candidates for a **trg**, to select the most appropriate synset, a classifier is applied to these candidates. As the classifier, SVMs trained with a polynomial kernel of degree 2 are used[4]. Moreover, the following features are used for training SVMs, which are selected by the ablation test reported in Section 4.4.

f1: **hyper**

f2: Name of SIM used for generating appropriate synset candidates

f3: Value of $PS(\mathcal{I}, syn)$ given by each SIM

f4: Synset ID of WordNet synset candidate

f5: Suffix of **trg**

f6: Suffix of **hyper**

Regarding f5 and f6, the suffixes are obtained in the same way as the procedure for longest-suffix matching described in Section 3.1. Finally, the synset which has the largest SVM score is selected as appropriate synset for **trg**.

4 Experiments

4.1 Experimental Set up

For our experiments, 4,057,879 hyponymy relation instances were acquired from the 2009-09-27 version of the Japanese Wikipedia dump (containing about 0.9 million articles). Hyponymy relation instances whose hyponyms are not found in the Japanese WordNet and are from a leaf node in a layout structure of a Wikipedia article (which usually corresponds to an itemized list like the movie names in Fig. 1) were then selected. After these processes, 2,039,417 hyponymy relation instances containing 1,231,172 unique hyponyms (**trg**), of which about 80% are not Wikipedia article titles, were acquired. **Sib**s for each hyponym (**trg**) were then acquired from the hyponymy relation instances. Finally, 2,039,417 $\mathcal{I}$s (note that $\mathcal{I} =< trg, hyp, N_{sib}(trg) >$ composed of **trg**, **hyper**, and **sib**s) were used for the experiments.

800 $\mathcal{I}$s were randomly selected for development data, and 1,800 $\mathcal{I}$s were selected for test data from the 2,039,417 $\mathcal{I}$s, where a **trg** in the selected $\mathcal{I}$s is unique over both development and test data. Candidate generation was applied to these development and test data, and the appropriate synsets

[4]TinySVM, available at `http://chasen.org/taku/software/TinySVM`, `wasused`

among candidates for each $\mathcal{I}$ were then manually labeled. In the labeling, three judges were asked to mark synset candidates as the correct synset for $\mathcal{I}$ if one of terms in the synset candidate is an appropriate hypernym[5]. Finally, the correct synset for $\mathcal{I}$ was determined by the judges' majority vote. The interrater agreement between the three judges (Siegel's Kappa) was 0.785, indicating substantial agreement.

We performed parameter optimization by using the development data. The parameters used in our method showing the best performance for development data were used in our experiments, namely, the number of similar terms $k = 60$, the parameter for score propagation $\lambda = 0.6$, and weights for $S(n, syn)$ in $PS(\mathcal{I}, syn)$ ($\alpha = 0.6$ and $\beta = 0.4$ for SIM_2 and $\alpha = 0.5$, $\beta = 0.4$, and $\gamma = 0.1$ for SIM_3).

4.2 Results

In the experiment, the eleven systems listed as follows (ten baseline systems and our proposed system) were evaluated.

- $B1$–$B3$: Bi represents a system that outputs the best candidate of SIM_i ($1 \leq i \leq 3$).
- $SB1$–$SB3$: SBi represents a system based on a classifier that selects the best synset among the top-5 candidates of SIM_i ($1 \leq i \leq 3$)
- $CB1$: randomly selects one of the outputs of B1–B3 as the appropriate synset.
- $CB2$: selects the most frequently observed synset in the training data among the outputs of B1–B3.
- $EB1$: randomly selects one of synsets, which contains a **hyper** in $\mathcal{I}$.
- $EB2$: selects the most frequently observed synset in the training data among synsets, which contains a **hyper** in $\mathcal{I}$.
- Proposed method: The proposed method using B1–B3

$B1$ is our implementation of the method proposed by Yamada et al. (2009). Evaluation of B1–B3 shows the performance of candidate generation by SIM_1, SIM_2, and SIM_3. $EB1$ and $EB2$ can be considered simple extensions of an existing research of Sumida et al. (2008) for estimating Wordnet synsets.

Table 2 shows the precision rate of each system. We could not evaluate all 1,800 samples for $B1$, $SB1$, $EB1$ and $EB2$. $B1$ and $SB1$ were able to generate outputs for 614 $\mathcal{I}$s, where trg in $\mathcal{I}$s was included in the target terms for calculating the distributional similarity. $EB1$ and $EB2$ can select the synset when **hyper** or the suffix of **hyper** is registered in WordNet. For this reason, it was not possible to select a synset for 174 **trg**s out of the 1,800 samples in $EB1$ and $EB2$. As a result, we used 1,636 samples in evaluating $EB1$ and $EB2$. $SB1$–$SB3$, $CB2$, $EB2$, and the proposed method were evaluated by five-fold cross validation with test data because these systems need training data for learning their classifier or finding the most frequently observed synset.

The precision rate of the proposed method is the highest among those of all the systems in Table 2. Comparison of the proposed method and one of $SB1$–$SB3$ shows the effectiveness of integration of different information generated by multiple SIMs. In the results for $B1$–$B3$ and $SB1$–$SB3$, $SB1$ and $SB2$ (which use a classifier), respectively, attain higher precision than systems $B1$ and $B2$ (which do not use a classifier). The precision of $SB3$ is, however, lower than that of $B3$, indicating that using a classifier is not always effective for synset identification.

System	Precision
$B1$	50.3 (309/ 614)
$B2$	70.9 (1,276/1,800)
$B3$	78.2 (1,408/1,800)
$SB1$	59.3 (364/ 614)
$SB2$	72.4 (1,303/1,800)
$SB3$	76.3 (1,374/1,800)
$CB1$	71.9 (1,294/1,800)
$CB2$	80.2 (1,444/1,800)
$EB1$	56.5 (924/1,636)
$EB2$	79.2 (1,296/1,636)
Proposed method	84.2 (1,515/1,800)

Table 2: Experimental results of each system.

4.3 Evaluation by Ranking

Figure 4 shows precision rates by their ranking for the system outputs of $B1$–$B3$, $SB1$–$SB3$, and the proposed method. The vertical axis indicates precision rate; the horizontal axis indicates the rank

[5]Judges were required to label the following ten synsets (00001740, 00001930, 00002137, 00002684, 00003553, 00004258, 00004475, 00023100, 00007347, and 00021939) as wrong one. These synsets were selected in descending order of the number of their lower nodes in the WordNet hierarchy.

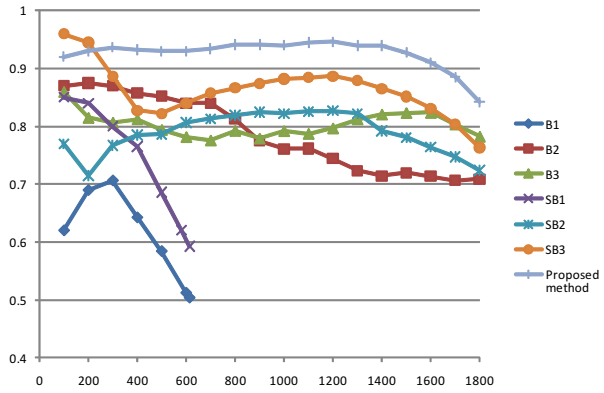

Figure 4: Precision rate by ranking.

of **trg** in scores, i.e., all the outputs are sorted in the descending order of scores. For $B1$, $B2$, and $B3$, $PS(\mathcal{I}, syn)$ is used as a score, while for $SB1$, $SB2$, $SB3$, and the proposed method, the distance from the hyperplane of an SVM is used as a score. For $SB1$, $SB2$, $SB3$, and the proposed method, averaged scores over the five folds were used.

It should be noted that the proposed method outperforms the other methods for almost all the ranks and keeps a precision rate of about 84%. This result implies that the method can identify synsets with a precision rate of about 84% for all 2,039,417 $\mathcal{I}$s.

Note also that the proposed method keeps a precision rate of about 91% until the top 88.9% (1600/1800). From this result, it is estimated that the method can identify synsets for 1,813,042 $\mathcal{I}$s (88.9% of all 2,039,417 $\mathcal{I}$s) with a precision rate of about 91%.

4.4 Contribution of Each Feature

To examine the effectiveness of each of the six features used for the classifier, ablation tests using the development data (which examined the change in the performance of the classifier when one of the features was ignored) were conducted. Table 3 lists the results of these tests. This table shows that

Feature set	Precision
All	82.6 (661/800)
w/o **Hyper** (f1)	82.1 (657/800)
w/o Name of SIM (f2)	82.5 (660/800)
w/o Value of $PS(\mathcal{I}, syn)$ (f3)	82.0 (656/800)
w/o Synset ID (f4)	81.1 (649/800)
w/o Suffix of the **trg** (f5)	82.1 (657/800)
w/o Suffix of the **hyper** (f6)	82.4 (659/800)

Table 3: Results of ablation test.

f4 (the synset ID of a WordNet synset candidate) is the most effective for the classifier.

4.5 Distribution of Output Synset IDs

freq.	Synset ids	Example terms in WordNet
336	04599396	work, piece of work
336	00007846	someone, person
132	06613686	moving picture,movie
68	06619428	broadcast, programme
44	08237863	cast, cast of characters
44	08008335	organisation, organization
28	06376154	drama
25	08276720	school
25	03315023	installation, facility
23	06616806	docudrama, documentary
22	07020895	music
22	04341686	construction, structure
19	00455599	game
17	06362953	writing, piece of writing
17	03129123	creation

Table 4: Distribution of output synset IDs.

Table 4 lists the distribution of output synset IDs determined by our method. About two-thirds of the results were assigned a very specific synset. The remaining terms were all assigned to the two most-frequent synsets: 04599396 or 00007846. In the case when a term was assigned to these most-frequent synsets, a more specific synset, like 06613686 (moving picture, movie) or 09765278 (actor), should have been chosen. However, our current scoring process does not take the synsets' granularity into account, so it sometimes favors the more general synsets, like 06613686 or 00007846. Fine-tuning our algorithm to compensate for this tendency will be an important future work.

4.6 Analysis

4.6.1 Advantage of Proposed Method

The advantage of the proposed method compared to previous methods that use nothing but either distributional similarity of a **trg** or co-occurrence with their hypernyms via lexico-syntactic patterns (Snow et al., 2006; Yamada et al., 2009) (or both) was demonstrated as follows. Specifically, it was shown that many terms do not have reliable distributional similarity (owing to their infrequency in a corpus) and do not co-occur with their hypernyms via any lexico-syntactic pattern in a sentence. Even so, our method can correctly identify the synset of such terms thanks to their **hy-**

pers and **sib**s acquired from the internal structure of Wikipedia articles.

First, 1,515 terms were extracted from all 1,800 $\mathcal{I}$s whose synset our method could correctly identify. The occurrence of each term in a corpus that consists of 600 million Japanese Web pages (a super set of the one-million-page TSUBAKI corpus) was then counted. According to the result of this counting, 430 terms occur less than 10 times. We believe that it is not possible to obtain reliable distributional similarity for these terms owing to their infrequency. Note that the distributional similarity of the suffix of **hyper** was used instead of that of the **hyper** itself. (Section 3.1). If the suffix of a term is used, it might be possible to obtain reliable distributional similarity even for the 430 terms. Accordingly, it was determined whether the suffix of a term can help the synset identification for each of the 430 terms by checking whether the suffix of each of the 430 terms is actually its subordinate concept. According to the results of this checking, 342 terms out of the 430 do not have a suffix that is their correct subordinate concept. Reliable distributional similarity is thus not available for them even when the suffix technique is used.

Next, the co-occurrence of each of the 342 terms and its **hyper** via some lexico-syntactic pattern within a sentence was checked by using the 600-million-page Japanese Web corpus. According to the results of this check, 290 terms out of 342 do not co-occur with their **hyper** within a sentence; thus, the co-occurrence with their **hyper** cannot be used to identify their synset.

In conclusion, it is difficult for the previous methods to correctly identify the synset of the 290 terms that do not co-occur with their **hyper** within a sentence, while our method can. From this result, it is estimated that the number of such terms in all the 2,039,417 $\mathcal{I}$s is 328,572.

4.6.2 Error Analysis

From the 285 incorrect synsets output by the proposed method, 124 were selected from B3, 110 were selected from B2, and 51 were selected from B1. For 232 of these 285 errors, all outputs of B1, B2, and B3 were judged incorrect. Because the proposed method's classifier chooses the final result from the outputs of B1, B2, and B3, it cannot help selecting the wrong candidate in these cases. 100 erroneous synsets were randomly selected from our results, and the following three types of error were found.

Missing terms for some senses in the Japanese WordNet (20/100): For instance, the Japanese term *anime* is defined in synset *06616464-n* as *animation originating in Japan*, but no term in the Japanese WordNet is linked to this synset (Bond et al., 2009). The Japanese WordNet does contain other meanings for the term *anime*, such as *a hard copal derived from an African tree* (synset *14896018-n*) and *any of various resins or oleoresins* (synset *14766265-n*). As a result, Japanese animation films with the hypernym *anime* are linked to either *14896018-n* or *14766265-n*. This type of error should be avoidable by adding such missing terms to the Japanese WordNet.

Terms incorrectly identified as persons (16/100): Many named entities such as companies or movie titles are often mistaken for references to people. For example, a movie titled "BROTHER" is distributionally similar to other movies as well as family terms like "sister" and "mother". Moreover, WordNet does not contain many movie titles, so the "family term" sense is selected as the dominant sense, and "BROTHER" was given the synset of *person*. We expect such problems can be alleviated by adding more named entities to WordNet.

Hyponymy relation acquisition error (10/100): The precision of hyponymy-relation acquisition was 90%, which accounted for the remaining 10% of the errors. For example, the term *acoustic guitar* was given the wrong hypernyms, namely, *musician*, which results in misclassification.

5 Conclusion

This paper proposed a method for extending WordNet with terms in Wikipedia, by exploiting hypernyms (**hyper**s) and siblings (**sib**s) of target terms (**trg**s) acquired from Wikipedia as additional sources of information. Experimental results showed that the proposed method could identify synsets for 2,039,417 inputs at precision rate of 84%. Furthermore, it was estimated that there were 328,572 terms among all the inputs whose synsets the proposed method could correctly identify. In contrast, previous methods relying on distributional similarity and lexico-syntactic patterns only could not identify these synsets.

What Psycholinguists Know About Chemistry: Aligning Wiktionary and WordNet for Increased Domain Coverage

Christian M. Meyer and **Iryna Gurevych**
Ubiquitous Knowledge Processing Lab
Technische Universität Darmstadt
Hochschulstraße 10, 64289 Darmstadt, Germany
http://www.ukp.tu-darmstadt.de

Abstract

By today, no lexical resource can claim to be fully comprehensive or perform best for every NLP task. This caused a steep increase of resource alignment research. An important challenge is thereby the alignment of differently represented word senses, which we address in this paper. In particular, we propose a new automatically aligned resource of Wiktionary and WordNet that has (i) a very high domain coverage of word senses and (ii) an enriched sense representation, including pronunciations, etymologies, translations, etc. We evaluate our alignment both quantitatively and qualitatively, and explore how it can contribute to practical tasks.

1 Introduction

Though WordNet has been extensively used in knowledge-rich natural language processing (NLP) systems, there is no best lexical resource for all purposes. Jarmasz and Szpakowicz (2003), for example, found better results for solving word choice problems when using Roget's thesaurus instead of WordNet. There is indeed a large number of different lexical resources: The ACL Special Interest Group on the Lexicon[1] lists, for instance, more than 40 different lexical resources on their homepage that have been proposed as a source of background knowledge for different NLP tasks.

These resources typically differ in two ways: (i) They have a different coverage of words and word senses, and (ii) they encode heterogeneous types of information that is attached to their words and word senses. This heterogeneity ranges from very fundamental differences, like the distinction between lexicographic and encyclopedic knowledge to more specific ones, such as one resource encodes semantic frames, while another focuses on subsumption relations between word senses. Using WordNet without further considerations thus limits the performance of a system, since each resource has its individual advantages.

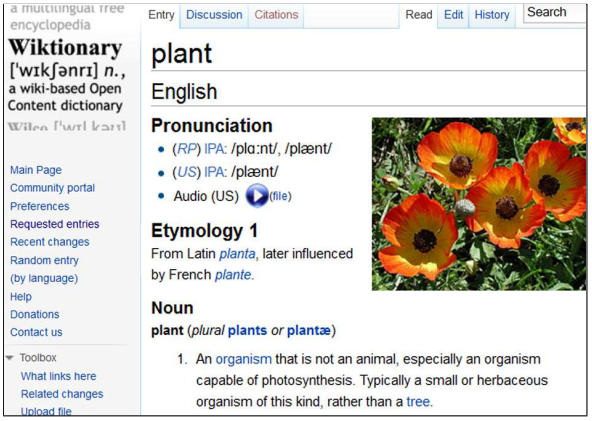

Figure 1: Wiktionary article *'plant'*

This has caused increasing research in the area of lexical resource alignment. It has been shown that aligned resources yield synergies, which lead to better performance than using the resources individually. For instance, Shi and Mihalcea (2005) improve semantic parsing using the knowledge of an aligned resource of FrameNet, WordNet, and VerbNet. Recently, Ponzetto and Navigli (2010) observed improvements for coarse-grained and domain-specific word sense disambiguation using an alignment between WordNet and Wikipedia for adding new relations to WordNet.

In another line of research, the community based online dictionary Wiktionary has been successfully applied in several NLP tasks, such as cross-lingual image retrieval (Etzioni et al., 2007), named entity recognition (Richman and Schone, 2008), or synonymy mining (Navarro et al., 2009; Sajous et al., 2010). Zesch et al. (2008b) compare different semantic relatedness measures using either WordNet, Wikipedia, or Wiktionary and find

[1] http://www.siglex.org/, accessed 2011-05-10

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 883–892,
Chiang Mai, Thailand, November 8 – 13, 2011.

the best results for Wiktionary. Besides its large coverage, Wiktionary also offers a great variety of linguistic information, such as pronunciations, etymologies, glosses, related words, translations, and many others. De Melo and Weikum (2010) exploit, for instance, alternative spellings and etymologies to enrich their lexical database.

In this work, we propose aligning WordNet and Wiktionary at the level of word senses. The resulting alignment has two important properties that go substantially beyond previous alignments: (i) increased domain coverage and (ii) enriched representation of senses. While Wiktionary is larger in size than most other previously aligned resources, such as Roget's thesaurus, Meyer and Gurevych (2010) analyze some word senses from WordNet and Wiktionary and come to the conclusion that certain domains are better covered by only one of the resources. This leads us to assume a very high domain coverage in our aligned resource.

Much work on lexical resource alignment involves Wikipedia, which contains lots of information about named entities. Wiktionary, in contrast, encodes common words and is not restricted to nouns. This opens up new possibilities for tasks including verbs, adjectives, or multiwords. Regarding the representation of senses, Wiktionary contains a great variety of linguistic information, like pronunciations or etymologies that are not found in previously aligned lexical resources.

The contributions of our work are threefold: (i) We present an automatic word sense alignment between the entire WordNet and Wiktionary, which we make publicly available. (ii) For evaluating the quality of our alignment, we introduce a new dataset based on human judgments to allow for future comparability of our results. (iii) We analyze the characteristics of our aligned resource, and how it can benefit different NLP tasks. We particularly point out that our resource has a much broader coverage of domain-specific word senses, which is important for processing real world data.

2 Notation and Lexical Resources

We first define the terminology used throughout the paper and introduce the two lexical resources WordNet and Wiktionary that are the subjects of our word sense alignment.

Lexical resources. By *lexical resource*, we mean a list of words and word senses. Our notion of *word* also includes multiwords, idioms, inflected forms, etc. Each word can have multiple *word senses*, which is one of multiple possible meanings for a word. A good illustration for this notion of words are the headwords in dictionaries, whereby the different meanings of the headword correspond to our notion of word sense.[2]

WordNet (Fellbaum, 1998) is a lexical resource for the English language that has been created by psycholinguists at the Princeton University. The resource is organized in synsets (i.e., sets of synonymous words) that are connected in a clear-cut subsumption hierarchy. The latest version 3.0 encodes 117,659 synsets. Each synset is represented by a gloss that is often followed by a short usage example. The synset {*plant, works, industrial plant*} is, for instance, represented by the gloss *"buildings for carrying on industrial labor"*.

Wiktionary[3] is a freely available, multilingual online dictionary. Similar to Wikipedia, the contents in Wiktionary can be edited by every Web user, which causes the resource to grow very quickly: by April 2010, the English Wiktionary contained over 1,700,000 article pages with linguistic knowledge about words in over 100 languages. For each word, multiple word senses can be encoded. Like in WordNet, they are represented by a gloss and example sentences illustrating the usage of a word sense. Additionally, there are hyperlinks to synonyms, hypernyms, meronyms, etc. Figure 1 shows the Wiktionary article *'plant'* as an example. For extracting the knowledge from Wiktionary, we use the Java-based Wiktionary Library (Zesch et al., 2008a). Using a Wiktionary dump of April 3, 2010, we counted 335,748 English words and 421,847 word senses.

Word sense alignment. A *word sense alignment*,[4] or *alignment* for short, is a list of pairs of word senses from two lexical resources. A pair of word senses that are aligned in a word sense alignment denote the same meaning. In WordNet, there is, for instance, a synset *"buildings for carrying on industrial labor"* for the word *'plant'*, which denotes the same meaning as the Wiktionary word

[2] Note that there is no commonly accepted standardized terminology in the field. Our notion of word is thus sometimes called *lemma* or *lexeme*; a *word sense* is also called *lexical unit*; whereas a lexical resource is also referred to as *sense inventory* or *(computational) lexicon*.

[3] `http://www.wiktionary.org`

[4] Other terms for *(word sense) alignment* are *mapping* or *matching*. This notion of alignment is not to be mixed up with *word alignment* or *sentence alignment*, which are used for processing parallel texts as in machine translation.

sense *"a factory or other industrial or institutional building or facility"*. Another Wiktionary sense *"an organism that is not an animal* [...]*"*, however, clearly denotes a different meaning and should thus not be aligned to the WordNet synset.

3 Related Work

In the last twenty years, there have been many works on aligning lexical resources at the level of word senses. Almost all alignment approaches for the English language include WordNet, which is the *de facto* standard resource in the field. Early works address the alignment of WordNet with: Roget's thesaurus and the Longman Dictionary of Contemporary English (Kwong, 1998) [K98], the HECTOR corpus (Litkowski, 1999) [L99], the Unified Medical Language System (Burgun and Bodenreider, 2001) [BB01], CYC (Reed and Lenat, 2002) [RL02], VerbNet and FrameNet (Shi and Mihalcea, 2005) [SM05], as well as the Oxford Dictionary of English (Navigli, 2006) [N06].

The great potential of the collaborative resource Wikipedia in many NLP applications, such as semantic relatedness (Gabrilovich and Markovitch, 2007; Milne and Witten, 2008), word sense disambiguation (Mihalcea, 2007; Ponzetto and Navigli, 2010), or named entity recognition (Bunescu and Paşca, 2006), motivates aligning WordNet and Wikipedia to benefit from the advantages of both these resources. One line of research is thereby the alignment of WordNet synsets and Wikipedia categories, which has been done based on the shared taxonomic structure (Toral et al., 2008) [T08], textual entailment and semantic relatedness methods (Toral et al., 2009) [T09], as well as graph algorithms (Ponzetto and Navigli, 2009) [PN09].

Since the vast majority of knowledge is encoded in the Wikipedia article pages, also those have been aligned to WordNet synsets. The first work in this direction has been carried out by Ruiz-Casado et al. (2005) [R05] for the Simple Wikipedia, which is a smaller version of the full Wikipedia. Most of the published work, however, focuses on the articles in the full Wikipedia and their alignment to WordNet synsets. This task has been done based on: human judgments (Mihalcea, 2007) [M07], giving preference to WordNet's first sense (Suchanek et al., 2008) [S08], word overlap (de Melo and Weikum, 2010; Navigli and Ponzetto, 2010) [MW10,NP10], and using semantic relatedness measures (Niemann and Gurevych, 2011) [NG11]. Each approach has been evaluated on a separate, manually annotated dataset: De Melo and Weikum (2010) report a precision of $P = .85$, Navigli and Ponzetto (2010) observe $F_1 = .79$, and the alignment described by Niemann and Gurevych (2011) evaluates to $F_1 = .78$. It should be noted that these numbers are not comparable to each other, since they are based on different datasets and annotation schemes.

Table 1: Previous work on aligning WordNet

Recently, also Wiktionary has been found to be a very promising resource for NLP tasks. So far, Wiktionary knowledge has been used for image search (Etzioni et al., 2007), calculating semantic relatedness (Zesch et al., 2008b), information retrieval (Müller and Gurevych, 2009), and synonymy detection (Navarro et al., 2009). An alignment has been done manually for a small number of word senses shared by Wiktionary and WordNet (Meyer and Gurevych, 2010) [MG10], but to the best of our knowledge, there is yet no word sense alignment covering the full resources. For applying an aligned resource in a practical system, such as word sense disambiguation, we, however, need a full alignment of the two resources. This is the subject of our work.

Table 1 shows an overview of related work on aligning WordNet with different lexical resources. Besides the resource that it is aligned to and whether the full resources have been processed, the table shows the utilized methods, which we classified into methods: aligning the first sense [mfs], counting weighted or normalized word overlaps (including the cosine measure) [overlap], using syntactic patterns [syntax], considering the (graph) structure of the resource [structure], uti-

lizing measures of semantic relatedness, such as semantic vectors or personalized PageRank [relatedness], and aligning senses manually [manual].

4 Word Sense Alignment

Most previous alignments are based on a one-to-one alignment assumption – i.e., that each sense is aligned with exactly one sense in the other resource. Niemann and Gurevych (2011), however, argue that there are senses requiring none, one, or multiple aligned senses.

This also holds for alignments of Wiktionary and WordNet. For example, the Wiktionary word sense *"the people who decide on the verdict; the judiciary"* for the word *'bench'* can be aligned to the two WordNet synsets *"persons who administer justice"* and *"the magistrate or judge or judges* [...]*"*. Accordingly, the Wiktionary word sense *"the bottom part of a sand casting mold"* for the noun *'drag'* is not covered by any WordNet synset and should thus not be aligned.

Therefore, we follow the alignment approach by Niemann and Gurevych (2011), which includes a state-of-the-art word sense disambiguation method by Agirre and Soroa (2009) that is known to outperform word overlap based measures. The method consists of the two steps (i) candidate extraction and (ii) candidate alignment that we briefly review in the following.

In the *candidate extraction* step, the algorithm iterates over all word senses in one lexical resource and extracts suitable candidates within the other resource that *might* form a valid alignment. In our case, we iterate over all synsets in WordNet and extract all word senses from Wiktionary that are encoded for one of the synset's synonymous words. For example, we extract all 9 Wiktionary word senses from the article *'plant'* and all 4 word senses from *'works'* for the WordNet synset {*plant, works, industrial plant*}. The word *'industrial plant'* is not encoded in Wiktionary. In the *candidate alignment* step, each candidate is then scored with two similarity measures:

(i) The *cosine similarity* (COS) calculates the cosine of the angle between a vector representation of the two senses s_1 and s_2:

$$\mathrm{COS}(s_1, s_2) = \frac{\mathrm{BoW}(s_1) \cdot \mathrm{BoW}(s_2)}{||\mathrm{BoW}(s_1)||\,||\mathrm{BoW}(s_2)||}$$

To represent a sense as a vector, we use a bag-of-words approach – i.e., a vector $\mathrm{BoW}(s)$ containing the term frequencies of all words in the definition of s. Note that there are different options for choosing the definition of sense s: For WordNet, the gloss of the synset can be used alone or in combination with its hyponyms and/or hypernyms. For Wiktionary, we can choose between gloss, usage examples, and related words of the word sense. We will discuss the best configuration during our evaluation in the following section.

(ii) The *personalized PageRank based measure* (PPR) estimates the semantic relatedness between two word senses s_1 and s_2 by representing them in a semantic vector space and comparing these semantic vectors $\mathbf{Pr}_{s_1}$ and $\mathbf{Pr}_{s_2}$ by computing

$$\mathrm{PPR}(s_1, s_2) = 1 - \sum_i \frac{(\mathbf{Pr}_{s_1,i} - \mathbf{Pr}_{s_2,i})^2}{\mathbf{Pr}_{s_1,i} + \mathbf{Pr}_{s_2,i}},$$

which is a χ^2 variant introduced in Niemann and Gurevych (2011). The main idea of choosing $\mathbf{Pr}$ is to use the personalized PageRank algorithm for identifying those synsets that are central for describing a sense's meaning. The sense *"buildings for carrying on industrial labor"* is, for instance, well represented by the WordNet noun synsets {*plant, works, industrial plant*}, {*building complex, complex*}, or the adjective synset {*industrial*}. These synsets should have a high centrality (i.e., a high PageRank score), which is calculated as

$$\mathbf{Pr} = cM\mathbf{Pr} + (1 - c)\mathbf{v},$$

with the damping factor c controlling the random walk, the transition matrix M of the underlying semantic graph, and the probabilistic vector $\mathbf{v}$, whose i^{th} component $\mathbf{v}_i$ denotes the probability of randomly jumping to node i in the next iteration step.[5] Unlike in the traditional PageRank algorithm, the components of the jump vector $\mathbf{v}$ are not uniformly distributed, but personalized to the sense s by choosing $\mathbf{v}_i = \frac{1}{m}$ if at least one synonymous word of synset i occurs in the definition of sense s, and $\mathbf{v}_i = 0$ otherwise. The normalization factor m is set to the total number of synsets that share a word with the sense definition, which is required for obtaining a probabilistic vector.

Having calculated the similarity scores, we add the pair of the WordNet synset and the Wiktionary

[5] We use the publicly available UKB software (Agirre and Soroa, 2009) for calculating the PageRank scores and utilize the WordNet 3.0 graph augmented with the Princeton Annotated Gloss Corpus as M. The damping factor c is set to 0.85.

```
1  function ALIGN(WordNet, Wiktionary)
2    alignment := ∅;
3    for each synset ∈ WordNet.getSynsets() do
4      // Candidate extraction
5      candidates := ∅;
6      for each word ∈ synset.getWords() do
7        candidates := candidates
               ∪ Wiktionary.getWordSenses(word);
8      // Candidate alignment
9      for each candidate ∈ candidates do
10       sim_cos := COS(synset, candidate);
11       sim_ppr := PPR(synset, candidate);
12       if sim_cos ≥ τ_cos ∧ sim_ppr ≥ τ_ppr then
13         alignment := alignment
                 ∪ (synset, candidate);
14   return alignment;
15 end.
```

Figure 2: Pseudo code of the alignment algorithm

sense to our alignment if both similarity scores are above a certain threshold τ_{cos} and τ_{ppr}. We learned these thresholds in a 10 fold cross validation on our dataset that is explained in the following section. The optimal thresholds have been determined independently from each other using a simple binary split of the fold's items. The final thresholds are $\tau_{cos} = .13$ and $\tau_{ppr} = .49$.

Figure 2 shows the alignment algorithm in pseudo-code. Further details can be found in (Niemann and Gurevych, 2011).

5 Evaluation

To evaluate our WordNet–Wiktionary alignment, we follow the methodology of previous approaches and compare the result of our automatic alignment algorithm with human judgments. Therefore, we create a new manually annotated dataset, as we are not aware of any other datasets that could be used for this task. Our dataset is publicly available for future work on aligning WordNet and Wiktionary.

Dataset creation. Niemann and Gurevych (2011) introduce a well-balanced dataset for the alignment of WordNet and Wikipedia. Their sampled WordNet synsets are uniformly distributed in the number of synonyms, distance to the root node, and unique beginners. This way, a quantitative judgment of the alignment quality is as unbiased as possible. Since lexical resources are known to be very diverse (e.g., in terms of domain coverage (Burgun and Bodenreider, 2001; Meyer and Gurevych, 2010)), this is very important to get an impression about the alignment in general. Therefore, we reuse 320 synsets from their dataset as a primer for our evaluation dataset. For each synset, we extract all possible Wiktionary senses according to the candidate extraction step introduced in the previous section. This results in 2,423 sense pairs.

We asked 10 annotators to rate each sense pair as describing the same meaning (class 1) or describing a different meaning (class 0). The annotators are students in computer science, math, or linguistics, whereby two of them had previous experience with annotation studies. We described the annotation task in an annotation guidebook[6] and trained the annotators with some example cases.

Inter-rater agreement. To ensure the reliability of our annotated dataset, we calculate the inter-rater agreement between the annotators using the measures described by Artstein and Poesio (2008). The average observed agreement is $A_O = .93$ and the multi-rater chance-corrected agreement is $\kappa = .70$. Table 2 shows the pairwise κ for each pair of raters. The annotators C and F have the lowest inter-rater agreement between each other (.58) and with all other raters (.62 and .65). These two raters are thus on the opposite sides of the scale. Further analysis reveals that C is biased towards class 0 (different meaning) and F is biased towards class 1 (same meaning). We removed the annotations of these two raters, which yields an inter-rater agreement of $\kappa = .74$.

A dataset with such an agreement is considered reliable and allows to draw tentative conclusions (Krippendorff, 1980), although its agreement is lower than for WordNet–Wikipedia alignment datasets. More precisely, Niemann and Gurevych (2011) report $\kappa = .87$ and Navigli and Ponzetto (2010) measure $\kappa = .9$. Since even the two skilled annotators I and J only obtained an agreement of .80, we conclude that the alignment task of WordNet and Wiktionary is harder than the alignment of WordNet and Wikipedia. This does not come as a surprise, because Wikipedia contains encyclopedic knowledge that is largely complementary to the linguistic knowledge in WordNet and thus does not require to make fine-grained sense distinctions. WordNet and Wiktionary, however, both encode lexicographic knowledge about common words of the English language and thus require the distinction of very subtle differences in

Table 3: Performance of our alignment algorithm

the word sense definitions. We will discuss some examples during our error analysis.

Alignment quality. From our annotated data, we create a gold standard using majority vote of the remaining 8 annotators. An additional rater is asked to break the 27 ties. Following Navigli and Ponzetto (2010), we compare our automatic sense alignment with the gold standard using accuracy A, precision P, recall R, and the $F_1 = \frac{2PR}{P+R}$ score.

As baseline approaches, we implemented a first sense heuristic (MFS) and a method making a random selection (RAND). Table 3 shows the results of these baselines as well as our COS and PPR measures and their combination (COS&PPR). As noted in the previous section, there are multiple options for representing a sense. For WordNet, the synonyms, the gloss of the synset, and its direct hypernym and hyponyms have been tried as features. For Wiktionary, we experimented with the word, its gloss, usage examples, and synonyms. We tried all possible combinations and found the best result for using the synonyms and the gloss of the WordNet synset and its hypernym together with all four Wiktionary features. The table shows only the results for these features.

Our COS, PPR, and COS&PPR methods outperform the baseline by far. The difference is statistically significant at the 1% level in each case.[7] While COS has the highest recall and PPR has the highest precision, COS&PPR is a reasonable trade-off yielding the highest F_1 score. The difference of PPR and COS&PPR over COS is again statistically significant at the 1% level. The difference between PPR and COS&PPR is not statistically significant, which leads us to the conclusion that the PPR and COS&PPR methods perform equally well for our alignment task.

When analyzing the dataset, we observed a lower inter-rater agreement than for WordNet–Wikipedia alignments. This effect also becomes visible in our evaluation results: While Niemann and Gurevych (2011) measure an F_1 score of .53 for their MFS baseline and .78 for their COS&PPR method, the results are between .12 to .14 lower for the WordNet–Wiktionary alignment, which again shows that the word sense alignment between WordNet and Wiktionary is a more complex task than for WordNet and Wikipedia.

Error analysis. We carried out a detailed error analysis to identify the main types of errors made by our algorithm. Of the 2,423 sense pairs in the dataset, our COS&PPR algorithm yields 98 false positives and 110 false negatives.

Regarding the false negatives (i.e., the sense pairs that the method could not align, although they represent the same meaning), we found three main error classes: (i) The sense definitions were very different in their choice of words, such as in *"good discernment"* and *"ability to notice what others might miss"* for the word *'eye'*. These errors are hard to resolve, as they require a deep understanding and world knowledge. (ii) The sense definitions are very similar (e.g., *"any of various plants of the genus Centaurea* [...]*"* and *"any of various common weeds of the genus Centaurea"* for the word *'knapweed'*), but the similarity scores of the two measures were slightly below the chosen thresholds. These errors are caused by our choice of fixed similarity thresholds, which could, for instance, be improved by using machine learning for aligning the sense pairs. (iii) References to derived words occur in the sense definitions. An example is the word *'pacification'*, which is described as *"the process of pacifying"* and thus refers to the definition of *'pacifying'*. Such errors might be alleviated by taking the definitions of the derived words into account. This, however, raises again a word sense disambiguation challenge for finding the correct word sense of the derived word.

Amongst the false positives (i.e., the automatically aligned sense pairs with different meanings), we mainly found (i) highly related senses, such

[7] We use McNemar's test with Yates' correction.

as *"a computer that provides client stations with access to files and printers as shared resources to a computer network"* and *"any computer attached to a network"* for *'host'*, which are clearly related, but differ in their specification. The latter word sense does not require the host to provide file access or resources, but the former does. Although these two senses do not represent exactly the same meaning, their alignment is very useful for many NLP applications; e.g., for a semantic information retrieval system, which usually does not require to make subtle sense distinctions when searching relevant documents. Future work could distinguish between sense alignments sharing the same meaning and sharing a highly related meaning. (ii) Another large class of errors is due to an erroneous interpretation of a definition's meaning. Consider again the computing related sense of *'host'*. This sense is also aligned to *"any organization that provides resources and facilities for a function or event"*, because the words *resource, facility, function,* and *event* also frequently occur in the computer science domain. These errors are hard to tackle, but we plan to further investigate the influence of a sense's position in the taxonomy of a lexical resource.

6 Characteristics of the Wiktionary–WordNet Alignment

Aligning lexical resources is only one side of the coin. Another one is the question, how the aligned resource can be applied in practice and which NLP tasks can benefit from it. Our alignment of Wiktionary and WordNet yields a new resource with (i) increased coverage and (ii) an enriched representation of word senses.

Increased coverage. Coverage is crucial for almost every NLP task. Our final Wiktionary–WordNet alignment consists of 315,583 candidates, of which 56,970 pairs are marked as alignments. For 60,707 WordNet synsets there has been no corresponding word sense found in Wiktionary, and, vice versa, there are 371,329 Wiktionary word senses that have not been aligned with any WordNet synset. The word *'devisor'* is, for instance, only found within WordNet, and *'libero'* merely has an entry in Wiktionary. The new aligned lexical resource contains 488,988 word senses.

Table 4 shows the number of word senses per part of speech (POS) that are shared by both resources and that have no alignment with the respective other resource. The high number of word senses only occurring in Wiktionary can be explained by the 106,328 inflected word forms that are not encoded by WordNet. While the vast majority of encoded senses are nouns, also the coverage of other parts of speech benefits from the alignment of the two resources. This is a clear advantage over Wikipedia–WordNet alignments, which usually focus on nouns only. Besides verbs, adjectives, and adverbs that are also encoded by WordNet, Wiktionary additionally contains pronouns, phrases, idioms, sayings, etc.

	Overlap	only Wiktionary	only WordNet
Nouns	34,464	158,085	47,651
Verbs	8,252	29,119	5,515

Table 4: POS and domains of our aligned resource

Pantel and Lin (2002) note that manually compiled lexicons are often missing domain-specific word senses, which is an important aspect for domain-aware NLP tools. In their manual Wiktionary–WordNet alignment, Meyer and Gurevych (2010) come to the conclusion that WordNet has a focus on humanities and social sciences, while Wiktionary has a higher coverage of natural sciences and sports. Their findings are, however, limited to a very small set of word senses and thus might not hold for the entire resources. Therefore, we analyze the encoded domains for the whole aligned resource. To identify the domain of a sense, we use WordNet Domains (Bentivogli et al., 2004) to classify the WordNet synsets into 157 domains (e.g., *'biology'*). For Wiktionary, we use the domain markers encoded in the glosses. An example is the sense *"(snooker) A play in which the cue ball knocks one (usually red) ball onto another* [...]" of the word *'plant'*, labeled with the *'snooker'* domain. We count 714

different labels in Wiktionary.[8] For being able to relate WordNet's and Wiktionary's labels, we manually grouped them into 14 general classes listed in Table 4. The specialized domains *'genetics'* and *'botany'*, for instance, have been grouped together in a more general domain *'biology'*. For each of these general domains, we count the number of word senses that are either overlapping between the resources or found in only one of them.

In the analysis, we confirm the findings of Meyer and Gurevych (2010): WordNet encodes a larger number of word senses from humanities and social sciences. About twice as many senses are only found in WordNet compared to the respective number in Wiktionary. Moreover, word senses from natural sciences and information sciences are, in general, better represented by Wiktionary. In particular, word senses related to chemistry, math, and IT are almost exclusively found in Wiktionary. Examples are the computer science related sense of *'host'* discussed above or the chemistry related sense *"an intramolecular valence bond, atom or chain of atoms that connects two different parts of a molecule"* of *'bridge'*, which both have no counterpart in WordNet. The situation is, however, different for the biology domain. WordNet covers the entire taxonomy of plants and animals, which is only fragmentarily found in Wiktionary. A high overlap between the two resources can be observed for linguistics and medicine. Aligning Wiktionary and WordNet hence allows for fast adaptation to a certain domain and fosters the development of high quality cross-domain applications.

Enriched sense representation. Besides its coverage, Wiktionary is also very rich in its lexical semantic information, which includes etymologies, alternative spellings, pronunciations, glosses, related words, translations, and many more. De Melo and Weikum (2010) exploit, for example, alternative spellings and etymologies for enriching their lexical database. They, however, do not align their resource with Wiktionary and thus cannot make use of the semantic information contained in glosses or related words. WordNet, on the other hand, is known for its rigid subsumption hierarchy and contains a large number of synonyms that proved useful for many NLP tasks.

[8] To avoid noise, we only consider labels occurring at least 10 times and manually filter register or style labels, such as *'poetic'* or *'archaic'*.

Applicability. The potential of aligned resources has been previously shown by many researchers: Shi and Mihalcea (2005), for instance, align FrameNet and VerbNet with WordNet and obtain improved results for semantic parsing. A similar approach has been followed by Loper et al. (2007), who align VerbNet and PropBank for improving semantic role labeling. Recently, Ponzetto and Navigli (2010) have used their Wikipedia–WordNet alignment to improve a knowledge-based word sense disambiguation system.

Our alignment of Wiktionary and WordNet now allows for further work in these directions by (i) exploiting the high coverage of our aligned resource, and (ii) using the enriched representation of senses. Apart from semantic parsing and word sense disambiguation noted above, also semantic relatedness is an interesting task, since Zesch et al. (2008b) found very good results using Wiktionary alone. This might be even surmounted by using our aligned resource. In our future work, we plan to investigate these applications in greater detail.

7 Conclusion

In this paper, we propose a novel word sense alignment between the entire WordNet and the collaborative online dictionary Wiktionary. This work goes beyond previous research efforts in aligning WordNet with Wikipedia, FrameNet, VerbNet and similar lexical resources, as Wiktionary allows for (i) an increased coverage of word senses and (ii) an enriched representation of senses, including pronunciations, etymologies, translations, etc. In our analysis, we particularly found a higher coverage of technical domains in Wiktionary and of humanities and social sciences in WordNet, which are consolidated in our aligned resource. For our alignment, we follow the method by Niemann and Gurevych (2011). We create a well-balanced evaluation dataset, which we make publicly available together with the entire aligned resource.[9]

Acknowledgments. This work has been supported by the Volkswagen Foundation as part of the Lichtenberg-Professorship Program under grant No. I/82806. We thank Elisabeth Niemann, Christian Kirschner, Christian Wirth, and Dr. Judith Eckle-Kohler for their contributions to this paper, and the IXA group at the University of the Basque Country for sharing their UKB software.

Abstract

We investigate the problem of parsing the noisy language of social media. We evaluate four Wall-Street-Journal-trained statistical parsers (Berkeley, Brown, Malt and MST) on a new dataset containing 1,000 phrase structure trees for sentences from microblogs (tweets) and discussion forum posts. We compare the four parsers on their ability to produce Stanford dependencies for these Web 2.0 sentences. We find that the parsers have a particular problem with tweets and that a substantial part of this problem is related to POS tagging accuracy. We attempt three retraining experiments involving Malt, Brown and an in-house Berkeley-style parser and obtain a statistically significant improvement for all three parsers.

1 Introduction

With the explosive growth in social media, natural language processing technologies, including parsers, need to adapt to reflect the linguistic changes brought about by new forms of online communication. The availability of the Penn Treebank has encouraged much research in supervised parsing for English and facilitated comparision between parsers. This has led to impressive performance for in-domain parsing. Some progress has also been achieved in adapting parsers to new domains using semi-supervised and unsupervised approaches involving some labelled source domain training data, little, if any, labelled target domain data and large quantities of unlabelled target domain data. Much of the work on parser adaptation has focused on biomedical text and questions - very little has focused on the informal language prevalent in much of the user-generated content of Web 2.0. Domain adaptation to the language of social media is particularly challenging since Web 2.0 is not really a domain, consisting, as it does, of utterances from a wide variety of speakers from different geographical and social backgrounds.

Foster (2010) carried out a pilot study on this topic by investigating the performance of the Berkeley parser (Petrov et al., 2006) on sentences taken from a sports discussion forum. Each misparsed sentence was examined manually and a list of problematic phenomena identified. We extend this work by looking at a larger dataset consisting not only of discussion forum posts but also microblogs or tweets. We extend the parser evaluation to the Brown reranking parser (Charniak and Johnson, 2005), MaltParser (Nivre et al., 2006) and MSTParser (McDonald et al., 2005), and we examine the ability of all four parsers to recover typed Stanford dependencies (de Marneffe et al., 2006). The relative ranking of the four parsers confirms the results of previous Stanford-dependency-based parser evaluations on other datasets (Cer et al., 2010; Petrov et al., 2010). Furthermore, our study shows that the sentences in tweets are harder to parse than the sentences from the discussion forum, despite their shorter length and that a large contributing factor is the high part-of-speech tagging error rate.

Foster's work also included a targeted approach to improving parser performance by modifying the Penn Treebank trees to reflect observed differences between Wall Street Journal (WSJ) sentences and discussion forum sentences (subject ellipsis, non-standard capitalisation, etc.). We approach the problem from a different perspective, by seeing how far we can get by exploiting unlabelled target domain data. We employ three types of parser retraining, namely, 1) the McClosky et al. (2006) self-training protocol, 2) uptraining of Malt using dependency trees produced by a slightly more accurate phrase structure parser (Petrov et al., 2010), and 3) PCFG-LA self-training (Huang

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 893–901,
Chiang Mai, Thailand, November 8 – 13, 2011.

and Harper, 2009). We combine the benefits of the dependency parsing uptraining work of Petrov et al. and the self-training protocol of McClosky et al. by retraining Malt on trees produced by a self-trained version of the Brown parser.

We find that considerable improvements can be obtained when discussion forum data is used as the source of additional training material, and more modest improvements when Twitter data is used. Grammars trained on the discussion forum data perform well on Twitter data, but the reverse is not the case. For Malt, we obtain an absolute LAS increase of 8.8% on the discussion forum data and an improvement of 5.6% on the Twitter data. For Brown, we obtain an absolute f-score improvement of 2.4% on the discussion forum data and an increase of 1.7% on Twitter. For the Berkeley-style parser that we use in the PCFG-LA self-training experiment, the f-score improvements are 4.7% and 1.2% respectively.

The novel contributions of the paper are:

1. A new dataset consisting of 1,000 hand-corrected phrase structure parse trees for sentences from two types of social media (discussion forums and tweets).
2. A detailed evaluation of four popular WSJ-trained parsers on this new dataset.
3. An investigation of how well the most successful unsupervised parser adaptation methods perform on this new dataset. Since Web 2.0 is not really a domain, it is important not to assume that the methods that have been developed for more clearly defined domains will work without carrying out the experiments.
4. A discussion of the main issues involved in parsing Web 2.0 text.

The new dataset is discussed in §2 and the baseline parser evaluation is detailed in §3. The retraining experiments are described in §4. §5 contains a discussion of how this work could be extended.

2 Web 2.0 Data

Our Web 2.0 dataset, summarised in Table 1, consists of a small treebank of 1,000 hand-corrected phrase structure parse trees and two larger corpora of unannotated sentences. The sentences in the treebank originate from discussion forum comments and microblogs (tweets). The sentences in the larger corpora are taken from the same sources as the treebank sentences.

2.1 Tweets

Hand-Corrected Parse Trees 60 million tweets on 50 topics encompassing politics, business, sport and entertainment, were collected using the public Twitter API between February and May 2009 (Bermingham and Smeaton, 2010). The microblog section of the Web 2.0 treebank contains 519 sentences taken from this corpus. The development set contains 269 sentences and the test set contains 250. Hyperlinks and usernames were replaced by the generic names *Urlname* and *Username* respectively, and the tweets were split by hand into sentences. Tweets containing just a hyperlink were not included in the treebank. For the rest of this paper, we refer to the development set as *TwitterDev* and the test set as *TwitterTest*.

Unannotated Sentences From the full Twitter corpus, we constructed a sub-corpus of approximately 1 million tweets. As with the treebank tweets, hyperlinks were replaced by the term *Urlname* and usernames by *Username*. Tweets with more than one non-ASCII character were removed, and the remaining tweets were passed through our in-house sentence splitter and tokeniser, resulting in a corpus of 1,401,533 sentences. We refer to this as the *TwitterTrain* corpus.

2.2 Discussion Forum Comments

Hand-Corrected Parse Trees The discussion forum section of the Web 2.0 treebank is an extension of that described in Foster (2010). It contains 481 sentences taken from two threads on the BBC Sport 606 discussion forum in November 2009.[1] As with the tweets, the discussion forum posts were split into sentences by hand. The development set contains 258 sentences and the test set 223. For the remainder of the paper, we use the term *FootballDev* to refer to this development set and the term *FootballTest* to refer to the test set.

Unannotated Sentences The same discussion forum that was used to create *FootballDev* and *FootballTest* was scraped during the final quarter of 2010. The content was stripped of HTML markup and passed through an in-house sentence splitter and tokeniser, resulting in a corpus of 1,009,646 sentences. We call this the *FootballTrain* corpus.

Corpus Name	*#Sen*	*SL Mean*	*SL Med.*	σ
TwitterDev	269	11.1	10	6.4
TwitterTest	250	11.4	10	6.8
TwitterTrain	1,401,533	8.6	7	6.1
FootballDev	258	17.7	14	13.9
FootballTest	223	16.1	14	9.7
FootballTrain	1,009,646	15.4	12	13.3

Table 1: Basic Statistics on the Web 2.0 datasets: number of sentences, average sentence length, median sentence length and standard deviation

2.3 Annotation

The sentences in the Web 2.0 treebank (*TwitterDev/Test* and *FootballDev/Test*) were first parsed automatically using an implementation of the Collins Model 2 generative statistical parser (Bikel, 2004). They were then corrected by hand by one annotator, using as a reference the Penn Treebank (PTB) bracketing guidelines (Bies et al., 1995) and the PTB trees themselves. For structures which do not appear in the PTB, new annotation decisions needed to be made. An example is the annotation of hyperlinks in tweets. These were annotated as proper nouns in a single word noun phrase, and, if occurring at the end of a tweet, were attached in the same way as a nominal adverbial.

The annotator went through the dataset twice, and a second annotator then annotated 10% of the sentences (divided equally between discussion forum posts and tweets). Agreement between the two annotators on labelled bracketing is 94.2%. The sources of the disagreements involved 1) the PTB bracketing guidelines leaving open more than one annotation option (usually placement of adverbs), 2) (almost) agrammatical fragments (e.g. *USA, USA, USA* or *Wes Brown > Drogba*) and 3) multiword expressions (e.g. *in fairness*).

3 Baseline Evaluation

We first evaluate four widely used WSJ-trained statistical parsers on our new Web 2.0 datasets:

Berkeley (Petrov et al., 2006) We train a PCFG-LA using 6 iterations and we run the parser in *accurate* mode.

Brown (Charniak and Johnson, 2005) We employ this parser in its out-of-the-box settings.

Malt (Nivre et al., 2006) We use the *stacklazy* algorithm described in Nivre et al. (2009). We train a linear classifier where the feature interactions are modelled explicitly.

Parser	**F-Score**	**POS Acc.**
WSJ22		
Berkeley Own Tagging	90.0	96.5
Berkeley Predicted Tags	89.0	96.6
Berkeley Gold Tags	90.0	99.7
Brown	91.9	96.3
FootballDev		
Berkeley Own Tagging	79.0	92.2
Berkeley Predicted Tags	78.8	92.7
Berkeley Gold Tags	81.5	98.0
Brown	79.7	93.5
TwitterDev		
Berkeley Own Tagging	71.1	84.1
Berkeley Predicted Tags	70.1	84.1
Berkeley Gold Tags	76.5	97.2
Brown	73.8	85.5

Table 2: Evalb Results for Berkeley and Brown

MST (McDonald et al., 2005) We use the settings described in Nivre et al. (2010).

Our training data consists of §02-21 of the WSJ section of the PTB (Marcus et al., 1994). Although our main aim in this experiment is to establish how well WSJ-trained parsers perform on our new Web 2.0 dataset, we also report performance on §22 as a reference. We use Parseval labelled f-score to compare the two phrase structure parsers. We then compare all four parsers by training the dependency parsers on WSJ phrase structure trees converted to labelled dependency trees and by converting the output of the two phrase structure parsers to labelled dependency trees. For the dependency evaluation, we use the CoNLL evaluation metrics of labelled attachment score (LAS) and unlabelled attachment score (UAS).

The labelled dependency scheme that we use is the Stanford basic dependency scheme (de Marneffe et al., 2006). We experiment with the use of gold POS tags, POS tags obtained using a POS tagger (Giménez and Màrquez, 2004) and, for the phrase structure parsers, POS tags produced by the parsers themselves. The Brown parser always performs its own POS tagging. The Berkeley parser can be supplied with POS tags but it is not guaranteed to use them – trees containing the supplied POS tag for a given word may be removed from the chart during coarse-to-fine pruning.[2]

3.1 Results

Table 2 shows the Parseval f-score and part-of-speech (POS) tagging accuracy for the Berkeley

[2]In the interest of replicability, detailed information on experimental settings is available at `http://nclt.computing.dcu.ie/publications/foster_ijcnlp11.html`.

Parser	LAS	UAS	LAS	UAS	LAS	UAS
	WSJ22		*FootballDev*		*TwitterDev*	
Berk O	90.5	93.2	79.8	84.8	68.9	75.1
Berk P	89.9	92.5	80.1	84.9	68.2	74.2
Brown	91.5	94.2	82.0	86.3	71.4	77.3
Malt P	88.0	90.6	76.1	81.5	67.3	73.6
MST P	88.8	91.3	76.4	81.1	68.1	73.8
Berk G	91.6	93.4	83.1	86.4	76.8	80.8
Malt G	90.0	91.6	80.4	83.7	78.3	81.6
MST G	90.7	92.3	80.8	83.4	78.4	81.3

Table 3: Dependency Evaluation Results: O (Own Tagging), P (Predicted Input from POS Tagger), G (Gold Tags)

and Brown parsers on the three development sets.[3] We observe the following: Twitter data is harder to parse than the discussion forum data; parsing accuracy is slightly higher when the Berkeley parser does its own POS tagging than when a pipeline model is employed; POS errors are a bigger problem for the Web 2.0 datasets than for the in-domain test set, particularly for *TwitterDev*.

The LAS and UAS scores for all four parsers are presented in Table 3. The relative ranking of the four parsers is the same as that reported in Cer et al. (2010). One striking aspect of the results is the bigger performance discrepancy between the phrase structure and dependency parsers for the discussion forum data than for the Twitter data. There is also a bigger performance discrepancy between LAS and UAS for the Web 2.0 data than for the WSJ data — this could be related to the fact that the Stanford converter has been developed using Penn Treebank trees, and it is certainly related to POS tagging accuracy since the difference is less pronounced when the input to the parsers is gold POS tags. In gold tag mode, the dependency parsers achieve slightly higher performance than the Berkeley parser for the Twitter data. This might have something to do with the 97% POS tagging accuracy for Berkeley gold tagging mode (see Table 2) but this cannot be the whole story since we do not see the same trend for the discussion forum data even though POS tagging accuracy is not 100% here either.

3.2 Error Analysis

In order to better understand the results in Tables 2 and 3, we examine POS confusions for the three datasets and we provide a breakdown of parsing performance by dependency type.

[3]The Brown parser makes use of non-PTB tags to mark auxiliary verbs (AUX and AUXG). We take this difference into account when calculating POS tagging accuracy.

3.2.1 POS Tagging

Something we notice in Tables 2 and 3 is the difference in parsing accuracy between the scenario in which the parser is supplied with the correct POS tag for each word in the input string and the realistic scenarios in which it is supplied with POS tags produced by a POS tagger or in which it produces the POS tags as part of the parsing process. It is clear from this difference that a proportion of the parsing errors can be attributed to POS tagging errors, and it is also clear that this proportion is greater for the out-of-domain Web 2.0 text than it is for the in-domain WSJ text. The proportion of unknown words in the development sets already tells us something: 2.8% of the tokens in *WSJ22* do not occur in *WSJ2-21* compared to 6.8% for *FootballDev* and 16.6% for *TwitterDev*.[4]

We look in more detail at the POS tagging errors produced by the Berkeley parser in own tagging mode, the Brown parser and SVMTool (the POS tagger used in the Malt, MST and Berkeley pipelines). Instead of looking at the most common POS tagging errors, we attempt to locate the tagging errors that are associated with inaccurate phrase structure trees. For each POS confusion that occurs more than 5 times in the particular development set, we find the relative frequency of this confusion in sentences receiving a Parseval f-score under 70.0. We then order the POS confusions by these relative frequencies. The top-ranking confusions (gold/system) common to all three systems are as follows:

1. *WSJ22*: NNS/VBZ, VBZ/NNS
2. *FootballDev*: RB/JJ, RB/RP, VB/VBP
3. *TwitterDev*: JJ/NNP, NN/VB, NNP/VB, NNP/JJ, VBZ/NNS

The tendency for the noun/verb confusion that we see in *WSJ22* and *TwitterDev* to affect parser accuracy has been documented before (Dalrymple, 2006). The following is a *TwitterDev* example:

```
(FRAG
   (NP (JJ Username)
       (S (NP (JJ fantastic))
          (VP (VB win))))
   (. !) (. !))
```

The *RB/JJ* confusion in *FootballDev* can be explained by the tendency of some posters to drop the *-ly* suffix on adverbs (e.g. *played* ***bad***). The

[4]The tokens *Username* and *Urlname* are unknown and occur repeatedly. But even discounting these, the ratio is 14.0%.

prominence of *NNP* in *TwitterDev* is interesting and suggests, for one thing, that less emphasis should be placed on capitalisation in the tagging of unknown words:

```
(S
   (NP (NNP grrr))
   (: ...)
   (VP (VB spotify)
       (PP (IN in)
           (NP some kind of
           infinite update loop))))
```

3.2.2 Stanford Dependencies

We analyse the deprel+attachment f-scores of the best non-gold-tagged configuration of each parser. This means that for the Berkeley parser we use the version that performs its own tagging.

For most of the dependency types there is a general trend as exemplified in Figure 1: for each of the three datasets, the relation Brown > Berk > MSTParser > MaltParser holds. The *WSJ22* results are around 5-10% absolute better than the *FootballDev* results while the drop for *TwitterDev* is in the 15-20% range on average. Frequent dependencies like nominal subjects (`nsubj`), direct objects (`dobj`), adverbial clauses (`advcl`), `cop`ulars, open complements (`xcomp`), `prep`ositional modifiers follow this trend. The relations `det`, `root`, `aux`, `pobj`, `poss`, `possessive`, `neg` are easy to recover in all datasets, with no big drops observed for *FootballDev* or *TwitterDev*. For adjectival modifiers (`amod`), adverbial modifiers (`advmod`), and complements (`complm`), the decreasing pattern over the three datasets holds but the dependency parsers outperform the constituency parsers.

Coordination is one of the harder relations to recover. According to the Stanford scheme, the first conjunct is the head of the coordination. The conjunction is attached to the head via the `cc` relation and the other conjuncts are attached via the `conj` relation. For *WSJ22*, the phrase structure parser scores are around 85% for `cc` and slightly lower for `conj`, and the dependency parsers scores are around 80% for `cc` and 71% for `conj`. For the Web 2.0 data the scores decrease from *WSJ22* to *FootballDev* but increase again for *TwitterDev*. The drop in performance for *FootballDev* is in line with Foster's (2010) observation that the discussion forum data contain difficult coordination cases involving coordination of unlike constituents. It is possible that the length of the Twitter sentences acts as a natural inhibitor to such cases. We also note that Brown clearly outperforms the other parsers on *TwitterDev*.

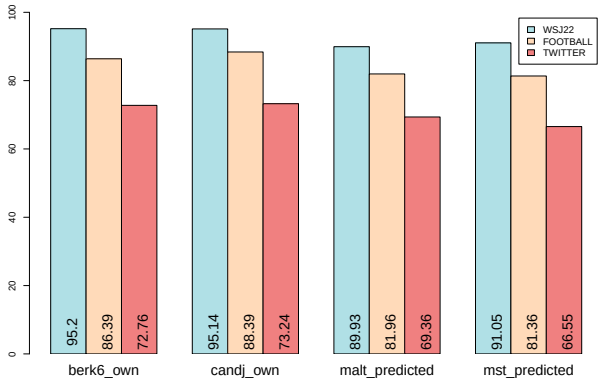

Figure 1: F-scores for `nsubj`

4 Making Use of Unlabelled Data

One approach to the parser domain adaptation problem is to train a new system using large quantities of automatically parsed target domain text. We experiment with two retraining methods: *self-training* in which the training data of the parser we are attempting to adapt is augmented by adding trees produced by the same parser for the sentences in our unannotated target domain corpus, and *uptraining*, in which the training set of a less accurate parser is augmented with trees for the unannotated corpus sentences produced by a more accurate parser.

4.1 Charniak and Johnson Self-Training

McClosky et al. (2006) demonstrate that a WSJ-trained parser can be adapted to the fiction domains of the Brown corpus by performing a type of self-training that involves the use of the Brown parser. Their training protocol is as follows: sentences from the LA Times are parsed using the first-stage parser and reranked in the second stage. These parse trees are added to the original WSJ training set and the *first-stage* parser is retrained. The sentences from the target domain, in this case, Brown corpus sentences are then parsed using the newly trained first-stage parser and reranked using the original reranker, resulting in a performance jump from 85.2% to 87.8%. One of the factors that make this training protocol effective are the non-generative features in the discriminative reranker (McClosky et al., 2008), and the use of the reranker means that this method is not a pure

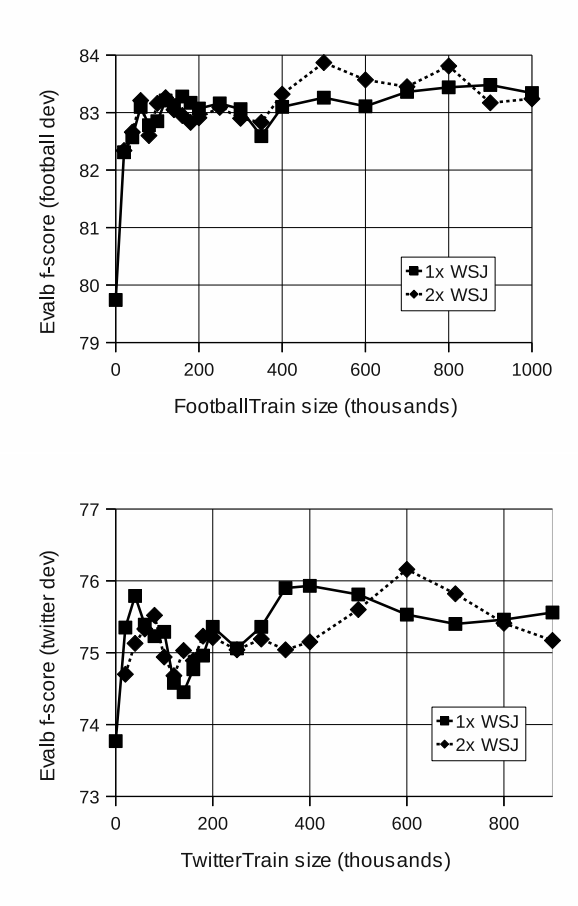

Figure 2: Brown self-training results

self-training one, but rather a type of uptraining.

We apply the procedure McClosky at el. to determine whether the performance of Brown can be improved on Web 2.0 data. The top graph in Figure 2 shows the results obtained for *FootballDev* when the first-stage parser is retrained on various combinations of *WSJ02-21* and parse trees produced by the reranking parser for sentences in *FootballTrain*. The bottom graph represents the f-scores for *TwitterDev* using *TwitterTrain* instead of *FootballTrain*. It is clear from the top graph that adding material from *FootballTrain* results in a significant improvement over the baseline f-scores of 79.7. The highest f-score is 83.8, obtained using two copies of *WSJ2-21* and 500,000 *FootballTrain* trees. The improvements achieved using *TwitterTrain* are less pronounced, with an absolute improvement of 2.4% obtained using 600,000 *TwitterTrain* trees and two copies of *WSJ02-21*.

4.2 Malt Uptraining

Petrov et al. (2010) perform a Stanford-dependency-based parser evaluation, with sentences from QuestionBank (Judge et al., 2006) as their test data. They find that deterministic dependency parsers such as MaltParser suffer more from the domain differences between QuestionBank and WSJ than phrase structure parsers such as the Berkeley parser. They then attempt to improve the accuracy of MaltParser on questions by training it on questions parsed by the Berkeley parser, arguing that the linear time complexity of a parser such as Malt is needed for real-time processing of web data. They demonstrate that the same improvement in accuracy can be obtained by using 100,000 automatically parsed questions as can be obtained using 2,000 manually parsed QuestionBank trees.

We perform two uptraining experiments. In the first, we retrain MaltParser using a combination of *WSJ02-21* and trees produced by Brown for sentences in the *FootballTrain* or *TwitterTrain* corpora (we call this *vanilla uptraining*). In the second and novel approach, we use a *self-trained* Brown grammar to parse the trees for uptraining (we call this *domain-adapted uptraining*).[5] For all configurations, the POS tagger, SVMTool, is retrained on the same data as MaltParser.

The results of the uptraining experiments show that significant improvements are obtained for both types of uptraining, but as expected, the domain-adapted uptraining is superior. The graph in Fig. 3 shows that the best *FootballDev* grammar is obtained using domain-adapted uptraining with 350,000 *FootballTrain* trees and one copy of *WSJ02-21* (an improvement of 5.7% over the baseline). The corresponding Twitter graph (not shown due to lack of space) shows that an improvement of 4.6% can be obtained on *TwitterDev* using domain-adapted uptraining with 200,000 *TwitterTrain* trees and one copy of *WSJ02-21*.

4.3 Latent Variable Self-Training

Experiments with pure self-training, i.e. training a parser on its own output, have had mixed results over the years. Charniak (1997), Steedman et al. (2003) and Plank (2009) provide evidence that it is not effective, whereas the experiments of Reichart and Rappoport (2007), Huang and Harper (2009) and Sagae (2010) suggest that it can be useful. Huang and Harper (2009) are the first to ap-

[5]The Brown grammar used for domain-adapted uptraining is trained on the first half of *FootballTrain* and *TwitterTrain*. We parse the second half of *FootballTrain* and *TwitterTrain* for both types of uptraining.

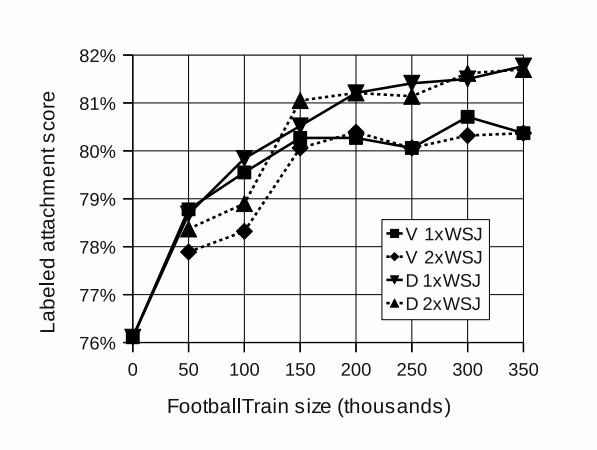

Figure 3: Malt uptraining LAS results for *FootballDev*: V stands for Vanilla Uptraining and D for Domain-Adapted Uptraining

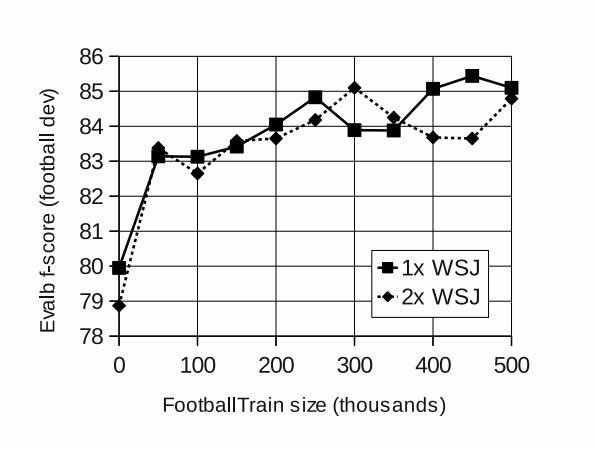

Figure 4: PCFG-LA self-training results

ply self-training using a PCFG-LA — with positive results. They argue that self-training works in this scenario because the additional training data prevents the split-merge process from overfitting.

We apply the self-training method of Huang and Harper to our new datasets. Like Huang and Harper, we use our own PCFG-LA parser because the trainer is multi-threaded, allowing us to handle the computation needed to train a PCFG-LA on large corpora. We train a 6-iteration PCFG-LA using *WSJ02-21* and use it to parse the *FootballTrain* and *TwitterTrain* corpora. We then add the automatically parsed material to our WSJ training set and retrain more 6-iteration PCFG-LAs. The result for *FootballDev* using *FootballTrain* is shown in Table 4. We achieve an absolute f-score improvement of 5.5% on *FootballDev*. The corresponding *TwitterTrain* graph is not shown for space reasons. The *TwitterTrain* improvements are more modest, with an f-score increase of approximately 2% on *TwitterDev*.

Grammar	***FootballTest***	***TwitterTest***	***WSJ23***
Charniak and Johnson self-training (F-Score)			
Baseline	81.2	73.3	91.4
Best FootballDev	83.6*	75.0*	91.1*
Best TwitterDev	81.0	74.7*	91.1*
Latent variable PCFG self-training (F-Score)			
Baseline	77.7	69.5	89.8
Best FootballDev	82.4*	70.6*	89.4*
Best TwitterDev	81.7*	70.7	89.6
Malt uptraining (LAS)			
Baseline	71.8	64.1	87.7
Best FootballDev	80.6*	69.7*	86.5*
Best TwitterDev	76.7*	68.2*	87.1*

Table 4: Test Set Results

4.4 Test Set Results

For each of our three retraining experiments, we take the best grammar for *FootballDev* and the best grammar for *TwitterDev* and apply them to the three test sets. In the PCFG-LA self-training experiments, a *FootballTrain* grammar actually outperforms all *TwitterTrain* grammars on *TwitterDev* and so we use this for final testing. The results are provided in Table 4. Statistically significant differences between the relevant baseline are marked with an asterisk.

5 Discussion

Parser retraining The variance in the size of improvements between the development and test sets (a greater improvement for Malt uptraining and a smaller improvement for Brown self-training) and the fact that, for Brown and Malt, the best grammar on *TwitterDev* is outperformed on *TwitterTest* by the best grammar on *FootballDev* is most likely due to the small size of the datasets. However, the results are promising, and clearly demonstrate that unlabelled user-generated content can be used to improve parser accuracy.

The reasons for the improvements yielded by the three types of retraining need to be determined.[6] The underperformance of the *TwitterTrain* material in comparison to the *FootballTrain* material suggests that sample selection involving language and topic identification needs to be applied before parser retraining. We also intend to test the combination of PCFG-LA self-training

[6]See Foster et al. (2011) for a preliminary analysis of the effect of Malt uptraining on sentences from *TwitterDev*.

and product grammar parsing described in Huang et al. (2010) on our Web 2.0 dataset.

Combination Parsing Several successful parsing methods have employed multiple parsing models, combined using techniques such as voting, stacking and product models (Henderson and Brill, 2000; Nivre and McDonald, 2008; Petrov, 2010). An ensemble approach to parsing seems particularly appropriate for the linguistic melting pot of Web 2.0, as does the related idea of selecting a model based on characteristics of the input. For example, a preliminary error analysis of the Malt uptraining results shows that coordination cases in *TwitterDev* are helped more by grammars trained on *FootballTrain* than on *TwitterTrain*, suggesting that sentences containing a conjunction should be directed to a *FootballTrain* grammar. McClosky et al. (2010) use linear regression to determine the correct mix of training material for a particular document. We intend to experiment with this idea in the context of Web 2.0 parsing.

Preprocessing Foster (2010) and Gadde et al. (2011) report improved parsing and tagging performance when the input data is normalised before processing, This work employs very little data cleaning and future work will involve exploring the interaction between preprocessing and parser retraining. Hyperlinks and usernames in tweets were replaced by the terms *Urlname* and *Username* respectively — to make life easier for parsers and POS taggers, proper nouns that are in the systems' lexicons should be used. The automatic sentence splitter and tokeniser that was used to create the Web 2.0 training sets makes use of abbreviation statistics in order to determine sentence boundaries. We compiled an abbreviation table using football discussion forum data but made no attempt to modify it for Twitter data. What is needed is a sentence-splitter tuned to the punctuation conventions of Twitter. However, more fundamental question remain: what is the correct unit of analysis for tweets and does it even make sense to talk about sentences in the context of Twitter? Our next step in this direction is to experiment with the Twitter-specific resources (tagset, tagger, tokeniser) described in Gimpel et al. (2011).

More Datasets We have focused on WSJ material as the source for our labelled training data. Future work will involve the use of other syntactically annotated resources including Brown and Switchboard, as well as Ontonotes 4.0, which has recently been released and which contains syntactically annotated web text (300k words).

More Parser Evaluation The cross-parser evaluation we have presented in the first half of the paper is by no means exhaustive. For example, to measure the positive effect of discriminative reranking, the first-stage Brown parser should also be included in the evaluation. Other statistical parsers could be evaluated, and it would be interesting to examine the performance of systems which employ hand-crafted grammars and treebank-trained disambiguators in order to determine whether a system less tuned to the PTB is more appropriate for this kind of heterogeneous data (Plank and van Noord, 2010). We have employed the Stanford dependencies in this work —- other labelled dependency schemes are available and it might be informative to examine the relative performance of the parsers from the perspective of many such schemes rather than just one. Gold standard dependency annotations for the new sentences would also be a bonus.

Abstract

Recent advances in automatic knowledge acquisition methods have enabled us to construct massive knowledge bases of semantic relations. Most previous work has focused on semantic relations explicitly expressed in single sentences. Our goal in this work is to obtain valid *non-single sentence* relation instances, which are not written in any single sentence and may not be even written in a large corpus. We develop a method to infer new semantic relation instances by applying auto-discovered inference rules, and show that our method inferred a considerable number of valid instances that were not written in single sentences even in 600 million Web pages.

1 Introduction

Recent advances in automatic relation acquisition methods (Agichtein and Luis, 2001; Etzioni et al., 2004; Pantel and Pennacchiotti, 2006; Paşca et al., 2006; Banko and Etzioni, 2008; De Saeger et al., 2009) have opened the way to build large knowledge bases containing a huge number of semantic relation instances such as "CAUSE(*allergen*, *allergy*)" and "PREVENTION(*coffee*, *drowsiness*)". Such a massive knowledge base is valuable for applications like innovation and risk management (Torisawa et al., 2010), like finding potential and unexpected causes of a disease, unknown side-effects of a drug, and so on. In such tasks overlooking a small piece of information can have grave consequences.

In this work, our goal is to acquire *Non-single Sentence relation instances* (**NS instances**), which are not written in any single sentences, in order to reduce the possibility of overlooking valuable information. More precisely, if the two nouns in an instance (e.g., "allergen" and "allergy" in "CAUSE(*allergen*, *allergy*)") do not appear in any single sentences in a given corpus together with the other clues indicating the relation type (e.g., the verb "cause"), the instance is an NS instance. *NS instances* may be *indirectly* written in a sequence of several sentences using anaphora or may not be written at all even in a given corpus. In the following, we call the complement of NS instances *Single Sentence relation instances* (**SS instances**), which consist of two nouns that co-occur in some single sentences in a given corpus together with some evidence for a relation type.

Most existing relation acquisition methods acquire relation instances using lexico-syntactic patterns (Pantel and Pennacchiotti, 2006; Paşca et al., 2006; De Saeger et al., 2009) such as "X causes Y" or probabilistic sequence labeling models (Banko and Etzioni, 2008). These methods basically rely on the structure of single sentences and they are for acquiring SS instances. Thus we consider that NS instances are practically beyond their reach. A few attempts to overcome this limitation include inference-based methods. These methods take SS instances provided by other methods as input and infer relation instances including NS ones using auto-discovered inference rules (Schoenmackers et al., 2010; Carlson et al., 2010) or distributional similarities (Tsuchida et al., 2010). We consider such inference approaches to be promising for acquiring NS instances.

This paper proposes an inference-based method for acquiring NS instances. We start from a set of *seed relation instances* of a target relation, which are acquired by an existing semi-supervised

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 902–910,
Chiang Mai, Thailand, November 8 – 13, 2011.

pattern-based method (De Saeger et al., 2009), and induce a large number of *recursive* inference rules to infer new relation instances. The instances inferred by the rules are ranked based on the scores assigned to the rules and the top instances are produced as final output.

Specifically, our method infers new instances of particular *target* relations by applying the following type of *recursive rules* to large corpora.

$$\text{“X } \textit{pattern} \text{ Y”} \wedge \mathrm{R}_{\mathrm{SEED}}(\mathrm{Y,Z}) \rightarrow \mathrm{R}_{\mathrm{HYPO}}(\mathrm{X,Z})$$

Here, “X *pattern* Y” indicates that X and Y co-occur in a certain lexico-syntactic pattern, $\mathrm{R}_{\mathrm{SEED}}$ (Y,Z) is one of the seed relation instances, and an inferred instance of the target relation is denoted by $\mathrm{R}_{\mathrm{HYPO}}$ (X,Z). Though we distinguish $\mathrm{R}_{\mathrm{SEED}}$ (Y,Z) and $\mathrm{R}_{\mathrm{HYPO}}$ (X,Z) by the subscripts “SEED” and “HYPO”, they are supposed to be the same target relation, and thus the rules are recursive. Note that this type of recursive rules could not be employed in an existing inference-based method (Schoenmackers et al., 2010) as described in Section 4.1.

For acquiring *NS instances*, rules combine patterns and relation instances (“X *pattern* Y” and $\mathrm{R}_{\mathrm{SEED}}$ (Y,Z)) scattered throughout many distinct documents. The following is an example rule learned by our method.

$$\text{”X } \textit{is rich in} \text{ Y”} \wedge \mathrm{PREVENTION}_{\mathrm{SEED}}(\mathrm{Y,Z}) \rightarrow \mathrm{PREVENTION}_{\mathrm{HYPO}}(\mathrm{X,Z})$$

This can be interpreted as: “If X *is rich in* Y and Y *prevents* Z, then X *prevents* Z.”, and seems valid in many cases. An interesting example is that the rule generated the relation instance “PREVENTION(*X=blue-backed fish*, *Z=cerebral thrombosis*)“ where “*Y=eicosapentaenoic acid*”. This is a rather well-known fact in Japan these days, and you can find many Web pages stating this fact in early 2011. However, the words “*blue-backed fish*” and “*cerebral thrombosis*” do not co-occur in any four sentence window in the 600M Web page corpus used in our experiments, which was crawled in 2008. Thus, “PREVENTION(*blue-backed fish*, *cerebral thrombosis*)“ is an NS instance and exemplifies the importance and necessity of inferring NS instances.

This example also introduces the idea underlying our evaluation scheme. Proper evaluation of new relation hypotheses that are not mentioned together in the extraction corpus would require verification by domain experts, which is clearly beyond our resources. We therefore evaluate new relation hypotheses using a larger and newer corpus (i.e. a commercial search engine), under the naive assumption that *correct* instances will be found in this bigger corpus. We realize this evaluation scheme cannot do justice to genuinely unknown instances but only gives a lowerbound of the true precision.

Through a series of experiments for acquiring three semantic relations, *causality*, *prevention*, and *material*, from a 600 million page Japanese Web corpus, we show that our method can infer *valid* NS instances. We also compare our method to the markov logic inference algorithm introduced in Schoenmackers et al. (2010) and show that our procedure, while considerably simpler, outperforms it.

2 Related Work

Previous work can be categorized into three groups: 1) methods for *extracting* SS instances (Etzioni et al., 2004; Pantel and Pennacchiotti, 2006; Paşca et al., 2006; Banko and Etzioni, 2008; De Saeger et al., 2009), 2) methods for *inferring* relation instances (Carlson et al., 2010; Schoenmackers et al., 2010; Tsuchida et al., 2010), and 3) work in bioinformatics aiming at helping users to discover unseen relation instances as novel knowledge (Swanson, 1986; Srinivasan, 2004; Hu et al., 2006; Hristovski et al., 2008).

The methods in the first category aim at extracting a large number of instances by employing automatically induced *paraphrases* of lexico-syntactic patterns or probabilistic sequence labeling methods. In this category, we focus on De Saeger et al. (2009), which is the seed instance extractor employed in this work. This takes *seed patterns*, such as “X causes Y”, as input and learns a large amount of *paraphrase patterns* to extract relation instances from a corpus. Unlike other pattern-based methods, De Saeger et al. (2009) learns *class dependent paraphrase patterns*, which place semantic word class restrictions on the noun pairs they may extract, like “*X:*`chemical` causes *Y:*`disease`”. These class restrictions enable to distinguish between multiple senses of frequent but highly ambiguous patterns. For instance, given a class *independent* pattern “X causes Y” as seed, if we restrict X and Y in “Y from X” to the classes of chemicals and diseases (as in “*cancer* from *cadmium*”), the class dependent pattern “*Y:*`disease` from *X:*`chemical`” becomes a valid paraphrase of “X causes Y”. Note that, other class restric-

tions of the same pattern (e.g., "*Y:*products from *X:*company", as in "iPhone from Apple") may not yield a valid paraphrase of "X causes Y". To obtain word classes they use a large-scale word clustering algorithm (Kazama and Torisawa, 2008), and rank each instance in the corpus according to a score based on the semantic similarity between the seed patterns and each class dependent pattern the instance co-occurs with.

Although much work in this category successfully extracts the instances *implicitly* written in a single sentence based on a wide range of non-trivial evidence including paraphrases (e.g., "Y by X" for causality), the applicability of these methods is restricted to SS instances.

In the second category, Schoenmackers et al. (2010), which is the most relevant to our work, takes relation instances provided by TextRunner (Banko and Etzioni, 2008) as input and induces Horn clauses as inference rules. The weights of the rules and the probabilities of the hypothesized instances are estimated by a markov logic network (Richardson and Domingo, 2006; Huynh and Mooney, 2008). They also proposed a weighted counting method for discounting the effects of uncertain (or infrequent) instances, and a method for discounting weights of longer rules by strong Gaussian prior.

The goal of Schoenmackers et al. (2010) was to acquire *implicit* relation instances. Note that their "implicit" instances cover what we call SS and NS instances, while our target are only NS instances. For instance, they regarded the instances acquired by simple paraphrase rules such as "CAN_CAUSE(X,Y) $\rightarrow$ CAUSE(X,Y)" as *implicit instances*. For "CAUSE(a,b)" to be inferred by this rule, "CAN_CAUSE(a,b)" must be written in single sentences so that TextRunner can recognize it. This means that such instances are SS instances.

Actually their algorithm was tuned to prefer SS instances and around 70% of the acquired valid instances were in this category. Certainly, their method uses more complex rules that can infer NS instances, but the precision of the instances inferred by such non-paraphrase rules is quite low (around 20%) [1]. Also they have not empirically examined how many NS instances are actually found in their output.

In contrast, we focus on more complex rules that can infer NS instances. An important point is that their method cannot deal with considerable parts of our complex rules because their inference algorithm for markov logic network (Huynh and Mooney, 2008) poses some restrictions on recursive rules as discussed in Section 4.1. We also empirically show that their scoring mechanism does not lead to higher precision at least in our setting, although we have not checked whether this is due to the restrictions on recursive rules or is due to some other reasons.

Another work in this category, Carlson et al. (2010) hypothesized instances using Horn clauses discovered by Inductive Logic Programming (Quinlan and Cameron-Jones, 1993). Tsuchida et al. (2010) generates hypothesized relation instances by substituting words in seed instances with distributionally similar words.

In bioinformatics, there are attempts to develop methods to help discoveries of relation instances by linking clues from different literatures (Swanson, 1986; Srinivasan, 2004; Hu et al., 2006; Hristovski et al., 2008). These methods cannot be easily adapted to other domains, because they require heavily engineered resources like databases of MEDLINE records and hand-annotation with MeSH [2] metadata. These also require some input and/or interactions to capture the interests of the human expert. Our aim is to infer unseen NS instances without such resources and human effort.

Recently, De Saeger et al. (2011) have shown that it is possible to acquire SS instances from highly complex and infrequent expressions, using word classes and lexico-syntactic pattern fragments, which they call *partial patterns*. Such approach may prove useful for acquiring NS instances too, as the method can acquire relation instances without considering any pattern connecting the two words of the instance. Yet their work focused only on SS instances.

3 Proposed Method

Our method takes a set of seed relation instances and a large corpus as input. The seed instances are obtained using De Saeger et al. (2009), after some rudimentary cleaning (Section 4). Then, our method induces possible inference rules, and assigns scores to the instances inferred by the rules. The high-ranked instances are provided as output.

[1] They acquired a total 2.6M instances with 50% precision for a variety of relation types. Also, about 1.25M SS instances in those were inferred by simple paraphrase rules with 80% precision. The precision of the instances inferred by non-paraphrase rules can be estimated as the solution for $0.50 = \frac{1.25 \times 0.80 + (2.6 - 1.25) \times x}{2.6}$ as x $(= 0.22)$.

[2] http://www.nlm.nih.gov/mesh/

In the following, we describe the details of each step. Note that the algorithm presented here can produce SS instances as well as NS instances. In the evaluation, *potential* SS instances are excluded from the output by checking the co-occurrence of the word pairs in the instances in single sentences.

3.1 Inducing Inference Rules

We consider inference rules (a special case of Horn-clauses) that have the following form:

$$\text{“X } \textit{pattern} \text{ Y”} \wedge \mathrm{R}_{\mathrm{SEED}}(\mathrm{Y,Z}) \rightarrow \mathrm{R}_{\mathrm{HYPO}}(\mathrm{X,Z})$$

This rule hypothesizes relation instances by substituting the first argument Y of a seed instance with X where the connection between X and Y is provided by “X *pattern* Y”. [3] To handle multi-word expressions such as “*red wine*”, we allow NP chunks to fill the slots of the X, Y or Z variables. Our motivation here is to have a more exhaustive set of relation instances for a given relation type. As a starting point we focus on the simple rules as the one above, although a wide range of other forms are possible. Sharing a variable (i.e. Y) guarantees that at least some relationship between X and Z holds and reduces the risk of generating meaningless rules, while the arbitrariness of the pattern allows us to consider a broad range of evidence to find new instances.

For inducing inference rules, first we find two seed instances that have the same second argument. Suppose that the target relation is causality, and we have two seed instances, $\mathrm{CAUSE}(\textit{bronchitis}, \textit{cough})$ and $\mathrm{CAUSE}(\textit{mold}, \textit{cough})$, with common second argument “*cough*”. Then, we can search for “X *pattern* Y”, which informs us of a certain relation between the first arguments of the two seed instances, *bronchitis* and *mold* in this example. We may be able to find “X causes Y” from the expression “.. *mold* causes *bronchitis* ..” and induce the following rule that infers one seed instance from another seed instance.

$$\text{”}\textit{mold}\text{ causes }\textit{bronchitis}\text{”} \wedge \mathrm{CAUSE}_{\mathrm{SEED}}(\textit{bronchitis},\textit{cough}) \rightarrow \mathrm{CAUSE}_{\mathrm{HYPO}}(\textit{mold}, \textit{cough})$$

By generalizing *mold*, *bronchitis*, and *cough* to variables X, Y and Z, we can obtain the following acceptable rule that can be interpreted as “if X is a cause of a cause (Y) of Z, X is a cause of Z”.

$$\text{“X causes Y”} \wedge \mathrm{CAUSE}_{\mathrm{SEED}}(\mathrm{Y,Z}) \rightarrow \mathrm{CAUSE}_{\mathrm{HYPO}}(\mathrm{X,Z})$$

[3] We also consider the rules where Z appears as the first arguments, i.e., “X *pattern* Y” $\wedge$ $\mathrm{R}_{\mathrm{SEED}}$(Z,Y) $\rightarrow$ $\mathrm{R}_{\mathrm{HYPO}}$(Z,X).

Here, by assuming that $\mathrm{CAUSE}_{\mathrm{HYPO}}$ (*bronchitis*, *cough*) is inferred from $\mathrm{CAUSE}_{\mathrm{SEED}}$ (*mold*, *cough*), we also obtain the following unacceptable rule, which contradicts with common sense.

$$\text{“Y causes X”} \wedge \mathrm{CAUSE}_{\mathrm{SEED}}(\mathrm{Y,Z}) \rightarrow \mathrm{CAUSE}_{\mathrm{HYPO}}(\mathrm{X,Z})$$

We can say that the former is a *swapped rule* of the latter and vice-versa. The above rule can be interpreted as “If Y is a cause of X and Z, then X is a cause of Z”, which is nonsense. In Section 3.2.1, we introduce a heuristic to remove such unacceptable swapped rules.

To alleviate pattern ambiguity, all the patterns in the rules are *class dependent patterns* (Section 2). The induced rules are augmented with class restrictions on the variables in the pattern:

$$\text{“X:}\texttt{virus}\text{ causes Y:}\texttt{sickness}\text{”} \wedge \mathrm{CAUSE}_{\mathrm{SEED}}(\mathrm{Y,Z}) \rightarrow \mathrm{CAUSE}_{\mathrm{HYPO}}(\mathrm{X,Z})$$

As word classes for the class restrictions, we used a word clustering result obtained by applying a probabilistic word clustering algorithm (Kazama and Torisawa, 2008) to dependency relations extracted from 100M Web pages. The results are represented by the probability distribution $P(c|w)$ where w is a word (the number of words is 1M in this paper) and c is a class identifier, which is a hidden variable in a predefined set C.

To have a *discrete* boundary of class membership, we assume w belongs to class c if and only if $P(c|n) \geq 0.2$ or $c = \arg\max_{c \in C} P(c|n)$. We set $|C|$ to 500, following De Saeger et al. (2009). Also, the classes are just class identifiers (i.e., integers). To simplify the explanation, we omit these class restrictions in the rest of our paper.

Finally, to discard unproductive rules, all the rules that cannot generate more than M seed relation instances using the other seed instances are discarded. In this work, we set M to 10.

3.2 Scoring Hypothesized Instances

After inducing the rules, we hypothesize relation instances by applying the rules to an input corpus, and assign scores to the instances. *Instance score* for a hypothesized instance is defined as the sum of the scores of the rules that generated the instance. Rule score $r\_score(r)$ is an approximated precision of the instances inferred by the rule, assuming that the seed instances are *correct* relations and the others are not.

$$r\_score(r) = \frac{\text{\# of seeds in hypotheses by } r}{\text{\# of hypotheses by } r}$$

Here, r is an inference rule.

Instance score h_score is defined as the sum of the applicable rule scores.

$$h\_score(h) = \sum_{r \in \mathbf{Irules}(h, \mathbf{Seeds}, \mathbf{Rules})} r\_score(r)$$

Here, h is a hypothesized instance, and **Rules** is a set of inference rules. **Seeds** is a set of seed relation instances, and **Irules** is a set of rules in **Rules** that infer h from **Seeds**.

We use the following additional heuristics during this ranking scheme.

3.2.1 Removing unacceptable swapped rules

The first heuristic is introduced for removing unacceptable swapped rules. Recall that our inference rule always has its swapped rule like the following two example rules.

A "X causes Y" $\wedge$ $\text{CAUSE}_{\text{SEED}}$ (Y, Z) $\rightarrow$ $\text{CAUSE}_{\text{HYPO}}$ (X, Z)

B "Y causes X" $\wedge$ $\text{CAUSE}_{\text{SEED}}$ (Y, Z) $\rightarrow$ $\text{CAUSE}_{\text{HYPO}}$ (X, Z)

Here, we have three observations: 1) if one rule is acceptable, its swapped rule is not (e.g., rule A is acceptable but rule B is not), 2) if a rule often generates reflexive relation instances, i.e., R_{HYPO} (x,x) for some word "x", the rule is likely to be unacceptable, and 3) the swapped rule of such an unacceptable rule (like rule B) often represents a transitive relation. For example, above rule A represents a transitive relation for causality (X $\rightarrow$ Y $\rightarrow$ Z then X $\rightarrow$ Z). On the other hand, the seed instance and the pattern in rule B represent that the same cause Y results in X and Z. If the seed instance and the pattern represents the same causal relation instance, $\text{CAUSE}_{\text{HYPO}}$ (X,Z) becomes $\text{CAUSE}_{\text{HYPO}}$ (x,x).

We found that rules generating many R_{HYPO} (x,x) attain a high score in our rule scoring. To remedy this we set $r\_score(r)$ to 0 if r generates more R_{HYPO} (x,x) than its swapped version. If the two rules do not generate R_{HYPO} (x,x) or the number of R_{HYPO} (x,x) by the two rules are the same, this is not applied. We refer to this as (X,X)-based rule filtering hereafter.

3.2.2 Excluding highly vague words

Our inference rules are based on *pivot* words, i.e., the shared variable Y in "X pattern Y $\wedge$ R_{SEED}(Y,Z) $\rightarrow$ R_{HYPO}(X,Z)". If the pivot is so vague that it likely refers to different objects in the seed and the pattern, the inference would be wrong (Schoenmackers et al., 2010). For example, we can generate false hypothesis $\text{CAUSE}_{\text{HYPO}}$ (*cerebral stroke*, *pneumonia*) from "*cerebral stroke* causes *disease*" and $\text{CAUSE}_{\text{SEED}}$ (*disease*, *pneumonia*). Here "*disease*" is highly vague, and likely refers to different types of diseases in different texts.

To address this problem we prepared a stop word list and discarded relation instances that contain one of these stop words. We calculate the document frequency of each word in the 600M page Web corpus, and regard a word whose document frequency is higher than threshold T as a stop word. We set T to 400,000 and obtain about 15,000 stop words in our experiments.

4 Evaluation

Our evaluation focuses on three main questions: 1) How accurate are the *NS instances* hypothesized by our method? 2) How accurate are all the instances hypothesized by our method? 3) Does our method infer relation instances with higher precision than competing methods? After explaining the experimental setting we answer each question from our experimental results. We also analyze the cause of errors at the end of this section.

4.1 Experimental Setting

We evaluated our results on the three relations:

***Causality*(X,Y):** X can directly or indirectly cause Y. e.g., CAUSE(*allergen*, *allergy*).

***Prevention*(X,Y):** X can directly or indirectly help to avoid the occurrence of Y. e.g., PREVENTION(*coffee*, *drowsiness*).

***Material*(X,Y)** X is a material or ingredient of Y. e.g., MATERIAL(*grape*, *wine*).

We employed the evaluation scheme introduced in Tsuchida et al. (2010). To evaluate the correctness of a given hypothesized instance, we presented three human judges with short texts as possible evidence. For each hypothesized instance, we collected up to 20 short texts from the search results provided by Yahoo! API [4] for a query consisting of the two nouns and a priming term for each target relation, i.e., the Japanese word for "*cause*", "*material*" or "*prevention*". All texts were collected from February to the middle of March in 2011.

The expectation behind this scheme is that many of correct *NS instances* in a smaller corpus,

[4] http://developer.yahoo.co.jp/webapi/search/

i.e., the 600M page Web corpus, can be found with explicit evidence in a larger corpus, i.e., pages accessible through a commercial search engine.

In our evaluation scheme, our three annotators mark a hypothesized instance as correct if they find "sufficient evidence" (see below) in at least one of the presented text snippets. We say a text snippet contains "sufficient evidence" if it either explicitly asserts the target relation between the word pair, or implicitly presupposes it. A hypothesized instance is judged incorrect when 1) the provided texts do not present sufficient evidence, or 2) a relation instance is not informative enough without further context (e.g., CAUSE(*insulin, change*), we don't know what *change* can be caused by *insulin* without further context). Correctness of a hypothesized instance is determined by the judges' majority vote. The inter-rater agreement (Fleiss' kappa) was 0.57 for causality, 0.56 for prevention and 0.57 for material, indicating the judgements are reasonably stable.

For each relation, the seed instances were the top 20,000 instances given by our implementation of De Saeger et al. (2009) with the class-based cleaning that took about 15 minutes. More precisely, we discarded inappropriate instances by manually identifying and removing semantic classes that are inappropriate for the target relation. The precision of the seed instances was 81% for *causality* , 78% for *material* and 44% for *prevention*. We used about 25 seed patterns for each relation, which were created by one of the authors with one hour tuning. We show some examples of the seed patterns (translated from Japanese).

***Causality*(X,Y)** "X causes Y", "Y caused by X", "X that causes Y", ...

***Prevention*(X,Y)** "X prevents Y", "Y prevented by X", "X that prevents Y", ...

***Material*(X,Y)** "X is material of Y", "Y made from X", "X that is material of Y", ...

From the seed instances, our method induced 24,044 rules for causality, 17,868 for prevention and 14,978 for material, and obtained 3.04M hypothesized instances for causality, 2.44M for prevention and 2.17M for material. These hypothesized instances do not include the seed instances. Table 1 shows some hypothesized instances.

In our experiments we compared three systems.

SUM: Proposed method.

MLN: Markov logic network based scoring method of Schoenmackers et al. (2010).

MLN(X,X): MLN with the weight of the rules removed by (X,X)-based rule filtering set to 0.

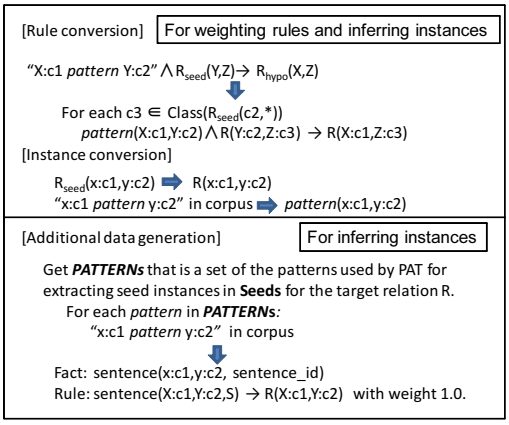

Figure 1: Data generation for MLN. X, Y and Z are variables, x, y and z are nouns. c1, c2 and c3 are noun classes, and Class(R_{SEED} $(c, *)$) is a set of classes, c_i, for which some R_{SEED} (y:c, z:c_i) exists. "x:c" indicates that x belongs to class c, and "X:c" means that X restricts possible nouns by class c.

We do not compare our method to Carlson et al. (2010), since Schoenmackers et al. (2010) already showed that MLN outperforms that method.

In preparing MLN, we converted our rules to the format used in Schoenmackers et al. (2010) as shown in Figure 1. Unlike our method, all rule variables in their work have class (or hypernym) restrictions, and predicates with different argument classes are treated as different. Truly recursive rules that have the same predicate with the same class restrictions in both head and body were removed due to limitations in their inference algorithm.[5] We removed 10,944 rules for causality (46% of all rules), 8,614 (48%) for prevention and 7,074 (47%) for material, respectively. When inferring instances, we also generated the additional rules and facts (lower half of Figure 1) that reflect their assumption that an instance frequently extracted from single sentences is likely to be true. Also, we empirically set the standard deviations of the Gaussian prior for learning rule weights and the prior weight of all unknown facts for inference to 2.0 and -3.0. We did not use the variable Gaussian prior to discount the weights of longer rules, because the lengths of all our rules are the same.

4.2 Evaluation Results

For SUM, MLN and MLN(X,X), we investigated the precision of the top 10,000 *NS instances* —

[5] The freely available inference system for markov logic Alchemy (`http://alchemy.cs.washington.edu/`) allows recursive rules, but turned out to be too slow for practical use. In our experiments we gave up on it after waiting more than a week for the program to finish.

Table 1: Examples of evaluated hypothesized instances and the rules that inferred the instances (translated from Japanese). The meaning of "N4S" is described in Section 4.2. All the instances marked with"NS", "N4S" and "SS" were judged as *correct*. "*UR" marks incorrect instances generated by *unacceptable rules*. "*AR" denotes incorrect instances generated by *acceptable rules*. "*NE" denotes instances having *no evidence* in the provided texts, though we expected that the instances may be correct based on their original rules and seed instances. For simplicity, we omit the class restrictions of rules.

	Label	Inferred instance	Samples of rules that generated the left hypothesized instance.
Causality	N4S	CAUSE$_{\text{HYPO}}$ (Z=*SO2 gas*, X=*allergy symptoms*), Y= *asthma*	CAUSE$_{\text{HYPO}}$ (Z,X) ← **X** *is caused by* **Y** ∧ CAUSE$_{\text{SEED}}$ (Z,Y) CAUSE$_{\text{HYPO}}$ (Z,X) ← **X** *gets worse by* **Y** ∧ CAUSE$_{\text{SEED}}$ (Z,Y)
	NS	CAUSE$_{\text{HYPO}}$ (X=*reactive oxygen species*, Z=*aneurysm*), Y=*high blood pressure*	CAUSE$_{\text{HYPO}}$ (X,Z) ← **X**'*s increase causes* **Y** ∧ CAUSE$_{\text{SEED}}$ (Y,Z) CAUSE$_{\text{HYPO}}$ (X,Z) ← **X** *is a cause of* **Y** ∧ CAUSE$_{\text{SEED}}$ (Y,Z)

	*AR	MATERIAL$_{\text{HYPO}}$ (X=*sugarcane*, Z= *zero-emisions vehicle*), Y=*ethanol*	MATERIAL$_{\text{HYPO}}$ (X,Z) ← **Y** *extracted from* **X** ∧ MATERIAL$_{\text{SEED}}$ (Y,Z) MATERIAL$_{\text{HYPO}}$ (X,Z) ← **Y** *made from* **X** ∧ MATERIAL$_{\text{SEED}}$ (Y,Z)

Table 2: Results from the binomial one-tailed test between SUM and the other methods. The significance level is 0.05. For each relation, cells show the number of data points (8 max) in the precision graph (like Figure 3) where "SUM wins / SUM loses / no significant difference".

	MLN(X,X)	MLN	MAX	No (X,X) filtering	No rule score
Causality	0 / 0 / 8	6 / 0 / 2	8 / 0 / 0	6 / 0 / 2	3 / 0 / 5
Prevention	8 / 0 / 0	7 / 0 / 1	6 / 0 / 2	0 / 0 / 8	0 / 0 / 8
Material	7 / 0 / 1	7 / 0 / 1	1 / 0 / 7	8 / 0 / 0	2 / 0 / 6

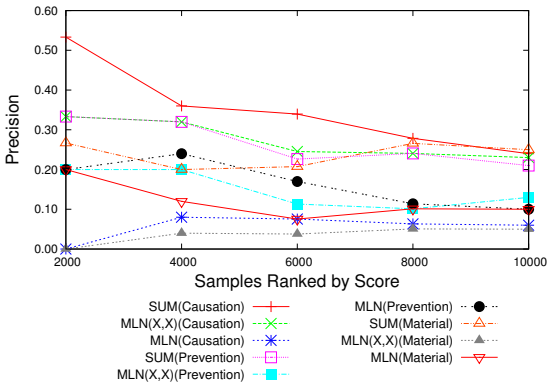

Figure 2: Precision of the top 10,000 NS instances.

word pairs that do not co-occur in any single sentence — using 100 random samples. The precision curves in Figure 2 show that SUM outperforms both MLN and MLN(X,X). Although the precision of the top 10,000 NS instances obtained by SUM is relatively low (20% to 30%), we do think this is a promising result given the difficulty of the task. In tasks such as innovation support and risk management, one must explore the border between the known and unknown. We expect even hypothesized instances with 20 to 30% precision can be useful in such contexts.

Next, we would like to address the question of how many acquired NS instances are not written in our corpus at all. Answering this question precisely is difficult because of anaphora and ellipsis. Therefore we assume that if the two nouns of an NS instance do not co-occur in any four sentence window ("N4S") in the corpus, the instance is unlikely to be mentioned explicitly in any form in the corpus. For causality, 44 of the 100 evaluated samples were N4S instances, 8 of which were correct

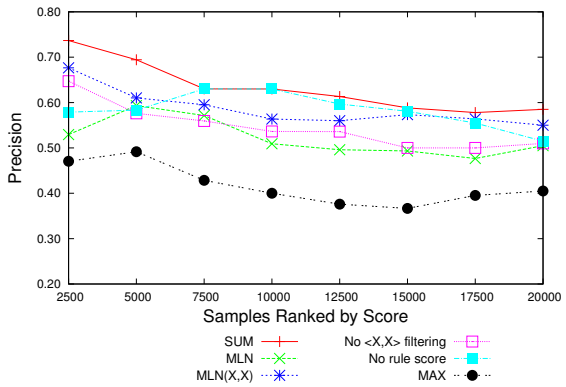

Figure 3: Causality: top 20,000 results' precision

(18% precision). The evaluated prevention and material samples respectively contained 22 and 35 N4S instances, with 2 and 8 correct ones (9% and 23% precision). We expect that at least some of these instances are not mentioned in our corpus.

To confirm the superiority of the proposed method, we investigated the precision of the top 20,000 instances of each method without removing SS instances from the evaluation data using 200 random samples. Our method showed 59% for causality (Fig. 3), 46% for prevention and 43% for material of the top 20,000 in precision, which is considerably higher than the precision of the NS samples only.

In addition to MLN and MLN(X,X) we also evaluated the following three baseline methods to confirm that all the design choices effectively contribute to the performance of our method.

No (X,X) filtering: SUM without (X,X)-based filtering.
No rule score: SUM, where all rule scores are constant.
MAX: A variant of the instance scoring function,

$$\max_{r \in \mathbf{Irules}(h,\mathbf{Seeds},\mathbf{Rules})} r\_score(r).$$

Figure 3 shows the precision curves for causality. In all relations SUM outperforms MLN, MLN(X,X) and all baseline methods. Table 2 shows the results of the binomial one-tailed test between SUM and each compared method, and suggests that SUM had statistically significant improvements in many cases. SUM showed only minor improvements compared with "No rule score". This suggests that the instances inferred by *many* rules tend to be correct, irrespective of the rule scores. We think this is due to the overall quality of the rules, as this would not be the case if many rules were invalid. Table 2 also shows that for transitive relations (causality and material), (X,X)-based rule filtering is effective.

4.3 Error Analysis

Table 1 shows some instances hypothesized by the proposed method. We distinguish between incorrect instances generated by unacceptable rules (marked "*UR" in Table 1) and others. We found that about 60% of incorrect instances are generated by unacceptable rules. For example, "$\text{CAUSE}_{\text{HYPO}}$ (X=*bilirubin*, Z=*colorectal cancer*)" was generated by the rule "$\text{CAUSE}_{\text{HYPO}}$ (X,Z) $\leftarrow$ X *is contained in* Y $\wedge$ $\text{CAUSE}_{\text{SEED}}$ (Y,Z)".

Incorrect instances generated by seemingly correct rules are marked with "*AR" in Table 1. These can further be categorized into three types (examples of each are in Table 1).

Type A: Uninformative instances for our evaluation criteria (See Section 4.1).
e.g., $\text{CAUSE}_{\text{HYPO}}$ (Z=*potato crisps*, X=*atherosclerosis*). The validity of this instance depends on context, i.e., the amount of potato crisps that one eats.

Type B: Instances generated with vague pivot words (See Section 3.2.2).
e.g., $\text{CAUSE}_{\text{HYPO}}$ (X=*tobacco*, Z=*food poisoning*), Y=*harmful component*. *harmful component* is vague.

Type C: Instances generated from incorrect seed instances.
e.g., $\text{MATERIAL}_{\text{HYPO}}$ (X=*sugarcane*, Z=*zero-emissions vehicle*), derived from the incorrect seed instance $\text{MATERIAL}_{\text{SEED}}$ (Y=*ethanol*, Z=*zero-emisions vehicle*).

The ratio was roughly 10% for type **A**, 5% for type **B** and 5% for type **C** for all the relation types. For the remaining incorrect instances (about 20%), the judges could not find sufficient evidence in the presented text snippets, although some such instances do appear to be valid. Such instances are marked "*NE". This suggests our evaluation scheme may be underestimating the true precision.

5 Conclusion

This paper introduced an inference-based method that takes a set of seed relation instances as input, and outputs hypothesized instances using inference rules induced from these seed instances.

We showed that our method can infer valid relation instances whose component nouns do not co-occur in any single sentence or any four sentence window even in a 600M page Web corpus. We expect this result is promising for inferring new knowledge, because such instances may contain instances not mentioned in the context of that particular semantic relation even in 600M Web pages.

Abstract

Although some multiword expressions (MWEs) like *How do you do?* have exclusively idiomatic meaning, other MWE-types like the phrase *kick the bucket* may be idiomatic or literal depending on context. The recently developed *OpenMWE* corpus provides the largest freely available collection of annotated MWE-tokens suitable for supervised classification, but so far its potential has only been superficially investigated and only for classification of MWE-types in the corpus. Instead, we train and evaluate classifiers for crosstype classification and introduce novel features specialised to this task. Our best crosstype classifiers performed as well on non-trained MWE-types as a majority class baseline which has knowledge of the MWE-type.

1 Introduction

A **multiword expression (MWE)** is an idiosyncratically interpreted linguistic unit which consists of more than a single word (or "crosses word boundaries") (Sag et al., 2002; Baldwin and Kim, 2009). The nature of these idiosyncrasies can vary greatly — from *traffic light* and *street light* which are remarkable only in that they are not interchangeable — to *how do you do?*, the meaning of which is non-compositional in modern English.

MWEs will typically resist lexico-syntactic variation to some extent (Fazly et al., 2009). For example, the phrase *a picture is worth a thousand words* does not allow the freedom of lexical substitution and modification that its constituent words would usually enjoy, making otherwise equivalent variations — *an image is worth fifty score words*, *a picture is worth approximately a thousand words* — sound wrong or at least unnatural to a native speaker.

The meaning of a MWE as a whole may not derive literally from the composition of its constituent words (Baldwin et al., 2003). For example, the English expression *kick the bucket* may be used to refer to *death* in any number of ways unrelated to either kicking or buckets. In these cases we say the MWE has an idiomatic interpretation.

When talking about MWEs we make a distinction between an MWE lexeme out of context, which we call an **MWE-type**, and specific instances of the MWE in context, which we call an **MWE-token**.

Some MWE-types have only an idiomatic meaning, such as the English greeting *How do you do?*, interpretation of which can be perplexing if attempted literally. However for others, the literal uses are still perfectly valid, and individual MWE-tokens may be ambiguous between an idiomatic and literal meaning. For example, *kick the bucket* may indeed refer to a violent act against a bucket and have nothing to do with death at all.

Relation to Word Sense Disambiguation

MWE-token disambiguation can be approached as if it were a word sense disambiguation (WSD) task where the MWE-types correspond to word types and MWE-tokens to word tokens (Hashimoto and Kawahara, 2009). In this conception, the analogue of word senses are the idiomatic and literal classes for an MWE-type.

In WSD, supervised methods are by far the most successful but large amounts of data are required for *each* word type to be disambiguated (Navigli, 2009). However, unlike in WSD, we can expect to

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 911–919,
Chiang Mai, Thailand, November 8 – 13, 2011.

find *some* linguistic commonality between the idiomatic senses of distinct MWE-types. This leads us to hope for more general **crosstype** classification algorithms, which might alleviate the knowledge acquisition bottleneck. In this paper we will refer to WSD (more specifically "word expert") style classification of ambiguous MWE-tokens as **type-specialised** classification.

The **first sense** or **majority class** baseline, in which a word is always labelled with its predominant sense, is known to perform very well at WSD due to a Zipfian distribution of senses (Preiss et al., 2009). We expect no different for the MWE-token disambiguation task where the two-class problem is virtually guaranteed a majority class baseline accuracy of over 50%. There has been work in unsupervised first sense learning for WSD using lexical resources (McCarthy et al., 2007), but the de facto baseline in WSD is a supervised first sense baseline (Navigli, 2009). We make use of a **type-specialised baseline**, which is a supervised majority class baseline modelled on the WSD first sense baseline. We also introduce a **corpus baseline** which, calculated based on idiomatic and literal counts of a collection of MWE-types, is the type-specialised baseline's crosstype analogue.

Our Contribution

In this paper we explore the supervised classification of ambiguous MWE-tokens using the *OpenMWE* corpus of Japanese idioms (Hashimoto and Kawahara, 2009). We introduce new features tailored to the crosstype classification task and refine features for type-specialised classification. To our knowledge, our experiments are the largest in supervised MWE-token classification to date. We explore more deeply the interaction between several aspects of the task, including differences between crosstype and type-specialised classification; combinations of major classes of features; and finally, the size of the training corpus.

We find that:

1. Our new WSD inspired features offer consistent improvements in performance, and our new idiom features usually offer marginal improvements. The extended WSD and idiom features used together for type-specialised classification yield state-of-the-art results in terms of raw performance.

2. Our new features for crosstype classification interact with the task and with other features in interesting ways, and in some cases give substantial improvements to performance.

3. Our best results in crosstype classification use *only* our extended WSD features. Despite using no tagged data for the target MWE-types, they achieved a performance in excess of the (supervised) type-specialised baseline.

This last result is significant because it demonstrates the readiness of our crosstype classifiers to work on previously unseen MWE-types. It is also interesting because it uses only semantic features and none of the lexico-syntactic fixedness features widely expected to be effective for MWE classification (Fazly et al., 2009; Hashimoto et al., 2006; Li and Sporleder, 2010).

2 Related Work

The *OpenMWE* corpus was compiled by Hashimoto and Kawahara (2009). To our knowledge it is by far the largest freely available gold-standard corpus of ambiguous MWE-tokens in any language, comprising 146 ambiguous MWE-types with 102,856 annotated MWE-tokens in total.

Apart from the enormous task of constructing the *OpenMWE* corpus, Hashimoto and Kawahara (2009) also used it to perform some experiments with supervised MWE-token classification. Noting the similarities between this task and WSD, they employed the most effective WSD features and machine learning algorithm surveyed by Lee and Ng (2002). They also included linguistic features explored by Hashimoto et al. (2006) designed to capture the relative fixedness of Japanese idioms, which we will refer to as idiom features. The machine learning algorithm used was *Support Vector Machines* and models were trained on the WSD features with various combinations of the idiom features. Type-specialised classifiers were trained for the 90 MWE-types which were deemed to have sufficient idiomatic and literal examples in the corpus. The model trained on WSD features was found to improve greatly on the type-specialised baseline, with some additional performance added by one of the idiom features.

Only being able to classify MWE-tokens of the 90 MWEs with sufficient training examples is a severe limitation on the usefulness of type-specialised classifiers in natural language processing applications. Our goal is to escape this limita-

tion by training classifiers which work on MWE-types on which they have not been trained. To that end, we have extended the features used by Hashimoto and Kawahara (2009) with complementary features and introduced a new class of features designed for crosstype classification.

Li and Sporleder (2010) conducted a thorough investigation of features used for supervised MWE-token classification. Context features similar to the WSD features of Hashimoto and Kawahara (2009) were used, as were a number of linguistically motivated features. Like us, Li and Sporleder (2010) performed crosstype classification. Unfortunately many of the features were too sparse to have a significant effect and only the context features produced significant results. This may have been due to the relatively small size of the corpus used, which comprised around 4000 MWE-tokens across 13 MWE-types. In our results the context features still dominate, but the effects of idiom based features can be seen and those features hold up well on their own as well.

Diab and Bhutada (2009) described a novel supervised MWE-token classification system based on a sequence labelling model. Unlike our method, their model identifies the position of the token in the text as part of the process. Like Li and Sporleder (2010), the size of the corpus is small (2500 MWE-tokens of 53 MWE-types), and classifiers were trained on collections of MWE-types. Anecdotally, the classifiers were able to pick some MWEs out of running text without even knowing their constituents beforehand, however their performance at this was not tested. A major finding of Diab and Bhutada (2009) was that reducing the feature space of context features by replacing word lemmas with their named-entity category had a significant positive effect on classification performance, a finding that is consolidated by Diab and Krishna (2009).

Fazly et al. (2009) observed that idiomatic uses of MWEs tend to occur in one of a small set of canonical forms, and developed an unsupervised method for learning these canonical forms, based on a set of linguistically-motivated features which built on the work of Cook et al. (2007). They applied the learned set of canonical forms to the task of MWE-token identification with remarkable success. Our method similarly uses linguistically-motivated features to perform MWE-token identification, but using a cross-type supervised model.

3 Feature Extraction

We extracted features in three main groups: WSD features, idiom (token) features and idiom type features. The first two categories include the features used by Hashimoto and Kawahara (2009) and our own extensions. The third category was introduced by us and is specialised to crosstype classification.

3.1 Preprocessing

Our feature extraction makes extensive use of the Japanese dependency parser *KNP* (Kurohashi and Nagao, 1994),[1] however features should be reproducible in other languages with a suitable dependency parser, morphological analyser, and electronic thesaurus or ontology. Each instance in the corpus was preprocessed by running it through *KNP* to extract specific linguistic information.[2] To help elucidate both the details of our feature extraction and how it might be replicated for another language, we will look at the information extracted for the sentence in Example (1):

(1) 桂子さんは、サッカーの腕を
keiko-saN-wa, sakkā-no ude-o
Keiko-TOPIC soccer-GEN arm-OBJ
上げた。
ageta.
raised.

“Keiko raised her soccer arm.” (literal)

“Keiko improved her skills at soccer.” (idiomatic)

Japanese is a non-segmenting language in that it has no clearly marked word boundaries. In Figure 1, Example (1) has been segmented by *KNP* into tokens[3] which are then grouped into chunks. Each chunk has a *parent* link to a higher chunk describing the dependency parse of the sentence. In the conventional word order for Japanese, dependency links are always forwards so the head of a phrase is also its rightmost (final) chunk. From Figure 1, we see that *keiko* “Keiko” and *ude* “arm” are the dependents of *ageta* “raised”, with *sakkā* “soccer” modifying *ude* “arm”. This gives rise

[1] http://nlp.ist.i.kyoto-u.ac.jp/EN/?KNP

[2] *KNP*’s memory usage is high and on some sentences exceeded the available memory in our machine (32GB). Those instances were excluded from our analysis.

[3] In fact, *KNP* delegates the initial segmentation and token feature annotation to the morphological analyser *Juman*.

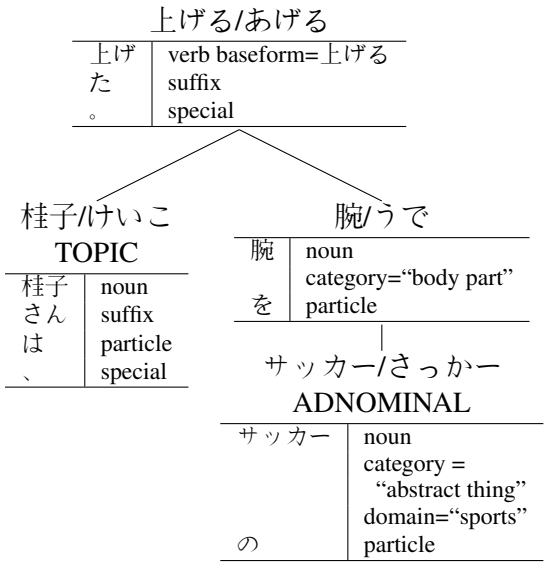

Figure 1: English summary of the select parts of the output of *KNP* when run on the sentence in Example (1)

to the incorrect literal interpretation *#Keiko raised her soccer arm*. In fact, *ude-o ageru* "to improve one's skills" is an ambiguous MWE.

In this paper when we refer to *words* we are in fact referring to the chunks returned by *KNP*. This is the most appropriate level of segmentation for our purposes because it is the level at which the dependency parse exists and because the tokenisation level includes affixes and particles which would need filtering. *KNP* labels each chunk with a normalised form, which we use as the *lemma* of the word for our feature extraction. We also extract the part of speech, category and domain of tokens corresponding most closely to the lemma, as additional features of the word.

The category and domain information performs a similar function to the named entity information used by Diab and Bhutada (2009): it collapses classes of words into a single feature while retaining relevant semantic information. An information source such as an ontology or thesaurus could be substituted for use in other languages. Hashimoto and Kawahara (2009) translate the *category* output of *KNP* as *hypernym*, and we will adopt the same terminology hereafter.

Returning to Figure 1, take note of the *TOPIC* flag on the first chunk and the ADNOMINAL flag on the second. *KNP* produces many chunk annotations; we made use of five main kinds:

ADNOMINAL appearing on adnominal modifiers;

TOPIC appearing on sentential topics and emphasised chunks;

VOICE of inflected verbs;

NEGATED denoting negation; and

VOLITIONAL denoting a volitional modality.

For all but the volitional modality group, *KNP* outputs only one or two annotation variants (e.g. there are two voices in Japanese: passive and causative). For the volitional modality, Hashimoto and Kawahara (2009) used five classes: request, invitation, order, volition and prohibition. We made use of the same subset of modalities output by *KNP*.

The *KNP* chunk annotations we used chiefly capture inflections on words in the text, something which Diab and Bhutada (2009) approximate with a character n-gram feature. For implementation in other languages, the n-gram heuristic or any available morphological analyser might be used.

3.2 Word sense disambiguation features

We adopted the WSD inspired features of Hashimoto and Kawahara (2009) and extended them with our own new features.

Hashimoto and Kawahara (2009) features

Hashimoto and Kawahara (2009) put together a set of features based on WSD best practice as espoused by Lee and Ng (2002). They included:

1. full context, in the form of bag features for lemma, hypernym and domain of single words in the full surrounding context.[4]

2. local context, in the form of part of speech and lemma features for indexed word offsets to each side of the MWE.

3. syntactic context, in the form of lemmas and POS for context words in a syntactic relationship with either the first or last constituent word of the MWE.

For more details on implementation of these features, see Hashimoto and Kawahara (2009).

[4]Note that due to the way the corpus was constructed, the full context is a single sentence, albeit a long one.

full context features

lemma keiko, majime, ...
hypernym abstract thing, body part, person.
domain sports, familial associations.

local context features

lemma majime$_{-3}$, reNshū$_{-2}$, sakkā$_{-1}$, ...
(majime, sakkā)$_{-3,-1}$, ...
POS adjective$_{-3}$, noun$_{-2}$, noun$_{-1}$, ...
(adjective, noun)$_{-3,-1}$, ...
hypernym abstract thing$_{-2}$, abstract thing$_{-1}$, ...
(NULL, abstract thing)$_{-3,-1}$, ...
domain sports$_{-1}$, ...
(NULL, sports)$_{-3,-1}$, ...

syntactic context features

lemma sakkā$_{\text{child}}$
POS noun$_{\text{child}}$
hypernym abstract thing$_{\text{child}}$
domain sports$_{\text{child}}$

Figure 2: A sample of the WSD inspired features extracted for Example (2).

New WSD features

We introduce hypernym and domain features for the local and syntactic contexts. Use of hypernym and domain features in the syntactic context is particularly interesting. The intent of the syntactic features is to capture selectional restrictions involving constituents of the MWE. Violation of selectional restrictions for or by constituents of the MWE leads us to strongly suspect an idiomatic usage. In the case of Example (2) we see that having *sakkā* "soccer" modifying *ude* "arm" is strongly indicative of the idiomatic *ude-o ageru* "to raise skills". For this MWE, any sport has the same implication. We can see from Figure 1 that *KNP* has extracted the domain *sports* for *sakkā* "soccer" so a classification algorithm can use this feature to make a valid generalisation. Our local context hypernym and domain features are less targeted, but we consider them to be worthwhile in light of the success of named-entity features in the literature (Diab and Bhutada, 2009).

Note that we use the same definitions of local and syntactic context as Lee and Ng (2002), with the specialisations to MWEs outlined by Hashimoto and Kawahara (2009).

Figure 2 contains a sample of all original and new WSD features, extracted for the MWE-token in Example (2), which expands Example (1):

(2) 桂子さんは　真面目に 練習して、
keiko-saN-wa majime-ni reNshū-shite,
Keiko-TOPIC diligent-ly practice,
サッカーの 腕を　　上げた。
sakkā-no ude-o ageta.
soccer-GEN arm-OBJ raised.
お母さんは　喜んだ。
okāsan-wa yorokoNda.
Mother-TOPIC pleased.
"Keiko practised diligently and improved her skills at soccer. Her mother was pleased."

3.3 Idiom token features

As with the WSD features, we adopted the idiom features of Hashimoto and Kawahara (2009) with additional features of our own.

Hashimoto and Kawahara (2009) features

The idiom features of Hashimoto and Kawahara (2009) included a single binary feature for each of the *KNP* chunk annotation groups listed at the end of Section 3.1. For each of the groups, the feature fires if one of the annotations appears on a relevant word in the MWE. Details of each are given in the outline of our extensions below.

The final idiom feature of Hashimoto and Kawahara (2009) was the adjacency feature. This feature fires if the constituents of the MWE are contiguous, i.e., there are no intervening chunks. They found that this feature had a greater impact on classification performance than the other idiom features combined.

New idiom features

Each of the boolean idiom features of Hashimoto and Kawahara (2009) captures some variation of the form of the MWE. We introduce features capturing details on the kind of variation:

- The ADNOMINAL modification feature fires if a non-constituent adnominal modifies a noun in the MWE. We include features for the lemma, POS, hypernym and domain of such a modifier whenever it exists.
- The TOPIC feature fires if a constituent noun is marked as a sentential topic. In this case we include features for the lemma, POS, hypernym and domain of the constituent.
- The VOICE, NEGATION and VOLITIONAL features fire if the MWE has a head

verb and it has voice marking or is negated. We include features specifying what for of voice, negation or volitional marking is used.

- Finally for the adjacency feature, we include lemma, POS, hypernym and domain features from a single intervening chunk where any existed. When more than one is found, we take the rightmost.

In the sentence of Example (2), features only fire for adnominal modification. Since *sakkā* "soccer" modifies the constituent *ude* "arm", the adnominal modification boolean feature fires, as do our lemma, POS, hypernym and domain features for the modifier: *sakkā*, *noun*, *abstract thing* and *sports* respectively. As was the case when *sakkā* "soccer" was considered in its role as a modifier of *ude* "arm", we note that it is in fact informative that the adnominal modifier is a sport and not, for example, a person.

3.4 Type features

The features we have discussed so far have, for the most part, ignored the constituent words of the MWE-type itself. For type-specialised classifiers this is inconsequential since the constituents are constant. However features of the MWE-type may be important for crosstype classification where similarities between different MWEs could be leveraged. Therefore, for each MWE-type, we use the lemma, POS, hypernym and domain of the headword in particular and a bag feature for each across all words in the MWE.

One motivation for these features is to allow a crosstype classifier to make more informed decisions when confronted with tokens of types it was trained on. For example, if a collection of constituents has been encountered in training, a supervised statistical classifier may capture the prior probability for idiomaticity of the training MWE-type. For crosstype classification, some constituents — in particular the headword — may be indicative of the relative idiomaticity of an idiom. For example, common verbs such as *take* and *make* are common in idioms such as *take a shot* and *make a stand*.

4 Results

We evaluated classifiers using combinations of the three main classes of features. For all tasks, a ten-fold cross-validation partitioning was used, and a feature count cutoff of one was used to filter out uninformative features. Given the binary classification nature of the task we used accuracy as our performance metric, microaveraging across all instances in the corpus.

Feature Types			Accuracy	
idiom	*type*	*wsd*	*basic*	*extended*
	∗		0.623	–
∗			0.630	0.627
∗	∗		0.626	0.651
		∗	0.737	0.745
	∗	∗	0.736	0.743
∗		∗	0.738	0.746
∗	∗	∗	0.739	0.745
corpus baseline			0.612	–
type-specialised baseline			0.741	–

Table 1: Results of combining different features for crosstype classification. "Basic" results restrict the idiom and WSD features to those of Hashimoto and Kawahara (2009); "extended" results include our extensions.

For statistical significance we used the sign test because our crosstype classification testing partitions were unevenly weighted, making a t-test inappropriate. Unless otherwise stated, comparisons were significant with $p < 0.05$.

We constructed two kinds of majority class baseline using class counts from the corpus: the corpus baseline, which achieved an accuracy of 0.612, and the type-specialised baseline, with an accuracy of 0.741. All other systems were linear kernel *Support Vector Machine* models trained using the *libSVM* package.[5]

4.1 Crosstype classification

For the purposes of testing crosstype classification we partitioned the set of 90 MWE-types for cross-validation. Thus classifiers were trained on the instances of 81 types and tested on the instances of the 9 unseen types. Note that since the corpus contains a different number of instances for each type, the partition size was not strictly constant. Results across all feature combinations appear in Table 1.

The idiom type and token features did manage to improve on the corpus baseline by a little over one percentage point each. However, this is over

[5]We initially used the *TinySVM* package and quadratic kernels of Hashimoto and Kawahara (2009) for comparability reasons, but eventually changed system and kernel for consistency and speed of convergence.

Feature Types			Accuracy	
idiom	*type*	*wsd*	*basic*	*extended*
	∗		0.741	–
∗	∗		0.748	0.752
∗			0.630	0.639
		∗	0.844	0.847
	∗	∗	0.851	0.854
∗		∗	0.847	0.849
∗	∗	∗	0.854	0.856
corpus baseline			0.612	–
type-specialised baseline			0.741	–

Table 2: Results for classification of MWE-tokens of MWE-types seen in the training corpus. As in Table 1, "Basic" results restrict the idiom and WSD features to those of Hashimoto and Kawahara (2009).

ten percentage points behind the results when using WSD features alone. In fact, the WSD features *with our extensions* achieved effectively our best results. The addition of idiom features with our extensions achieved fractionally better performance without statistical significance and all feature combinations which did not include our full complement of WSD features had lower performance. The WSD features' performance exceeds even the type-specialised baseline, which was built on gold-standard data which the crosstype classifier has no access to.

It is a surprising result, for two reasons: first, that idiom features are widely assumed to be a key information source, particularly for unsupervised disambiguation (Cook et al., 2007), and second, that WSD features — paragraph context in particular — are typically used as a model of the *meaning* of a token. It is counterintuitive that models of semantics are more informative than models of lexico-syntactic variations when the testing and training sets that are explicitly disjoint with respect to MWE-type.

The idiom token or type features alone did not stand up well in comparison. However, we note that combining our type features with the complete idiom token features provided a disproportionate boost to a classification accuracy of almost four percentage points above the baseline.

What happens when a nominally crosstype classifier encounters an instance of a MWE-type which it *has* seen in its training set? To test this, we partitioned the corpus stratified across types.

Feature Types		Accuracy	
idiom	*wsd*	*basic*	*extended*
∗		0.768	0.769
	∗	0.882	0.886
∗	∗	0.886	0.890
type-specialised baseline		0.741	–

Table 3: Results of combining different features for type-specialised classifiers. "Basic" results restrict the idiom and WSD features to those of Hashimoto and Kawahara (2009); "extended" results include our extensions.

That is, classifiers were trained on 90% of instances from *all* MWE-types in the corpus and tested on the remaining 10%. The results are shown in Table 2.

The idiom features once again improved a couple of percentage points on the baseline. In this instance, the type features produced much better results, achieving the same results as the type-specialised majority class baseline. It is not possible for any deterministic classifier to do better on the same input because the idiom type features are constant across all instances of a MWE-type.

Once again the WSD features did far better than any of the others at 23 percentage points over the corpus baseline and over ten points above even the type-specialised baseline. This is more to be expected than the equivalent result for crosstype classification since, by their origin, WSD features are designed to capture differences in semantics for known types.

The indisputable dominance of WSD features observed in these experiments warrants further investigation, which we leave for future work.

4.2 Type-specialised classification

If a known MWE-type can be explicitly detected, the general crosstype classifier need not be used: we can fall back on type-specialised classifiers like those of Hashimoto and Kawahara (2009). To see how much better we can do by selecting an appropriate type-specialised classifier, we trained and tested classifiers on the same partitioning as the previous task but restricted to instances of one MWE-type at a time. The results appear in Table 3.

In this case the idiom features improved a little even on the type-specialised baseline. This indicates that the idiom features do contain information about MWE-token idiomaticity even if it does

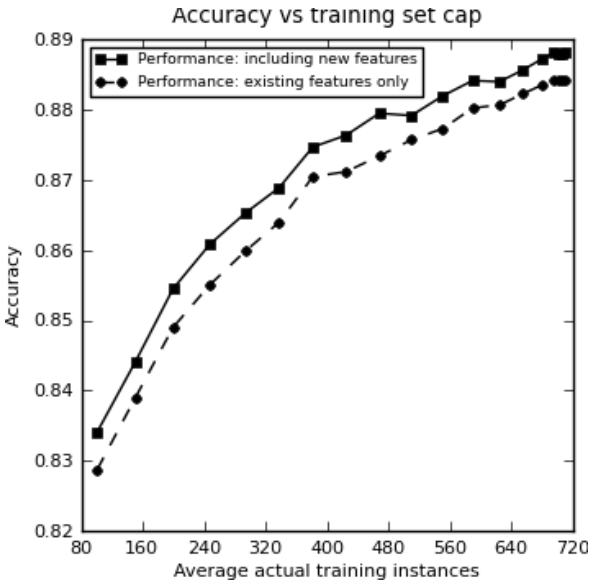

Figure 3: Results for type-specialised classifiers with capped training set sizes.

not generalise well across types.

The WSD features achieved close to the best results seen across all our experiments. An improvement of four percentage points is seen compared to the previous task, which is indicative of the noise introduced by simultaneously training on data of 90 idioms. Our best results were achieved using all of the idiom and WSD features together, hitting an even 0.890.

Finally, we used the type-specialised task to investigate the significance of the size of the *OpenMWE* corpus. To do this we measured cross-validation accuracy while limiting the total number of training instances. Training set size caps ranging between 100 and 1000 instances were used, but in practice most of the MWE-types had between 500 and 1000 available training instances, so the average actual training instances used was less than the cap. We performed these experiments using our complete WSD and idiom features and, for comparison, with the original features of Hashimoto and Kawahara (2009). The results appear in Figure 3.

Even with 100 instances per MWE-type, we achieved an accuracy of 0.834, which is an appreciable improvement on the type-specialised baseline. However the data show a definite positive trend with the number of instances, reaching 0.884 under a cap of 650 instances (and 589 average actual instances) per MWE-type.

Setting the maximum number of instances per MWE-type to 1000 achieved an accuracy of 0.888. Additionally, when restricted to the original features used by Hashimoto and Kawahara (2009) a performance of 0.884 is observed. Since Hashimoto and Kawahara (2009) also capped instance counts at 1000 this is our most comparable result to their best of 0.893. We note that with our new features, results were consistently around half a percentage point higher, so consider this to be state of the art performance.

5 Conclusions

We have shown that crosstype classification of ambiguous MWE-tokens can surpass the type-specialised baseline while alleviating the requirement on labelled token instances, thus enabling classification of tokens of previously unseen MWE-types.

Our type features and new idiom features, working in concert with the idiom features of Hashimoto and Kawahara (2009), substantially increase crosstype classification performance over the baseline. However their effect is wholly subsumed by the inclusion of WSD features. On type-specialised classification, our new idiom and WSD features achieve more consistent gains.

Finally, we conclude that the size of the *OpenMWE* corpus raises potential performance by leaps and bounds, but additional performance is still to be had by more data.

For future work we would like to investigate the dominance of WSD features at crosstype classification. The success of semantic features where the training and test sets have — by design — different semantics, making this an intriguing counter-intuitive result, as does the relatively poor performance of features targeted at linguistic properties of MWEs.

Abstract

Community-based Question Answering services contain many threads consisting of a question and its answers. When there are many answers for a question, it is hard for a user to understand them all. To address this problem, we focus on logical relations between answers in a thread and present a model for identifying the relations between the answers. We consider that there are constraints among the relations, such as a transitive law, and that it might be useful to take these constraints into account. To consider these constraints, we propose the model based on a Markov logic network. We also introduce super-relations to give additional information for logical relation identification into our model. Through the experiment, we show that global constraints and super-relations make it easier to identify the relations.

1 Introduction

Community-based Question Answering services, such as Yahoo! Answers[1], OKWave[2] and Baidu Zhidao[3], have become popular web services. In these services, a user posts a question and other users answer it. The questioner chooses one of the answers as the best answer. These services have many threads consisting of one question and a number of answers, and the number of threads grows day by day. The threads are stored and anyone can read them. When a user has a question, if there is a similar question in the service, he or she can refer to the answers to the similar question. Herefrom, these services are useful for not only the questioner but also other users having a similar question.

When more answers get posted for a question, the answers in the thread might become more diverse. Some of these answers will be similar or oppositional to each other. Also, when a question tends to have various answers, e.g. the questioner asks for opinions (e.g. "What are your song recommendations?"), it is insufficient to read only the best answer. Generally, as the only one best answer is chosen from the answers, a user may miss other beneficial answers. When a user checks these services with a mobile device, its small display is inefficient to browse all answers.

To alleviate these problems, it would be useful to get an overview of answers in a thread, such as by identifying the relations between the answers or by summarizing them (Jimbo et al., 2010; Liu et al., 2008). The purpose of this study is to identify logical relations between answers with a high degree of accuracy, as a basis of these methods.

We propose an identification model with global constraints on logical relations between answers. Among the relations, there are some constraints like a transitive law. To this end, it is necessary to identify relations in a thread at once, and identified relations need to satisfy as many of these constraints as possible. Our model is based on a Markov logic network and incorporates these constraints as formulas of first order logic.

Also, we group logical relations on the basis of semantic similarity and transitivity and call these grouped relations "coarse relations" and "transi-

tive relations", respectively. We consider that these relations might be useful for identification of logical relations and that identification of these relations is easier than that of logical relations. Thus, we incorporate identification of these super-relations into our model.

We briefly describe our related work in section two. Then, we show the logical relations between answers in section three and present our model with global constraints using a Markov logic network in section four. We explain the experiment and the results in section five and conclude our paper in section six.

2 Related Work

The growing popularity of Community-based Question Answering services has prompted many researchers to investigate their characteristics and to propose models for applications using them.

Question search and ranking answers are an important application because there are many threads in these services. Jeon et al. discussed a practical method for finding existing question and answer pairs in response to a newly submitted question (Jeon et al., 2005). Surdeanu et al. proposed an approach for ranking the answers retrieved by Yahoo! Answers (Surdeanu et al., 2008). Wang et al. proposed the ranking model for answers (Wang et al., 2009). Wang et al. proposed a model based on a deep belief network for the semantic relevance of question-answer pairs (Wang et al., 2010).

The user's qualifications affect the quality of his or her answer. For example, an IT expert may provide a good answer to a question about computers. Jurczyk and Agichtein proposed a model to estimate the authority of users as a means of identifying better answers (Jurczyk and Agichtein, 2007). Pal and Konstan proposed the expert identification model (Pal and Konstan, 2010) .

Each user has a background. If a user is an amateur in some field, he or she cannot understand a difficult question of the field. For a user-oriented question ranking, Chen and Kao proposed a model to classify a question as easy or difficult (Chen and Kao, 2010).

When there are many answers in a thread, multi-answer summarization is a good way to understand the answers. Liu et al. proposed taxonomies for a question and answers, and automatic summarization model for answers (Liu et al., 2008). Their best answer taxonomy is based on reusability for similar questions, factuality and so on, and their question type taxonomy is based on the expected answer. Achananuparp et al. proposed a model to extract a diverse set of answers (Achananuparp et al., 2010). Their approach is based on a graph whose edges have weight about similarity and redundancy.

Meanwhile, identification of discourse relations in meetings or dialogs was tackled by some researchers. Hillard et al. demonstrated that automatic identification of agreement and disagreement is feasible by using various textual, durational, and acoustic features (Hillard et al., 2003). Galley et al. described a statistical approach for modeling agreements and disagreements in conversational interaction, and classified utterances as agreement or disagreement by using the adjacency pairs and features that represent various pragmatic influences of previous agreements or disagreements to the target utterance (Galley et al., 2004).

Jimbo et al. proposed a model of relation identification for Community-based Question Answering services (Jimbo et al., 2010). Their model identified relations using Support Vector Machines with various features. We think considering constraints among relations might contribute to improve the performance of identifying relations. Therefore, we realize it with a Markov logic network.

Relation identification is considered as a problem to find labeled edges between pairs of nodes, where a node is an answer in a thread. Structured output learning is a method to predict such a structure (Tsochantaridis et al., 2004; Crammer et al., 2006). Morita et al. proposed a model based on structured output learning to identify agreement and disagreement relations in a discourse (Morita et al., 2009). Yang et al. used structured Support Vector Machines to extract contexts and answers for questions in threads of online forums (Yang et al., 2009).

3 Logical Relations between Answers

A thread consists of a question and some answers and the answers are sorted in order of posted time. Thus, in this paper, we try to identify to which preceding answer and in what relation an answer is related. However, some answers are irrelevant to a question and these answers might be unnecessary for an overview of a thread. Therefore, we con-

sider not only answer-answer relations, but also question-answer relations. We consider two relations for question-answer pairs, and seven relations for answer-answer pairs.

3.1 Relations for Question-Answer Pairs

The relations for question-answer pairs are "answer" and "unrelated". The "answer" relation is that the answer answers the question directly and is beneficial for the questioner. The "unrelated" relation is that the answer has no relation with the expected answer for the question.

The reason why we consider the "unrelated" relation is that some answers are replies to other answers or questions to the original questioner to ask for further details.

3.2 Relations for Answer-Answer Pairs

We define the logical relations for answer-answer pairs according to Radev's work that defines 24 types of relations between texts for multi-document summarization (Radev, 2000). Table 1 shows the relations we consider.

Table 1: Logical relations between answers

Relation	Description
equivalence	Two answers have same contents.
elaboration	The content of the latter includes that of the former.
subsumption	Two answers do not have same contents directly, but they are related to each other.
summary	The content of the latter is a summary of the former.
partial	Two answers have partially-duplicated contents, and they also have mutually different contents.
contradiction	Two answers are completely inconsistent with each other.
unrelated	The contents of two answers have no relation. For example, two answers are different answers for the question.

Figure 1 shows an example of a thread.

Answers (a1) and (a2) include the same content, i.e. they recommend XXX, while answer (a3) expresses a different opinion. Answer (a4) mentions about XXX as well as answers (a1) and (a2), but contains the opposite opinion.

Hence, the relation between (a1) and (a2) is "equivalence" and the relations between (a1) and (a3) and between (a2) and (a3) are "unrelated". The relations between (a1) and (a4) and between (a2) and (a4) are "contradiction" and the relation between (a3) and (a4) is "unrelated".

Question (q).
Can anyone recommend me a good internet provider?
Answer 1 (a1).
XXX is good, though I use only this provider.
Answer 2 (a2).
I prefer XXX. It is cheap and fast.
Answer 3 (a3).
I use YYY and it is no problem.
Answer 4 (a4).
The customer support of XXX is the worst.

Figure 1: Example of a QA thread

Here, since the relation between (a1) and (a2) is "equivalence" and the relation between (a1) and (a4) is "contradiction", we expect that the relation between (a2) and (a4) will be the same as the one between (a1) and (a4). This type of constraint is what we incorporate into the model.

4 Relation Identification Model with Global Constraints

We propose a joint identification model of logical relations between answers in a thread.

We consider that there are some constraints between logical relations. However, since not all relations satisfy a same constraint, we group logical relations into two types of super-relations on the basis of two kinds of commonality; transitivity and semantic similarity.

To incorporate constraints between relations, we try to identify relations for all pairs in a thread jointly. For these purposes, we take an approach with a Markov logic network.

4.1 Super-Relations for Answer-Answer Relations

We consider two kinds of super-relations for answer-answer relations; coarse relations and transitive relations. Coarse relations are based on semantic similarity and transitive relations are based on transitivity, that is, whether a transitive law is satisfied for relations.

Tables 2 and 3 show the correspondences between coarse relations and logical relations and between transitive relations and logical relations, respectively.

It might be easier to identify these two super-relations than logical relations, because these relations are coarser than logical relations. Furthermore, these information might be useful for identification of logical relations.

Table 2: Coarse relations

Relation	Logical relation
similar	equivalence, subsumption, elaboration, summary, partial
contradiction	contradiction
unrelated	unrelated

Table 3: Transitive relations

Relation	Logical relation
transitive	equivalence, subsumption, elaboration, summary
intransitive	contradiction, partial, unrelated

4.2 Markov Logic Network

A Markov logic network (MLN, in short) is a model combining first order logic and a Markov network (Richardson and Domingos, 2006). In this framework, we can take account of domain knowledge as formulas of first order logic. In first order logic, if there is at least one predicate that violates formulas in a possible world[4], the world is not valid. Therefore, a model with first order logic can only have strict constraints.

On the other hand, a MLN assigns a weight to each formula and can tolerate violation of the formula.

A MLN L is defined as a set of tuples $(\{F_i, w_i\})$, where F_i is a formula of first order logic and w_i is its weight. The distribution for a possible world x is as follows:

$$P(X = x) = \frac{1}{Z} \exp\left(\sum_i w_i n_i(x)\right)$$

where $n_i(x)$ is the number of F_i's ground formulas which are true on x, and Z is a normalization factor. A ground formula is a formula whose terms are constants.

The advantage of this model is that it can treat not only multiple relation identification tasks but also constraints between relations.

In this paper, according to the terminology of *markov thebeast*[5] (Riedel, 2008), which is one of the implementations of a MLN, we call the predicates that indicate aspects obtained from input data as **observed predicates**, the predicates that indicate aspects to be estimated as **hidden predicates**. The observed predicate corresponds to a feature in a general machine learning framework, and the hidden predicate corresponds to a label.

In addition, we call the formulas that express relations between observed predicates and a hidden predicate **local formulas** and formulas that express relations between hidden predicates **global formulas**.

4.3 Proposed Model

To identify the logical relation, our model consists of five subtasks: identification of question-answer relations, identification of whether two answers have a relation, identification of coarse relations, transitive relations, and logical relations. Table 4 shows the hidden predicates corresponding to these subtasks. For the question-answer relation, the relation between question i and answer j is "answer" if the predicate $hasqarelation(i, j)$ is true, and "unrelated" otherwise. For the answer-answer relation, the term l of the predicate $aarelation(i, j, l)$ corresponds to the logical relation to be identified originally.

Table 4: Hidden predicates

Predicate	Description
$hasqarelation(i, j)$	Answer j replies question i directly.
$hasaarelation(i, j)$	There is a relation between answer i and answer j.
$coarserelation(i, j, c)$	The coarse relation between i and j is c.
$transrelation(i, j, t)$	The transitive relation between i and j is t.
$aarelation(i, j, l)$	The logical relation between i and j is l.

In our model, when an answer is "unrelated" to the question, we exclude it from the identification of the answer-answer relation.

4.3.1 Local Formulas

In a MLN, there is only one hidden predicate in a local formula. We describe the relation between observed predicates and a hidden predicate on local formulas. For observed predicates, based on Jimbo et al.'s model (Jimbo et al., 2010), we consider thread features (e.g. order of answers and question type), n-gram features (e.g. word unigram and word bigram), semantic features, named-entity features, and similarity features. Table 5 lists some of the observed predicates. Since our model uses these features both for question-answer relations and answer-answer

[4] A possible world is a set of ground atoms. A ground atom is a predicate whose term is constant.

[5] http://code.google.com/p/thebeast/

relations, we use a term "article" for a question and an answer in this section.

Table 5: Some of the observed predicates

Predicate	Description
$question(i)$	Article i is a question.
$questiontype(q)$	The question type of the thread is q.
$first(i)$	Article i is the first answer in the thread.
$neighbor(i, j)$	Article j adjoins article i.
$longer(i, j)$	Article i is longer than article j.
$timegap(i, j, t)$	A time interval between article i and j is t.
$antonym(i, j)$	Article i and j contain antonyms.
$sameurl(i, j)$	Article i and j include a same URL.
$unigram(i, u)$	Article i contains word unigram u.
$bigram(i, b)$	Article i contains word bigram b.
$questionfocus(i)$	Article i contains the question-focus.
$samefocus(i, j)$	Article i and j contain the same question-focus.
$focusedneclass(i)$	Article i contains a word of the focused NE class.
$namedentity(i)$	Article i contains a named entity.
$samene(i, j)$	Article i and j contain the same named entities.
$samequoted(i, j)$	Article i and j contain the same quoted expression.
$scosine(i, j, c)$	Cosine similarity between article i and j in terms of sentences is c

For identification of relations between articles, the information obtained from the question, such as a class of an expected answer for a question, might be useful.

A question usually consists of multiple sentences such as in Figure 2. In this example, the es-

Question.
I'm planning a journey to Hokkaido.
Can you suggest some good sightseeing places?

Figure 2: Example of a question

sential question is the latter sentence. Therefore, we extract the core sentence and the question-focus and estimate the question type, on the basis of Tamura et al.'s model (Tamura et al., 2005).

The core sentence is the most important sentence, that is, the one requiring an answer in the question. Usually, the core sentence is an interrogative one such as "Where is the most famous place in Hokkaido?". But questioners sometimes ask questions without an interrogative form, such as "Please tell me some good sightseeing places in Hokkaido.". To cope with this diversity, a machine learning approach is taken to extract the core sentence.

The question-focus is then extracted from the core sentence. The question-focus is the word that determines the answer class of the question. For example, the question-focus in Figure 2 is "places".

We extract the question-focus according to the following steps[6]:

step 1. Find the phrase including the last verb of the sentence or the phrase with "?" at the end.

step 2. Find the phrase that modifies the phrase found in step 1.

step 3. Output the nouns and the unknown words in the phrase found in step 2.

Question types are categorized in terms of the expected answer into the thirteen types in table 6.

Table 6: Question types

Nominal answer	Non-nominal answer
Person	Reason
Product	Way
Facility	Definition
Location	Description
Time	Opinion
Number	Other (text)
Other (noun)	

We use a model based on Support Vector Machines (SVM, in short) to identify the question type for the question. In this model, the feature vector is obtained from the core sentence.

The question types whose answers are nouns require a specific class of named entity for the answer, e.g. the class of named entity, PERSON for the question type, Person. We call this class **focused NE class**. Table 7 shows the correspondence between a question type and a named entity class.

Table 7: Question type and focused NE class

Question type	Focused NE class
Person	PERSON
Product	ARTIFACT
Facility	LOCATION, ORGANIZATION
Location	LOCATION
Time	DATE, TIME
Number	MONEY, PERCENT

For n-gram features, we also consider unigram and bigram for the first five words and the last five

[6]This procedure is specific to Japanese.

words in each article. For similarity features, we also consider cosine similarities in terms of word unigram, word bigram, phrase unigram, noun unigram, and noun category unigram.

The score c for sentence-based cosine similarity is calculated as follows:

$$c = \max_{s_{i_m} \in S_i, s_{j_n} \in S_j} \mathrm{sim}_{\cos}(s_{i_m}, s_{j_n})$$

where s_{i_m} is a m-th sentence of article i and S_i is a set of sentences in article i. $\mathrm{sim}_{\cos}(x, y)$ means a cosine similarity between sentence x and y. For the predicate about similarity like $scosine(i, j, c)$, we do not use the score itself for c but rather a value from 0 to 1 divided up into tenths.

For t in the predicate $timegap(i, j, t)$, we choose the one from {"less than an hour", "an hour $\sim$ 3 hour", "3 hour $\sim$ 6 hour", "6 hour $\sim$ 12 hour", "12 hour $\sim$ 24 hour", "24 hour $\sim$ 48 hour", "48 hour $\sim$ 72 hour", "more than 72 hour"} for the actual time gap between article i and j.

We consider the same pattern of local formulas for each hidden predicate. Some examples of local formulas are:

$$question(i) \wedge first(j) \Rightarrow hasqarelation(i, j) \quad (1)$$
$$bigram(i, +w_1) \wedge bigram(j, +w_2) \Rightarrow hasaarelation(i, j) \quad (2)$$
$$samequoted(i, j) \Rightarrow coarserelation(i, j, +c) \quad (3)$$
$$scosine(i, j, +v) \Rightarrow transrelation(i, j, +t) \quad (4)$$
$$lastunigram(i, +u_1) \Rightarrow aarelation(i, j, +l) \quad (5)$$

where "+" indicates that the weight of the formula depends on each constant to be grounded. For example, formula (1) has one weight in spite of values for i and j, but formula (3) has a separate weight for each value of c.

4.3.2 Global Formulas

Global formulas have more than one hidden predicates, and we can use these formulas to incorporate constraints between hidden predicates into the model. Figure 3 shows some global formulas that we consider.

There are two kinds of formulas in a MLN: hard constraints and soft constraints. Hard constraints are formulas that must be satisfied in a possible world. This kind of constraint is realized by assigning a huge value for its weight. For a possible world where a formula of hard constraints is false, its probability is almost zero. In our model, formulas from (6) to (12) are hard constraints.

We describe preconditions for each hidden predicate (formulas (6)-(10)) and correspondences between super-relations and logical relations (formulas (11) and (12)) as hard constraints. For example, formula (10) represents that if there is any transitive relation between answer i and j, there needs to be any logical relation between the answers.

Soft constraints are formulas that are allowed to be false in a possible world. It is obvious that a possible world where soft constraints are satisfied is more probable than a world where soft constraints are not satisfied. Thus, the model identifies relations to satisfy as many of these constraints as possible. In our model, formulas from (13) to (16) are soft constraints. We describe soft constraints for relations among three answers i, j, and k.

Formula (13) represents a semantic relevancy and formula (14) represents a transitive law. As shown in the example in Figure 1, when a relation between two answers is "equivalence", it is reasonable to assume that logical relations from these answers to other answers are identical with each other. Formula (15) represents this situation, and formula (16) represents the opposite direction of formula (15), that is, relations from other answers to these answers.

5 Experiment

To evaluate our model, we conducted an experiment with annotated question-answers threads in Japanese.

5.1 Experimental Settings

We used 299 threads of three genres from Yahoo! Chiebukuro[7], which is a Japanese Community-based Question Answering service. Table 8 shows the statistics of the data we used.

Table 8: Statistics of the data

Genre	the number of threads	the number of answers	Average number of answers in a thread
Cook	99	776	7.83
PC	100	618	6.13
Love	100	813	8.13

For each question-answer pair and answer-answer pair, five annotators annotated a relation. In annotating relations, answers whose question-answer relation had been annotated with "unre-

[7] http://chiebukuro.yahoo.co.jp/

$$\neg hasqarelation(i,j) \Rightarrow \neg hasaarelation(j,k) \quad (6)$$

$$\neg hasqarelation(i,k) \Rightarrow \neg hasaarelation(j,k) \quad (7)$$

$$hasaarelation(i,j) \Rightarrow \exists t(transrelation(i,j,t)) \quad (8)$$

$$hasaarelation(i,j) \Rightarrow \exists c(coarserelation(i,j,c)) \quad (9)$$

$$transrelation(i,j,t) \Rightarrow \exists l(aarelation(i,j,l)) \quad (10)$$

$$coarserelation(i,j,\text{“similar”}) \Rightarrow \neg(aarelation(i,j,\text{“contradiction”}) \vee aarelation(i,j,\text{“unrelated”})) \quad (11)$$

$$transrelation(i,j,\text{“transitive”}) \Rightarrow \neg(aarelation(i,j,\text{“partial”}) \vee aarelation(i,j,\text{“contradiction”}) \vee aarelation(i,j,\text{“unrelated”})) \quad (12)$$

$$coarserelation(i,j,\text{“similar”}) \wedge coarserelation(j,k,\text{“similar”}) \Rightarrow coarserelation(i,k,\text{“similar”}) \quad (13)$$

$$transrelation(i,j,\text{“transitive”}) \wedge transrelation(j,k,\text{“transitive”}) \Rightarrow transrelation(i,k,\text{“transitive”}) \quad (14)$$

$$aarelation(i,j,\text{“equivalence”}) \Rightarrow aarelation(i,k,+l) \wedge aarelation(j,k,+l) \quad (15)$$

$$aarelation(j,k,\text{“equivalence”}) \Rightarrow aarelation(i,j,+l) \wedge aarelation(i,k,+l) \quad (16)$$

Figure 3: Some of the global formulas

lated” were excluded from the annotation of the answer-answer relation. We considered only relation labels that more than two annotators agreed on the experiment. The number of pairs that we used and the distributions of relations are shown in Tables 9 and 10, respectively.

Table 9: Number of pairs

	Cook	PC	Love
question-answer	775	616	811
answer-answer	2194	1012	1626

Table 10: Distribution of relations

	Relation	Cook	PC	Love
question-answer	answer	0.925	0.924	0.905
	unrelated	0.075	0.076	0.095
answer-answer	equivalence	0.115	0.186	0.192
	elaboration	0.026	0.083	0.033
	subsumption	0.000	0.009	0.008
	summary	0.012	0.033	0.025
	partial	0.073	0.078	0.113
	contradiction	0.055	0.084	0.187
	unrelated	0.716	0.528	0.442

To acquire the semantic category for nouns, we utilized a Japanese thesaurus, Nihongo-Goi-Taikei (Ikehara et al., 1997). For antonyms, we used the Japanese dictionary, Kadokawa-Ruigo-Shin-Jiten (Ohno and Hamanishi, 1981).

For dependency parsing, we used Japanese dependency parser CaboCha[8]. For named entities, we utilized CaboCha's output.

We used SVM^{light}[9] for the implementation of SVM and *markov thebeast* for a MLN.

5.2 Results

For each genre, we performed 10-fold cross validation and evaluated the F-value.

The baseline model was one using SVM based on (Jimbo et al., 2010). In this model, we used the observed predicates for our model as features and trained a binary classifier for the question-answer relation and a one-versus-rest classifier for the answer-answer relation. The algorithm for the baseline model is as follows:

step 1. Identify the question-answer relation between the question and each answer.

step 2. For answers to be identified as an “answer”, identify the answer-answer relation.

Our work is different from Jimbo et al.'s work with respect to the number of relations. We considers seven relations for answer-answer pairs, while they consider four relations. Also, we used a different data from their experiment. Therefore, we could not conduct an accurate comparison experiment between our model and their model.

Table 11 shows the results. Bold face indicates that F-value of our model was higher than the baseline model and symbols $^{**}(p < 0.01)$ and $^{*}(p < 0.05)$ indicate the F-value was significantly different from the baseline with a sign test. Compared with the baseline model, our model was better for most relations.

While the baseline model considered only the target pair in identification, our model considers the relations of all pairs at the same time and identifies relations to satisfy as many constraints as possible. These constraints on relations contribute to improve the performance for the identification of relations.

Also, to evaluate the effectiveness of introducing the super-relations, we evaluated the model without coarse relations and transitive relations (w/o-super).

Table 12 shows the results for the data for PC. Bold face indicates the best value for each relation. For most relations, the w/o-super model was better than the baseline model. Although the w/o-super model does not leverage global formulas about super-relations (e.g. formula (13)), it leverages global formulas about logical relations (e.g. formula (16)) as well as the MLN model. We consider that the reason why the w/o-super model outperformed the SVM model is that these constraints worked well.

Table 12: Results for the model w/o super (F-value)

Relation	SVM	w/o-super	MLN
QArelation	**0.959**	0.952**	0.958
AArelation	0.470	0.546**	**0.653****
Coarse (similar)	0.315	–	**0.326****

Trans (intransitive)	0.498	–	**0.506****
Logical (equivalence)	0.164	**0.264****	0.245**
Logical (elaboration)	0.000	0.000	**0.022**
Logical (subsmption)	0.000	0.000	0.000
Logical (summary)	0.000	0.000	**0.014**
Logical (partial)	0.000	0.044	**0.098****
Logical (contradiction)	0.000	0.018	**0.033**
Logical (unrelated)	**0.406**	0.251**	0.380**

Furthermore, the MLN model is better than the w/o-super model. Because super-relations focus on transitivity and semantic similarity, identifying these relations is easier than the logical relations and the information about these relations is useful for identifying the logical relations.

In our model, there are some constraints between the predicate $aarelation$ and the other predicates. When the performances for the identifications of auxiliary relations (i.e. $hasaarelation$, $coarserelation$, $transrelation$) are worse, the performance of the identification of logical relations would be worse too. Therefore, in order to improve the performance of logical relation identification, it is necessary to improve the performance of identifying these auxiliary relations.

6 Conclusion

We proposed a logical relation identification model with a Markov logic network. There are constraints between relations and we incorporated them into the model. These constraints may be violated and a MLN permits violation of them.

Through the experiment, we showed that our model is better than a baseline model using SVM and that incorporating super-relations improves the performance. However, since the accuracy was not so high, we need to improve our model.

The relation between answers is the effective information for understanding the overview of a thread. Our future work is to propose answers summarization model and thread visualization model, based on these logical relations.

Abstract

This paper proposes a method that automatically generates questions from queries for community-based question answering (cQA) services. Our query-to-question generation model is built upon templates induced from search engine query logs. In detail, we first extract pairs of queries and user-clicked questions from query logs, with which we induce question generation templates. Then, when a new query is submitted, we select proper templates for the query and generate questions through template instantiation. We evaluated the method with a set of short queries randomly selected from query logs, and the generated questions were judged by human annotators. Experimental results show that, the precision of 1-best and 5-best generated questions is 67% and 61%, respectively, which outperforms a baseline method that directly retrieves questions for queries in a cQA site search engine. In addition, the results also suggest that the proposed method can improve the search of cQA archives.

1 Introduction

In recent years, community-based question answering (cQA) services become popular, such as Yahoo! Answers (answers.yahoo.com) in English and Zhidao (zhidao.baidu.com) in Chinese. In cQA, people can have their questions answered by other people rather than by automatic QA systems, which usually better guarantee the answer quality. Till Oct. 2010, Zhidao has accumulated over 100 million answered questions, which form an extremely large and valuable knowledge base.

Lin (2008) first proposed the idea of automatically generating questions from queries. The underlying assumption is that when a user issues a query to a search engine, he could have a question in mind but it is more convenient and efficient for him to realize the question as a query. This technique could have a great impact on cQA services.

First, it can improve the search of cQA archives. As we know, most of cQA resources can be searched with general search engines like Google and Baidu (www.baidu.com). Many of them also have their own site search engines. However, since user queries are mostly short and incomplete, it is quite often that many less relevant questions are retrieved when searching cQA archives. By generating questions from short queries, we can expand the queries and estimate questions that are more likely to be interested in, which could help to retrieve more related questions from cQA archives.

Second, this technique can be useful in enlarging cQA resources. For example, in some search engines like Baidu, if a query is found to be frequently searched, the query will be automatically submitted to a cQA site and expected to be answered by some users. However, a problem is that the frequent queries are usually short and incomprehensible, which makes it hard for users to understand and answer the queries. If we can generate questions from queries, it will become more natural for users to answer the questions, thus contribute new data to the cQA resources[1].

Third, the technique can also be used in query analysis. Through reformulating queries to well-formed questions, it will get easier to analyze the relationship of the query terms as well as the focus of the users' requirement.

In this paper, we follow the proposal of (Lin, 2008) and put forward a novel method for query-to-question generation. The method includes two stages, i.e., template acquisition and question generation. In the former stage, the method collects query-to-question pairs from search engine query

[1]The generated incorrect questions will be ignored by users, which will not evidently influence the performance.

logs and further extracts question generation templates. In the latter stage, it generates questions for input queries using the obtained templates. Figure 1 illustrates these two stages.

We conducted experiments on a set of 1000 short queries randomly selected from Baidu's query logs. The results show that our method is effective. Specifically, the method generates questions for 76.5% test queries. The precision of 1-best and 5-best questions is 67% and 61%, respectively, which evidently outperforms a baseline that directly retrieves questions for queries using a cQA site search engine. In addition, we designed a strategy to improve the search of cQA archives through query-to-question generation, and the result is quite promising. Although our experiments were carried out in Chinese, the method can be extended to other languages in which cQA archives exist.

2 Proposed Method

2.1 Template Acquisition

As mentioned above, the cQA archives are frequently searched and viewed through search engines. Therefore, we can find a large number of records in search engine query logs, in which users searched a query Qr and clicked on a question Qs from the cQA archives. Such $\langle Qr, Qs\rangle$ pairs can be collected and used for training question generation models. In our method, we mine $\langle Qr, Qs\rangle$ pairs from Baidu's query logs. In detail, suppose a user issued a query Qr in Baidu and clicked on a search result with the title T, then $\langle Qr, T\rangle$ will be extracted as a $\langle Qr, Qs\rangle$ pair if it meets the following constraints:

- Qr is not a question[2], and it contains at most three terms. Our intuition is that long queries might be clear enough which need not to be expanded into questions.
- T should be a question Qs and must be from a cQA web site (Zhidao in our experiments).
- Qr should be subsumed in Qs. This constraint limits that Qr can only be *extended* to questions, whose terms are not allowed to be transformed or deleted during question generation.

From the identified $\langle Qr, Qs\rangle$ pair, we can induce a template Tp by substituting query terms in the question Qs with slots $\{[x_i]|1 \leq i \leq n\}$, where n is the number of query terms of Qr. An example is shown in Figure 2. In what follows, we term Qs as an *instantiation* of Tp.

In our experiments, we obtained over 15 million $\langle Qr, Qs\rangle$ pairs from the query logs used, and accordingly extracted 547,325 templates. To eliminate templates that are rarely instantiated, we filtered those templates with less than 10 unique instantiations. 18,929 templates were left after filtering, each with 80 unique instantiations on average. Analysis result reveals that 80% of the eliminated templates are those long and complicated ones, which may seldom be used in practice.

[2]We developed a rule-based tool to identify whether a Chinese word sequence is a question.

Note that a query could instantiate more than one templates. For example, query "故宫 门票 (*The Imperial Palace / ticket*)" can instantiate "*[x1] [x2]* 多少 钱 (*How much is the [x2] of [x1]*)", "*[x1] [x2]* 价格 是 多少 (*What is the price of [x1]'s [x2]*)", and "*[x1] [x2]* 贵 吗 (*Is the [x2] of [x1] expensive*)", etc. We therefore need to compute the likelihood that a query instantiates each template, which can be used in template ranking and selecting during question generation. In our work, given query Qr and all templates it can instantiate $\{Tp_1, ..., Tp_n\}$, we compute the likelihood of Qr instantiating $Tp_i (1 \leq i \leq n)$ based on maximum likelihood estimation:

$$p(Tp_i|Qr) = \frac{c(Qr, Tp_i)}{c(Qr)} \quad (1)$$

where $c(Qr, Tp_i)$ is the frequency that Qr instantiates Tp_i in the query logs, $c(Qr)$ is the frequency that Qr occurs in the query logs. The acquired templates along with the queries that can instantiate each template are stored in a database D_{Tp}.

2.2 Question Generation

With the induced templates, we can generate questions for any input query qr[3]. Since most of the templates are unsuitable for qr, we need a strategy to select the templates and only retain the useful ones. Our observation is that similar queries usually have close search intent. They may tend to instantiate identical templates and generate similar questions. For example, we found that queries about the tickets of something are mostly interested in the price and instantiate template "*[x1] [x2]* 多少 钱 (*How much is the [x2] of [x1]*)". Thus when we get a new query qr about tickets, it is reasonable for qr to instantiate the same template and generate a question qs asking about the price.

Guided by this intuition, we generate questions for query qr using the templates of qr's similar queries. In practice, we first retrieve qr's similar queries from D_{Tp}, each of which must contain the same number of terms and share at least one identical term with qr. After that, we collect all templates that can be instantiated by the retrieved similar queries, which are then instantiated by qr to generate a list of questions. All the generated questions are ranked and the top-N are returned. The example in Figure 3 illustrates this process.

We take two factors into account when ranking the generated questions. The first is the likelihood that query qr instantiates template Tp, and the second is the fluency of the generated question qs. Hence we define:

$$\begin{aligned} \hat{qs} &= \arg\max_{qs} f(qs, Tp, qr) \quad (2) \\ &= \arg\max_{qs} \{\lambda f_{TP}(Tp, qr) + (1-\lambda) f_{LM}(qs)\} \end{aligned}$$

where $f(qs, Tp, qr)$ is the score function for question ranking, which is decomposed into two parts, i.e., $f_{TP}(Tp, qr)$ and $f_{LM}(qs)$. The former computes the likelihood that qr instantiates Tp, while the latter measures the fluency of qs generated by instantiating Tp with qr.

Definition of $f_{TP}(Tp, qr)$. Let $\{Qr_i|1 \leq i \leq I\}$ be the similar queries of qr that can instantiate template Tp, we define $f_{TP}(Tp, qr)$ as:

$$f_{Tp}(Tp, qr) = \log \sum_{i=1}^{I} p(Tp|Qr_i) p(Qr_i|qr) \quad (3)$$

where $p(Tp|Qr_i)$ is the probability that Qr_i instantiates Tp, which has been defined in Equ. (1). $p(Qr_i|qr)$ reflects the degree that qr resembles Qr_i, which is defined as the query similarity $sim(qr, Qr_i)$ and is computed as:

$$sim(qr, Qr_i) = \prod_{j=1}^{J} sim(t_{qr\_j}, t_{Qri\_j}) \quad (4)$$

where $sim(t_{qr\_j}, t_{Qri\_j})$ is the similarity between the j-th term of qr and Qr_i, and J is the number of terms in both qr and Qr_i[4]. According to Equ. (4), qr and Qr_i are deemed similar only when they are similar term by term. This guarantees that each term of qr can safely fill in the slot induced from the corresponding term of Qr_i. The similarity between two terms t_1 and t_2 is computed based on distributional hypothesis, which assumes that words occurring in similar contexts tend to have similar meanings (Harris, 1985). We therefore define $sim(t_1, t_2)$ as the similarity of the context words of the two terms:

$$sim(t_1, t_2) = \cos(V_{ctx}(t_1), V_{ctx}(t_2)) \quad (5)$$

[3]Here we use qr and qs to denote a new query and its generated question, so as to differentiate from Qr and Qs that represent query and question mined from query logs.

[4]Recall that each similar query of qr must have the same number of terms as qr.

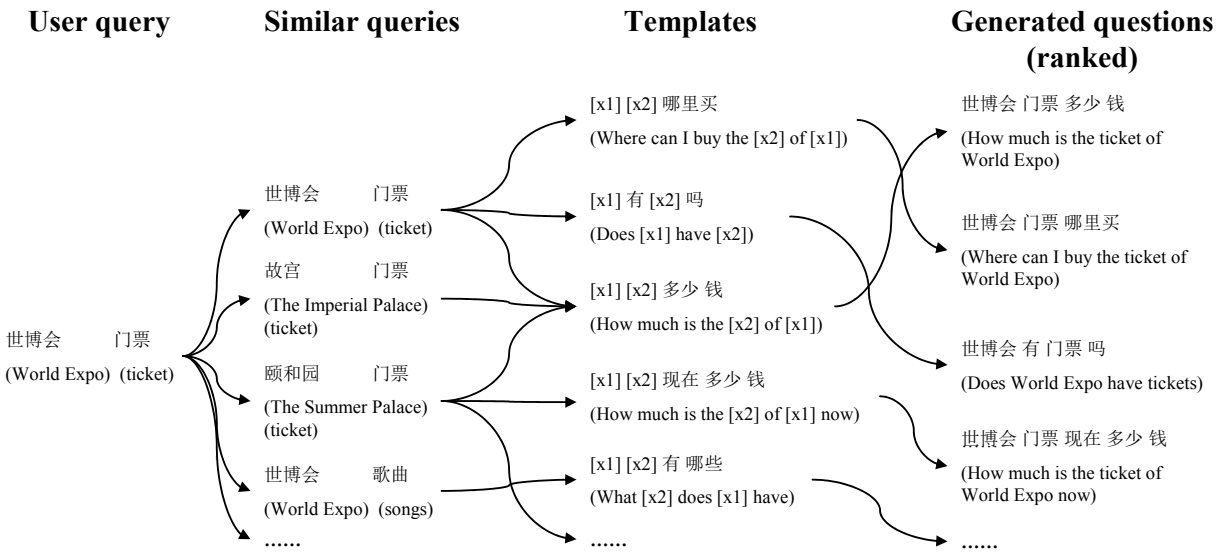

Figure 3: Generating questions from queries with templates induced from search engine query logs.

where $\cos(.,.)$ is the cosine similarity between two vectors. $V_{ctx}(t)$ is the vector of context words of t, which is constructed using Baidu query logs. Specifically, words occurring within the same queries as t are extracted as t's context words. The weight of each context word w is computed in a similar way as tf-idf:

$$W_t(w) = tf_t(w) \times \log \frac{N}{n(w)} \quad (6)$$

where $tf_t(w)$ is the frequency that w occurs in the contexts of t. $n(w)$ is the number of terms whose context words contain w. N is the total number of terms, i.e., the size of vocabulary.

Definition of $f_{LM}(qs)$. The other score function $f_{LM}(qs)$ is designed to measure the fluency of the generated questions, which is defined based on a tri-gram language model:

$$f_{LM}(qs) = \frac{1}{L} \log(p_{LM}(qs)) \quad (7)$$

in which L is the number of terms in qs, and $p_{LM}(qs)$ is the language model score of qs:

$$p_{LM}(qs) = \prod_{l=1}^{L} p(t_l | t_{l-2} t_{l-1}) \quad (8)$$

In our experiments, the language model was trained using over 15 million questions from the collected $\langle Q_r, Q_s \rangle$ pairs. We estimated the parameter λ in Equ. (2) using a development set with 247 random queries. In detail, we generated questions for each query and had all questions manually annotated (Section 3.1). We then examined λ ranging from 0 to 1 and evaluated $P@5$ precision (Section 3.2) under each setting. The setting that obtained the highest performance was selected, which was $\lambda = 0.3$.

3 Evaluation

Our experiments contain two parts. In the first part, we evaluated the precision of the generated questions based on human annotation. In the second part, we used the query-to-question generation algorithm to improve the search of cQA archives.

3.1 Experimental Setup

Comparison method. To our knowledge, there is no existing system that can automatically generate questions from queries. We therefore design a baseline method for comparison, which retrieves questions from cQA archives (termed as RcQA hereafter). Given a query qr, RcQA searches qr in Zhidao site search engine and retrieves questions containing qr[5]. The questions are ranked according to the orders assigned by the site search engine. We compare our query-to-question generation method (QtQG for short) and RcQA on precision. The reason why we employ the cQA site

[5]The retrieved titles from Zhidao are not necessarily questions. We ignored the non-question results when collecting questions from Zhidao.

search engine in the baseline instead of computing the similarity between queries and questions by ourselves is that we believe the cQA site search engine has adopted a state-of-the-art method when computing query-question similarity.

Experiment data. To construct a test set, we randomly sampled 1000 queries from Baidu query logs, each of which contains no more than 3 terms. The test queries cover a variety of domains, including *health*, *food*, *sport*, *music*, *movie*, *software*, *computer game*, etc. As described in Section 2, we used our method to generate questions for each test query, which were ranked according to Equ. (2). We kept up to top-5 questions of each query for evaluation. Meanwhile, we also retrieved up to top-5 questions for each query from Zhidao with RcQA.

Human annotation. Questions produced with both QtQG and RcQA were evaluated based on human annotation. We had two annotators, both of whom are native Chinese speakers. The questions produced with two methods were mixed before being presented to the annotators, so as to avoid bias during annotation. Two annotators evaluated the questions separately. For a query qr, a generated question qs is annotated as *correct* if it is fluent, comprehensible, and likely to be asked by people when they search qr. Otherwise, qs is annotated as *incorrect*. For instance, for the query "*世博会 门票* (*World Expo / ticket*)", question "*世博会 门票 多少钱* (*How much is the ticket of the World Expo*)" was annotated as correct whereas "*世博会 门票 哪里 可以 下载* (*Where can I download the ticket of the World Expo*)" was annotated as incorrect. In addition, a question was annotated as incorrect if it contains too much extra information that is impossible to be induced from the query[6]. For instance, question "*在 昆山 怎么 买 世博会 门票 (学生票)* (*How can I buy student tickets of Word Expo in Kunshan*)" was judged as incorrect for the above query, since "*学生票* (*student tickets*)" and "*在 昆山* (*in Kunshan*)" cannot be induced from the query.

After the first round of annotation, we calculated the kappa statistic between two annotators. The result shows that kappa $K = 0.78$, indicating a substantial agreement (K: 0.61-0.8) according to (Landis and Koch, 1977). Data with different annotations were then annotated by a third-party judge, so as to get the final annotations.

[6]Note that question descriptions written by question askers to further explain the questions are not extracted and evaluated together with questions, thus our evaluation metrics are not biased against questions with long and verbose descriptions.

	$P@1$	$P@2$	$P@3$	$P@4$	$P@5$
QtQG	0.67	0.66	0.64	0.62	0.61
RcQA	0.47	0.44	0.42	0.40	0.40

Table 1: $P@N$ results of QtQG and RcQA.

3.2 Evaluation of Precision

Experimental results show that, QtQG can generate at least one question for 765 queries, while RcQA can retrieve at least one question from Zhidao for 660 queries. It suggests that QtQG achieves a larger coverage than RcQA. After the questions were manually annotated, we computed the precision at top-N results ($P@N$):

$$P@N = \frac{|S_{CQs}(N) \cap S_{Qs}(N)|}{|S_{Qs}(N)|} \quad (9)$$

where $S_{Qs}(N)$ denotes the set of top-N questions and $S_{CQs}(N)$ denotes the set of correct ones. Table 1 summarizes the $P@N$ results ($1 \leq N \leq 5$) averaged on the test set for the two methods, from which we can see that QtQG significantly outperforms RcQA. Especially, we observed the results and found that QtQG can generate correct questions for some unpopular queries, about which we cannot even find questions from the web. For example, query "*昆明 KTV 沙发* (*Kunming / KTV / sofa*)" can retrieve no question from the web, but our method can generate question "*昆明 哪里 有 卖 KTV 沙发 的* (*Where to Buy KTV sofa in Kunming*)", which makes perfect sense and is quite likely to reflect users' requirement. Please note that some of the learned templates can reorder the query terms when generating questions. For example, for the query "*门票 颐和园* (*ticket / the Summer Palace*), the template "*[X2] 的 [X1] 多少钱*" can be matched and the correct question "*颐和园 的 门票 多少钱* (*How much is the ticket of the Summer Palace*)" can be generated.

We then conducted error analysis on the data set. Specifically, we sampled 100 incorrect questions produced with QtQG and RcQA, respectively. Analysis results reveal that 84% of incorrect questions generated with QtQG are those incomprehensible or not fluent questions, such as question "*德州 到 天气预报 怎么走* (*How can I get to weather forecast from Dezhou*)" for query "*德*

州 天气预报 (*Dezhou / weather forecast*)". The rest errors are questions that are well formed but less likely to be asked by people. On the other hand, for RcQA, 91% errors are questions containing too much extra information. For example, for query "*温州 歌曲* (*Wenzhou / songs*)", RcQA retrieves the question "*谁 能 提供 给 我 一些 关于 温州小吃 的 诗 歌， 歌曲 或者 趣味 知识* (*Who can give me some poems, songs, or interesting knowledge about Wenzhou snacks*)" . Obviously, it is too specific and not so good as the question generated with QtQG "*关 于 温州 的 歌曲 有 哪些* (*Are there any songs about Wenzhou*)".

Further more, we also analyzed queries for which QtQG or RcQA failed to generate questions. We sampled 100 such queries for the two methods and had them manually annotated. Results show that, 84% queries for which QtQG cannot generate questions are single-word queries. This is due to our limitation when searching similar queries for a new query qr (Section 2.2), that the similar queries for qr must share at least one identical word with qr. This constraint is designed to restrict search space when looking for similar queries. However it also limits that a single-word query can find similar queries and be rewritten as questions only when the same query has appeared in the D_{Tp} database (Section 2.1). This is a drawback of our method, which will be addressed in the future work. On the other hand, 82% queries for which RcQA did not retrieve questions are because the queries are unpopular. No question about them has been asked in Zhidao.

3.3 Improving cQA Search

As mentioned above, one application of query-to-question generation is to improve the search of cQA archives. We therefore carried out an experiment to examine its effectiveness. We design a strategy to integrate the QtQG module into the cQA site search engine. The basic idea is that, given a query qr, its generated question qs, and a cQA site search engine CQA, if qr's search result in CQA is unsatisfactory, but qs's result is good, then we can return qs's result for qr. The strategy is formally described in Table 2. The key problem here is how to estimate the quality of the search results. This is an interesting research topic but out of the scope of this paper. In our experiment, we adopted a simple criterion, namely, computing the similarity between the query and the title of the search result. The larger the similarity, the better the result. This criterion is naive, but our experiment result below shows that it is enough to verify the effectiveness of QtQG in cQA search.

Input:	qr: user query
	qs: generated question for qr
	CQA: cQA site search engine
Output:	$RST(qr)$: search result of qr in CQA
1.	Search qr in CQA, get result $R(qr)$
2.	Search qs in CQA, get result $R(qs)$
3.	Estimate the quality of $R(qr)$, get $E(R(qr))$
4.	Estimate the quality of $R(qs)$, get $E(R(qs))$
5.	**If** $E(R(qr)) = BAD$ and $E(R(qs)) = GOOD$
6.	Return $RST(qr) = R(qs)$
7.	**Else**
8.	Return $RST(qr) = R(qr)$

Table 2: Strategy for improving cQA search with automatically generated questions.

We experimented with the 765 test queries for which at least one question can be generated with our method. We only examined the 1-best question generated for each query. The cQA site search engine used is Zhidao. In addition, when evaluating and comparing the search results of the original query and generated question, we just considered the top-1 search result, which is not only for convenience, but also because the top-1 result usually means more to users in a search engine. The practical strategy used in the experiment is shown in Table 3, in which $sim(qr, R(qr))$ denotes the similarity between the query qr and the title of the top-1 search result $R(qr)$. The similarity is computed based on word overlap rate. $sim(qs, R(qs))$ is computed in the same way. Thresholds T_1 and T_2 were empirically set as 0.7 and 0.8, respectively.

Experimental results show that the top-1 search results for 65 (out of 765) test queries were changed using the above strategy, which means that our method has replaced the original search results of these queries with that of the generated questions. We asked the annotators to compare the search results before and after using the strategy. A query is annotated as *Good* if its new result is better than the old one, *Bad* if the new result is worse than the old one, and *Same* if the quality of the result is not evidently changed. Annotation result is shown in the first line of Table 4. As can be seen, the top-1 search results for 27

Input:	qr: user query
	qs: generated 1-best question for qr
	ZD: Zhidao cQA archive
Output:	$RST(qr)$: top-1 search result of qr in ZD
1. Search qr in ZD, get top-1 result $R(qr)$	
2. Search qs in ZD, get top-1 result $R(qs)$	
3. Compute similarity $sim(qr, R(qr))$	
4. Compute similarity $sim(qs, R(qs))$	
5. **If** $sim(qr, R(qr)) < T_1$ and $sim(qs, R(qs)) > T_2$	
6. Return $RST(qr) = R(qs)$	
7. **Else**	
8. Return $RST(qr) = R(qr)$	

Table 3: Strategy used in the experiments.

	Good	Same	Bad	Total
All que.	27	31	7	65
Correct que.	26	23	4	53
Incorrect que.	1	8	3	12

Table 4: Evaluating the effectiveness of query-to-question generation in cQA search.

queries get better, while that for only 7 queries get worse. This result demonstrates that our question generation technique can improve the performance of cQA search. Take the following case for example. The original query is " *读后感* (*book review*)"， whose top-1 search result is "*假如给我三天光明的读后感* (*book review of 'Three Days to See'*)". Our method can generate a question "*读后感怎么写* (*How to write a book review*)" for the query and accordingly retrieve this question as the top-1 result from Zhidao. It is obvious that the new result is much more likely to be looked for by users than the old one.

We also analyzed the search results that got worse after using our strategy. It is found that 6 of the 7 are still correct but not so good as the old ones. There is only one search result becomes unrelated to the query. Moreover, we should note that the 1-best questions used for improving cQA search are not necessarily correct. Hence we further evaluated the performance when only considering the correct or incorrect 1-best questions. The evaluation results are depicted in line 2 and 3 of Table 4. It is interesting to find that the performance did not evidently decrease when we only used the incorrect 1-best questions in our strategy. This result indicates that the performance of the query-to-question generation module in cQA search is not sensitive to the generation errors if we adopt a proper strategy to integrate it into the cQA site search engine.

4 Related Work

4.1 Research on cQA

Several studies have been carried out on cQA. Some of them have focused on retrieval and recommendation on cQA archives. For example, Xue et al. (2008) designed a retrieval model for cQA search, which considers both question and answer parts when measuring the relatedness between queries and cQA resources. Wang et al. (2009) presented a syntactic tree matching method for finding similar questions. Cao et al. (2008) proposed a question recommendation method based on tree cut model. Wang et al. (2010) proposed a graph-based approach to segmenting multi-sentence questions, so as to improve search performance. Another category of studies on cQA aims to estimate the quality of questions, answers, and users. For example, Song et al. (2008) examined the utility of questions in the cQA archives. Liu et al. (2008) presented a classification-based method to automatically predict whether a question-asker will be satisfied with the answers. Jurczyk and Agichtein (2007) tried to identify experts in a cQA community.

4.2 Question Generation

Question generation is a branch of natural language generation, which is defined as the task of automatically generating questions from some form of input (Rus and Graesser, 2009). The input may vary from a deep semantic representation to a raw text. Previous studies on question generation have mostly focused on text-to-question generation, which generates questions from declarative sentences or paragraphs. This technique is useful in education, especially in reading tutoring. Most previous studies employed rule-based methods in their text-to-question generation systems (Ali et al., 2010; Kalady et al., 2010; Mannem et al., 2010; Pal et al., 2010; Piwek and Stoyanchev, 2010; Varga and Ha, 2010).

Query-to-question generation is a sub-task of question generation, which was first proposed by Lin (2008). Lin has suggested to learn query-to-question generation models with query logs. However, no detail method or evaluation has been presented. There has been no other research since,

either, which may be mainly because few researchers can access the query log data.

4.3 Query Reformulation

Query reformulation is an important topic in the IR community, since it can improve users' search experience. Query reformulation mainly involves query reduction, expansion, and spelling correction. Query-to-question generation is closely related to query expansion. However, its goal is not only expanding useful information for the original query, but also organizing the information to produce a question, with which one can better understand the query's structure and the user's intent.

Several techniques have been proposed for query reformulation, which are mostly based on relevance feedback (Xu and Croft, 1996; Mitra et al., 1998) and query log analysis. Especially, the studies based on query logs can be divided into three categories. In the first one, researchers learn related query pairs from query sessions. The basic idea is that queries from the same session are more likely to be related to each other (Fonseca et al., 2005; Jones et al., 2006; Zhang and Nasraoui, 2006). The second kind of method identifies related queries using click-through information. They assume that queries leading to similar clicks are related in meaning (Wen et al., 2002; Baeza-Yates and Tiberi, 2007). The third category of method directly learns expansion terms from the clicked documents of the query. Their hypothesis is that terms in a query and a user-clicked document might be related (Cui et al., 2002; Riezler et al., 2008).

4.4 Template Induction

Template induction has been widely researched in NLP community, in which the following studies are close to our work. (1) Answer template learning in QA. Some QA systems use templates in answer extraction, which can be learned from large Web corpora or Web search results with handcrafted seed tuples (Ravichandran and Hovy, 2002). (2) Query template acquisition. For example, Agarwal et al. (2010) mine templates from search engine query logs with the goal of query interpretation. Szpektor et al. (2011) extract templates for long-tail queries so as to improve query recommendation. (3) Paraphrase template learning. Paraphrase templates are templates that can convey identical information when the variables are instantiated with the same contents. Paraphrase templates can be learned from monolingual corpora based on distributional hypothesis (Lin and Pantel, 2001), from comparable news articles based on alignment (Barzilay and Lee, 2003), or from bilingual corpora based on pivot approaches (Zhao et al., 2008). The above-mentioned studies are all related to our work. However, none of the previous work addresses the problem of query-to-question template generation.

5 Conclusions and Future Work

This paper addresses the problem of query-to-question generation for cQA and proposes a method based on search engine query logs. Several conclusions can be drawn from the experimental results. First, search engine query logs are powerful data for the research of query-to-question generation, from which we have acquired a large volume of question generation templates. Second, the proposed method is effective, which achieves promising precision and outperforms a baseline method. Third, the query-to-question generation technique can be used to improve the search of cQA archives.

In our future work, we will exploit larger-scale query logs for acquiring question generation templates. We will also improve the similar query retrieval strategy (Section 2.2), which underperforms now on single-word queries. In addition, we will have a deeper insight into the applications of question-to-query generation in cQA services.

Question Classification Based on an Extended Class Sequential Rule Model

Zijing Hui, Juan Liu*, Lumei Ouyang
Computer School, Wuhan University, Wuhan 40072, P. R. China
{zijinghui, liujuan, ouyanglumei}@whu.edu.cn

Abstract

Question classification is a crucial preprocessing for question answering system; it can help to make sure the user's intention. Most of previous researches focus on the feature driven methods that represent a question with a bag of features, which ignore the important information contained in the words order and distance. To take such information into account, this paper proposes to describe the questions via the ExCSR (Extended Class Sequential Rule) model. To mine ExCSR rules, a method based on PrefixSpan, called DS-SRM (Distance Sensitive Sequential Rule Miner), is presented as well. Due to the existence of redundancy in the mined rules, a rule selection algorithm MCRSelection (Most Cover Rule Selection) is also proposed to find the most interesting rules. Experiments results on UIUC question set[1] show that the proposed method can achieve the accuracy of 90.6%, which outperforms the previously reported results.

1 Introduction

Question classification, i.e., classifying questions into predetermined types, is quite an important problem in question answering (QA) system, it helps to make clear the intention of users so that the system can choose the appropriate strategies of answers searching and ranking. Similar to other classification problems, question classification usually needs to build the classifier from the training data which contains a set of labeled questions; the classifier is then used to classify the unlabeled questions.

Although questions are special kinds of texts, question classification is more challenging than text classification. Compared to normal texts, a question is usually a very short sentence (some even with few of words), and mostly one word just occurs once in one question, which results that the widely used vector space model (mainly based on TF/IDF) fails to work. To address this problem, researchers usually develop a lot of features, such as location, organization, name, etc., to annotate the words/phrases in the questions, and then use the bag of features to represent the questions. However, such methods still suffer some problems. (1) To get the satisfactory classification performances, they usually need an extremely large amount of features. For example, Li et al. used more than 200,000 features (Li et al., 2006) to represent questions in UIUC question set, while Huang et al. used 13,697 binary features in their best feature space (Huang et al., 2008). (2) The bag of features representation ignores the relationship and the order information among words within the questions, which will cause the misclassification. For example, "Which city is famous for rose?" and "Which rose is famous for city?" belong to two different classes (the former one asks about the <location>, while the later one is about the <entity> or <plant>), due to that "rose" and "city" have different orders. (3) The information of word distance is valuable in question classification yet is not considered by the present methods. For example, "How many people did Randy Craft kill?" asks about the <number>, while "How Randy Craft killed many people?" is about the <description>. The difference of the distances between "how" and "many" plays a role on the types of the questions. CSRs (Class Sequential Rules) originally proposed for opinion extraction (Hu and Liu, 2006) take the word sequences into account. However, it still ignores the distance information between words.

In this paper, we extend the representation of CSRs by integrating the distance information into it, and propose the ExCSR (Extended Class Sequential Rule) model. To mine the ExCSRs, we further propose an algorithm, called DS-SRM (Distance Sensitive Sequential Pattern Miner), based on PrefixScan (Pei et al., 2004). To remove the redundancy of the mined rules, we present an efficient rule selection method, MCRSelection (Most Cover Rule Selection). The remainder of this paper is organized as follows: section 2 introduces the related works; section 3

describes the CSR and its extension ExCSR; the rule mining and selection algorithms are presented in section 4; section 5 is the evaluation experiments and results; the paper ends with the concluding remarks in the last section.

2 Related Works

Question classification is a process that assigns a question to a single category or a set of categories. The categories can be organized as either flat or hierarchical taxonomies. Li & Roth (2002) defined a two-layered taxonomy shown in Table 1. The taxonomy consists of six coarse categories and a total of 50 finer categories. Since this taxonomy has been regarded as somewhat informal standard and has been used in much other work on question classification, it is also used in our paper. Given the taxonomy, the classification machinery is then needed to put the questions into specific category or categories. There are two main machineries for the classification, i.e., manual and automatic. The manual methods (Hermjakob, 2001) use hand-written rules and heuristics to do the classification, thus it is time consuming and hard to extend to new question categories; while the automatic methods classify the questions based on machine learning technologies or statistical methods, thus are much more efficient and easy to extend to new question types. Therefore, most of the work follows the automatic methods, which will be also adopted in our work. There are many machine learning methods have been proposed for automatic question classification. Radev et al. (2002) proposed to learn rules by using decision tree method, after trained on TREC-8 and TREC-9, it reached an accuracy of around 70% on TREC-10. Li and Roth (2002) reported a hierarchical approach based on the SNoW learning architecture. By trained on 5500 questions and tested on 500 questions from TREC-10, which are collected in UIUC dataset, it reached an accuracy of 84.2%. Zhang and Lee (2003) used linear SVMs with all possible question word grams, and obtained accuracy of 79.2%. Krishnan et al. (2005) used a short sequence called informer span as important features that are identified by the Conditional Random Field (CRF), and built a meta-classifier using a linear SVM on the features. Their model got the accuracy of 86.2% on UIUC question set. Li and Roth (2006) used more semantic information in WordNet, plus their originally proposed syntactic ones (Li & Roth, 2002), after being trained on 21500 questions, their model achieved an accuracy of 89.3% on a test set of 1000 questions. Li et al. (2008) propose to classify what-type questions by head noun tagging and achieve 85.60% accuracy. Huang et al. (2008; 2009) used much more compact feature set than Li and Roth's work, by taking the head words and their hypernyms as features, with other standard features such as unigrams, they obtained accuracy of 89.2% using linear support vector machine (SVMs), and 89.0% using Maximum Entropy (ME) model. Ray et al. (2010) used the semantic features of the WordNet and the vast knowledge repository in Wikipedia to build the classification model. They trained their model over 5500 questions in UIUC, and tested it over 2393 questions from five TREC collections, and got the average precision of 89.55%. However, to our best knowledge, all of the present works seldom consider the word sequence and word distance for question classification problem. In this paper, we exploit the information of word sequence and word distance in the questions and develop an efficient classification method. The details of the proposed methods will be provided in the next sections.

Coarse Class	Fine Class
ABBREVIATION	abbreviation, exp
DESCRIPTION	definition, description, manner, reason

Table 1. Two-layered taxonomy proposed by Li & Roth (2002)

3 Class Sequential Rule Model and Its Extension

Class sequential rule (CSR) model was originally proposed to represent the labeled sequences in the research of opinion feature extraction (Hu & Liu, 2006). For the completeness of this paper, we first introduce CSR model, then state its extension model ExCSR in this section.

3.1 Class Sequential Rule Model

Let $I = \{i_1, i_2, ..., i_n\}$ be a set of items, and an *element* or *itemset* be a non-empty set of items. A *sequence* is defined as an ordered list of elements, denoted by $\langle e_1 e_2 ... e_r \rangle$, where e_i is an *element* (Liu,

2007). An item can occur only once in an element of a sequence, but can occur multiple times in different elements.

A sequence $s_1 = \langle a_1 a_2 ... a_r \rangle$ is a *subsequence* of another sequence $s_2 = \langle b_1 b_2 ... b_m \rangle$ or s_2 *contains* s_1, if there exist integers $1 \leq j_1 < j_2 < ... < j_{r-1} < j_r \leq m$ such that $a_1 \subseteq b_{j1}$, $a_2 \subseteq b_{j2}$, ..., $a_r \subseteq b_{jr}$.

Let $D = \{(s_1, y_1), (s_2, y_2), ..., (s_n, y_n)\}$ be the input data of labeled sequences, where s_i is a sequence and $y_i \in Y$ is its class, Y is the set of all classes, $I \cap Y = \emptyset$. A CSR is a production rule $X \rightarrow y$, where X is a sequence, and $y \in Y$.

Table 2 lists some examples of CSRs, where each English word is an item and the class label is in the right side.

Id	Sequence	Class
1	<What difference between>	Desc:desc
2	<Who>	Human:ind
3	<How much weight>	Count:weight
4	<How much>	Count:money
5	<What be NN>	Desc:def

Table 2. Examples of CSRs

A data instance (s_i, y_i) in D is said to cover the CSR $X \rightarrow y$ if s_i contains X. A data instance (s_i, y_i) is said to satisfy *t*he CSR if s_i contains X and $y_i = y$. The *support* of the CSR is the total instances in D that covers the rule. Given the minimum support threshold *min_sup*, a sequence X is called a *sequential pattern* in D if *support(X)* $\geq$ *min_sup*. The *confidence* of the CSR is the proportion of instances in D that covers the rule also satisfies the rule.

3.2 Extended Class Sequential Rule Model

Although the CSR takes the word sequence into account, it still ignores the distance information between words/phrases which should be also important to question classification. Therefore, we extend the representation of CSRs by considering the distance information. The extended class sequential rule model is called ExCSR hereinafter.

First, we define three simple kinds of distance constraints, shown in Table 3.

Index	Distance Constraint	Description
1	[NEIGH]	Two elements are neighbored. Used to extract the phrase, like "how [NEIGH] much"
2	[NEAR]	Two elements are not more than a give threshold away.
3	[ANY] or blank	Two elements can be of any distance, [ANY] can be omitted.

Table 3. Definition of distance labels

Suppose $\langle x_1 x_2 ... x_r \rangle \rightarrow y$ be a CSR rule, then we define an ExCSR as $\langle d_1 x_1 d_2 x_2 ... d_r x_r d_{r+1} \rangle \rightarrow y$, where d_i takes one of the distance constraints in Table 3, which limits the occurring distance between elements x_{i-1} and x_i when the rule is selected to match an instance for classification. For d_1, we can image that there is a special element "x_0" representing the beginning of a sentence, therefore, d_1 is used to constrain the occurring distance of x_1 apart from the beginning of a sentence. Similarly, d_{r+1} constrains the occurring distance of x_r to the end of a sentence.

Then, taking the CSR rules in Table 2 as examples, their extended ExCSR rules might be in the forms listed in Table 4. The support and confidence of an ExCSR is just the same as its original CSR.

Id	Sequence	Class
1	<[NEIGH] What [NEAR] difference [NEAR] between [ANY]>	Desc: desc
2	<[NEIGH] who [ANY]>	Human: ind
3	<[NEIGH] How [NEIGH] much [ANY] weight [NEIGH]>	Count: weight
4	<[NEIGH] How [NEIGH] much [ANY]>	Count: money
5	<[NEIGH] What [NEAR] be [NEAR] NN [NEIGH]>	Desc: def

Table 4. Possible ExCSR examples originated from CSRs in Table 2.

It is noticeable that if only [ANY] is used, then the ExCSR model is actually the same as CSR model. Furthermore, by using ExCSR model, more compact rules that are usually ignored in CSRs mining but play important roles in question classification will be considered. For example, the CSR "<in what year> → date" is too short that it may cover many questions belonging to different classes which causes its confidence may be lower than the threshold; while its corresponding ExCSR "< [NEIGH] in [NEIGH] what [NEIGH] year [ANY] > → date" cannot cover so many questions with conflicted classes as the CSR due to the distance constraint, thus it should have higher confidence and be included in the final classification model.

4 DS-SRM: ExCSRs Mining Method

DS-SRM consists of three parts: preprocessing, mining and rules filtering, shown in Figure 1.

Given a set of question texts, the preprocessing step parses every sentence and translates it into a sequence of elements labeled with se mantic information, and the mining step generates a set of ExCSRs satisfying the minimum

support (*min_sup*) and minimum confidence (*min_conf*) requirements from the sequences. Since the distance label [ANY] covers [NEIGH] and [NEAR], the mined ExCSR set should contains a lot of redundant rules with the same element sequences but different distance labels. Therefore, the filtering step is required to remove the redundancy of the rule set. The filtered ExCSRs are to be used to classify the unseen question sentences.

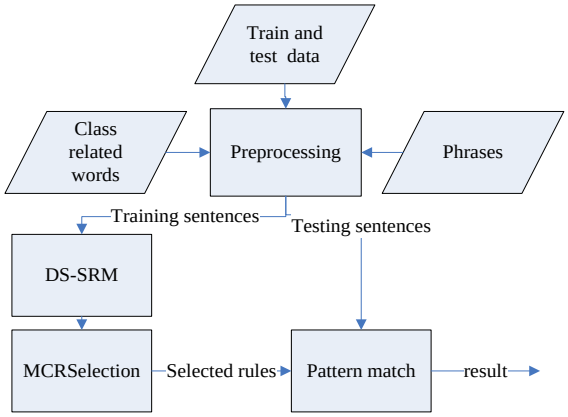

Figure 1. The workflow of DS-SRM

4.1 Preprocessing the Question Texts

Now that the question sentences are in the form of raw texts and cannot be directly used for the rules mining purpose, it's necessary to do the preprocessing by scanning each sentence to do annotation, chunking, and so on. By doing this, each sentence is re-organized by a set of elements with semantic information, especially with the words related to class information. This paper performs the following main preprocessing:

(1) Phrases recognition

There are some phrases consisting of several noun words, which can represent entity classes as a whole, yet each word of it may has different meanings. For example, "*state flower"* denotes a kind of "plant" where "state" is just as a modifier of "flower". While "state" could be regarded as a "location" and "flower" is a kind of "plant" if "state" and "flower" are separately considered. Therefore, we need to recognize such kinds of phrases to avoid ambiguity. We first collect a lot of frequent phrases by grouping the adjacently occurring words from the web pages according to the mutual information statistics. And then locate the ambiguous phrases within the question sentences and manually annotate them with the related class labels (It should be noticed that this processing just recognizes out the phrases of ambiguity, not all phrases or the name entities).

(2) Named entities recognition

A named entity recognizer (NER) of Stanford (Finkel et al., 2005) which defines four types of entities is used to assign a semantic type to noun phrases in a sentence.

For example, a question "*What was W.C. Fields ' real name?"* will be changed into "*What was [person_name] ' real name?*" after the using NER, which will be helpful to assign this question to correct class. However, if we do not tag "*W.C. Fields"* as a person's name, it will be difficult to correctly identify the question's class.

(3) Part-Of-Speech (POS) tagging

POS is important syntactic information in text preprocessing, and it allows us to generate general rules. In our wok, we have used the Stanford Log-linear Part-Of-Speech (Toutanova et al., 2003) to do POS tagging.

(4) Chunking

Besides POS tagging, we also use a chunker, also called as shallow parser, to find out some special structures and phrases and then to eliminate the adjunct words which may have bad impacts on the classification.

For example, in the following question: *What is a group of turkeys called?* (Huang, et al. 2008)

The word "*turkeys"* acts as the central word and contributes to classifying question as "animal", however, the phrase "*a group of"* would introduce ambiguity to misclassify this question to "human group". Therefore, we need to deal with such kinds of phrases. In this work, we adopt the Illinois chunker package (Mavronicolas et al., 1991).

(5) Class related words tagging

For each type of question, there are usually some words related to the question class. Li et al., (2002) have built a list of related words for each question class in their research. For example, for class "*food*", the related words set would be {*alcoholic, apple, beer, berry, breakfast, brew, butter, candy, cereal, champagne, cook, eat, sweat...*}. Using the class label to tag such related words would be very useful for the question classification. However, the class related words may be nouns, verbs and adjectives, and we have found that the verbs and adjectives would cause the ambiguity in our test. Therefore, we only use the nouns in the class related word sets collected by Li et al. (2002). Nevertheless, there still maybe exist the word ambiguity problem. At present, we just ignore it for it has less impact on the performance of our ExCSR rules.

After the preprocessing, the each question sentence will be transformed into a sequence of triplets <[pos], word, [cid]>, where "pos" and "cid" are the POS and class tags of the word respectively. For those *wh* words ("what", "when", "who", "how"…), the "pos" in the triplet is left blank; for any words except those class related nouns, the "cid" is left blank. From the sequences, we can mine out the ExCSRs.

4.2 Mining the ExCSR Rules

The mining procedure is extended from PrefixSpan (Pei et al., 2004), an efficient sequence rule mining method. We will not introduce the PrefixSpan method itself, which is beyond the topic of this paper. Instead, we present our modified version based on the framework of PrefixSpan. The mining algorithm, called DS-SRM (Distance Sensitive Sequential Rule Miner), is shown in Algorithm 1, which is composed of a recursive procedure DS-SPM (Distance Sensitive Sequential Pattern Mining).

It is noticeable that the imported distance information [NEIGH], [NEAR] and [ANY] are not exclusive: [ANY] covers [NEIGH] and [NEAR]; and [NEAR] covers [NEIGH]. Therefore, when counting the occurrence for each item in Step 1 of Procedure DS-SPM, if the current item is (NEIGH, b), then the counters for (NEIGH, b), (NEAR, b), (ANY, b) increase one; if the current item is (NEAR, b), then the counters for (NEAR, b), (ANY, b) increase one.

Algorithm 1: (DS-SRM)Distance Sensitive Sequential Rule Miner

Input: The training set $D = \{(s_1, y_1), (s_2, y_2), ..., (s_n, y_n)\}$, where each s_i is the preprocessed sequence;
The minimum support threshold: *min_sup*;
The minimum confidence threshold: *min_conf.*
//Rules with the confidence below *min_conf* or support below *min_sup* will be disregarded.

Output: A set of ExCSRs satisfying the support and confidence requirements

Parameters: Λ - a sequential pattern set;
α - a sequential pattern in Λ;.

Step 1: $S = \{s_1, s_2, \ldots, s_n\}$; $Y = \{y_1, y_2, \ldots, y_n\}$

Step 2: Λ = DS-SPM(<>, 0, S);

Step 3: for each α in Λ

(a) count the frequencies of all covered classes (the classes that the covered sequences belong to), and find the most frequent class label $y \in Y$;

(b) if support($\alpha \rightarrow$y) ≥ *min_sup* and confidence($\alpha \rightarrow$y) ≥ *min_conf* then output $\alpha \rightarrow$y.

Procedure DS-SPM (α, *len*, $S|_\alpha$)

Input: A sequence set S;
The minimum support threshold: *min_sup*;

Output: The complete set of sequential patterns

Parameters: α - a sequential pattern, where each element is a triplet originated from section 4.1 and have attached the distance information in the form of [(*d*, *pos*), (*d*, *word*), (*d*, *cid*)] (*d* is the distance information and initially is blank), each pair in a triplet is regarded as an item;
len - the length of α;
$S|_\alpha$ - the α-projected sequence set, the collection of labeled suffixes of sequences in S with regards to prefix α. If α is empty, then $S|_\alpha$= S.
Tnear - the threshold to indicate whether two triplets are NEAR.

Step 1: Scan $S|_\alpha$ once to find each frequent item, (d_b,b), such that

a) (d_b,b) can be assembled to the last element of α to form a sequential pattern; or

b) $<(d_b,b)>$ can be appended to the last item of α to form a sequential pattern ($<(d_b,b)>$ denotes the triplet containing (d_b,b)).

Step 2: for each frequent item (d_b,b), append it to α to form a sequential pattern α', and output α'.

Step 3: for each α', construct α'-projected set $S|_{\alpha'}$ by the following ways:

(a) $S|_{\alpha'}$ = set of suffixes of sequences in S with regards to prefix α';

(b) For each item (d_c,c) in $S|_{\alpha'}$, revising its distance information by one of the following ways:
(i) if (d_c,c) is in the same triplet with (d_b,b), then modify (d_c,c) to (b,c);
(ii) if (d_c,c)'s triplet is neighbor to (d_b,b)'s triplet, then modify (d_c,c) to (*NEIGH*, *c*);
(iii) if (d_c,c)'s triplet is near to (d_b,b)'s triplet with regards of *Tnear*, then modify (d_c,c) to (*NEAR*, *c*);
(iv) OTHERWISE, modify (d_c,c) to (*ANY*, *c*);

Step 4: call DS-SPM(α',*len*+1, $S|_{\alpha'}$).

Algorithm 1. The flow of DS-SRM algorithm

4.3 Filtering out Redundant ExCSR Rules

Since [NEIGH], [NEAR], and [ANY] are not exclusive, Algorithm 1 may generate quite a lot of redundant rules. In order to remove the redundancy, we first define the interestingness of a rule *r* as Equation (1):

$$\text{Interestingness}(r)=\text{support}(r)*\text{confidence}(r) \quad (1)$$

Then we can rank the rules according to their interestingness. Rules with high interestingness score tend to have high support as well as high confidence, thus should be remained.

Due to the use of overlapping constraints, there are usually some rules with the same support and confidence, exemplified in Table 5.

Rule Id	Class	Conf.	Sup.	Rule
1	DESC :desc	100%	32	<[what][be][difference][between]>
2	DESC :desc	100%	32	<[what][be][difference][NEAR][between]>

Table 5. Example rules with same support and confidence

Rule 1 and 2 are with the same confidence 100% and support 32 thus have the same interestingness. However, rule 1 is more general than rule 2 for it uses less distance constraints, so we prefer to remain rule 1 and discard rule 2. For this purpose, we further to define a measure as Equation (2):

$$\text{Distance\_Constraint}(r) = \sum_{i=1}^{k} \text{label\_value}(i) \quad (2)$$

Where *label_value(i)* denotes the value of the *i-th* distance label (the value of [NEIGH], [NEAR], [ANY] is set to 2, 1, 0.5 separately), and *k* is the total number of distance labels used in rule *r*.

Obviously, shorter rules with simpler distance constraint are more general and preferred.

Therefore, we propose a rule selection algorithm MCRSelection illustrated in Algorithm 2, which will be used iteratively for all classes, one run for one class, to remove the redundant rules.

5 Experiments and Discussions

In order to evaluate our proposed method, we have compared our method to other art-of-state methods on the UIUC question set. We first describe the data sets used in our experiments. In order to investigate which combination of the distance information is optimal to our method, we then test our method with different distance combination. Finally, we compare our method with the optimal distance combination to other representative methods. In the experiments, we set the threshold values of parameters *min_sup*, *min_conf* and *Tnear* as 3, 0.75 and 2 respectively by experience.

Algorithm 2: MCRSelection

Input: rule set $R = \{r_1, r_2...r_n\}$ for specific class;
The training question set D.
Output: rule set R' without redundancy

Step 1: R' = ∅;
Step 2: Calculate interestingness for each rule in R;
Step 3: Rank rules according to the interestingness and find the rule r with the highest interestingness. If there are one more than such rules, then choose the one with the least Distance-Constraint value;
Step 4: R' = R' ∪ {r}; R = R – {r};
Step 5: D = D- {instances satisfied by r};
Step 6: if D is empty, then return R';
Step 7: For each r∈R, update support(r) with regards to the updated D;
Step 8: go to **step 2**.

Algorithm 2. The flow of MCRSelection algorithm

DESC	138	size	0
def	123	weight	4

Table 6. The composition of TREC 10 test set

In order to facilitate the comparison, similar to previously reported results, we also use the same benchmark UIUC question training and test sets in our experiments, where the questions are labeled as six coarse categories and a total of 50 finer categories. Concretely, we train our model with training set containing 5500 labeled questions and test it on the TREC 10 question set with 500 questions. The composition of the test set is listed in Table 6.

5.2 Investigation on the Distance Combinations

In section 3.2, we have introduced three kinds of distance: [NEIGH], [NEAR] and [ANY]. In order to know whether all of them are necessary in our method, we have tested our method with different distance combination on the same data sets. Table 7 shows the overall performances on 6 coarse classes and 50 fine classes with different combinations separately; and Table 8 presents more details on the six coarse categories.

	ANY	NEAR+ ANY	NEIGH+ ANY	All
6 classes	90.6%	92.8%	92.1%	93.6%
50 classes	83.8%	87.8%	86.8%	90.6%

Table 7. Performances of our method with different distance constration combinations

	ABBR	ENTITY	DESC	HUMAN	LOC	NUM
ANY	81.8%	73%	82%	95%	86%	92.6%
NEAR+ ANY	90%	76%	87%	97%	87%	93%
NEIGH+ ANY	90%	75%	84%	95%	89%	93%
All	90%	79%	95%	98%	90%	95%

Table 8. More detailed investigation on the distance combinations

Obviously, with all of the three kinds of distance information, our method reaches the best performance. In fact, if only [ANY] is considered, our ExCSR model is just the CSR model without the distance constraints, with which the overall accuracies are 90.6% in coarse classes, and 83.3% in fine grained classes respectively, which are lower than the cases that the distance constraints are considered.

The more detailed results in Table 8 also show that including all of the distance information can get the highest prediction accuracies on all of the six categories. Especially for the DESC class, the previously feature bag based methods usually perform not very good due to the fact that question classes are distance sensitive, while our method with all distance information included can get 95% overall accuracy. For example, "What foods contain vitamin B12?" is labeled as "ENTY: food", while "What is fiber in food?" belongs to "DESC: define" in UIUC data sets. The main difference between above question texts is the distance between two words "what" and "food" that are critical to the classification. Due to ignoring the distance information, the feature-bag based method usually cannot correctly classify the second question and may label it as "ENTY: food". While our method can properly distinguish these two questions for they correspond to different ExCSRs. The similar cases occur in questions of class "DESC: desc".

All in all, our proposed ExCSR including all of the three distance constraints is an effective model to the question classification. Thus in the comparison experiment, we consider all of the distance constraints.

5.3 Comparing with other Methods

By considering all of the distance constraints, the performances on different categories of our method are listed Table 9.

Class	Pre.	Rec.	F	Class	Pre.	Rec.	F
ABBR	90	100	94.7	desc	100	85.7	92.3

DESC	94.8	92	93.4	size	/	/	/
def	95	92.7	93.8	weight	100	100	100

Table 9. The performances on different categories of our method

In order to know what is the rank of our method, we compare our methods with other representative methods: Zhang and Lee (2003); Huang et al., (2008); Krishnan et al., (2005). Since

Huang et al. (2008) have compared their method with Li et al. (2006) and show that their method is superior, we don't consider Li et al., (2006) method in this work.

The comparison results are shown in Table 10, showing that our method achieves the best accuracy. Although the results of Huang's method are competitive to our method, however, they use some manual regular expression patterns. Moreover, Huang et al. used a large amount of features 13697 to construct their model, while our ExCSRs model are more compact and final classifier only has 412 rules with length less than 4.

Method	6 classes	50 classes
Zhang & Lee, Linear SVM	87.4%	79.2%
Krishnan et al., SVM+ CRF	93.4%	86.2%
Huang et al., Maximum Entropy Model	93.6%	89%
Our method	93.6%	90.6%

Table 10. Overall comparison results with other three methods

Now that the results of Huang's method are competitive to ours, we further compare it with ours on each fine grained class, and the accuracies are shown in Table 11.

Class	Huang Method	Our Method	Class	Huang Method	Our Method
ABBR			desc	75	100
abb	100	100	manner	100	100
exp	88.9	100	reason	85.7	85.7
ENTITY			**HUM**		
animal	94.1	93.3	group	71.4	71.4
body	100	100	ind	94.8	94.8
color	100	100	title	/	/
creative	/	/	desc	100	100
currency	100	100	**LOC**		
dis.med.	40	66.7	city	100	100
event	100	66.7	country	100	100
food	100	100	mount	100	100
instrument	100	100	other	83.9	83.9
language	100	100	state	85.7	85.7
letter	/	/	**NUM**		
other	45.5	41.7	code	/	/
plant	100	83.3	count	81.8	81.8
product	100	75	date	95.9	95.9
religion	/	/	distance	100	100
sport	100	100	money	100	100
substance	88.9	73.7	order	/	/
symbol	/	/	other	85.7	85.7
technique	100	100	period	72.7	72.7
term	100	58.3	percent	75	75
vehicle	100	100	speed	100	100
word	/	/	temp	100	100
DESC			size	/	/
def	89	95	weight	100	100

Table 11. Precisions for fine grained question categories with Huang's method and our method

Table 11 shows that our method can achieve better results on most classes, especially for DESC coarse class that is considered to be difficult to identify (Li et al., 2006). By investigating the questions in that class we found that the question classes are sensitive to the word order and distance. Huang represents a sentence as a bag of features and ignore the relative order and of words their distances, thus performed not very well.

Of course, both our method and Huang's method show bad performance on Entity: other class, which is also shown to be difficult to identify, for the question texts in "other" class is quite fuzzy, we will put emphasis on this kind of class.

We also analyzed the incorrectly identified questions, and found that there are inherently ambiguity in training and testing questions (see examples in Table 12), which also conforms to Huang et al (2008)'s analysis.

Class	Rule
ENTITY:animal	What is a group of frogs called ?
ENTITY:termeq	What are the spots on dominoes called ?
ENTITY:termeq	What 's the term for a young fox ?
ENTITY:animal	What is the scientific name for elephant ?

Table 12. Ambiguous questions in testing set

6 Conclusion

In this paper, we first present ExCSR model for question classification, which is extended from the CSR model by integrating the distance information. Compared to CSR model, ExCSR is more compact intuitive, yet effective; then we describe the ExCSR mining algorithm, DS-SRM, and the rule filtering algorithm MCRSelection. By MCRSelection algorithm, we can keep the most interesting rules with less redundancy. Experiment results on the UIUC question set show that our method outperforms previously reported results.

In the future, we will consider more sophisticated method to address the questions with fuzzy information such as those of "other" class in UIUC data set.

Abstract

Garbage in and garbage out. A Q&A system must receive a well formulated question that matches the user's intent or she has no chance to receive satisfactory answers. In this paper, we propose a keywords to questions (K2Q) system to assist a user to articulate and refine questions. K2Q generates candidate questions and refinement words from a set of input keywords. After specifying some initial keywords, a user receives a list of candidate questions as well as a list of refinement words. The user can then select a satisfactory question, or select a refinement word to generate a new list of candidate questions and refinement words. We propose a User Inquiry Intent (UII) model to describe the joint generation process of keywords and questions for ranking questions, suggesting refinement words, and generating questions that may not have previously appeared. Empirical study shows UII to be useful and effective for the K2Q task.

1 Introduction

Keyword search has long been considered an unnatural undertaking task, but it works well with search engines. When entering a question to a Q&A system such as Yahoo! Answers and Quora, however, the keyword paradigm simply does not work. A question must be articulated specifically in the form of natural language. For instance, keywords such as *New York restaurant* is ambiguous in its intent. The user may want restaurants in New York, or want to know the tipping practice at New York restaurants, or something else under the myriad other possible interpretations. For a question to be answered, the asker must articulate her intent with sufficient specificity. Partly because we have been detrained by search engine from writing a question in a complete sentence, and partly because a question is hard to articulate completely when the asker is in a learning mode, a Q&A system should provide tools to users to help them clarify their questions so as to get good answers.

In this paper, we propose K2Q, a system that converts keywords to questions by considering both query history and user feedback. More specifically, given a set of keywords, K2Q generates a list of ranked questions as well a list of refinement words. A user can select a satisfactory question, or she can select a refinement word to generate a new list of candidate questions and refinement words. This process iterates until the user finds a good question matching her intent or quits.

To build an effective K2Q system, there are three aspects that need to be researched. A user issues a question typically because the desired information cannot be found. Our first task, therefore, is in the generation of unseen questions (*unseen questions* refer to those questions which are not known in advance by a K2Q system). After all, popular questions being asked before can be searched via search engines. Second, we must address the challenge of ranking candidate questions. Questions, unlike keywords, rarely repeat. (The same question can be asked in many different forms.) Among the questions we have collected, only occur more than once. Therefore, a simple ranking scheme based on frequency is not feasible. Third, the suggestion scheme of refinement words must consider maximizing information gain. It is thus desirable to generate diverse refinement words. An intuitive method is to use the most frequent words in candidate questions (after the removal of functional words). However, this method only considers the strength of relatedness between the words and the candidate questions, and may generate several refinement words indicating the same subtopic. For example, when a user inputs *cat feed*, if we simply use the most frequent words as refinement words, we will suggest both *food* and *eat* which indicate the same topic of *feed cat*. Diverse refinement

Proceedings of the 5th International Joint Conference on Natural Language Processing, pages 947–955,
Chiang Mai, Thailand, November 8 – 13, 2011.

words lead to more efficient feedbacks, and thus produce a fewer number of iterations before getting a satisfactory question.

To overcome the aforementioned three challenges, we propose a User Inquiry Intent (UII) model, which describes the joint generation process of keywords and questions. We employ an adaptive language model to describe the process of forming questions, and use automatically induced question templates to create unseen questions. Candidate questions are sorted by their fluency, i.e., the probability of being seen in a Q&A system. We compute the entropy on the distribution of the user's intent and generate refinement words. We then suggest refinement words that maximize entropy gain. Consequently, a satisfactory question can be generated in fewer iterations. Our experiments show that: 1) a template-based approach improves the coverage of suggestions; 2) compared with the baseline method, our UII model improves the ranking of the suggested questions; and 3) the UII model generates better refinement words than the baseline method of suggesting most frequent words. The results suggest that our proposed UII model is effective.

The contributions of this paper can be summarized as follows:

1. We propose a K2Q system, which benefits users to articulate and refine their questions to be more specific and more overtly express their intent.
2. To address the technical challenges of developing K2Q, we propose the UII model, which models the joint generation process of keywords and questions.
3. We show that the UII model is effective in both generating and refining questions by experiments conducted with real-world query logs.

This paper proceeds as follows. Section 2 presents a brief survey of related work. Section 3 details the UII model, which describes the joint generation of both search keywords and natural language questions. Experiments are described in Section 4 and conclusions are given in Section 5.

2 Related Work

To the best of our knowledge, there is no direct research on the K2Q problem. However, query suggestion and question recommendation are among the most relevant tasks that have been researched.
